Springer Handbook of Science and Technology Indicators

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook of Science and Technology Indicators

Preface

The *Springer Handbook of Science and Technology Indicators* offers a collection of state-of-the-art contributions on quantitative science and technology research. Organized in six parts, the individual chapters focus on various aspects of the development and application of indicators derived from data on scholarly publications, patents, and electronic communication. The 44 chapters are written by leading specialists in the topics selected for this Springer Handbook. These chapters deal with theoretical and methodological issues, illustrate applications, highlight their policy context and relevance, and point to future research directions. In particular, the authors present a survey of the research topics they address, and show their most recent achievements and contribution to the advancement of quantitative studies of science and technology.

The chapters are arranged into six parts:

Part A: Analysis of data sources and network analysis
Part B: Advancement of methodology for research assessment
Part C: Science systems and research policy
Part D: New indicators for research assessment
Part E: Advancement of methodology for patent analysis
Part F: Patent system, patents, and economics.

The Editors' Introduction provides a further specification of the handbook's scope and of the main topics addressed in its chapters. This Springer Handbook aims at four distinct groups of readers: practitioners in the field of science and technology studies; research students in this field; information scientistsa and practitioners in informatics; scientists, scholars, and technicians who are interested in a systematic, thorough analysis of their activities; policy-makers and administrators who wish to be informed about the potentialities and limitations of the various approaches and about their results.

The current handbook can be considered a successor of the *Handbook of Quantitative Science and Technology Studies* edited by Anthony van Raan and published in 1988 and the *Handbook of Quantitative Science and Technology Research. The Use of Publication and Patent Statistics in Studies of S&T Systems* edited by Henk F. Moed, Wolfgang Glänzel, and Ulrich Schmoch in 2004.

We are grateful to all contributors for their enormous efforts to share their longstanding experience as experts in their research topics and to provide us with excellent chapters for this handbook.

Editors' Introduction

The *Springer Handbook of Science and Technology Indicators* continues the tradition and scope set by two predecessor reference works: The *Handbook of Quantitative Studies of Science and Technology*, edited by Anthony F.J. van Raan and published in 1988, and a little more than 15 years later, the *Handbook of Quantitative Science and Technology Research* (editors: Henk Moed, Wolfgang Glänzel, Ulrich Schmoch). Similarly to the previous volumes, this handbook deals with quantitative studies of the science and technology (S&T) system which is conceived as a part of the various national or regional innovation systems.

The current work provides the state of the art of the development and application of methods and models that have been developed to understand and study processes and networks of scientific communication, the indicators for the S&T system that are derived from the documented output of research and patenting activities. Besides reporting and reviewing methodologies and application fields, there is a strong focus on tracing the developments that took place in the field of quantitative S&T studies since the first and second volumes appeared. The three decades since the publication of van Raan's Handbook were characterized by increasing internationalization, the duality of global collaboration and competition in science and technology, challenges to S&T studies that have also created opportunities and proved to be one of the main driving forces for the advancement of our field, and the gradual supplementation and replacement of traditional publishing by electronic communication media and publication channels. Several of these and related issues had already found their way into the second handbook, including the science-technology interface, research collaboration and network analysis, emerging economies and the changing global research landscape, the internationalization of knowledge generation, and data and text mining for S&T studies and webometrics.

The new millennium has sped up development and brought new challenges but also solutions. Increased computing capacity, practically infinite storage capacities, and the development of new algorithms have helped researchers to cope with the challenges of big data that emerged during the last decade. Both the quantity and quality of data now allow the analysis and linkage of huge document corpora, large-scale text mining, and study of the evolution of huge document and actor networks. Open access and open science have improved accessibility to research results and broadened the usage of published information, while scientific blogging provided a platform to communicate science to major stakeholders and the public. The extension of communication and publication channels with new actor and user groups introduced the necessity and possibility of building new measures of usage exchange and networks, which makes it possible to examine new kinds of impact, and to study societal impact beyond the traditional scholarly domain. With the growth of user groups and communities and the wide scope of data sources for information transfer and usage the demand for connectability and interoperability with the necessity of harmonization, standardization, and integration of data emerged (Daraio and Glänzel, 2016).

Software development in recent decades and publicly available data sources, such as Google Scholar and academic licenses for commercial abstract and citation databases with bibliometric features, have opened up bibliometrics to a broader user group among scientists, librarians, and bibliometric semiprofessionals. This has fostered uninformed use of bibliometrics and technometrics, most notably in an evaluative context. This development underlines the necessity of providing an up-to-date handbook on quantitative S&T research to scientists and practitioners, not only reporting the state of the art in the discipline but also giving guidance to practitioners and potential users of S&T indicators.

The contributions to the *Springer Handbook of Science and Technology Indicators* reflect a wide variety of attributes of the contemporary S&T system. Most central concepts have not changed since the previous edition as these include scientific or technological performance, and the productivity or efficiency of the S&T system and its constituent parts. The question of how performance or productivity could be measured also remains a crucial issue but contexts and applications have created new challenges, data provide more and better information, the general trend towards the meso and increasingly micro level has continued, requiring more accuracy and finer granularity. The question of how the various parts in an S&T system react with one another and how this interaction affects the overall performance is still of foremost importance. The need for measuring the impact of research beyond scholarly communication, including policy impact and impact on society, called *broader impact*, has become one of the driving forces for the development of our field. This also includes the necessity of exploiting and mining unstructured and nonstandardized sources for relevant information, a new challenge of big-data processing that has broadened our field further towards computer and information science with the development of new algorithms and new retrieval techniques. These sources and techniques are not replacing the traditional ones based on well-standardized bibliographic and patent databases but they essentially extend traditional quantitative science and technology studies by giving them a new perspective and dimension. To stay abreast of these changes, this handbook includes a new part on the development and application of new indicators (Part D: New Indicators for Research Assessment).

Many new web indicators have been developed since the last handbook was published. In addition to a small set of webometrics, the Altmetrics initiative, started by Jason Priem in 2010, led to the creation of a wide range of new indicators derived from social web sources. It also led to the creation of organizations devoted to collecting and selling altmetric values, including ImpactStory, Altmetric.com, and Plum Analytics. Altmetrics are now widely deployed by publishers in their digital libraries alongside citation counts and are being considered for (limited) research evaluation contexts. Their promise is that they may reflect nonscholarly types of impacts that are ignored by citations from other journal articles, and/or that they may appear more quickly than citations, allowing earlier impact evidence. Most alternative indicators are also easily manipulated and subject to irrelevant uses, however. This makes them difficult to use in most research evaluation contexts. Nevertheless, they can be valuable for self-evaluation and ongoing monitoring purposes (e. g., by funding organizations), if used carefully. They may also be useful on an ad-hoc basis to support narrative claims for nonscholarly impacts. For example, there are instances of this type of use in the case study parts of the 2016 UK Research Excellence Framework evaluations.

In terms of individual new indicators, counts of readers in the social reference manager Mendeley are worth a special mention. These are like citation counts in that they primarily reflect scholarly impact but appear a year earlier, allowing timelier evaluations. In contrast, Altmetric.com scans many policy documents for citations to academic research. Policy mentions give clear evidence of important nonscholarly impacts for academic research. There are also alternative indicators that reflect arts and humanities impacts (e. g., Google Books citations, online reviews), educational impacts (syllabus mentions), and commercial impacts (e. g., Google Patents citations). One of the best-known indicators, tweet counts, appear to primarily reflect publicity, however, and there is no alternative indicator yet that gives good evidence of public interest in research. For this, media mentions are probably the best proxy available. Indicators like download counts are particularly useful for investigating the scholarly communication process by giving insights into patterns of use for documents, including by scholars and students.

In the following, we will give an overview of the chapters that are included in this handbook.

Part A: Analysis of Data Sources and Network Analysis

The chapter by *Vincent Larivière* and *Cassidy R. Sugimoto* deals with the journal impact factor, probably the most widely used bibliometric construct. They argue that this indicator is, by far, the most discussed bibliometric indicator, and has been widely dissected and debated by scholars of every disciplinary orientation. Their chapter presents a brief history of the indicator and highlights a series of well-known limitations, and draws on the existing literature as well as on original research. They highlight the adverse effects of the use of this indicator on authors and publishers, and describe alternative journal-based indicators. Their chapter ends with a call for responsible application of journal indicators, and a commentary on future developments in journal indicators.

Subject delineation has become one of the prominent tasks in bibliometric domain studies. *Michel Zitt*, *Alain Lelu*, *Martine Cadot*, and *Guillaume Cabanac* describe this complex task using three models as a question of disciplines versus invisible colleges. The models, which can be favorably combined with each other, are existing classification schemes, information retrieval, and clustering exercises. The authors discuss the opportunities and limitations of the bibliometric techniques underlying information retrieval, data analysis, and network analysis. They show how multiple network approaches allow the comparison and combination of bibliometric networks. The authors focus on textual and citation networks, but outline possibilities and methods for hybridization. The chapter concludes with a discussion of typical subject delineation schemes and protocols.

In their chapter, *Ronald Rousseau*, *Lin Zhang*, and *Xiaojun Hu* provide a systematic review of interdisciplinarity in scientific research. First, they examine the phenomenon of interdisciplinary research (IDR) from a conceptual perspective and discuss its characteristics and driving forces. The second part is devoted to its quantification and measurement from the information science perspective. The authors proceed from the assumption that IDR is mirrored in the published research documents by the integration of knowledge from different subjects. The authors review existing approaches to measure knowledge integration and show their limitations. Proceeding from the notion by Stirling, Rafols, and Meyer proposing three main components of interdisciplinarity (diversity, variety, and evenness), they propose a true diversity measure. An example from the field of synthetic biology provides an illustration and the chapter concludes with suggestions for future research.

Emilio Delgado López-Cózar, *Enrique Orduna-Malea*, and *Alberto Martín-Martín* argue that the launch of Google Scholar (GS) marked the beginning of a revolution in the scientific information market, because of its automatic indexing of information directly obtained from the web, its ease of use, and its wide coverage. Their chapter lays the foundations for the use of GS as a supplementary source for scientific evaluation, by giving an overview of how GS works, and providing statistics about its size, coverage, and growth rate. In addition, the authors conduct a systematic analysis of the main limitations of GS as an evaluation tool, and compare GS with traditional citation indexes. They conclude that GS presents a broader view of the academic world than the traditional indexes as it includes many previously invisible sources.

The next chapter is devoted to the analysis of current publication trends in gold Open Access (OA). In the first part, *Daniel Torres-Salinas, Nicolas Robinson-Garcia*, and *Henk F. Moed* give a comprehensive review of the current literature on Open Access, specifically in relation to its "citation advantage." This chapter has three dimensions: countries, subject fields, and journals. In the light of this, the authors investigate national gold OA publication patterns, OA journal characteristics and citation differences between gold OA and nongold OA publications, and factors that may affect differences in citation impact between OA and conventional, toll-access journals. The authors also discuss scientists' OA publication strategies and patterns as well as the role of predatory OA journals.

Forecasting future developments in science, technology, and innovation (STI) is the subject of the chapter by *Katy Börner* and *Staša Milojević*. Such forecasts are based on advanced mathematical-statistical and computational models of the STI system, and are facilitated by advances in computational power and in the availability of numerous "big" datasets containing not only bibliometric, but also funding, stock market, social media, and other types of data. Advanced models can be used to simulate and understand the structure and dynamics of the STI system, and enhance human decision-making.

Science mapping in the form of studies of structural aspects of document and actor networks plays an important role in quantitative science studies. The following three chapters tackle this important topic within contemporary scientometric research. The first gives an overview of the advanced bibliometric tool for structural analysis and visualization. The second chapter is devoted to the challenges of the analysis of large-scale bibliometric networks and the third deals above all with fundamental methodological questions of science mapping and topic identification.

Science mapping involves the development and application of computational techniques for the visualization, analysis, and modeling of scientific and technological activities. It is an advanced bibliometric tool to analyze and mine scientific output. *Jose A. Moral-Munoz*, *Antonio G. López-Herrera*, *Enrique Herrera-Viedma*, and *Manuel J. Cobo* review six freely available, comprehensive science mapping tools: Bibexcel, CiteSpace II, CitNetExplorer, SciMAT, Sci2 Tool, and VOSviewer. The authors discuss the strengths and limitations of these tools related to data processing, analysis options, and visualization. They argue that each tool has different properties, and the choice of one over another depends on the type of actors to be analyzed and the type of output expected.

Kevin Boyack and *Richard Klavans* point to the new challenges that have emerged since the last *Handbook of Quantitative Science and Technology Research* was published. The recent science mapping evolution has been facilitated by the availability of full text databases, increased computing capacity, and the development of new algorithms. This has allowed mapping technology to transition from the analysis of small networks to large-scale exercises. The focus is on the analysis of large-scale, global bibliometric networks. The authors give a state-of-the-art report and discuss the commonly used data sources and methods from a historical perspective, continuing to the most recent developments. Their own large-scale topic-level model is used to illustrate the analysis of large-scale bibliometric networks and potential applications.

In his chapter, *Bart Thijs* identifies three drivers of scientometric mapping of science: information-technological innovation; improved community detection; and methodological advancements in the field of scientometrics itself. The author shows that scientometric methodologies using citation-link and lexical approaches lagged the development of the first two drivers. He discusses methodological issues related to community detection. The different approaches to the creation of global maps and the possibility of achieving comparable results at higher levels of granularity are contrasted with the fine-grained solutions possible from local mapping.

Part B: Advancement of Methodology for Research Assessment

Anthony F.J. van Raan gives a comprehensive overview of the methodology and application of advanced bibliometric indicators and introduces bibliometrics as a powerful instrument for the study of science. His historical review starts from the beginning of professional bibliometrics and covers the role of citation indexing in the emergence of the discipline of scientometrics. The review discusses how citation indexing revolutionized quantitative science studies and continues until the stage of contemporary bibliometrics in the internet age. This introduction is followed by a description of advanced state-of-the-art bibliometrics with its rationale and practical needs. The author proceeds from the two main pillars, citation analysis and mapping of science, which can be reduced to a single principle. The author deduces a set of main indicators to be used for research performance assessment with regard to the developments at the Leiden Institute. The conceptual-methodological part is followed by applications of indicators in an evaluative context with various real-life examples. In this context, the author discusses also problematic and controversial issues, such as the use of journal impact factors, the h-index, publication assignment, subject delineation, and university rankings. The last part of the chapter deals with the above-mentioned second pillar of bibliometrics, the mapping of science. Hybrid techniques, the combination of citation analysis and science mapping, and new fields of application are described and discussed.

Ludo Waltman and *Nees Jan van Eck* present a comprehensive overview of a class of bibliometric indicators that are among the most important in bibliometrics, namely field-normalized indicators. The term field indicates a branch of knowledge, such as a research discipline, specialty, or topic. Field-normalized indicators make corrections for differences among fields, so that groups of researchers from different fields can be compared with one another. The authors give an overview of the various field-normalization approaches. Most importantly, they also illustrate how indicators themselves can be evaluated, and how the choice of an approach may affect the outcomes of a bibliometric analysis.

The h-index and its derivatives have become perhaps the most popular and most commonly used bibliometric indicators besides the journal impact factor. Research and applications of Hirsch-type indexes have consequently yielded a large body of literature within our field over the last decade. *András Schubert* and *Gábor Schubert* provide a guided bibliometric tour through more than 3000 papers on this topic. Special attention is paid to the theoretical, mathematical and axiomatic background and various applications as well as the possibility of applying the h-index as a network indicator.

The method of Characteristic Scores and Scales (CSS) was originally proposed in the second half of the 1980s, when their large-scale calculations were still a computational challenge. Because of increased data availability and computational capacity, the method has now become practical. *Wolfgang Glänzel, Bart Thijs*, and *Koenraad Debackere* provide an overview of the various fields of application of this method, which aims to replace the traditional linear approach to citation impact evaluation by a distributional one with a focus on the high end of performance. A discussion of the mathematical background and statistical properties is followed by the implementation of the method in assessment exercises at different levels of aggregation as well as in various disciplinary and multidisciplinary contexts.

The development and application of bibliometric indicators of research performance at the level of individual authors is one of the most debated and complex issues in quantitative science and technology studies. *Lorna Wildgaard* presents a critical overview of the development of this type of indicator. She discusses characteristics and mathematical properties of 68 author-level indicators, and highlights their potential and limitations. The major theme of her contribution is setting the argument for the need to monitor and evaluate current indicator production.

Policy implementation of relevant science, technology, and innovation indicators requires appropriate data management methods, and data integration has become a central issue in this regard. Two main approaches to data integration are in use: procedural and declarative. *Maurizio Lenzerini* and *Cinzia Daraio* follow the latter approach by focusing on the ontology-based data integration (OBDI) paradigm. They discuss the five main principles of this paradigm and the challenges of data integration. Finally, *Sapientia* (the ontology of multidimensional research assessment and its OBDI system) developed at Sapienza University of Rome is provided as an example of an open and collaborative platform for research assessment.

Synergy in innovation systems is studied by *Loet Leydesdorff*, *Inga Ivanova*, and *Martin Meyer* within the framework of the Triple Helix model of university–industry–government relations. This is used as a metaphor in modeling the knowledge-based economy and innovation. Synergy is introduced and analyzed here in the context of the generation of redundancy, the measures of which are derived from an information-theoretic model. Using examples from several countries, it is shown how the Triple-Helix synergy indicator can be applied to analyze regions or sectors in which uncertainty has been significantly reduced and which contribute most to the generation of redundancy. The model and its indicators thus allow the quantification and measurement of the quality of innovation systems at different geographical scales and in terms of sectors.

Part C: Science Systems and Research Policy

The interrelationship between scientometrics and research policy is studied and discussed by *Koenraad Debackere*, *Wolfgang Glänzel*, and *Bart Thijs*. Scientometrics is shown to be a discipline that emerged from the library and information needs of scientific communities and grown into a powerful instrument providing advanced tools and indicators for policy-relevant research assessment. This development is depicted as a symbiosis between scientometrics and science policy. The authors use the example of the *Flemish Expertise Center for R&D Monitoring* (ECOOM) to illustrate this coevolution, pointing to its opportunities, challenges, and limitations.

Research assessment exercises monitoring and evaluating national or regional research performance have a high priority in research management and national research policies. In their chapter, *Sybille Hinze*, *Linda Butler*, *Paul Donner*, and *Ian McAllister* use bibliometric tools to analyze and compare the effects and efficiency of the research assessment regimes of three selected countries (UK, Australia, and Germany). Although the assessment systems of the three countries differ considerably, large differences could not be found regarding their effects and efficiency. They conclude that the systems make less difference than the implementation of an assessment exercise. They further conclude that to understand the mechanisms behind changing performance, indicators are not enough and need to be supplemented by contextual information at various levels of aggregation.

The globalization of research and the use of bibliometric indicators to study this process are the subject of a chapter by *Jacqueline Leta*, *Raymundo das Neves Machado*, and *Roberto Mario Lovón Canchumani*. Given the growing importance of the BRICS countries Brazil, Russia, India, China, and South Africa in the global economy and the science system, the authors focus on scientific collaboration among these countries. They also illustrate how bibliometric techniques can be used to examine traces of the effects of the foundation of the BRICS group upon the international collaboration among its members. A series of techniques was used, including diachronic analysis, Bradford's law, and journal cocitation analysis.

As China publishes over 5000 scientific-scholarly journals, it has developed extensive expertise in journal publishing and journal evaluation. *Zheng Ma* reviews the development of the Chinese journal system in scientific, technical, and medical (STM) fields. The author describes the characteristics of evaluation systems of national journals as compared to those related to international periodicals, in terms of their respective evaluation purposes, evaluation methods, key features, and evaluation criteria. Two cases are presented of China's research work on the evaluation of STM journals, namely the development of the so-called boom index and of comprehensive performance scores for Chinese STM journals. The author also presents analyses of the English-language STM journals in China, and introduces an atomic structure model for evaluating English-language scientific journals published in non-English countries.

Gali Halevi focuses on a crucial issue in science policy, namely the gaps between men and women in the domain of science and scholarship. She provides a thorough review of the various approaches combining bibliometric and other types of research information to the identification of gender among authors of scientific-scholarly literature, and to the measurement of gender disparities. She discusses a series of studies explaining barriers to female participation, and argues that for a comprehensive picture of the underrepresentation of women, bibliometric studies have become an essential tool for tracking not only research participation itself, but also its impact on scientific discovery.

Two chapters are devoted to the measurement of research impact beyond scholarly communication. The first chapter shows how the medical literature is used by clinicians and by the public, while the second reviews and discusses societal impact indicators in recent literature.

The study presented by *Elena Pallari* and *Grant Lewison* analyses how biomedical research could influence its two main goals in improving healthcare: better patient treatment and prevention of illness. They examine two approaches: the research base underlying clinical practice guidelines (CPGs) linked to patient treatment, and stories in the mass media as an expression of healthcare policy. The authors collected CPGs and newsletters from 21 and 22 European countries, respectively, and used Web of Science (WoS) journal articles as their evidence base. The medical research stories from newspapers were linked to research by the WoS papers they cited. The authors found a discrepancy between the papers cited by CPGs and in newspaper stories, on one hand, and those that are frequently cited in scholarly literature, on the other hand. They found that even relatively neglected subject areas could be an important source for medical practice and the general public.

Lutz Bornmann and *Robin Haunschild* give an overview of the literature on societal impact measurement. They first delineate the concept of societal impact, describe the reasons for its emergence, and point to the problems in measuring this kind of impact. Using examples of major projects, they illustrate how frameworks for the measurement of societal impact can be integrated into evaluative contexts. In the last part of their chapter, the authors discuss the possibility of alternative metrics (altmetrics) to measure societal impact.

The use of econometric approaches for the measurement of research productivity, an important concept in research policy and for the wider public, is the subject of a chapter by *Cinzia Daraio*. It explains the benefits of econometric models in research assessment and shows their added value compared to more traditional bibliometric or informetric approaches. Moreover, it gives a theoretical discussion of the nature as well as the ambiguities of the concept of productivity and other key notions in research performance measurement. On the practical side, it presents a checklist for developing econometric models of research assessment.

Gunnar Sivertsen describes the development of a new type of data source for science studies. Institutional and national current research information systems (CRIS) are used to standardize and facilitate research output reporting and research administration. With their high standard of coverage, quality, and standardization, CRIS systems also have the potential to be used as data sources for science studies. Basic requirements are interoperability and data integration at the institutional and national levels. The chapter focuses on challenges and solutions to the development of internationally integrated CRIS. Challenges and possible solutions reaching far beyond the technical are described from the international level to a concrete national example. The authors also show that internationally integrated CRIS can be used for science studies.

Part D: New Indicators for Research Assessment

Indicators for academic outputs derived from social media, such as Twitter, are sometimes known as altmetrics. These are typically quicker to appear than citation counts but are not subject to peer review. These properties make social media indicators fundamentally different from citation-based indicators and there is uncertainty about how they should be used. *Paul Wouters*, *Zohreh Zahedi*, and *Rodrigo Costas* propose principles and conceptual frameworks for using social media data effectively and responsibly in research evaluation contexts. Their chapter gives practical advice as well as theory-based arguments and applies to current as well as future social media indicators.

Monographs, edited books, and book chapters are central to areas of the social sciences and humanities, and can sometimes be important outputs for other researchers. *Alesia Zuccala* and *Nicolas Robinson Garcia* review studies assessing the value of scholarly books. They show that important contributions have been made by four different expert communities, which they define as monitors, subject classifiers, indexers, and indicator constructionists. This unique perspective helps to clarify the advances that need to be made if this relatively under-researched area is to mature as a standard part of the bibliometric landscape.

The pioneering microblog site Twitter is widely used by academics to post about academic publications, such as by announcing the journal articles that they are reading. Counts of tweets about academic outputs are often described as altmetrics. *Stefanie Haustein* reviews studies about the value and interpretation of Twitter altmetrics in many fields. In addition, she uses an analysis of 24 million tweets about scholarly documents to give a detailed exploration of the context of Twitter altmetrics. This information includes the types of documents tweeted about and different types of tweeting patterns, including the problem of nonhuman tweeters.

The social reference manager Mendeley can be used for evidence of the impact of academic publications by counting the number of Mendeley users that have registered them in their personal libraries. *Ehsan Mohammadi* and *Mike Thelwall* discuss how this information is an indicator of the scholarly readership of scholarly outputs and gives citation-like impact evidence. They argue that Mendeley provides earlier impact evidence than citations and its readership data is therefore useful for research evaluations where timely impact data is important. Mendeley is also useful for the background information that it gives about readers, including their job, subject area, and national base.

Any empirical use of web indicators involves gathering data from the web at some stage. This is not as straightforward as downloading citation data from bibliometric or patent databases. *Judit Bar-Ilan* gives a historical overview of methods to gather informetric data from the web, including the main problems and proposed solutions. She shows that researchers have often had to use imperfect methods, such as queries in commercial search engines, to gather their data and this can give misleading results. She emphases that it is important for those collecting data to devote time to data cleansing and other techniques that will help to produce the most accurate and reliable information.

Although scholarly indicators derived from the social web have attracted more attention than indicators derived from the web, the latter seem to be more effective at providing evidence of nonscholarly impacts. *Kayvan Kousha* demonstrates that online data gathering, often through clever standardized queries in commercial search engines, can give indicators of educational, health, informational, general, and other impacts. The methods sometimes take advantage of individual important websites, such as Wikipedia, and sometimes search for evidence from a large part of the web. Kousha's chapter discusses the methods used to generate a range of web-based indicators and reviews evidence of their limitations and value.

Scholarly articles are usually available in electronic form and sometimes only in digital versions. Before an article can be cited, it must be accessed and this may well involve downloading it from a publisher website or a digital repository. Data from such sources may therefore give earlier evidence of the academic impact of publications and perhaps also evidence of interest from nonpublishing audiences. *Edwin A. Henneken* and *Michael J. Kurtz* demonstrate how analyzing the log files of a digital repository can give new types of detailed information about how academic research is accessed. They illustrate this with a detailed analysis of clickstream data from the Astrophysics Data System of peer reviewed and other publications about astronomy and physics.

Although most research evaluations focus mainly on journal articles and perhaps also books, a range of other types of activity and output are important to the missions of academia. It is important that the contributions of scholars producing nonstandard outputs are recognized and one way of achieving this is by generating impact indicators to support qualitative claims for their value or impact. *Mike Thelwall* introduces online indicators for different types of scholarly output that take advantage of easily available online quantitative data, such as view or download counts published online or available for automatic harvesting. Whilst interpreting the numerical information is complex due to the variety of different goals and audiences for ostensibly similar outputs, the survey shows that useful data is often available, although always with limitations.

Part E: Advancement of Methodology for Patent Analysis

The present handbook covers both science and technology indicators, as they are closely intertwined. Science is primarily linked to publication indicators, and technology to patent indicators. Nevertheless, the logic behind publication and patent statistics are quite different, so that multiple chapters are needed to explain different aspects of patent statistics. Furthermore, in addition to patents, trademarks and standards are also used as technology indicators. These alternative indicators are discussed in two chapters.

A general challenge of patent analysis is the growing number of patent applications, so that it is increasingly difficult to identify all relevant documents referring to a specific topic. For this purpose, *Carson K. Leung*, *Wookey Lee*, and *Justin Jongsu Song* present an advanced text-based retrieval system and compare three different retrieval algorithms. With their approach, patent documents that are relevant to keyword terms in a user query can be retrieved efficiently without returning many irrelevant patent documents.

A specific characteristic of patents in comparison to publications is that the text is not written by the inventors, but by patent attorneys. The latter have a decisive influence on the successful process of a patent application. *Rainer Frietsch* and *Peter Neuhäusler* analyze the differences between experienced and less experienced attorneys in more detail.

A further peculiarity of patents is that most include images of the invention. On this basis, images can be used for patent retrieval as well. *Ilias Gialampoukidis*, *Anastasia Moumtzidou*, *Stefanos Vrochidis*, and *Ioannis Kompatsiaris* describe different computer-based approaches and illustrate them with examples.

Ulrich Schmoch and *Mosahid Khan* deal with new methodological issues of retrieval for patent indicators linked to the change of the patent system in the last 20 years and the new ways to access patent data. It describes international flows of patent applications between the US, Europe, and Southeast Asia and illustrates methods for an appropriate cross-country comparison. A central topic of this chapter is the implications of the frequently used Patent Cooperation Treaty (PCT) route of patent applications on the conception of search strategies and the interpretation of search results. Furthermore, the possibilities of search with the new international Cooperative Patent Classification (CPC) are explained. In addition, the patenting activities of very large companies and the patent value are discussed.

For knowledge-based technologies, scientific and technological activities are performed in parallel and influence each other. Here it is useful to identify similar patents and publications. *Tom Magerman* and *Bart Van Looy* present linguistic text mining approaches to identify similarities and illustrate them with examples. They discuss the advantages and disadvantages of different retrieval methods.

Contributions in this handbook show that more powerful computer systems have increased the power of text mining in science and technology analysis. *Samira Ranaei*, *Arho Suominen*, *Alan Porter*, and *Tuomo Kässi* give a broad literature review of the most relevant approaches and show by examples their usefulness. For instance, text mining classification analysis of patents can lead to additional results. It is insightful to compare the methods of other chapters on text mining in this handbook to the assessment of the authors of this chapter.

Other contributions in this handbook also illustrate the potential of text mining. However, the quality of results are influenced by the quality of the texts analyzed. Thus, the yield of text-based retrieval at some patent offices is higher than at others depending on the legal requirements for technical disclosure of the patent abstracts. For instance, the text quality at the US Patent and Trademark Office is commendable.

An advantage of patents compared to scientific publications is their detailed classifications, so that in many cases a precise definition of a topic is feasible. However, it is possible that similar items are classified in different parts of the classification, so that it is difficult to identify all documents relevant to a topic. *Andrea Bonaccorsi*, *Gualtiero Fantoni*, *Riccardo Apreda*, and *Donata Gabelloni* suggest a functional classification system for patents which supports new types of patent searches based on functional dictionaries. Again, the approach is based on advanced text mining. The authors present some examples of contexts for which their approach is useful.

Part F: Patent System, Patents, and Economics

A widespread misconception is that software inventions can be patented only in the USA, but not in Europe. The chapter of *Peter Neuhäusler* and *Rainer Frietsch* shows that in many cases software can also be patented in Europe and that the share within all patent applications is steadily increasing. In addition, the introduction of the subclass G06Q (data processing systems or methods, specially adapted for administrative, commercial, financial, managerial, supervisory, or forecasting purposes) in 2006 confirms that the attitude of the European Patent Office about software has substantially changed.

Patents and trademarks are competitive tools for research-intensive technologies. *Sandro Mendonça*, *Ulrich Schmoch*, and *Peter Neuhäusler* show with the example of enterprises from the EU Industrial R&D Scoreboard that trademarks, product and service marks have become increasingly important, especially in the case of service marks. They illustrate with examples the fact that the strategies of enterprises for patents and trademarks vary considerably between sectors and sometimes even within sectors. They argue that trademarks should be considered in parallel to patents whenever possible.

In most countries, the annual number of patent applications is stable and changes only in the long term. A new phenomenon for threshold countries, such as South Korea and China, is the tremendous increase in the annual number of patent applications within a decade. *Chan-Yuan Wong* and *Hon-Ngen Fung* analyze South Korea and China, highlighting parallel increases in scientific activities. These types of explorations will be important for understanding the worldwide landscape of science and technology and the emergence of a new regime in international trade.

The final contribution to the technology section of this handbook is concerned with standards. It shows that new technologies are not sufficient for market success, but that the development of standards is a further decisive step. *Knut Blind* explains why standards are important for technology and that they can be used as indicators for describing supplementary aspects of technological performance.

About the Editors

Wolfgang Glänzel is Director of the Center for Research and Development Monitoring (ECOOM) and Full Professor at KU Leuven, Belgium. He is also affiliated with the Department of Science Policy and Scientometrics at the Library of the Hungarian Academy of Sciences in Budapest, Hungary. Wolfgang Glänzel studied Mathematics at the Eötvös Lorand University (ELTE) in Budapest. He holds a doctorate in Mathematics from ELTE obtained in 1984 as well as a PhD in the Social Sciences which he obtained from Leiden University, The Netherlands, in 1997. He is also Guest Professor at several Universities in China and the UK.

Wolfgang Glänzel's research activities comprise probability theory and mathematical statistics, quantitative science studies, and research policy. In the field of probability theory he has published on the characterization of probability distributions, in quantitative science studies and research policy his research is mainly focused on models of scientific communication, the development of scientometric indicators, the analysis of coauthorship patterns and research collaboration, the structural-cognitive mapping of science, bibliometrics-aided retrieval, and the measurement of research performance at various levels of aggregation. Wolfgang Glänzel has published numerous journal articles, proceedings, and book chapters and coauthored/coedited several books. He was Alexander von Humboldt Fellow for two years in Germany. He has published in probability theory and mathematical statistics, computer science and various topics in quantitative science studies, scientometrics, and informetrics.

In 1999, Professor Glänzel received the international *Derek deSolla Price Award* for outstanding contributions to the quantitative studies of science. He is Secretary-Treasurer of the *International Society for Scientometrics and Informetrics* (ISSI) and Editor-in-Chief of the Society's Newsletter. Wolfgang Glänzel has been Editor-in-Chief of the international journal *Scientometrics* since 2014 and Academic Editor of the multidisciplinary OA journal PLoS ONE since 2013.

Henk F. Moed holds a PhD degree in Science Studies and was a senior staff member and Full Professor in Research Assessment Methodologies at the Centre for Science and Technology Studies at Leiden University, The Netherlands between 1981 and 2010. He was a Senior Scientific Advisor at Elsevier, Amsterdam, from 2010–2014.

Henk Moed has been active in numerous research topics, including: the creation of bibliometric databases; the development and use of bibliometric indicators; studies of the effects of *Open Access*; bibliometric studies of international scientific migration and collaboration; comparisons of Web of Science, Scopus and Google Scholar; multi-dimensional assessment of research impact; the potential of altmetrics; ontology-based bibliometric data management.

Dr. Moed published over 100 research articles in international, peer-reviewed journals, was Program Chair of numerous international conferences in the field, and is an Editorial Board Member of several journals in his field. He was a winner of the *Derek deSolla Price Award* for outstanding contributions to the quantitative studies of science in 1999. He is currently an independent scientific advisor, and Visiting Professor at the Sapienza University of Rome and University of Granada.

Ulrich Schmoch holds a Doctoral Degree in Social and Political Sciences (University of Hannover, Germany), a Diploma of Mechanical Engineering (University of Hannover) with modules at the University of Grenoble, France, and a State Doctorate in Sociology of Science and Technology (Karlsruhe Institute of Technology KIT, Germany). From 1983–1985, he was employed in the office of a patent attorney.

Since 1986, Professor Schmoch has worked at the Fraunhofer Institute for Systems and Innovation Research (ISI), Karlsruhe, Germany, and performed and coordinated about 200 projects in the areas of innovation indicators, patent analysis, bibliometrics, systems of innovation, technology transfer, science management, innovation in threshold countries, innovations in the service sector, science-based technologies, and organization and mission of universities in an international comparison.

Between 1991–2002, Ulrich Schmoch was Deputy Head and from 2002–2004, Head of the Department *Technology Assessment and Innovation Strategies*. In 2011, he taught innovation indicators and patent statistics at the University of Stellenbosch, South Africa. Between February 2012 and September 2014 he taught as Stand-In Professor in Science Management at the German University of Public Administration in Speyer. Since 2015, he has once again been working at the Fraunhofer ISI as a Senior Researcher.

Mike Thelwall is a Professor of Data Science and leads the Statistical Cybermetrics Research Group at the University of Wolverhampton, UK, which he joined in 1989. He is also Docent at the Department of Information Studies at Åbo Akademi University in Turku, Finland, and a Research Associate at the Oxford Internet Institute. He obtained a PhD in Pure Mathematics from the University of Lancaster, UK.

Professor Thelwall has developed tools and methods for gathering and analyzing webometric and altmetric alternative indicators. His publications include 300 refereed journal articles, 30 book chapters, and 3 books.

Mike Thelwall is an Associate Editor of the Journal of the Association for Information Science and Technology and sits on four other editorial boards. He was a member of the UK's independent review of the role of metrics in research assessment (2014–2015) and is a member of the UK Forum for Responsible Research Metrics.

Part C Science Systems and Research Policy

Part F Patent System, Patents and Economics

List of Abbreviations

5G	fifth-generation wireless system

A

ABM	agent-based model
ADR	accumulation for dynamic ranking
ADS	astrophysics data system
AHDH	adaptive hierarchical density histogram
AHP	analytic hierarchy process
AIA	America Invents Act
AIDS	acquired immune deficiency syndrome
AIS	article influence score
AKM	axial *k*-means
ALIRP	author-level indicators of research production
ALM	article-level metrics
AMP	agent modeling platform
AN	attribute network
ANOVA	analysis of variance
ANT	actor–network theory
AP	advanced placement
AP	average precision
APC	article processing charges
API	application programming interface
ARC	Australian Research Council
ARI	adjusted Rand index
ASJC	All Science Journal Classification
ASM	atomic structure model
ASR	American Sociological Review
ATECO	attività economiche
AVA	autovalutazione, valutazione periodica, accreditamento
A&H	arts and humanities
A&HCI	Arts and Humanities Citation Index

B

BC	bibliographic coupling
BCCL	book classification for Chinese libraries
BDOA	Berlin Declaration on Open Access
Belspo	Belgian Federal Science Policy Office
BIS	bibliographic information system
BKCI	Book Citation Index
BKCI-S	Book Citation Index – Science
BKCI-SSH	Book Citation Index – Social Sciences & Humanities
BM25	best match 25
BMC	BioMed Central
BMJ	British Journal of Medicine
BOAI	Budapest Open Access Initiative
BOF	extraordinary research fund
BoW	bag-of-words
BRICS	Brazil, Russia, India, China and South Africa

C

CA	correspondence analysis
CAGR	compound annual growth rate
CARDI	cardiovascular disease
CAS	chemical abstracts service
CASRAI	Consortia Advancing Standards in Research Administration Information
CBA	cost–benefit analysis
CBIR	content-based image retrieval
CC	co-citation

CRISTIN	Current Research Information System in Norway
CSCD	Chinese Science Citation Database
CSS	characteristic scores and scales
CSSCI	Chinese Social Sciences Citation Index
CSTPCD	Chinese Scientific and Technical Papers and Citations Database
CSV	comma-separated values
CWTS	Centre for Science and Technology Studies

D

DALY	disability-adjusted life years
DBSCAN	density-based spatial clustering of application with noise
DC	direct citation
DCI	data citation index
DDC	Dewey Decimal Classification System

DDR	dispersion for dynamic ranking
DEA	data envelopment analysis
DGP	data generating process
DIABE	diabetes
DL	digital library
DOAJ	Directory of Open Access Journals
DOI	digital object identifier
DORA	San Francisco Declaration on Research Assessment
DORA	Declaration on Research Assessment
DSM	distributional semantic model
DSSC	dye-sensitized solar cells

E

ECLA	European classification
EDC	extended direct citation
EEA	European Economic Area
Ei	Engineering index
EM	expectation maximization algorithm
EMNPC	equalized mean-based normalized proportion cited
EMR	Elastic MapReduce
EOAC	edge orientation autocorrelogram
EPC	European Patent Convention
ER	entity resolution
ERA	Excellence in Research for Australia
ERiC	Evaluating Research in Context
ERIH	European Reference Index for the Humanities
ESCI	Emerging Sources Citation Index
ESI	Essential Science Indicators
ET	emerging technology
ETER	European Tertiary Education Register
EU FP7/H2020	EU Framework Program/Horizon 2020
EuroCRIS	European Current Research Information Systems
EV	electric vehicle

F

FAIR	findability, accessibility, interoperability, and reusability
FBS	function–behavior–structure
FCEV	fuel cell electric vehicle
FCM	fuzzy C-means method
FDI	foreign direct investment
FECR	field expected citation rate
FN	false negative
FoR	fields of research
FoS	fields of science and technology
FP	false positive
FPC	functional patent classification
FRBR	Functional Requirements for Bibliographic Records
FSS	fractional scientific strength
FTE	full time equivalent
FUSE	Foresight and Understanding from Scientific Exposition
FWCI	field-weighted citation impact
FWO	fund for scientific research Flanders

G

GAV	global-as-view
GDP	gross domestic product
GIF	Global Impact Factor
GLM	generalized linear model
GML	Graph Modeling Language
GMM	generalized method of moment

Part A

Analysis

Part A Analysis of Data Sources and Network Analysis

1. The Journal Impact Factor: A Brief History, Critique, and Discussion of Adverse Effects

Vincent Larivière, Cassidy R. Sugimoto

The journal impact factor (JIF) is, by far, the most discussed bibliometric indicator. Since its introduction over 40 years ago, it has had enormous effects on the scientific ecosystem: transforming the publishing industry, shaping hiring practices and the allocation of resources, and, as a result, reorienting the research activities and dissemination practices of scholars. Given both the ubiquity and impact of the indicator, the JIF has been widely dissected and debated by scholars of every disciplinary orientation. Drawing on the existing literature as well as original research, this chapter provides a brief history of the indicator and highlights well-known limitations—such as the asymmetry between the numerator and the denominator, differences across disciplines, the insufficient citation window, and the skewness of the underlying citation distributions. The inflation of the JIF and the weakening predictive power is discussed, as well as the adverse effects on the behaviors of individual actors and the research enterprise. Alternative journal-based indicators are described and the chapter concludes with a call for responsible application and a commentary on future developments in journal indicators.

1.1 Origins of the Journal Impact Factor

In the 1975 version of the Science Citation Index (SCI), Eugene Garfield and the Institute for Scientific Information (ISI) added a new component to their information products: the Journal Citation Reports (JCR). While *Garfield* and *Sher* proposed the concept of an *impact factor* as early as 1963 [1.1]—and tested it at a larger scale in 1972 [1.2]—the 1975 JCR was ISI's first comprehensive reporting of their data at the journal level. On the basis of more than 4.2 million references made in 1974 by 400 000 papers published in about 2400 journals, this new information source provided a detailed list of journal-to-journal citation linkages, as well as the first iteration of what would become the most discussed and derided bibliometric indicator: the journal impact factor (JIF). (For a detailed history of the journal impact factor see *Archambault* and *Larivière* [1.3].)

Garfield did not leave the community without a roadmap. In two short papers introducing the first edition of the JCR—entitled *I. Journals, References and Citations* [1.4], and *II. Why the Journal Citation Reports* [1.5]—*Garfield* provides words of both caution and optimism. Replying to some of the criticism leveled at the Science Citation Index from the scientific community, he provided a justification for interpreting citations as indicators of the *usage* of scholarly literature:

> The more frequently a journal's articles are cited, the more the world's scientific community implies that it finds the journal to be a carrier of useful information. [1.4, p. 1]

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_1

Understanding usage, wrote *Garfield*, would provide critical information on the economics of scholarly publishing and help librarians "counteract the inertia that too often prevails with regard to journal selection" [1.4, p. 1]. Data contained in the JCR would, Garfield argued, provide objective indicators for the use of journals so that librarians could make timely and informed decisions on collection management. The report would provide at scale what had required painstakingly manual analyses in previous decades [1.6]. For researchers, Garfield imagined that the JCR would help them to identify potential venues for publication. Garfield did not advocate for using the JCR to identify elite journals. Rather, he suggested that researchers use the journal-to-journal matrix to identify multidisciplinary venues at "the borders of their own fields." *Garfield* writes [1.5, p. 4–5]:

> the JCR© can be very helpful in deciding where to publish to reach the audience you want to reach. If, for example, you have a paper that deals with some interesting mathematical aspects of biological problems but is nevertheless definitely a biological paper, the JCR© show you which biological journals have the best 'connections' with math, and which are most likely to welcome the paper.

Furthermore, Garfield saw in these new reports the potential to uncover many important dimensions about the nature of science itself. In the conclusion of the introduction to the JCR, *Garfield* states [1.5, p. 5]:

> The use of the JCR can be of far-ranging significance in a field about which I can say least here – science – its planning, its evaluation, its sociology, its history. Citation analysis can be used to identify and map research fronts; to define disciplines and emerging specialties through journal relationships; to determine the interdisciplinary or multidisciplinary character and impact of research programs and projects. I say least about this, to me the most exciting aspect of its potential, because the JCR in its present form is, for such advanced applications, only a sketch of that potential, providing little more than suggestions for further and deeper examination of the massive data bank from which its sections have been extracted.

Garfield concludes with a statement of his hopes: that the JCR will "provide material for innovative research," prompting "imaginative analyses," and stimulate "with every answer it gives more questions that need answers" [1.5, p. 5]. Along these lines, *Garfield* writes in the preface of the first JCR:

> In the introduction I have tried to explain clearly what the JCR is, how it was compiled, how it can be used for some simple purposes for which, I think, it is certainly needed. I have tried also to suggest its usefulness in what I'll call more advanced research. If I have failed in the latter, it is because I have deliberately, and with some difficulty, restrained my own enthusiasm about the value of what some may find at first sight to be merely another handbook of data. Let me say only that the sociology of science is a relatively new field. I believe that JCR will prove uniquely useful in exploring it. [1.7, p. I]

The JCR did indeed provoke a reaction within the research community. Spurred by *Derek de Solla Price*'s call for a *science of science* [1.8], scholars turned to the ISI for data. The JCR and associated products became the backbone for the burgeoning field of scientometrics which sought to address, quantitatively, the questions of science: "its planning, its evaluation, its sociology, its history." In addition to fueling science studies, the JCR found new application alongside the growing emphasis on research evaluation as scholars, institutions, policy-makers, and publishers sought to find ways to measure the success of the research enterprise. This, in turn, had sizeable effects on the science system and scholarly publishing, orienting scholars' research topics and dissemination practices, as well as universities' hiring practices [1.9, 10].

The primary indicator of the JCR—the JIF—has received global attention. As of August 2017, the Core Collection of the Web of Science contained more than 5800 articles that mention the JIF. These papers are not solely in the domain of information or computing science; rather, the majority of papers dealing with JIF are published in scientific and medical journals, demonstrating the pervasive interest in this indicator across scientific fields. The goal of the present chapter is not to summarize this literature per se, but rather to focus on the central limitations that have been raised in the literature and among members of the scientific community.

Drawing on the existing literature as well as on original data, this chapter provides an overview of the JIF and of its uses, as well as a detailed, empirically based, discussion of common critiques. These include technical critiques—such as the asymmetry between the numerator and the denominator, the inclusion of journal self-citations, the length of the citation window, and the skewness of citation distributions—and interpretative critiques—such as the field- and time-dependency of the indicator. Adverse effects of the JIF are discussed and the chapter concludes with an outlook on the future of journal-based measures of scientific impact.

1.2 Calculation and Reproduction

The calculation of the JIF is relatively straightforward: the ratio between the number of citations received in a given year by documents published in a journal during the two previous years, divided by the number of items published in that journal over the two previous years. More specifically, the JIF of a given journal for the year 2016 will be obtained by the following calculation:

$$\frac{\begin{array}{c}\text{Number of citations received in 2016}\\ \text{by items published in the journal}\\ \text{in 2014–2015}\end{array}}{\begin{array}{c}\text{Number of citable items}\\ \text{published in the journal in 2014–2015}\end{array}}$$

Citable items are restricted, by document type, to articles and reviews in the denominator, but not in the numerator [1.11]; an issue we will discuss more in-depth later in the chapter. Therefore, the JIF is generally interpreted as the mean number of citations received by papers published in a given journal in the short term, despite not being exactly calculated as such.

Given its calculation, which uses one year of citation and two years of publication, it combines citations to papers that have had nearly three years of potential citations (i.e., papers published in early 2014) with citations to papers which have had slightly more than a year to receive citations (i.e., papers published at the end of 2015). The JIF is presented with three decimals to avoid ties. However, this has been argued as "false precision" [1.12] with critics advocating for the use of only one decimal point.

Each journal indexed by Clarivate Analytics in the Science Citation Index Expanded (SCIE) and the Social Science Citation Index (SSCI) receives an annual JIF. Given the long half-life of citations (and references) of journals indexed in the Arts and Humanities Citation Index (AHCI), these journals are not provided with a JIF (although some social history journals indexed in the SSCI are included). There has been a steady increase in the number of journals for which JIFs are compiled, in parallel with the increase in indexation. In 1997, 6388 journals had JIFs. This number nearly doubled 20 years later: in 2016, 11 430 received a JIF.

Despite the apparent simplicity of the calculation, JIFs are largely considered nonreproducible [1.13, 14]. However, in order to better understand the calculation of the JIF, we have attempted to recompile, using our licensed version of the Web of Science Core Collection (which includes the Science Citation Index Expanded, Social Science Citation Index, and Arts and Humanities Citation Index), the 2016 JIFs for four journals from the field of biochemistry and molecular biology: Cell, Nature Chemical Biology, PLOS Biology, and the FASEB Journal (of the Federation of American Societies for Experimental Biology). These journals were chosen to represent a range of publishers and open access models while maintaining relative homogeneity in terms of discipline and reputation.

We begin with a careful cleaning of journal names to identify citations that are not automatically matched in the Web of Science (WoS)—that is, citations that bear the name of the journal, but contain a mistake in the author name, volume, or number of pages. The inclusion of these unmatched citations provides the opportunity to essentially reverse-engineer the JIFs presented in the JCR. This reduces the opacity of the JCR, which many consider to be the results of calculations performed on a "separate database" [1.14].

Our empirical analysis (Table 1.1) shows that the inclusion of unmatched citations and the variants under which journal names appear (WoS-derived JIF) provides results that are very similar to the official JCR JIF. This suggests that there is no separate database and one can closely approximate the JIF using only the three standard citation indexes contained in the Core Collection. Furthermore, our results suggest that papers indexed in Clarivate's other indexes—e.g., the Conference Proceedings Citation Index and Book Citation Index—are not included. The inclusion of these databases would lead to an increase of the JIF for most journals, particularly those in disciplines that publish a lower proportion of their work in journals. Most importantly, our analysis demonstrates that with access to the data and careful cleaning, the JIF can be reproduced.

Table 1.1 Citations received, number of citable items, WoS-derived JIF, JCR JIF and proportion of papers obtaining the JIF value, for four journals from the field of biochemistry and molecular biology, 2014–2015 papers and 2016 citations

Journal	Citations		All citations	*N* citable items	WoS-derived JIF	JCR JIF
	Matched items	Unmatched items				
Cell	24 554	2016	26 570	869	30.575	30.410
Nat. Chem. Biol.	3858	356	4214	268	15.724	15.066
PLOS Biology	3331	290	3621	384	9.430	9.797
FASEB Journal	4088	802	4890	881	5.551	5.498

1.3 Critiques

The JIF has been called a "pox upon the land" [1.9], "a cancer that can no longer be ignored" [1.15], and the "number that's devouring science" [1.9]. Many scholars note the technical imperfections of the indicator—skewness, false precision, absence of confidence intervals, and the asymmetry in the calculation. Considerable focus has also been paid to the misapplication of the indicator—most specifically the use of the indicator at the level of an individual paper or author [1.16]. We will not review this vast literature here, much of which appears as anecdotes in editorial and comment pieces. Instead, we provide original data to examine the most discussed technical and interpretive critiques of the JIF. Furthermore, we provide new information on a previously understudied dimension of the JIF—that is, the inflation of JIFs over time.

1.3.1 The Numerator/Denominator Asymmetry

Scholarly journals publish several document types. In addition to research articles, which represent the bulk of the scientific literature, scholarly journals also publish review articles, which synthesize previous findings. These two document types, which are generally peer-reviewed, account for the majority of citations received by journals and constitute what Clarivate labels *citable items*. Over the 1900–2016 period, 69.7% of documents in the Web of Science were considered as citable items. This proportion is even more striking for recent years, with 76.0% of documents published in 2016 labeled as citable items. Other documents published by scholarly journals, such as editorials, letters to the editor, news items, and obituaries (often labeled *front material*), receive fewer citations, and are thus considered *noncitable items*. There is, however, an asymmetry in how these document types are incorporated into the calculation of the JIF: while citations received by all document types—citable and noncitable—are counted in the numerator, only citable items are counted in the denominator. This counting mechanism is not an intentional asymmetry, but rather an artifact of method for obtaining citation counts. As mentioned above, to account for mistakes in cited references and to try to be as comprehensive as possible, Clarivate focuses retrieval on all citations with the journal name or common variant [1.17] rather than using a paper-based approach to calculating citations. This has the effect of inflating the JIF: citations are counted for documents which are not considered in the denominator. The variations in document types (i.e., reduction of the number of citable items in the denominator) has also been argued as the main reason for JIF increases [1.18].

To better understand the effects of document types on the calculation of the JIF, we compiled, for the sample of four journals from the field of biochemistry and molecular biology, as well as for *Science* and *Nature*—both of which publish a high percentage of front material—citations received by citable items, noncitable items, as well as unmatched citations (Table 1.2). Following *Moed* and *van Leeuwen* [1.19, 20], our results show that noncitable items and unmatched citations account for a sizeable proportion of total citations received, from 9.8% in the case of *Cell* to 20.6% in the case of *FASEB Journal*. For the four journals from biochemistry and molecular biology, unmatched citations account for a larger proportion of citations than noncitable items. Given that these unmatched citations are likely to be made to citable items, this suggests that, at least in the case of disciplinary journals which do not typically have a large proportion of front material, the asymmetry between the numerator and the denominator does not inflate JIFs in a sizeable manner. The effect of noncitable items is much greater for interdisciplinary journals such as *Science* and *Nature*. As shown in Table 1.2, for both *Nature* and *Science*, more than 5000 citations are received in 2016 by noncitable items published in the journal in 2014–2015. This accounts

Table 1.2 Number and proportion of citations received by articles, reviews, noncitable items, and unmatched citations, for four journals from the field of biochemistry and molecular biology, as well as *Nature* and *Science*, 2014–2015 papers and 2016 citations

Journal	Articles		Reviews		Noncitable items		Unmatched citations		*N* citable items	Symmetric impact factor	JCR impact factor	Increase (%)
	N	(%)	*N*	(%)	*N*	(%)	*N*	(%)				
Cell	20 885	78.6	3068	11.5	601	2.3	2016	7.6	869	27.564	30.410	10.3
Nat. Chem. Biol.	3263	77.4	378	9.0	217	5.1	356	8.4	268	13.586	15.066	10.9
PLOS Biology	3088	85.3	6	0.2	237	6.5	290	8.0	384	8.057	9.797	21.6
FASEB Journal	3650	74.6	235	4.8	203	4.2	802	16.4	881	4.410	5.498	24.7
Nature	55 380	78.6	3925	5.6	5067	7.2	6047	8.6	1784	33.243	40.140	20.7
Science	45 708	73.0	4886	7.8	5657	9.0	6340	10.1	1721	29.398	37.210	26.6

for 7.2% and 9.0% of citations, respectively, which is greater than the percentages obtained by the sample of disciplinary journals (2.3–6.5%). Results also show that the difference in the "symmetric" JIF—with only citable items in the numerator and denominator—and the JCR JIF is greater for *Nature* and *Science* than *Cell* or *Nat. Chem. Biol.*, mostly because of citations to nonsource items. However, at scale—i.e., all journals having a JIF in 2016—the relationship between the JIF and the symmetric impact factor is quite strong, with an R^2 of 0.96 (Fig. 1.1).

These results demonstrate that the asymmetry has different effects based on (1) the proportion of front material, and (2) the completeness of citations received by the journal. Moreover, they show that most of the additional citations—i.e., citations not directly linked to citable items—are unmatched citations rather than direct citations to noncitable items. Given most of these unmatched citations are likely to be directed at source items, a more accurate calculation of the JIF could exclude citations to nonsource items, but retain unmatched citations. Of course, the ideal solution would be to perform additional data cleaning to reduce the proportion of unmatched citations and have perfect symmetry between the numerator and denominator.

1.3.2 Journal Self-Citations

The inclusion of journal self-citations in the calculation of the JIF has been a cause for concern, as it opens the door for editorial manipulations of citations [1.21–23]. Journal self-citations are those citations received by the journal that were made by other papers within that same journal. This should not be conflated with self-references, which is the proportion of references made in the articles to that journal. This is a subtle, but important difference: the proportion of self-citations is an indication of the relative impact of the work on the broader community, whereas the proportion of self-references provides an indication of the foundation of work upon which that journal is built. From a technical standpoint, the main concern in the construction of the JIF is the degree to which self-citations can be used to inflate the indicator. Given that self-citations are directly under the control of the authors (and, indirectly, the editors), this has been seen as a potential flaw that can be exploited by malicious authors and editors.

There are many myths and misunderstandings in this area. For example, it has been argued that authors in high-impact journals are more likely to self-cite than those in low-impact journals because "the former authors in general are more experienced and more successful" [1.13, p. 50]. However, this is a conflation of self-citations and self-references. Authors with longer publication histories are, indeed, more likely to have material to self-reference. However, successful authors are likely to have lower self-citation rates, as they are likely to generate citations from a broader audience. Furthermore, this conflates the practices of an individual author (who publishes in many journals) to the self-citation of a journal, which is much more dependent upon the specialization of the journal, among other factors [1.24]. There is also a distinction to be made between the number and proportion of self-citations. As ISI observed in internal analyses, "a high number of self-citations does not always result in a high rate of self-citation" [1.25, par. 15]. For example, a study of psychology journals found that articles in high-impact journals tend to receive a higher *number* of self-citations than articles in lower impact journals. However, the *ratio* of self-citations to total citations tends to be lower for high-impact journals [1.13].

Producers of the JIF thus face a Cornelian dilemma when it comes to self-citations: while including them can lead to manipulation, excluding them penalizes niche journals and certain specialties. In response to these concerns, ISI undertook an analysis of the prevalence and effect of journal self-citations [1.25]. In an analysis of 5876 journals in the 2002 Science Edition of the JCR, ISI found that the mean self-citation rate was around 12%. Our analysis of 2016 citation data for papers published in 2014–2015 reinforces this: we find that the percentage of self-citations across all disciplines remains around 12% (Fig. 1.2). However, the percentage varies widely by discipline, with arts and humanities having far higher degrees of self-citation than clinical and biomedical research. This suggests that, on average, the majority of citations do not come in the form of self-citations and makes abuses easier to identify.

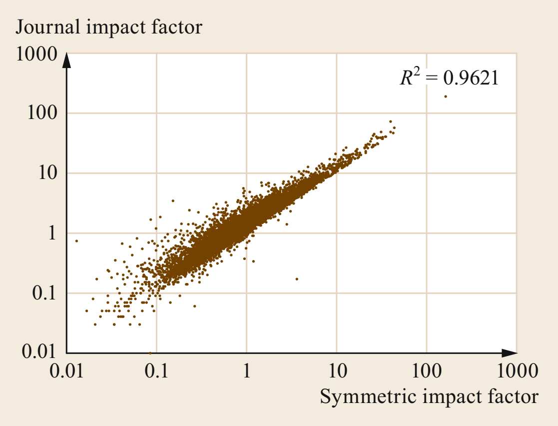

Fig. 1.1 Correlation between the JIF and the symmetric impact factor, 2016

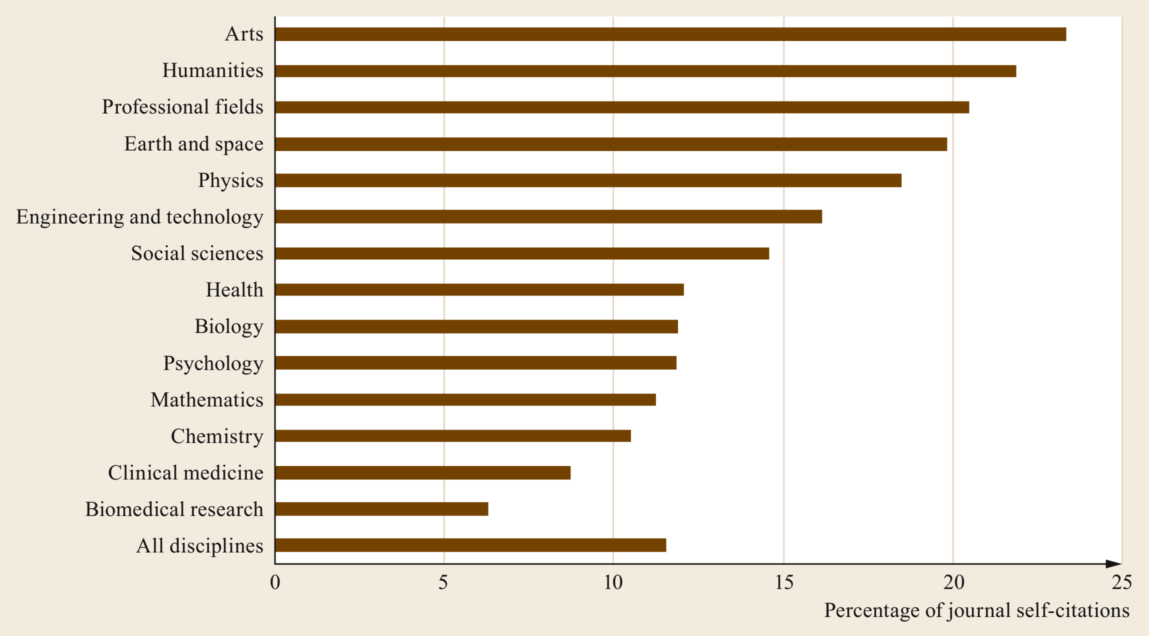

Fig. 1.2 Percentage of journal self-citations, by discipline, for citations received in 2016 by papers published in 2014–2015

The ISI analysis also examined the correlation between self-citation rates and JIFs. While studies focusing on particular domains have found varying results [1.13, 26, 27], the large-scale analysis by ISI found a weak negative correlation between JIF and rates of journal self-citation [1.25]. The analysis noted that self-citation had little effect on the relative ranking of high-impact journals, given that journals in the top quartile of JIFs tended to have self-citation rates of 10% or less. Lower impact journals, however, were more dependent upon self-citations [1.25]. We found similar results for all 2016 journals. As shown in Fig. 1.3a, there is a relatively strong correlation between a journal's total number of external citations (i.e., non self-citations) and its number of self-citations, which suggests that external- and self-citations are related, but also that there are other factors influencing the relationship, such as the level of specialism of the journal. For instance,

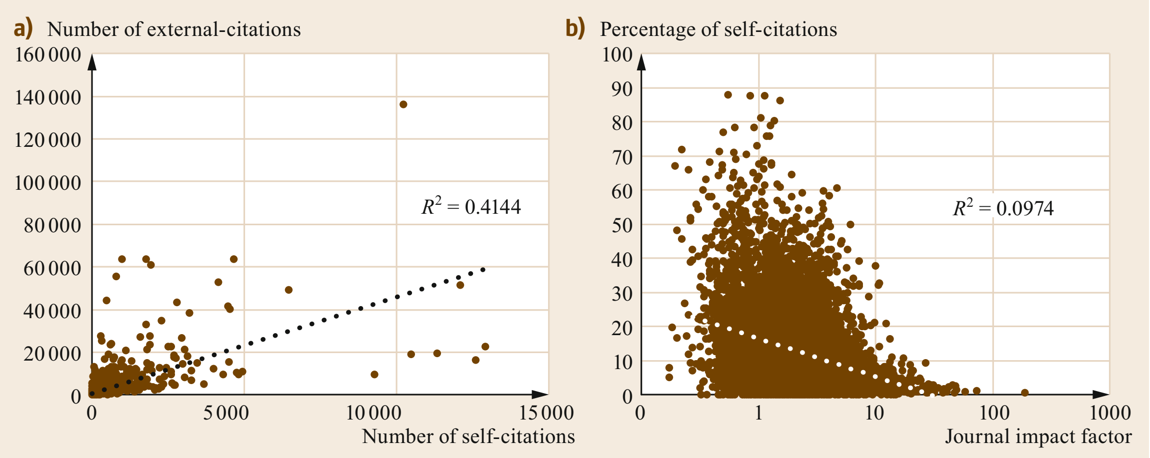

Fig. 1.3a,b Correlation at the journal level between **(a)** the number of journal *external* citations and number of journal self-citations and **(b)** the percentage of self-citations and the Impact Factor, for year 2016. Only journals with at least 50 citations in 2016 to material published in 2014–2015 are shown.

2014–2015 papers from the *Journal of High Energy Physics* received 18 651 citations in 2016, of which 9285 (50%) came from the same journal. Other more generalist journals in that domain—such as *Physical Review B* and *Monthly Notices of the Royal Astronomical Society*—exhibit a similar pattern.

The irony of the concern between self-citation and JIFs, however, is that the relationship is inverted: there is actually a negative relationship between the percentage of self-citations for a journal and the JIF (Fig. 1.3b). That is, those journals with the highest JIFs tend to have the lowest percentage of self-citations. There is, simply speaking, a limit on the advantages of self-citations. There are many more articles outside of the journal than within and relying on citations within can only generate a finite number of citations. A variant JIF omitting self-citations is now available in the JCR. However, the two-year JIF including self-citations continues to be the dominant form.

1.3.3 Length of Citation Window

The JIF includes citations received in a single year by papers published in the journal over the two preceding years. As such, it is generally considered to cover citations received by papers over a two-year window. This focus on the short-term impact of scholarly documents is problematic as it favors disciplines that accumulate citations faster. For example, comparing mean citation rates of papers published in the *Lancet* and in the *American Sociological Review* (ASR)—two journals with very different JIFs (47.83 versus 4.4 in 2016)—*Glänzel* and *Moed* [1.29] have shown that while papers published in the *Lancet* had a higher mean citation rate for two- and three-year citation windows, those published in *ASR* were more highly cited when a longer citation window was used.

This trend can be observed at the macrolevel: Figure 1.4 presents the annual number of citations (Fig. 1.4a), cumulative number of citations (Fig. 1.4b), and the cumulative proportion of citations (Fig. 1.4c), for all papers published in 1985 across four disciplines (biomedical research, psychology, physics, and social sciences). These data show that citations to biomedical research and physics peak two years following publication, while citations are relatively more stable following publication year in psychology and the social sciences. It is particularly revealing that psychology papers receive, on average, more citations (cumulatively) than physics papers. While physics papers generate more citations than psychology papers within the first five years, the reverse is true for the following 25 years.

Despite these disciplinary differences in the speed at which citations accumulate, the two-year window appears to be ill-suited across all disciplines, as it covers only a small fraction of citations received over time. For example, using a 30-year citation window, we find that the first two years captures only 16% of citations for physics papers, 15% for biomedical research, 8% for social science papers, and 7% in psychology. Figure 1.4

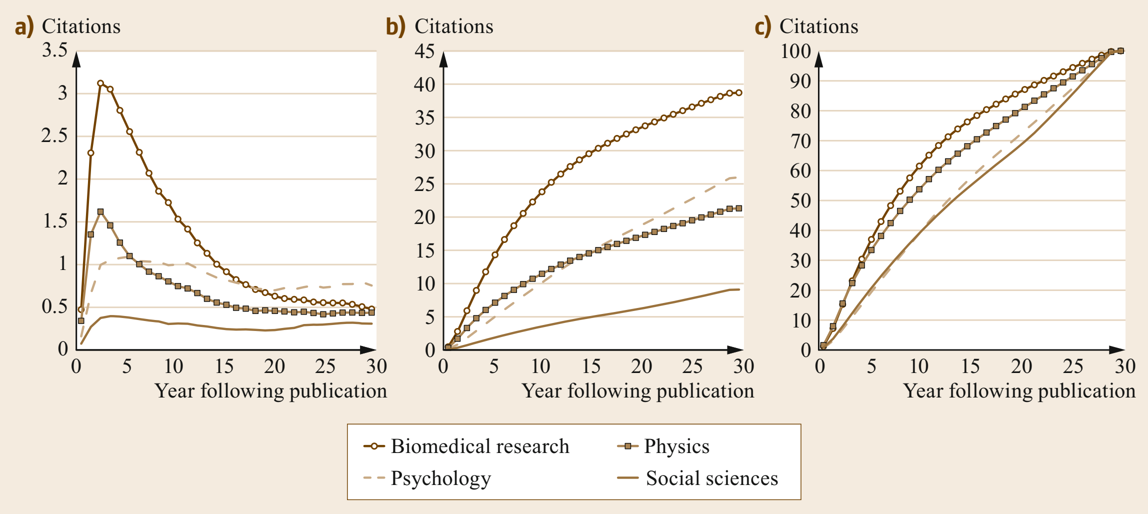

Fig. 1.4 Number of citations (**a**), cumulative number of citations (**b**), and cumulative proportion of citations (**c**), by year following publication for papers published in 1985 in biomedical research, psychology, physics and social sciences (according to the National Science Foundation (NSF) field and subfield classification (after [1.28])

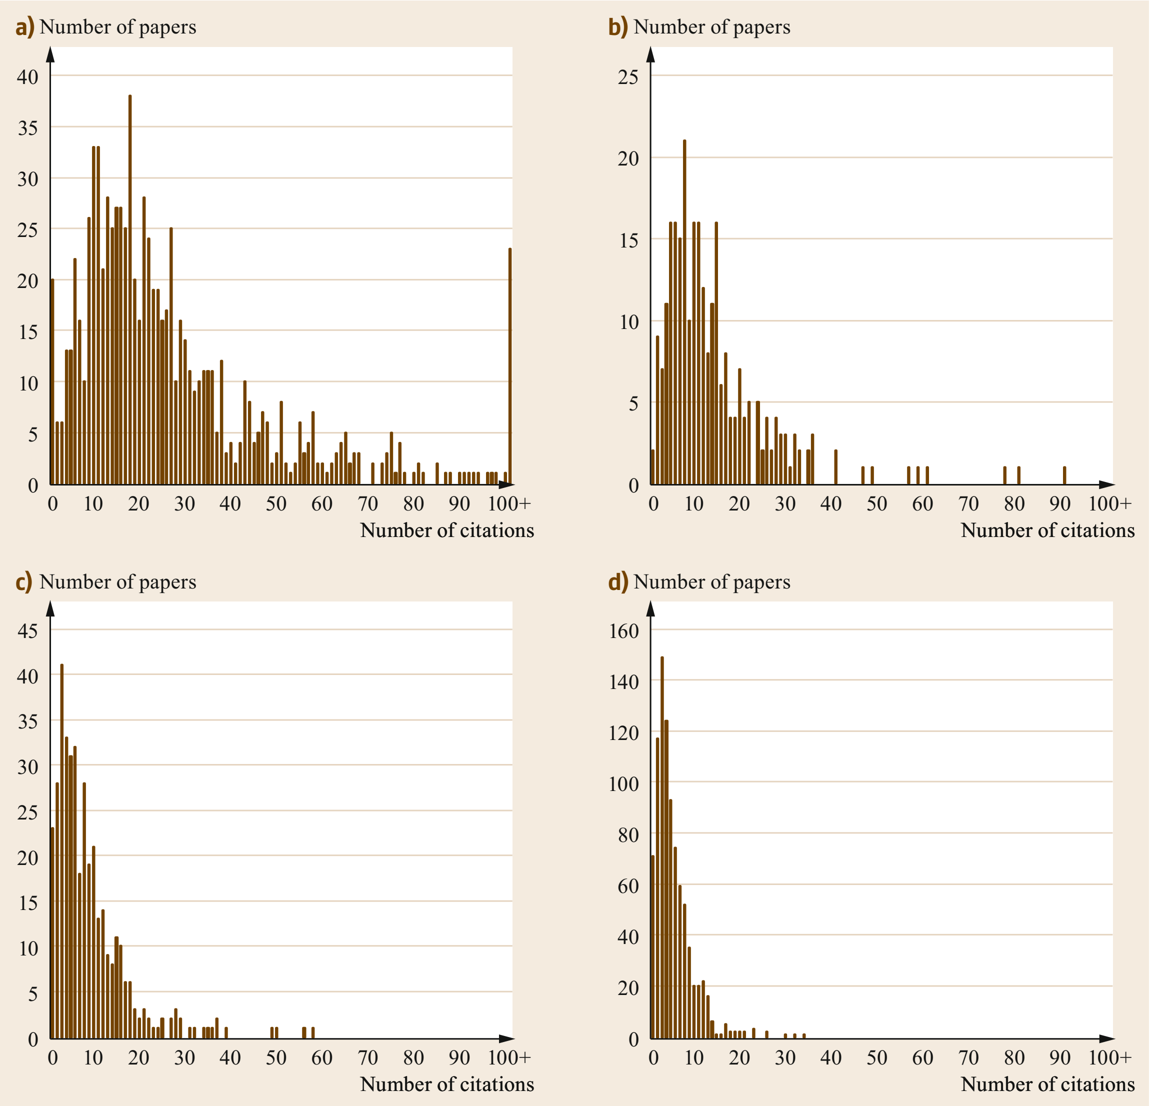

Fig. 1.5a–d Distribution of citations received by articles and reviews, for four journals from the field of biochemistry and molecular biology, 2014–2015 papers and 2016 citations. **(a)** Cell (JIF = 30.410), **(b)** Nat. Chem. Biol. (JIF = 15.066), **(c)** PLOS Biology (JIF = 9.797), **(d)** FASEB Journal (JIF = 5.498)

also shows that papers in biomedical research accumulate citations faster than in the other three domains. For instance, they accumulate 50% of their citations in the first eight years following publication, while it takes nine years for physics papers, 13 years for psychology papers, and 14 years for social science papers to reach the same threshold. In order to take such differences into account, the JCR has provided, since 2007, a 5-year JIF. Despite this improved citation window, which provides a more complete measurement of the impact of papers and journals, the two-year JIF remains the gold standard.

1.3.4 Skewness of Citation Distributions

Nearly a century of research has demonstrated that science is highly skewed [1.30] and that productivity and citedness are not equally distributed among scholars, articles, institutions, or nations. It is perhaps of little surprise, therefore, that the citedness of articles within a journal is also highly skewed. This was the main premise of an article published in 1992 by *Per O. Seglen* [1.31], who produced a robust empirical analysis demonstrating that a minority of papers in a journal accounted for the vast majority of citations. Given this

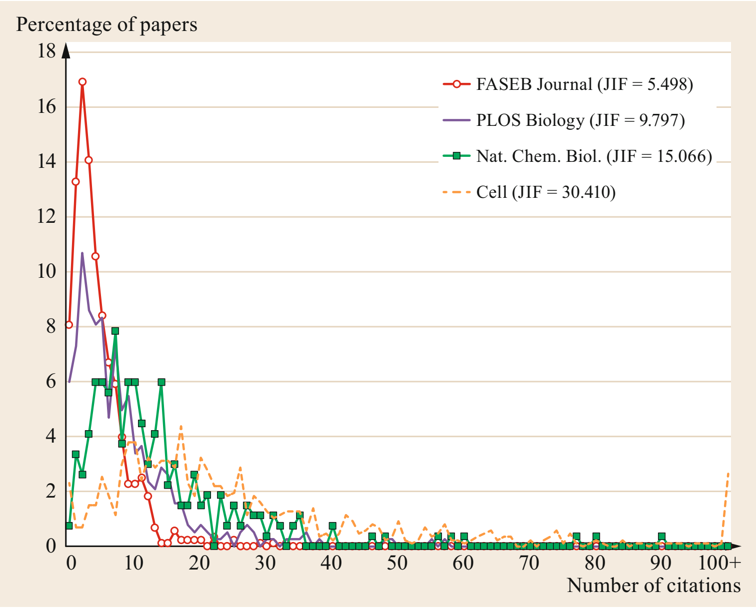

Fig. 1.6 Relative distribution of citations received by articles and reviews, for four journals from the field of biochemistry and molecular biology, 2014–2015 papers and 2016 citations

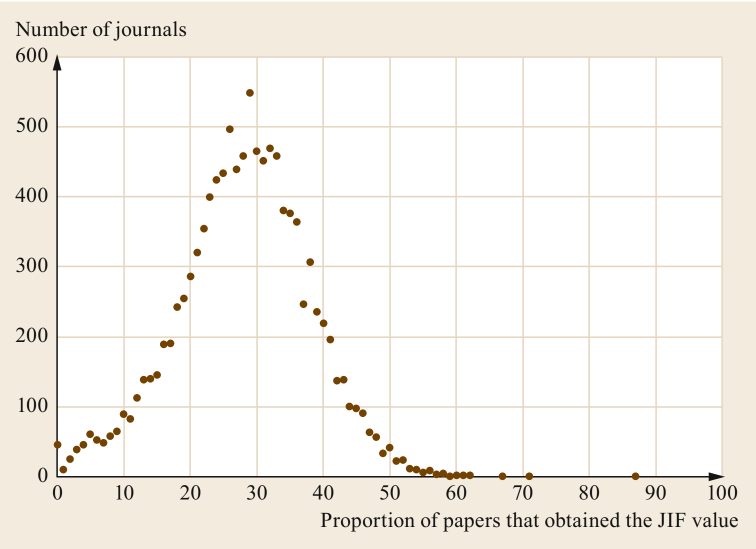

Fig. 1.7 Distribution of the number of journals, by proportion of papers that obtained the JIF value, 2014–2015 papers and 2016 citations

skewness in the citation distribution, Seglen argued that the JIF was unsuitable for research evaluation.

To illustrate this skewness, we provide—for the four biochemistry and molecular biology journals mentioned above—the distribution of citations received in 2016 by papers published in 2014–2015, both as absolute values (Fig. 1.5) and as percentages of papers (Fig. 1.6). It shows that, for all journals, most of the papers have a low number of citations and only a few obtain a high number of citations. Of course, the distribution for *Cell*—with a JIF of 30.410—is more right-skewed than *FASEB Journal*—which has a JIF of 5.498—but despite this, their citation distributions still have sizeable overlap, as shown in Fig. 1.6. Also striking is the similarity of the skewness: for all of these four journals, a nearly identical percentage of papers—28.2–28.7%—obtain a citation rate that is equal or greater to the JIF for that journal.

Extending the analysis across all journals indexed in the 2016 JCR confirms this pattern (Fig. 1.7). There is a fairly normal distribution when plotting journals by the percentage of their papers that obtain the corresponding JIF value or above. As shown, the vast majority are around 30%. Nearly 73% of the journals fall between 20–40%. Only in 1.3% of journals ($N = 141$) do at least 50% of the articles reach the JIF value. This fundamental flaw in the calculation—to compile an average on a nonparametric distribution—has been heavily discussed in the literature [1.32] as both a statistical aberration and also for the common misinterpretation: to use the JIF as an indicator at the article or individual level. Our analysis demonstrates the fairly weak predictive power of the JIF—that is, one cannot extrapolate from the impact factor of the journal to the potential citedness of the article as only one-third of the articles are likely to obtain that value. There have been many suggestions to account for the skewness, such as compiling a median-based JIF [1.33, 34] or reporting citation distributions [1.32]. However, contrary to other alternatives (such as the 5-year JIF and JIF excluding self-citations), no alternatives have been adopted by the JCR to address this limitation.

This is not to say, of course, that there is no relationship between JIF and future citedness. For example, using identical papers published in journals with different JIFs, *Larivière* and *Gingras* [1.35] found that the mean number of citations of the paper published in the journal with the highest JIF obtained twice as many citations as its twin published in the journal with the lowest JIF. However, the relationship between the JIF and the citedness of the articles has weakened over time: as shown by *Lozano*, *Larivière* and *Gingras* [1.36] using Web of Science data—and confirmed by *Acharya* [1.37] using Google Scholar—the correlation between the JIF and article-level citations has been decreasing since the mid-1990s. One potential explanation for this is the changing referencing practices of scholars. Citations are less concentrated over time [1.38] and scholars are citing increasingly older literature [1.39] and, as they do, more of the citations fall out of the two-year citation window of the JIF.

It would be irresponsible here not to mention the *Lucas* critique [1.40], which argues against predicting the effects of policy changes based on aggregated historical data. The Lucas critique was developed for economic data, but has wide applicability for the social sciences. In bibliometrics, one should be wary of making predictions about future citations, based on the past performance of scholarly objects. Referencing and citing patterns vary over time as do the sociopolitical factors of scholarship. Furthermore, the construction of citation indicators changes behavior (as we discuss later in this chapter). Therefore, we caution against making predictions with citation data.

1.3.5 Disciplinary Comparison

Field differences in citations are well established and field-normalized indicators have been the norm for several decades [1.41, 42]. However, the JIF is not among these. The simplicity of the calculation fails to normalize for the vast differences in citing practices across disciplines, such as the number of references per document and age of references. As shown in Table 1.3, disciplines that publish papers with longer cited reference lists—especially in terms of WoS-indexed papers—generally have higher JIFs than those with shorter lists. Furthermore, disciplines that cite more recent material—which fall in the JIF two-year citation window—are more likely to have higher JIFs than those that cite older material.

These differences also highlight the importance of references to other WoS-indexed material (source items), which are those that are taken into account in the compilation of the JIF. For instance, while the mean number of references in biology and biomedical research are almost identical, the mean JIF of journals in biology is less than half of those in biomedical research.

Table 1.3 Mean and maximum JIF of journals, mean number of cited references per paper (all material and only to WoS source items), and mean age of cited literature, by discipline, 2014–2015 papers and 2016 citations

Discipline	Mean JCR JIF	Maximum JCR JIF	Mean N references	Mean N references to WoS source items	Mean age of cited literature
Biology	1.683	22.81	48.99	34.45	14.72
Biomedical research	3.526	46.60	48.94	43.19	10.26
Chemistry	2.768	47.93	46.37	41.31	10.37
Clinical medicine	2.976	187.04	41.94	34.78	9.77
Earth and space	2.173	30.73	53.71	38.67	13.06
Engineering and technology	1.989	39.74	36.35	24.77	10.44
Health	1.647	17.69	39.08	24.52	9.86
Mathematics	1.017	9.44	26.56	16.53	16.65
Physics	2.699	37.85	36.57	29.58	12.55
Professional fields	1.565	11.12	53.51	27.68	13.09
Psychology	2.050	19.95	54.56	38.30	13.00
Social sciences	1.199	6.66	49.09	21.74	15.12

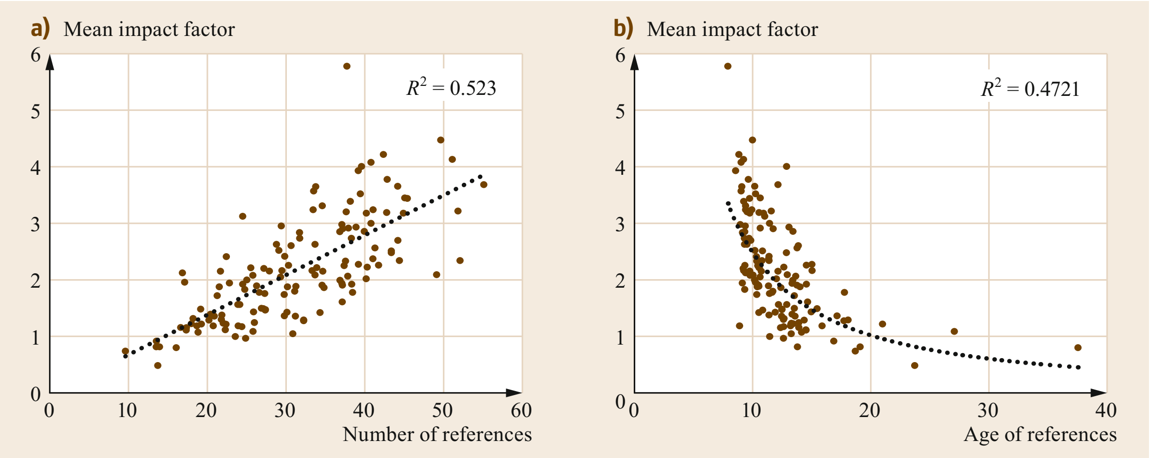

Fig. 1.8a,b Correlation between the journal impact factor and number of cited references to WoS source items **(a)** and age of references **(b)**, by NSF speciality, 2014–2015 papers and 2016 citations

This difference is explained by the fact that a large proportion of references made by biology journals do not count in the calculation of JIF as they are made to non-WoS (and, thus, JCR) material, while the vast majority of references of biomedical research journals are to WoS-indexed journals.

The same patterns are observed at the level of NSF specialities (Fig. 1.8). Specialties that cite a higher number of references per paper on average typically have higher JIFs (Fig. 1.8a), as are specialities that cite younger material (Fig. 1.8b). Therefore, the indicator cannot be used to compare across disciplines: medical researchers are much more likely to publish in journals with high JIFs than mathematicians or social scientists, and this is strictly due to different disciplines' publication and referencing practices rather than anything that relates to the scholarly impact of the journal.

1.3.6 Journal Impact Factor Inflation

While the calculation of the JIF has remained stable, values obtained by journals have not. The average JIF value has increased over time, both as a function of the number of papers in existence and the increasing length of their reference lists [1.39]. In 1975, the journal with the highest JIF was the *Journal of Experimental Medicine*, with a JIF of 11.874. In the 2016 JCR edition, the highest JIF was 187.040 for *CA: A Cancer Journal for Clinicians*. As shown by Fig. 1.9, a general inflation of the JIF has been observed over the last 20 years. For instance, while only 49 journals (0.8% of total) had a JIF above 10 in 1997, this increased to 105 (1.3%) in 2007, and to 201 (1.8%) in 2016. Average JIF values have increased from 1.125 in 1997, to 1.707 in 2007, and then to 2.178 in 2016. Of course, not all journals have observed these increases. One notable example is *PNAS*, which has remained quite stable—the 1975 JIF was 8.989 and, despite some intermittent increases, was only slightly higher at 9.661 in 2016.

The inflation of the JIF across time is an important element for interpretation. Many editors wait with baited breath for the release of the next JIF: increases are celebrated as an accomplishment of the editor and the journal [1.43–45]. Moreover, publishers, such as *Elsevier* [1.46], *Springer* [1.47], and *Wiley* [1.48] publicize their JIF increases with little to no conversation about the expected inflation rates. For example, the Wiley press release boasts that 58% of Wiley journals increased their JIFs between 2014 and 2015. What the press release fails to note is that 56% of all journals in the JCR increased during that same time period. Of course, reporting a relative increase is much less persuasive. As there is no established mechanism for acknowledging inflation in reporting, editors and publishers continue to valorize marginal increases in JIFs which have little relation to the performance of the journal.

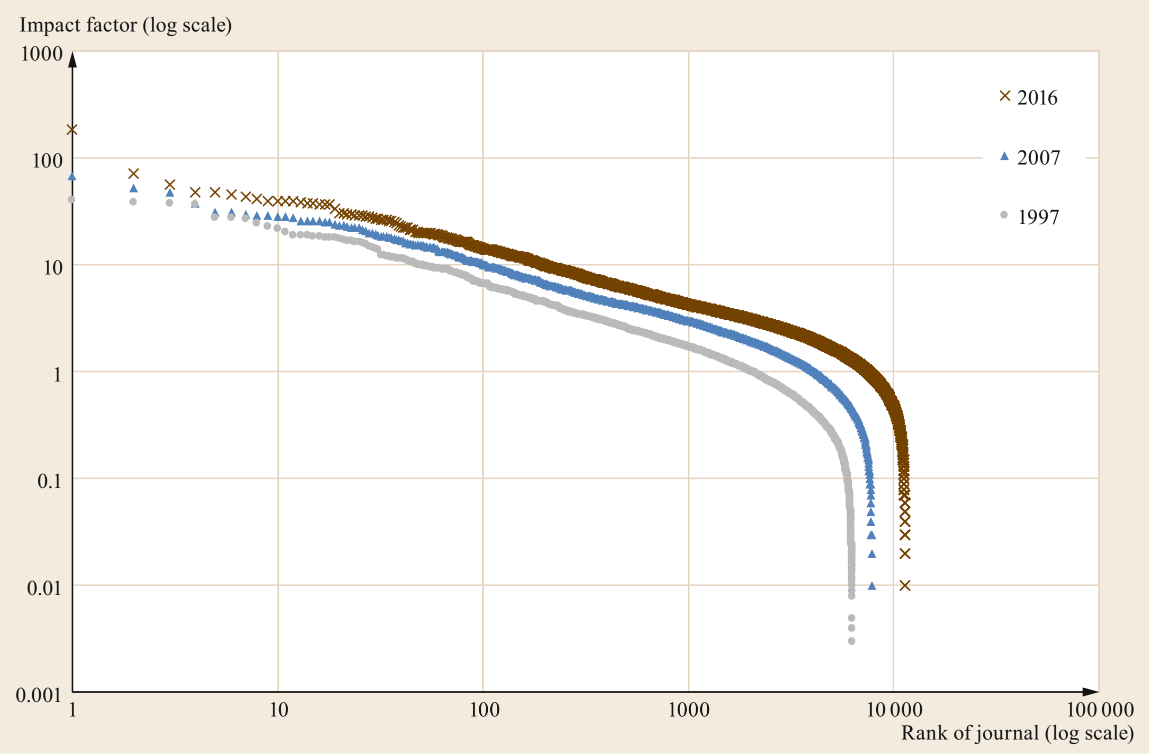

Fig. 1.9 Impact factor by journal as a function of rank, for years 1997, 2007, and 2016

1.4 Systemic Effects

There is no doubt that a political economy has emerged around citation indicators. Nearly two decades ago, *Sosteric* [1.49, p. 13] commented on

> the neoliberal need for surveillance, the push for administrative measures of scholarly performance and productivity, [and] the growing need for post-publication measures of scholarly impact.

He did not characterize scholars as resisters of this panopticon, but rather as adaptive actors in the system. Adaptation for survival and success is well-known across all fields of science: research evaluation is no different. Several scholars have warned against the negative consequences of constructing indicators of social activities [1.50–52]. As *Cronin* and *Sugimoto* summarized [1.53, p. 751]:

> The use of metrics, whether to monitor, compare or reward scholarly performance, is not a value-neutral activity. Metrics are shaped by, and in turn shape policy decisions; they focus the institutional mind, influence the allocation of resources, promote stratification and competition within science, encourage short-termism and, ultimately, affect the ethos of the academy... As reliance on metrics grows, scholars, more or less consciously, alter the way they go about their business; that is, their behaviors, motivations and values change, incrementally and unwittingly perhaps, as they adapt to the demands and perceived expectations of the prevailing system.

While it would be beyond the scope of the chapter to detail all the systemic effects of scholarly indicators, we focus on the negative and often intentionally malicious effects related to the use and promotion of the JIF. Specifically, we discuss JIF engineering, its relationship with institutional evaluation policies, the application of JIF for evaluating individual researchers and papers, and the creation of imitation indicators.

1.4.1 Journal Impact Factor Engineering

In a context where the JIF determines the fate of a journal—from submission rates to pricing—some editors and publishers have developed subterfuges to increase their JIF which, in turn, decreases the validity of the indicator. Such stratagems aimed at *artificially* increasing impact factors have been called *journal impact factor engineering* [1.22]. One well-documented tactic is to prey on the asymmetry in the calculation and to publish more *front material*—such as editorials, letters to the editor, etc., which are considered by Clarivate as noncitable items [1.22]. Another similar approach is to cite the home journal excessively in editorials and other front matter [1.22]. For example, many journals publish annual *highlights* or other documents with a high number of internal references [1.27]. Whether malicious or not, these documents unduly inflate—and thereby invalidate—the JIF.

A more subversive approach has been to engage in citation coercion or cartels [1.9, 23, 54–56]. The expression *citation cartel* is largely attributed to *Franck* [1.57], who used it to refer to the ways in which monopoly power is exercised by publishers and editors on authors in scientific publishing, and noted the complicity of authors who act as *citation-maximizers* in the scholarly communication system. This complicit behavior has been empirically demonstrated: in a study of nearly 7000 scholars, the majority reported that they would acquiesce to editorial coercion in order to get published [1.58]. The same study also showed that 20% of these scholars said they had been subject to coercive self-citation—that is, requests from editors to add references to irrelevant papers published within the journal [1.58]. An expansion of this study—with new disciplines added—placed this rate at 14.1%. Both the initial and follow-up studied confirmed that coercion was more common among higher impact journals [1.58, 59].

Faced with accusations of extortion [1.9], editors will often argue the innocence of and scientific rationale for these citations [1.60]. However, several editors themselves have been caught engaging in JIF boosting, by excessively citing their own journal in editorials [1.22]. There are also egregious examples of coercion. For example, in 2017, the editor of the journal *Land Degradation & Development*—who sat on the board and reviewed for other journals in the field—took advantage of his positions to increase the JIF of his own journal. Among the 82 manuscripts he handled as an editor and reviewer for other journals, he suggested 622 additional references, almost exclusively to the journal of which he was Editor-in-Chief [1.61]. The result was an astronomic rise in the JIF of the journal he edited, from 3.089 to 8.145 between 2014 and 2015. These flagrant abuses signal that editors are highly aware of the benefits derived from these manipulations.

Coercive self-citation is easier to identify than citation-stacking, which has become synonymous with the contemporary notion of *citation cartels*. There can be several legitimate explanations for tightly coupled exchange of citations between journals, particularly in highly specialized fields. However, when these exchanges are done with the explicit intent of increasing the citedness of the journal, these are referred to as citation cartels. Although there have been a few attempts to identify cartels [1.62–64], detection is difficult on a number of fronts. Technically, the ability to identify cartels becomes more difficult as the size of the cartel increases. Furthermore, the notion of a cartel implies intentionality and premeditation—something that is impossible to prove using bibliometric data alone.

Thomson Reuters (and, subsequently, *Clarivate Analytics*) has worked to police inappropriate citation activity—though they note that they do not "assume motive on behalf of any party" [1.65]. Each year, Clarivate provides a report of titles suppressed due to "anomalous citations patterns" and the reason for removal from the JCR [1.66]. Journals can be removed due to excessive self-citation or citation stacking, although thresholds are considered to be *extremely high* [1.67]. For example, in an analysis in 2002, the Institute for Scientific Information (the precursor to Thomson Reuters and Clarivate) found that for 82% of their titles, self-citation rates were at or below 20% [1.25]. It is assumed, therefore, that all journals will engage to some degree in self-citation. However, when the proportional increase in the JIF is due largely to an increase in self-citation, the journal is flagged for further analysis [1.65]. This is not an entirely uncommon practice and represents the dominant reason for suppression from the JCR. Perhaps as a result of reporting, cases of citation stacking have decreased over time [1.68].

Other scholars have also sought to create indicators for identifying excessive self-citations: *Chorus* and *Waltman* [1.69] created the Impact Factor Biased Self-citation Practices (IFBSCP) indicator to examine the relationship between the share of self-citations for the years included in the impact factor to those in the preceding five years. To validate this as an indicator of coercive self-citations, they examined the rates of IFBSCP for the 64 journals identified in *Wilhite* and *Fong* [1.58] as engaging in coercive citation behavior. They found that the named journals had IFBSCP rates 25% higher than the average social science journal, which suggests that their indicator measure is related to coercive behavior. This suggests that indicators may be developed to help identify—and hopefully curb—inappropriate citation behavior.

1.4.2 Role of Evaluation Policies

Impact factor engineering does not happen in a void: these actions are a consequence of evaluation policies and practices. Institutions and individuals are complicit actors in promoting the JIF in a research evaluation context. Although soft persuasions towards maximizing impact can be seen across the scientific system, they are made most manifest in the cash-based reward systems, such as those documented and publicized in China. Chinese policies offering financial reward based on WoS-indexed publications began in earnest in the 1990s, to motivate production and increase international visibility [1.70]. However, as noted by other studies [1.71], increasing national production does not necessarily equate to an increase in citedness, and might actually lead to a decrease. Therefore, China has moved steadily away from publication-based incentives in favor of citation-based indicators, particularly those based on JCR-quartiles of JIFs [1.70]. At face value, these policies seem well-intentioned and even laudable—encouraging quality over quantity. However, given that the cash award for a *Nature* or *Science* article can be 20 times an annual salary in China [1.70], these rewards can create strong incentives for inappropriate behavior. Although one cannot determine causality, the rise in fraudulent authorship, data falsification, and data fabrication in China [1.72] in parallel with these rewards is disconcerting. There is even evidence of an industry of authorship for sale in China, in which authorship is sold to scholars at rates that often exceed salaries [1.73].

Furthermore, cash incentive programs have been correlated with increased submission, but not with publication [1.74]. Although most authors are fairly efficient at selecting appropriate journals, many authors tend to submit to higher impact factor journals first and then resubmit down the JIF ladder until they find an acceptance [1.9, 75]. Increasing the pressure to submit to high-impact factor journals creates a burden on the scientific system and slows the pace of science as editors and reviewers are tasked with reviewing papers that are not submitted to the most appropriate venues. On a more fundamental level, financial rewards for papers externalizes the incentive to do scientific work. This contradicts central ideals of scholarship, in which scholars should be free from external pressures [1.76]. A reward more than 20 times an annual salary inverts the reward system—prioritizing external (i.e., economic capital) over intrinsic (academic capital) rewards.

There is also a danger in tying rewards to publication in particular journals. The most appropriate venue for many scholars—particularly those in the social sciences and humanities—may not be in a WoS-indexed publication at all. By emphasizing JIFs, the coverage biases of the WoS become prioritized [1.77]; that is, journal articles in the natural and medical sciences published in English are particularly incentivized. Some have argued that switching to English-language journals increases the visibility of science produced in countries where English is not the dominant language [1.78, 79]. However, others have expressed concern about the effects of a monolingual scholarly publishing industry [1.80]. For instance, *Larivière* [1.81] has shown that Canadian scholars in the social sciences and humanities were three times less likely to publish on Canada-related research topics when publishing in US journals than in Canadian journals, which demonstrates how journal venues directly affect the type of research performed.

1.4.3 Application at the Individual Level

As the JIF is based on a skewed distribution and, thus, is a weak predictor of individual papers' citation rates, its use as an indicator of the *quality* of individual researchers and papers—sometimes labeled the ecological fallacy [1.82]—is perhaps the most egregious misappropriation of the indicator. As Anthony van Raan noted (quoted in [1.83, p. 864–865]):

> if there is one thing every bibliometrician agrees, it is that you should never use the JIF to evaluate research performance for an article or for an individual—that is a mortal sin.

A less hyperbolic, but similarly unequivocal statement can be found from other bibliometricians: *Henk Moed* noted that such measures "have no value in assessing individual scientists" [1.84]. Despite these admonitions, the JIF is increasingly used as an indicator to evaluate individual scholars (among others, [1.70, 85]). While some might argue that publication in a journal with a high JIF is itself an achievement, given the relatively lower acceptance rates of these journals, the concern is more about the equation of the value of an article or individual with the past ranking of a journal [1.86]. This can lead to gross goal displacement [1.87], in which scholars tailor their topics for certain indicators.

Scholars are increasingly "thinking with indicators"—that is, allowing indicators to guide the process of science-making [1.10]. Specifically, scholars choose topics and dissemination venues not on scientific bases, but rather to meet certain incentive structures. In doing so, scholars substitute a "taste for science" with a "taste for rankings" [1.87]. This is not a particularly novel claim. As early as 1991, *Holub* and colleagues noted that "WHERE a scientist published has become much more important than WHAT he is publishing [capitalization in original]" [1.88]. However, the impact factor obsession [1.12] has grown to the level where some scholars would rather destroy a paper than publish below a certain JIF threshold [1.89]. This has led to a complicated and cyclical relationship between JIF, value, and reputation that is increasingly internalized into the process of scholarship [1.10].

Scholars are aware of these negative effects: several initiatives in recent years have sought to disentangle journal rankings from individual rankings. At the 2012 annual meeting of the American Society for Cell Biology (ASCB), a group of editors and publishers produced the san francisco declaration on research assessment, colloquially referred to as DORA [1.90]. The declaration called for the elimination of the use of JIFs for assessment of individual scholars and articles [1.90], stating that the JIF was not appropriate "as a surrogate measure of the quality of individual research articles, to assess an individual scientist's contribution, or in hiring, promotion or funding decisions" [1.90, 2]. As of July of 2017, the declaration had nearly 13 000 individual signers and nearly 900 organizational signers. Funding agencies have also responded: the National Health and Medical Research Council (NHMRC) in Australia produced a statement unequivocally denouncing JIFs for evaluating individual papers [1.91] and discontinued reporting of JIFs for evaluation. Nobel laureates and other high-profile scholars have also spoken out against JIFs [1.92] and boycotted high-impact factor journals [1.93]. However, these are privileged boycotts and resistance is much more difficult for those who are not well-established in the scientific system.

1.4.4 Knock-Off Indicators

The JIF has become a brand and, like any other luxury good, there is an industry of imitation. In recent years, a cottage industry of fake impact factors has emerged, with strong ties to predatory publishers. Librarian Geoffrey Beall—who for many years ran the well-known and controversial list of predatory publishers—identified more than 50 organizations that provide *questionable* or *misleading* metrics at the researcher, article, and journal level [1.94]. The complicated web of mimicry is difficult to disentangle: the names of the organizations often replicate the name or acronym of the Institute for Scientific Information—e.g., the *Institute for Science Information (ISI)*, the *Index Scientific Journals (ISJ)*, or the *International Scientific Indexing (ISI)*—or the JIF—e.g., the *Journal Influence Factor-JIF*, the *General Impact Factor*, or the *Science Impact Factor*. One organization even goes as far as to imitate both the name of the indicator and that of the organization: journals can apply to the "Global Institute for Scientific Information (GISI)" to obtain a "journal impact factor" [1.95]. Several journals seem to have either fallen prey or are complicit in this deceit: for instance, the list of journals to which GISI has attributed a "journal impact factor" increased from 24 in 2010 to a high of 668 in 2011–2013. The numbers have been steadily dwindling, but there are still 153 journals listed in 2016. The listed journals come from both predatory and well-established publishers.

The organizations often go to lengths to maintain their deceit. For example, one website includes a red pop-up box warning editors and publishers that another company is scamming the original predatory company. The text reads:

> This is to inform you that somebody is using our name (International Impact Factor Services) to deposit the fee for Impact Factor &he saying that he show your impact factor in our website, but do not reply those mails. If you answer those mails you will responsible for that [1.96].

This is not the only bait and switch in the impact factor market. For example, one of the only published articles on fake JIFs was published in *Electronic Physician: Excellence in Constructive Peer Review* [1.97]. This article provides an account of so-called "bogus" indicators such as the Universal Impact Factor (UIF), Global Impact Factor (GIF), and Citefactor. The article describes the threat of these indicators to reputable indicators such as Thomson Reuters *and* the Index Copernicus metric value (ICV). However, the ICV, which is prominently displayed on the website of the *Electronic Physician*, is itself under scrutiny for its association with predatory journals [1.98]. Therefore, this article seems to provide much the same function as the pop-up box of the International Impact Factor Services: It is a classic redirect technique, wherein the service attempts to legitimatize their own activities by delegitimizing others.

One of the biggest concerns with these products is the lack of transparency in the compilation of the indicators. The *Global Impact Factor* obliquely combines some form of peer review with the number of papers published [1.99]. Journals of the "Academy of IRMBR International Research in Management and Business Realities"—contained in Beall's list—rely on GoogleScholar to generate indicators [1.100], which seems a common approach for these fake JIFs. While one could argue that many of these indicators are legitimate competitors, rather than exploitative knock-offs, the mimicry of the names and acronyms as well as the cost structure begs caution. For example, the Global Impact Factor provides their indicator for an annual fee of $40 [1.99] and *International Scientific Indexing* charges $100–130 per journal for the indicator and indexation on their platform [1.101]. While the deceptive character of these sites might be apparent to many scholars, some have chosen to take a more neutral stance. For instance, a US university library guide on journal indicators lists these indicators alongside the JIF and other established indicators [1.102]. Other libraries have taken a more direct stance, urging their audience caution with these indicators and predatory publishers [1.103].

1.5 What Are the Alternatives?

Knock-off indicators abound, but there are also several other indicators that have emerged as complementary to or competitive with the JIF. This section examines four of the most established: the group of Eigenfactor Metrics, Source Normalized Impact per Paper (SNIP), CiteScore, and SCImago Journal Rank (SJR).

The Eigenfactor Metrics were introduced in 2010 as a new approach for ranking journals [1.104]. The metrics include two related indicators—the Eigenfactor Score and Article Influence Score (AIS)—both based on the Eigenfactor algorithm, which leverages the citation network to identify and weight citations from central journals. The underlying algorithm is derived from *Phillip Bonacich*'s [1.105] eigenvector centrality, which has been employed across several domains, most notably as the foundation for Google's PageRank algorithm. The Eigenfactor Score depicts the *total value* of a journal and is thus size-dependent—as the size of the journal increases, so too will the Eigenfactor Score. The Article Influence Score, however, measures the average influence of articles in the journal, and is therefore more comparable to the JIF. However, there are several important differences: the AIS is calculated over a five-year (rather than two-year) time window, excludes self-citations, and uses weighted citations. Like the JIF, both indicators rely on Web of Science (WoS) data and were added to the JCR in 2009. As such, they represent a supplement to the JCR portfolio, rather than direct competition.

Scopus—the largest competitor to Web of Science—also has several associated journal indicators. The Source Normalized Impact per Paper (SNIP) indicator was proposed in 2009 by *Henk F. Moed*, then at the Center for Science and Technology Studies (CWTS) of Leiden University [1.106] and later revised by *Waltman* and colleagues [1.107]. As discussed, one of the central interpretive critiques of the JIF is the inability to make cross-disciplinary comparisons. SNIP was developed to account for the different *citation potential* among fields. Rather than using an a priori journal-based classification, fields are defined according to the set of citing papers. In this way, the indicator is based on *contextual*, rather than absolute, citation impact. Furthermore, SNIP serves to address another limitation of the JIF: by focusing on the set of citing papers, there is no concern about the asymmetries created by noncitable items. However, like the JIF, self-citations are included, which can lead to distortions in extreme cases. Furthermore, SNIP tends to be higher in journals with a large proportion of review articles, which causes additional bias. SNIP uses a three-year citation window—one year more than the JIF, but two less than the Article Influence Score.

Another indicator contained in "the Scopus basket of journal metrics" [1.108] is the SCImago Journal Rank (SJR), which was developed and continues to be updated by the SCImago research group at the University of Granada [1.109]. Like the Eigenfactor Score, the SJR employs Bonacich's eigenvector centrality to calculate the prestige of a journal, weighting the links according to the closeness of co-citation relationships (on the basis of citable documents). The current version of the indicator uses a three-year window, in keeping with the other Scopus journal indicators [1.110]. Furthermore, several heuristics are applied to circumvent gaming and distortions: in generating the prestige of the journal, there are thresholds on how much a single journal and the journal itself can provide—protecting against citation cartels and self-citations—and prestige is calculated on the basis of proportions rather than number of citable documents, to control for size and the dynamicity of the database.

In 2016, Elsevier released a new journal impact indicator with the name CiteScore [1.108]. The indicator is obtained by averaging, for a given journal, the number of citations received in a single year by papers it published during the preceding three years. The appeal is the simplicity—it is merely an average of citations received for all document types, which removes concerns about asymmetries between cited and citing items. However, the inclusion of all document types shifts the bias in another direction. While journals with a high proportion of noncitable items (e.g., editorials, news items) tend to fare well in the JIF, they are ranked lower in CiteScore. Critics of CiteScore have noted that this favorably biases Elsevier's own journals, which tend to publish a lower proportion of front matter than other journals (such as Nature's journals) [1.111]. Broader concerns have also been raised about the conflict of interest inherent in vertically integrated companies: There is considerable concern about the construction of indicators within a company that also publishes, indexes, and provides analytic services for journals [1.112]. The increasing monopoly of Elsevier in this space has caused some to question the neutrality of the indicator.

However, none of these indicators have managed to displace the JIF's role in the scientific system. The Eigenfactor Metrics are included in the JCR, but have not gained the marketing appeal of the JIF, and the Scopus indicators have also not gained widespread traction after nearly a decade of existence. Part of this is the appeal of standardization: scholars working in research evaluation (whether hiring, promoting, or granting) have internalized the value of the JIF. Despite the well-known technical and interpretive concerns, the JIF remains the standard journal indicator.

1.6 The Future of Journal Impact Indicators

Building upon both original data and a review of the literature, this chapter provides a background for the creation of the JIF, an overview of its limitations, and a discussion of some of the most documented adverse effects. Several of the technical critiques can be or already are addressed by Clarivate. For instance, asymmetries between the numerator and denominator could be controlled by more careful analysis and cleaning of the data. Journal self-citations account for a minority of citations and can (and are already) flagged when excessive. The two-year JIF could be removed, in favor of a JIF with a longer citation window—which is already provided in more recent editions of the JCR. However, rather than replacing the original JIF with new indicators, these alternatives have merely been added to the JCR. This multiplicity of indicators is problematic from the perspective of standardization. When every researcher, administrator, evaluator, and policy-maker is constructing tailor-made indicators, the indicators lose their central function—to communicate globally and across disciplines in a standard fashion [1.112]. Of course, bibliometrics is not alone in dedication to an imperfect indicator. For example, despite heavy criticism and the creation of alternative indicators [1.113, 114], the body mass index remains, as per the World Health Organization, the standard for the measurement of obesity.

However, some of the most disconcerting aspects are not purely technical, but rather due to the misapplication of the indicator. For example, one common technical concern is the skewness of citation distributions. Given that less than a third of articles are likely to achieve the citation value of the JIF, the indicator is misleading for application at the individual paper level. Because of the skewness of citation distributions and the declining predictive power of the JIF, it is widely acknowledged that the indicator should not be used to evaluate individual articles or scholars (though there remains debate on this issue [1.115]). Furthermore, the lack of normalization by discipline and the continual inflation of the indicator over time means that the JIF can only be used to rank contemporary journals within the same discipline.

It is also clear that it is not the indicator, but rather the application of the indicator that is causing systemic disruptions in science. Several of the adverse effects observed are not directly linked to JIF; rather, they are linked to the research evaluation system and, more specifically, to journals as vectors of scientific capital. In other words, the JIF has become synonymous with academic capital, and despite well-publicized criticisms [1.90], it remains central to research evaluation. It would, of course, be naïve to assume that, in a pre-JIF era, there was no relationship between economic and scientific capital. Journals have long served at the heart of the race for scientific discovery: the certification and dissemination of knowledge allowed scholars to make priority claims, the traditional building blocks of scientific reputation [1.116]. However, the direct relationship between cash rewards and JIF is a gross perversion of the reward system in which economic incentives become the main objective of publishing. It is clear that measure has become the target [1.117], as evident by the explicit manipulations within the system and the gross goal displacement in favor of high-impact journals, whereby there is a prioritization of metrics over ethics [1.57, 87].

When he published the first iteration of the JCR, *Garfield* hoped that it could

> prove itself indispensable to people who cannot rely on economic criteria alone in making basic decisions about journals, since the law of supply and demand is not always allowed to prevail [1.5, p. 1].

The JIF became more than that: in many ways, it has become itself an economic item, capitalizing upon academic capital and the need for its measurement. As such, it has been grossly misapplied to make decisions about papers and authors, rather than journals, and caused distortions within the scholarly system. And while *Garfield* foresaw the use of the JIF for research evaluation, he also formulated recommendations for its proper use in his introduction of the first JCR [1.4, p. 1]:

> Like any other tool, the JCR cannot be used indiscriminately. It is a source of highly valuable information, but that information must be used within a total framework proper to the decision to be made, the hypothesis to be examined, and rarely in isolation without consideration of other factors, objective and subjective.

Among these subjective factors, Garfield noted the reputation of the author, the controversial nature of the subject, the circulation and cost of the journal, and the degree to which the work is accessible. Garfield cautioned against comparing citation rates for journals in different disciplines and noted the biases in accounting for journals which do not use the Roman alphabet. While those factors remain quite relevant today, it seems they have been forgotten along the way. Moreover, since Garfield made these recommendations, English has become the lingua franca of research [1.118], which has led to a decline of the relative importance of non-English journals in many disciplines and, thus, reinforced the Web of Science—and, by extension, the JCR—as a measurement tool.

Despite these well-documented limitations and consequences, the JIF will likely remain part of the research ecosystem and as long as journals remain the primary mechanism for diffusing new knowledge, their reputation—as established by JIF or an alternative—will remain a marker of capital. It is essential, therefore, that actors within this system are provided with the means to interpret and apply the indicators responsibly, in full awareness of the consequences [1.12, 119]. Perhaps more importantly, the scientific community must collectively ask: is the use of the journal impact factor good for science?

Vincent Larivière

École de bibliothéconomie et des sciences de l'information
Université de Montréal
Montréal, Canada
vincent.lariviere@umontreal.ca

Vincent Larivière is Associate Professor of Information Science at the École de bibliothéconomie et des sciences de l'information of the Université de Montréal, where he teaches research methods and bibliometrics. He is also the Scientific Director of the Érudit journal platform, Associate Scientific Director of the Observatoire des sciences et des technologies and a Regular Member of the Centre interuniversitaire de recherche sur la science et la technologie.

Cassidy R. Sugimoto

School of Informatics and Computing
Indiana University Bloomington
Bloomington, IN, USA
sugimoto@indiana.edu

Cassidy R. Sugimoto is Associate Professor at the School of Informatics, Computing and Engineering of Indiana University, where she researches within the domain of Scholarly Communication and Scientometrics, examining the formal and informal ways in which knowledge producers consume and disseminate scholarship. Sugimoto has an undergraduate degree in Music Performance, MS in Library Science, and PhD in Information and Library Science from the University of North Carolina.

2. Bibliometric Delineation of Scientific Fields

Michel Zitt, Alain Lelu, Martine Cadot, Guillaume Cabanac

Delineation of scientific domains (fields, areas of science) is a preliminary task in bibliometric studies at the mesolevel, far from straightforward in domains with high multidisciplinarity, variety, and instability. The Sect. 2.2 shows the connection of the delineation problem to the question of disciplines versus invisible colleges, through three combinable models: ready-made classifications of science, classical information-retrieval searches, mapping and clustering. They differ in the role and modalities of supervision. The Sect. 2.3 sketches various bibliometric techniques against the background of information retrieval (IR), data analysis, and network theory, showing both their power and their limitations in delineation processes. The role and modalities of supervision are emphasized. The Sect. 2.4 addresses the comparison and combination of bibliometric networks (actors, texts, citations) and the various ways to hybridize. In the Sect. 2.5, typical protocols and further questions are proposed.

2.1 Shaping the Landscape of Scientific Fields

Collecting literature that is both relevant and specific to a domain is a preliminary step of many scientometric studies: description of strategic fields such as nanosciences, genomics and proteomics, environmental sciences; research monitoring and international benchmarks; science community analyses. Although our focus here is on the intermediate levels, informally described in such terms as areas, specialties, subfields, fields, subdisciplines… this subject is connected to general science classification and, at the other end of the range, to narrow topic search.

In Sect. 2.2 we place delineation at the crossroads of two concepts: the first one is *disciplinarity* (what is a scientific discipline?), which crystallizes various dimensions of scientific activity in epistemology and sociology. The second one is *invisible colleges* in resonance with the core of bibliometrics, the study of networks created explicitly or implicitly by publishing actors. From this point of view, domains of science can be viewed as a generalized form of invisible colleges, sometimes in the form of relatively dense and segregated areas—at some scale. In other cases however, the structure is less clear and bounded, with high levels of both internal diversity and external connections and overlaps. Given a target domain, its expected diversity, interdisciplinarity, and instability are challenging issues. We outline the main approaches to delineation: external formalized resources, such as science classifications; ad hoc information retrieval (IR) search; network exploration resources (clustering–mapping).

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_2

Section 2.3 is devoted to the main approaches in domain delineation, IR search, and science clustering–mapping, when off-the-shelf classifications are not sufficient. Both take root in the information networks of science, but start from different vantage points, with some simplification: ex ante heavy supervision for IR search, typically with bottom-up ad hoc queries; ex post supervision for bibliometric mapping, with top-down pruning. In difficult cases, these approaches appear complementary, often within multistep protocols. As a result of the complex structure and massive overlaps of aspects of science, of the multiple bibliometric networks involved, of the multiple points of view, the frontiers are far from unique at a given scale of observation. The experts' supervision process is a key element. Its organization depends on the studies' context and demand, to reach decisions through confrontation and negotiation, especially in high-stakes contexts. Beforehand, we shall briefly address the toolbox of data analysis methods for clustering–mapping purposes.

Section 2.4 focuses on the multinetwork approach for delineation tasks, stemming from pragmatic practices of information retrieval (IR) and bibliometrics. The main networks are actor's graphs and other relations connected with invisible colleges based on documents and their main attributes, texts, and citations. Other scientometric networks (teaching, funding, science social networks, etc.) offer potential resources. The hybridization covers a wide scope of forms. There is a strong indication that multinetwork methods improve IR performance and offer a richer substance to experts'/users' discussions.

2.2 Context

2.2.1 Background: Disciplinarity and Invisible Colleges

Generally speaking there is no ground truth basis for defining scientific domains. Given a target domain, assigned by sponsors in broad and sometimes fuzzy terms, delineation is the first stage of a bibliometric study. It is tantamount to a rule of decision involving sponsors/stakeholders, scientists/experts, and bibliometricians on extraction of the relevant literature. Delineation also matters as research communities are an object of science sociology as well as a playground for network theoreticians.

The delineation of scientific domains should be understood in the context of the structure of science and scientific communities, especially through the game between diversity, source of speciation, and interdisciplinarity drive towards reunification. Disciplinarity and *invisible* colleges are two concepts from the sociology of science that symbolize two kinds of communities, the first one more formal and institutional, the second one constructed on informal linkages made visible by bibliometric analysis of science networks. The tradition of epistemology has contributed to highlight the specificity of science by contrast to other conceptions of knowledge. *Auguste Comte* proposed the first modern classification of science and at the same time condemned the drift of specialization [2.1], considered a threat to a global understanding of positive science. In reaction both to epistemology and normative Mertonian tradition [2.2, 3], *Kuhn* emphasized the role of central paradigms in disciplines at some point of their evolution [2.4]. The post-Kuhnian social constructivism proceeded along two lines—at times conflicting [2.5]—of relativist thinking: the *strong programme* (see *Barnes* et al. [2.6]) and the no less radical actor–network theory (ANT). The first one was initiated by Barnes and *Bloor* [2.7] and flourished in the science studies movement [2.8, 9]. The ANT also borrowed from Serres (*translation* concept [2.10]) and from the poststructuralist French theory (Foucault, Derrida, Bourdieu, Baudrillard), see [2.11–13]. These schools of thought emphasize disciplinarity rather than unity. *Lenoir* notes that [2.14, pp. 71–72, 82]:

> A major consequence of [social constructivism] has been to foreground the heterogeneity of science. [... Disciplines are] crucial sites where the skills [originating in labs] are assembled and political institutions that demarcate areas of academic territory, allocate privileges and responsibilities of expertise, and structure claims on resources.

Bourdieu stressed the importance of personal relationship and *shared habitus*. Disciplines exhibit both a strong intellectual structure and a strong organization. The institutional framework, with, in most countries, an integration of research and higher education systems, ensures evaluation and career management. Some communities coin their own jargon, amongst signs of differentiation, and norms and patterns. Potentially, all dimensions of research activity (paradigms and theories, classes of problems, methodology and tools, shared vocabulary, corroboration protocols, construction of scientific facts and interpretation) appear as discipline-informed, with particular tensions between superdisciplines, natural sciences and social sciences and humanities. Scientists discuss, within their own disciplines, the subfield breakdown and the structuring role of particular dimensions, for example research objects in microbiology, versus integration drive [2.15, 16].

The endless process of specialization and speciation in science, erecting barriers to the mutual understanding of scientists, is partly counteracted by interdisciplinary linkages which maintain and create solidarity between neighbor or remote areas of research. *Piaget* [2.17] coined the term transdisciplinarity as the new paradigm re-engaging with unity of science. A few rearrangements of large magnitude, such as the movement of convergence between nanosciences, biomedicine, information, and cognitive sciences and technologies (NBIC, Nanotechnology, biotechnology, information technology, and cognitive science; concept coined by NSF (National Science Foundation) in 2002), tend to reunite distant areas or at least create active zones of overlap.

In contrast with disciplinarity, the concept of *invisible college* in its modern acceptation, popularized by *Price* and *Beaver* [2.18] and *Crane* [2.19], chiefly refers to informal communication networks, personal relationship, and possibly interdisciplinary scope. These direct linkages tend to limit the size of the colleges, although no precise limit can be given. Science studies devote a large literature to those informal groups, which exemplify how networks of actors operate at various levels of science [2.20, 21].

Although more formal expressions emerge from the self-organization of those microsocieties (workshops, conferences, journals), the invisible colleges do not claim the relative stability and the social organization of disciplines. The various communication phenomena of the colleges are revealed by sociological studies or, more superficially but systematically, by analysis of bibliometric networks such as coauthorship, text relations and citations. The *bibliometric hypothesis* assumes that the latter process mirrors essential aspects of science: the traceable publication activity, in a broad sense, expresses the collective behavior of scientific communities in most relevant aspects (contents and certification, production and structure of knowledge, diffusion and reward, cooperation and self-organization). It does not follow that bibliometrics can easily operationalize all hypotheses [2.22]. Affiliations can, in the background, connect to the layers of academic institutions or corporate entities. Mentions to funding bodies are increasingly required in articles reporting grant-supported works. These relations, however, as well as personal interactions, generally require extrabibliometric information. Variants of the invisible colleges in sociology of science are known as epistemic communities, involving scientists and experts with shared convictions and norms [2.8, 23] and community of practice [2.24]. The mix of behavior, stakes and power games, in the interaction of virtual colleges and institutions, remains an appealing question. A revival of the interest for delineation studies has been observed at the crossroads of sociology of science and analyses of networks [2.25, 26].

Disciplinary views, as well as colleges revealed by bibliometrics, lead to different partitions of literature, depending on the vantage points. In particular, bibliometricians can be confronted with conflictual situations when revealed networks and institutional normative perceptions and claims as to the disciplinary structure and boundaries diverge. The exercise of delineation generally consists in reaching some form of consensus, or at least a few consensual alternatives amongst sponsors, stakeholders, experts, and scientists. The toolbox contains information retrieval, data analysis, and mapping. Bibliometricians act as organizers of experts' supervision, suppliers of quantitative information, and facilitators of negotiations (Fig. 2.1).

2.2.2 Operationalization: Three Models of Delineation

In their review of (inter)disciplinarity issues, *Sugimoto* and *Weingart* [2.27] stress that the rich conceptualization of disciplinarity, quite elaborate in sociology and iconic of science diversity, does not imply clear operationalization solutions for defining fields. Scientists' claims and co-optation ("Mathematicians are people who make theorems" with several formulations, including a humoristic one by Alfréd Rényi), university organizations and traditions, epistemology, sociology, bibliometrics offer many entry points. The stakes associated to disciplinary interests and funding, for both scientists and policy makers may interfere with definitions. Introducing the national dimension, for example, shows that the coverage of disciplines is perceived differently in national research systems. Bibliometrics cannot capture the deep sociocognitive identity of disciplines but contributes to enlighten some of the facets that collective scientists' behavior let appear. The difficulty extends to multidisciplinarity measurement.

In practice, the description of disciplines available in scientific information systems takes the form of classification schemes at some granularity (articles, journals) from a few sources: higher education or research organizations for management and evaluation needs (international bodies or national institutions, for example

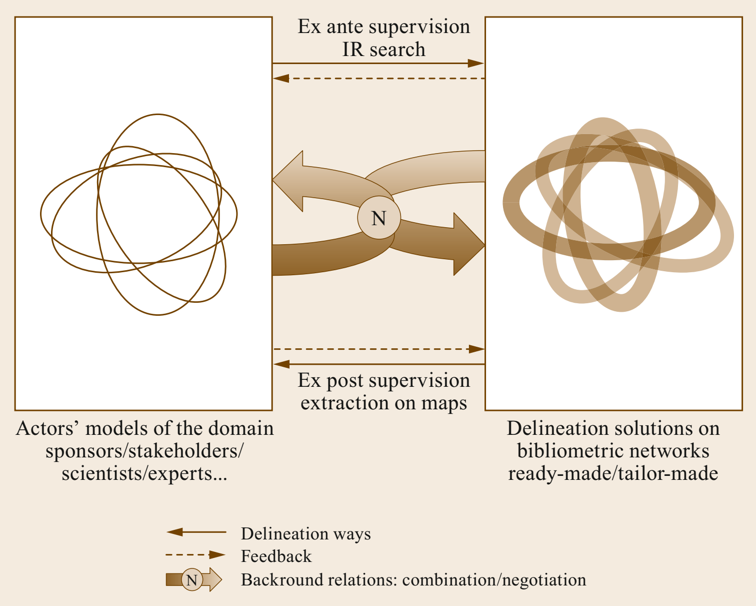

Fig. 2.1 Actors' models/bibliometric models. This scheme evokes the interaction between actors' mental or social models of science, disciplines, and domains on the one hand and models from data analyses (clustering–mapping) on bibliometric data sources, based on different methods and networks on the other. The two sides are engaged separately or together in negotiated combinations to reach (almost) consensual views. Two ways of domain delineation are singled out, ad hoc IR search and extraction from maps, with different degrees and moments of supervision. A third way, allowing direct IR search, supposes permanent classification resources

the National Center for Scientific Research (CNRS) in France); schemes associated to databases from academic societies, generally thematic; and/or from publishers or related corporations (Elsevier, ISI/Thomson Reuters/Clarivate Analytics) dedicated to scientific information retrieval.

We term *model A* the principle of these institutional science classifications, which do not chiefly proceed from bibliometrics but from the interaction between scientists and librarians. Subcategories and derived sets offer ready-made delineation solutions. The effect of methodological options, the social construction of disciplines by institutions or scientific societies, with struggles for power and games of interests are unlikely to yield convergence: the various classifications of science available, not necessarily compatible, should be taken with caution. Depending on the update system, they also tend to give a *cold* image of science. Often based on nonoverlapping schemes, they tend to handle multidisciplinarity phenomena poorly. Resources associated with classifications in S&T databases which often include various nomenclatures (species, objects) are a distinct advantage. With its limitations this model nevertheless offers a rich substance to bibliometric studies. Since the development of evaluative scientometrics in the 1970s, in the wake of Garfield and Narin's works, categories are used as bases for normalization of bibliometric measures, especially citation indicators, but classification-free alternatives exist (Sect. 2.3.2). The rigidity of classifications has an advantage, making a virtue out of a necessity, the easy measure of knowledge exchanges between categories over time. Techniques of coclassification [2.28, 29], coindex, or coword methods (see below) make it possible to transcend the rigidity of the classification scheme.

The concept of virtual college, originally thought of as micro- or mesoscale communities with informal contours, exchanging in various ways, can be generalized to communities in science networks at any scale. Since the 1980s, this is implicit in most bibliometric studies [2.30]. Global models of science, either small worlds or self-similar fractal models, are consistent with this perspective. This scheme, termed here *model C*, is the very realm of bibliometrics. Formal and institutional aspects are partly visible through bibliometric networks but need other *scientometric* information on institutional structure of science systems. Bibliometrics and also scientometrics are blind to other networks/relations such as interpersonal networks and to the complete picture of science funding and science society relations. It follows that the delineation of fields in model A, which accounts for complex mixes nontotally accessible to bibliometric networks, cannot be retrieved by *model C* approaches. The other way round, model C makes visible implicit structures ignored by the panel of actors involved in model A classification design.

For large academic disciplines, model C merely proposes high-level groupings which might emulate the categories *disciplines* from model A and share the same label, however with a quite coarse correspondence. In the practice of model C, large groups receive a sort of *discipline* label through expert supervision. Neither the bibliometric approach nor model A have the property of uniqueness. Various tests were conducted by external bibliometricians on SCI-WoS (Science Citation Index of the Web of Science) subject categories, and the agreement is not, usually, that good [2.31] and the existing ready-made classifications cannot pretend to the status of ground truth or gold standard for domain delineation. Depending on the organization, the clustering–mapping operations often fulfill two needs in bibliometric studies, first helping domain delineation, secondly identifying subdomains/topics within the target. In the absence of ground truth, the challenge of model C is to find trade-offs for reflecting a fractal reality quite difficult to break down, since boundaries are hardly natural except for configurations with clear local minima. They are then subject to optimization with partial information and negotiations [2.32, 33].

Model B based on IR search, borrows from both A and C. In model A, the operationalization of discipline definition and classification relied on heavily supervised schemes, aiming chiefly at information retrieval. Model B shares the same ground, with an ad hoc search strategy established by bibliometricians and experts for the needs of the study. Ad hoc search is sometimes necessary in order to go beyond the synthetic views provided by clustering and mapping, and to address analytical questions from users (in terms of theory, methods, objects, interpretation). The default granularity is the document level.

The three models can incorporate a semantic folder. Some indexing and classifications systems provide elaborate structures of indexes and keywords: thesaurus and ontologies (Sect. 2.2.4). Model B depends on expert's competence and resources of queried databases to coin semantically robust queries. Model C can treat metadata of controlled language, indexes of any kind, as well as natural language texts, and reciprocally shed light, through data/queries treatment, on the revealed semantic structures of universes.

Reflexivity is present under many aspects: scientists are involved in heavy ex ante input in ready-made classifications (model A), in IR ad hoc search (model B), and in softer ad hoc intervention on bibliometric maps (model C). The supervision/expertise question goes beyond within-community reflexivity, with partners associated to projects: decision-makers and stake-holders and bibliometricians.

Table 2.1 sums up the main features of the three models. They are just archetypes: in practice, blending is the rule. If classical disciplinary classification schemes belong to the first model, the Science Citation Index and variants incorporate bibliometric aspects. Purely bibliometric classifications, if maintained and widely available, give birth to ready-made solutions. In the background of the three models, the progressive rapprochement of bibliometrics and IR tools, addressed below in Sect. 2.3 should be kept in mind.

Table 2.1 Typical features of the three models for delineating scientific fields

	Model A **Ready-made breakdown and tools**	**Model B** **Ad hoc IR search**	**Model C** **Bibliometric networks**
Basic concept	Science classifications and nomenclatures	Union of queries	Groupings in science networks, generalizing the concept of invisible colleges
Origin	Academic societies and database providers. Originally little/no input of bibliometrics	Publication records (e.g., article metadata) and possibly full text	Analysis of bibliometric networks from any field in publication records
Structure	Classification schemes, often hierarchical and hard breakdown (categories: subdisciplines, fields, specialities, journals, etc.)	Categories: only when at low risk (e.g., core categories)	Networks and clusters/groups at various scales (actors, topics, documents...)
Supervision/expertise	Heavy ex ante embodied input by scientists, experts, librarians	Heavy involvement of scientists, experts, librarians in conception/check of queries	Ad hoc softer supervision at various stages (mapping)
Data–granularity	Richness of added metadata, especially keywords and indexes of objects default granularity: category	All available information, especially text fields, citation, authors' affiliations Default granularity: document	All available information, especially text fields, citation, authors' affiliations Default granularity: cluster
Semantic aspects	Thesauri, ontologies	Structure of queries, use of ready-made resources	Latent or explicit dimensions in networks
Time features	Relative stability of framework, favoring fixed-structure longitudinal analysis, at the expense of tensions in the system between updates	No structural constraint	Immediacy and aptitude to dynamic analysis of changing entities

2.2.3 Challenges at the Mesolevel

Interdisciplinarity

Interdisciplinarity is quite an old question and rose to the forefront in the early 1970s with an OECD (Organization for Economic Cooperation and Development) conference devoted to the topic, which gave rise to a wealth of literature and programs. The distinction between multi-, inter-, and transdisciplinarity formulates various degrees of integration, see [2.5, 34]. As *Choi* and *Park* put it [2.35]:

> Multidisciplinarity draws on knowledge from different disciplines but stays within their boundaries. Interdisciplinarity analyses, synthesizes and harmonizes links between disciplines into a coordinated and coherent whole.

Jahn et al. [2.36] examine two interpretations of *transdisciplinarity* in literature. Both make sense in a delineation context. One privileges the science–society relationship: integration between social sciences and humanities (SSH) and natural sciences with the participation of extrascientific actors, as a response to heavy and controversial socioscientific problems such as climatic change, genetically modified organisms, medical ethics, etc. The second interpretation considers that transdisciplinarity simply pushes the logic of interdisciplinarity towards integration. *Russell* et al. [2.37], cited by *Jahn* et al. [2.36],

> emphasize that where interdisciplinarity still relies on disciplinary borders in order to define a common object of research in areas of overlap [...] between disciplines, transdisciplinarity truly transgresses or transcends [them].

Klein [2.38] and *Miller* et al. [2.39] stress the theoretical and problem-solving capability of the transdisciplinary view. Many publications evoke the paradox of multidisciplinarity, a source of radical discoveries, laboring however to convince evaluators in the science reward system. *Yegros-Yegros* et al. [2.40] list a few controversial studies on the topic, and note a specific difficulty for distal transfers. *Solomon* et al. [2.41] recall that the impact of many multidisciplinary journals is misleading in this respect, since their individual articles are not especially multidisciplinary.

Bibliometric operationalization has to account for those different multi/inter/transdisciplinarity forms. *Multidisciplinarity* involves sustained knowledge exchanges in a roughly stable structure; *interdisciplinarity*, with an organization and systematization nuance, supposes strong exchanges creating some structural strain, between domain overlap and autonomization of merging fractions; *transdisciplinarity* paves the way for the autonomy of the overlapping region, within the strong interpretation involvement of SSH and possibly of extrascientific considerations. Clearly model C is apter than A to depict those forms and their transitions when they occur, rather than waiting for the institutionalization of the emerging structures.

Interdisciplinarity may be outlined at the individual level by copublications of scholars with different educational or publication backgrounds, by measures of knowledge flows (citations), contents proximity, authors' coactivity or thematic mobility—if such data exist [2.42]. Other sources include joint programs, joint institutions or labs claiming disciplinary affiliation, generally found in metadata. Most disciplinary databases lagged behind the Garfield SCI model as to the integral mention of all authors' affiliations on an article. The large scope of bibliometric measures of multidisciplinarity was reviewed in many articles, e.g., [2.27, 43].

In model A the first entry point to multidisciplinary phenomena is the category classification schemes, with measures of knowledge exchanges by citation flows between categories (*Pinski* and *Narin*'s seminal work on journal classifications [2.44], *Rinia* et al. [2.45]), transposable to textual proximity (on patents [2.46]) or authors coactivity. Despite the heavy input of experts in science classification, the delimitation of particular fields varies across information providers and none can be held as a gold standard. It finds its limits in the inertia and often the hard scheme of classes, albeit the derived coclassification and coindex treatments noticed above relax the constraint and instil some of the bibliometric potential of model C.

Model C is more realistic in depicting the combinatory, flexible, multinetwork relationships in science and the demography of topics. Ignoring disciplinarity as such, it conveys a broader definition of interdisciplinarity, ranging from close to distant connections, the latter loosely interpretable, in the common acceptation, as interdisciplinary and possibly forerunners of more integrated relations. More generally, the network perspective of model C builds bridges between networks formalization and scientific communities life, leaving open the question of how profoundly the sociocognitive phenomena are captured. Data analysis methods such as correspondence analysis (CA), latent semantic analysis (LSA), latent Dirichlet allocation (LDA) addressed below, claim light semantic capabilities at least. Bibliometrics cannot substitute for sociological analysis, which exploits the same tools but goes further with specific surveys. Similarly, it is dependent on computational linguistics and semantic analysis for deep investigations of the knowledge contents. Model C is a potential competitor for offering taxonomies, with recent advances (Sect. 2.2.4). It does not follow that dynamics captured by this model are easy to handle: for example, flow variations in a fixed structure (A) read more conveniently than multifaceted structural change (C).

Internal Diversity

Diversity and multidisciplinarity are two facets of a coin. Internal diversity in a delineation process qualifies communities inside the target domain. Figure 2.2b,c expresses the internal diversity of multidisciplinary domains, already striking for nanosciences and massive for proteomics (Fig. 2.2).

Internal diversity is treated in quite different ways depending on the model. In the cluster analysis part of model C, the balance of internal diversity and external connectivity (*multidisciplinarity* in the looser sense) is part of the mechanism which directly or indirectly rules the formation of groups, with a wide choice of protocols. Many solutions of density measurement are available in clustering or network analysis, with some connections with diversity measures developed in ecology and economics especially. The synthetic Rao index discussed by *Stirling* [2.49] combines three measures on forms/categories: variety (number of categories), balance (equality of category populations), and disparity (distance of categories). Delineation through mapping will use smaller scale clusters rather than attempting to capture the target as a whole large-scale cluster. There is no risk of missing large parts of the domain, but the way the different methods conduct the process raises questions about the homogeneity of clusters obtained and the loss of weak signals especially in hard clustering (Sect. 2.3).

In model B internal diversity, especially when generated by projected multidisciplinarity, is a threat on recall. Entire subareas may be missed out if the diversity in supervision (panels of experts) does not match the diversity of the domain. Unseen parts will alter the results. In contrast, on prerecognized areas, model B can be tuned to recover weak signals.

In model A, the existence of a systemic silence risk particularly depends on how interdisciplinary bridges are managed.

Unsettlement

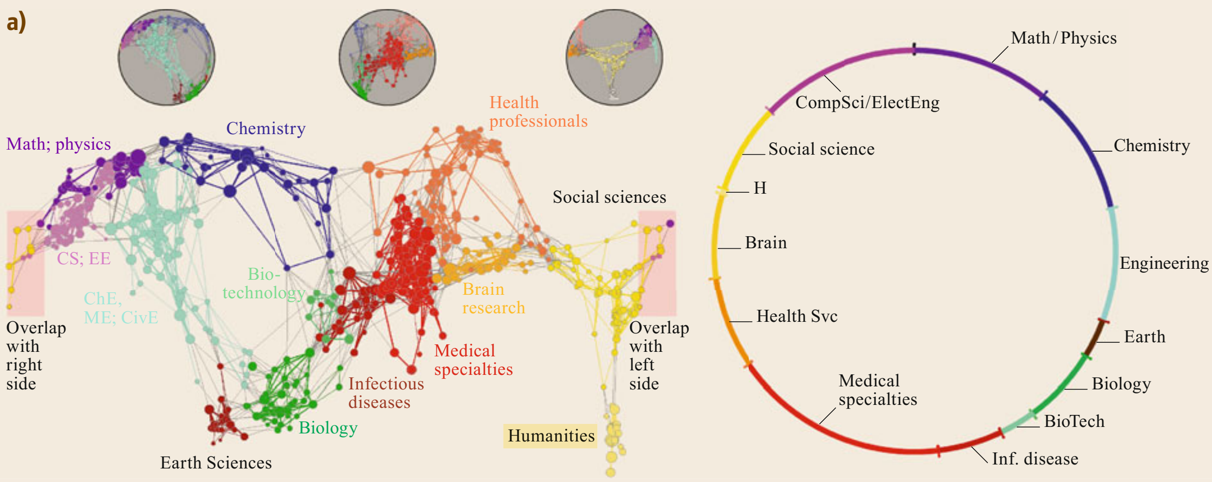
The third challenge of domain delineation lies in the science network dynamics. Conventional model A classifications hardly follow evolutions and need periodic adjustments. The convenience of measures within a fixed structure is paid for by structural biases. Bibliometric mapping can translate evolutions in cluster or factor reconfiguration, but the handling of changes in a robust way remains delicate (Sect. 2.3). Model B pictures networks, but intuitively, a fast rhythm of reconfiguration in the somewhat chaotic universe of science networks makes it particularly difficult to settle delineation on firm roots. This casts a shadow on the time robustness of the solutions reached on one-shot exercises, but also on the predictive value of extrapolations on longitudinal trends. We will return later to dynamic studies and semantic characterization (Sect. 2.3.2). Emerging domains seldom embody institutional organization but bear bibliometric signatures of early activity. The difficulty is to capture weak signals with a reasonable immediacy. Fast manifestations of preferential attachment around novel publications, whatever the measure (citations, concept markers, or altmetric linkages) are amongst the classical alerts of topic emergence at small scale, to confirm by later local cluster growth.

Source Coverage

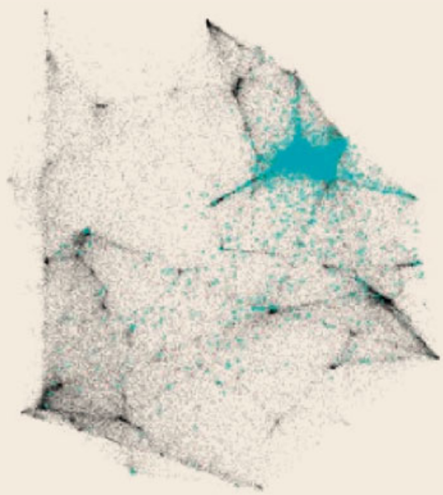
For memory's sake, the question of data coverage is recurrent in practical bibliometrics and is raised at the delineation stage of any study. The literature on the subject is abundant, conveying different points of view: *Hicks* [2.50] first stressed the limitations of both the reference database SCI and the mapping algorithm of cocitation for research policy purposes. *Moed's* review [2.51, esp. Sect. 6.2.2] and *Van Raan* et al. [2.52] showed the differential coverage of disciplines by journals in SCI-WoS using references to nonsource items. Keeping pace with the growth of visible science is another challenge. The latest United Nations Educational, Scientific and Cultural Organization (UNESCO) science report estimates that 7.8 million scientists worldwide publish 1.3 million publications a year [2.53]. SCI-WoS producers proposed new products beginning to fill the gap of book literature, essential to social sciences and humanities (SSH) and conference proceedings, essential to computer science [2.54]. The coverage of social science and humanities with issues of publication practices and national biases was addressed in many works, e.g., [2.55–57]. This is distinct from the within-discipline approach where an extensive coverage causes instability of indicators due to tails (language biases, national journals biases), to document types or adaptation issues [2.58–61]. Former studies' figures are outdated but the basic principles remain.

Extensive databases with enhanced coverage for IR purposes (modern WoS, Scopus) might require truncation of tails for comparative international studies. The PageRank selection tool limits the noise of a massive extension of sources in Google. However, Google Scholar is not considered a substitute for biblio-

a)

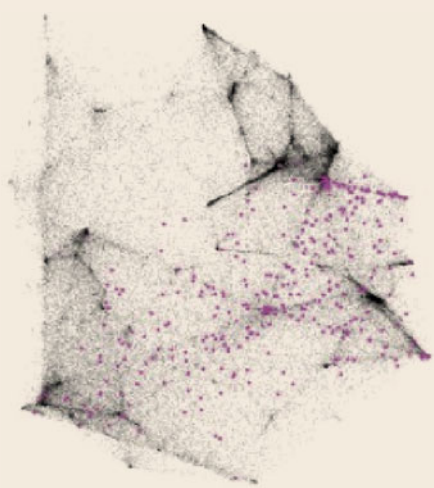


b)



Nanotechnology
Most research communities in nanotechnology are concentrated in **physics**, **chemistry**, and **materials science**, However, many disciplines in the life and medical sciences also have nanotechnology applications.

c)



Proteomics
Research communities in proteomics are centered in **biochemistry**. In addition, there is a heavy focus in the tools section of chemistry, such as **chromatography**. The balance of the proteomics communities are widely dispersed among the life and medical sciences.

Fig. 2.2a–c Map of science and multidisciplinary projections. **(a)** A world-map-type science map from a spherical representation [2.47]. **(b)** and **(c)** Hotspots of activity of nanoscience and proteomics projected in a fraction of a global science map. It basically crosses the map's holistic picture with an overlay of hits from simple term queries. After *Boyack* and *Klavans* [2.48] ◄

graphic databases for common librarian tasks, but rather a complement especially for coverage extension in long tails [2.62] with variations amongst disciplines. The same applies to another large bibliographic database: the Microsoft Academic Graph [2.63–65]. The lack of transparency in the inclusion process and the lack of tools beyond original ranking (sorting, subject filters) are stressed by *Gray* et al. [2.66]. Strong concerns with the quality of bibliographic records were also reported [2.67, 68]. The coverage of databases has recently been compared by several authors [2.69, 70], with an extension to alternative sources such as altmetrics: http://mendeley.com, http://academia.edu, http://citeulike.org, http://researchgate.com, http://wikipedia.org, http://twitter.com, etc. [2.71, 72]. Online personal libraries like Mendeley shed new light on knowledge flows between disciplines through publication records stored together [2.73]—a kind of cocitation data from readers instead of authors. In addition, these sources, often difficult to qualify properly [2.74], have been addressed by altmetric studies [2.42, 75, 76]. The way scientists and the general public communicate about science on (social) media is field-dependent and it is not easy for now to anticipate the complementary role of altmetrics and traditional data in delineation of fields. Altmetric resources can help exploratory and supervision tasks.

In emerging and multidisciplinarity topics that typically justify careful delineation, controversies and conflicting interests are frequent and the importance of transdisciplinary problems makes the issues of sources coverage, experts panel selection, and supervision organization more acute.

2.2.4 Ready-Made Classifications

Classifications

Table 2.2 presents some types of science classifications valuable in domain delineation. These coexisting classification schemes reflect various perspectives, such as cognitive, administrative, organizational, and qualification-based rationales according to *Daraio* and *Glänzel* [2.77] who stress the difficulties arising when trying to harmonize them.

The first named classifications directly stem from professional expertise of scientists and librarians (pure model A). Some are linked to institutional or national research systems, mainly oriented towards staff management or evaluation, or international instances (UNESCO). More relevant for bibliometric uses are classifications within complete information systems on S&T literature, proceeding from a few sources: specialized academic societies (CAS (Chemical Abstracts Service), Inspec, Biosis, MathSciNet, Econlit, etc. which usually extend beyond their core discipline) and/or scientific publishers, and patent offices for technology. Classifications are typically hierarchical, complemented by metadata (keywords of various kinds, indexes from object nomenclatures: vegetable or chemical species, stellar objects, and so on).

Table 2.2 Science classifications

1.	International classifications, often high level. OECD high-level a.k.a. *Frascati Manual*. Fields of science introduced in 2002. Last revision in 2007. Correspondence table with WoS [2.78]. Six major fields were subcategorized.
2.	Institutional nomenclature frameworks (ex. CNRS sections[a]). Reflects the vision of the institution and its involvements.
3.	Bibliographic databases from science societies. Involve nomenclatures and/or classifications, with a disciplinary focus, sometimes very large (ex. *Chemical Abstracts Service* CAS). Typically based on a classical documentation system, with heavy expert input. Another example of classification in computer science: *association of computer machinery classification*[b] 1964–2012.
4.	Alternative *ISI model* ISI (Institute for Scientific Information)/Thomson/Thomson Reuters/Clarivate; Scopus/SCImago Journal Rankings[c] (SJR) as "a publicly available portal that includes the journal and country indicators developed from the information contained in the Scopus database." First used the editorial entity *journal* as the basic molecule, and impact as a principle of selection (see historical account by *Garfield* [2.79]). Extensions at a more detailed level. The balance expertise/bibliometrics to design subject categories is unclear (see WoS notices on the topic and [2.80, p. 1113]). Gives a one- or multilevel hierarchy of groups. The database offers both nonoverlapping schemes (essential indicators) and overlapping schemes (SCI-WoS).
5.	Bibliometric mapping classifications, either at the journal or the document level: tailor-made maps potentially usable as permanent resources for public purposes.

[a] http://www.cnrs.fr/comitenational/english/section_acc.htm
[b] http://www.acm.org/about/class
[c] http://www.scimagojr.com/aboutus.php

Bibliometrics then entered the competition for science classifications, in contrast with the traditional documentation model involving heavy manpower for indexing individual documents. The prototype is *Garfield's* SCI/WoS based on the *journal* molecule and a selection tool, the impact factor [2.81, 82]. The supervision was still heavy in the elaboration of classification, although the journal citation report is a powerful auxiliary for actual bibliometric classification based on journals' citation exchanges [2.83]. The model of citation index inspired Elsevier's Scopus [2.84, 85]. The Google Scholar alternative, with a larger scope of less normalized sources, is the extreme case with very little supervision and does not include a classification scheme.

Following Narin's works, several journal classifications were developed (factor analysis in [2.86], core–periphery clustering in [2.87]). Many others have been proposed over the past decades, some with overlay facilities for positioning activities [2.88]. Other proposals use prior categories and expert judgments as seeds [2.89, 90], with reassignment of individual papers. *Boyack* and *Klavans*, whose experience covers mapping and clustering at several granularity levels (journals, papers) [2.91], recently reviewed seven journal-level classifications (Elsevier/Scopus ASJC (All Science Journal Classification), UCSD (University of California San Diego), Science-Metrix, ARC (Australian Research Council), ECOOM (The Center for Research and Development Monitoring), WoS (Web of Science), NSF, JID (Journal IDentification) and ten article-level classification (five from ISI and Center for Research Planning (CRP), four from MapOfScience, one from CWTS (Center for Science and Technology Studies)) [2.92]. The latter authors privilege the concentration of references in review articles (>100 references) considered as *gold standard* literature, as an accuracy measure (a heavy hypothesis). They conclude in favor of paper-level (versus journal-level approaches) and in favor of direct citations (versus cocitations or bibliographic coupling) for long-term smoothed taxonomies, distinguished from current literature analysis, for which they rank first bibliographic coupling.

Those developments mark a new turn in the competition between institutional classification and bibliometric approaches for long-term classifications of science. It is not clear, however, whether the variety of classifications from bibliometric research, not always publicly available, can supersede the quasistandards of SCI type for current use in bibliometric studies. High-quality delineation of fields cannot solely rely on journal-level granularity, and this is still more conspicuous for emerging and complex domains.

Semantic Resources

Science institutions and database producers have a continuous tradition of maintenance of linguistic and semantic resources, in relation to document indexing. The best known is probably the MeSH (Medical Subject Headings; National Library of Medicine) used in Medline/PubMed. INSPEC, CAS, and now Public Library of Science (PLoS) offer such resources. Controlled vocabulary and indexes, archetypal tools of traditional IR search were also the main support of new coword analysis in the 1980s. A revival of controlled vocabulary and linguistic resources is observed in recent works, associated to the description of scholarly documents [2.93] and bibliometric mapping [2.94]. We shall return to the role of statistical tools in the shaping of semantic resources.

2.2.5 Conclusion

Science, seen through scientific networks, is highly connected, including long-range links reflecting interdisciplinary relations of many kinds. Global maps of science, with the usual reservation on methods settings and artifacts, display a kind of continuity of clouds along preferential directions (Fig. 2.2c, from [2.47]). The extension of domains has to be pragmatically limited by IR trade-off with the help, in the absence of ground truth, of more or less heavy supervision. Three models of delineation appear: ready-made delimitation in databases, rather limited and rigid as is, but prone to creative diversions from strict model A (coclassification, etc.); model B, ad hoc search strategies combining several types of information; model C, by extraction of the field from a more extended map, regional or global.

Networks of science may locally show cases of domains ideal for trivial delineation: a perfect correspondence between the target and ready-made categories, or insulated continents surrounded by sea. Such domains will not require sophisticated delineation. This is the exception not the rule.

Areas such as environmental studies, nanosciences, biomedicine, information and cognitive sciences and technologies (converging NBIC, concept coined by NSF in 2002) exhibit both internal diversity and strong multidisciplinary connections. Commissioned studies often target emerging and/or high-tech strategic domains which witness *science in action* prone to socio-scientific controversies à la Latour. These areas combine high levels of instability and interdisciplinarity. As to transdisciplinarity, the question arises of whether to include SSH and alternative sources in data sources and panels of experts.

2.3 Tools: Information Retrieval (IR) and Bibliometrics

This section focuses on some technical approaches to the delineation problem: information retrieval and bibliometric mapping. They share the same basic objects and networks, chiefly actors and affiliations, publication supports, textual elements, and citation relations. Although the general principles of bibliometric relation studies are quite well established, new techniques from data analysis and network analysis, including fast graph clustering, open new avenues for achieving delineation tasks on big data at the fine-grained level. The quality of results remains an open issue. Domain delineation confronts or combines the three approaches previously stated: ready-made categories (model A) are seldom sufficient; we shall envision ad hoc IR search (model B) with an occasional complement of ready-made categories; and bibliometric processes of mapping/clustering along the lines of model C.

2.3.1 IR Term Search

The question of delineation spontaneously calls for a response in terms of information-retrieval search. The only particularity is the scale of the search or more exactly, as mentioned before, the diversity expected in large domains, which is particularly demanding for the a priori framework of information search. The verbal description of the domain requires, beforehand, an intellectual model of the area. In addition to the methodological background brought by IR models, a broad range of search techniques address delineation issues:

- Ready-made solutions in the most favorable cases, with previously embodied expertise, sketched above.
- Search strategies of various levels of complexity, also depending on the type of data, relying on expert's sayings.
- Multistep protocols: Query expansion, combination with bibliometric mapping.

IR models are outside the scope of this chapter. In the tools section below, we recall some of the techniques shared by IR and bibliometrics, especially the vector-space-derived models.

IR Tradeoff at the Mesolevel

The recall–precision trade-off is particularly difficult to reach at the mesolevel of domains exhibiting high diversity. Generic terms (say the *nano* prefix if we wish to target nanosciences and technology) present an obvious risk to precision. A collection of narrower queries (such as *self-assembly*, *quantum dots*, etc.) is expected to achieve much better precision. In the simpler Boolean model, this will privilege the union operator of subarea descriptors (examples for nanoscience [2.33, 95, 96]). However, nothing guarantees a goodness of coverage of the whole area by this bottom-up process. An a priori supervision of the process by a panel of experts is required, but the experts' specialization bias, especially in diverse and controversial areas, generates a risk of silence. Similar risks are met in the selection of training sets in learning processes. Another shortcoming is the time-consuming nature of supervision, again worsened by the diversity and multidisciplinarity of the domain. A light mapping stage beforehand may reduce the risk of missing subareas. As mentioned above, focused IR searches are, in contrast, able to retrieve weak signals lost in hard clustering.

Polyrepresentation and Pragmatism

Scientific texts contain rich information, most of it made searchable in the digital era. Pragmatically, all searchable parts of a bibliographic record, data or metadata are candidates for delineating domains: word *n*-grams in titles, abstracts, and full texts; authors, affiliations, date, journal or book, citations, acknowledgements, transformed data (classification codes, index, controlled vocabulary, related papers. . .) depending on the database. These various elements exhibit quite different properties. In theoretical terms, the variety of networks associated to these elements are one aspect of the *polyrepresentation* of scientific literature [2.97]. We will return to this question later (Sect. 2.3.2). A specific advantage of lexical search is the easy understanding of queries—whereas other elements (aggregated elements such as journals; citations) are more indirect. However, the ambiguity of natural language reduces this advantage.

Bibliometric literature is packed with examples of pragmatic delineation of domains based on IR search. By and large, apart from ready-made schemes when available (indexes, classification codes), a typical exploration combines a search for specialized journals if any, and a lexical search in complement. At times, an author-affiliation entry is used, especially in connection with citation data. Bradford and Lotka ranked lists are therefore good auxiliaries, with evident precautions on journals' or authors' degree of specialization.

Granularity

We noted above that some ready-made classifications such as the SCI scheme (journals or journal issues) are essentially based on full journals—or journal sections. These ready-made categories very seldom fit the needs of targeted studies. Instead, ad hoc groupings of selected journals relatively easy to set up with the help of experts, are a convenient starting point within a Bradfordian logic. The journal level presents obvious advantages. Journals exhibit a relative stability in the medium term; they are institutionalized centers of power through gatekeeping, and a (controversial) evaluation entity in the impact factor tradition.

However, the journal level is problematic for delineation studies. Journals whose specialization is such that they indisputably belong to the target domain, can be taken as a whole, but of course target domain literature are rarely covered by specialized journals only, and investigations should be extended to moderately or heavily multidisciplinary sources. Conditions of diversity and multidisciplinarity—which prevail in the targets of studies where elaborate delineation is worthwhile—hinders the efficiency of global Bradford/Lotka-based selections, with problems of normalization (refer also to [2.98]). We will return to these issues in the Sect. 2.3.2 devoted to clustering and mapping.

To conclude, the IR resources in scientific texts, data and metadata, suggest a polyrepresentation of scientific information (cognitive model [2.97]), which is akin to the multinetwork representation of the scientific universe. *Ingwersen* and *Järvelin* [2.99, p. 19] propose a typology of IR models and the perspective of the *cognitive actor*. IR protocols generally involve multistep approaches, with various core–periphery schemes. In conventional search, heavy ex ante supervision is needed for covering the variety of domains, ideally with good analytic/semantic capability. In the absence of a gold standard, proxy measures of relevance are needed.

Multistep Process

Multistep processes, possibly associated with combinations of various bibliometric attributes, are run-of-the-mill procedures (for example [2.32]).

Core–periphery rationale is common, in accordance with the selective power of concentration laws, both in IR and bibliometrics (journal cores in [2.100], cocitation cores in [2.101], *h*-core in [2.102], emerging topics in [2.103]). For example, working on highly cited objects—authors, journals, or articles—gives a set of reasonable size, amenable to further expansion with enhanced recall. Cores inspired from the Price law on Lotka distributions or from application of the *h*-index are helpful. Proxies such as seeds obtained from initial high-precision search stages can do as well. The core or seed expansion process is global or cluster-based. The risk of core–periphery schemes, by and large favorable to robustness, is to miss lateral or emerging signals. This may need some input of dynamic characterization of hotspots at the fine granularity level.

A parent method is bibliometric expansion on citations, which also uses information from a first run (set of documents retrieved by a search formula or a prior top cited selection, considered as the core) to enhance the recall through the citation connections, typically operating at the document level with or without a clustering/mapping step. In this line the Lex+Cite approach mentioned in Sect. 2.3 relies on a default global expansion, rather than a cluster-based one, to limit the risk of an exclusive focus on cluster-level signals that would miss across-network bridges.

Query expansion by adaptive search is along the same lines. Interactive retrieval with relevance feedback identifies the terms, isolated or associated (cooccurrences), specifically present in the most relevant documents retrieved according to various measures [2.104–106]. An efficient but heavy process consists in submitting the output of a search stage to data analysis/topic modeling, able to reconstruct the probable structure likely to have generated the data. By providing information on the linguistic context—also citation, authoring context, etc.—they in turn help to improve the search formulas by a kind of retro-querying. This ranges from simple synonym detection to construction of topics, orthogonal or not, suggesting the rephrasing of queries. Variants of itemset mining uncovering association rules ([2.107], with earlier forerunners) are promising in this respect (see below). Evaluation of output from unsupervised stages can also call for a manual improvement of queries.

Delineation protocols may also use the seed as a training set for learning algorithms. A difference is that core–periphery schemes usually rely on the selective power of bibliometric laws, whereas the training set might be extracted on various sampling methods, provided that the seed does not miss the variety of the target. As big data grows bigger, *semisupervised* approaches are gaining popularity in the machine learning community. This recent approach should prove attractive in the bibliometrics community, as there seems to be considerable interest in linking metadata groups and algorithmically defined communities [2.108].

To conclude on this part, whilst typical IR search relies on an a priori understanding of the field, multistep schemes involve stages of data analyses quite close to bibliometric mapping practices, the topic of the next subsection. IR and bibliometrics share roots and features, which soften the differences: adaptive loops, learning processes, seed-expansion, and core–periphery schemes. Bibliographic coupling, at the very origin of bibliometric mapping, came from the IR community [2.109] and the *cluster hypothesis* about relevant versus nonrelevant documents [2.110] voices the common interests of IR and bibliometrics, beyond the background methodology of information models (Boolean, vector space, or probabilistic) and general frameworks such as the above-mentioned cognitive model. The tightening of bibliometrics–IR relations has been echoed in a series of workshops and in dedicated issues of *Scientometrics* ([2.111, 112], see also [2.113] for a focus on domain delineation) and in the *International Journal on Digital Libraries* [2.114].

2.3.2 Clustering and Mapping

In contrast with conventional IR search, bibliometric mapping starts at a larger extension level than the targeted domain. This broad landscape, typically built by unsupervised methods, is scrutinized by experts to rule out irrelevant areas. The supervision task is limited to the *postmapping* stage. This is in principle less demanding than the a priori conception of a search formulation or of a training set. The default solution is a zoomable general or regional map of science, with availability and cost constraints. The alternative is the construction of a limited overset including almost certainly the anticipated domain, using a general search set for massive recall, an operation much lighter than setting up a precise search formula. In terms of scale, the final result is tantamount to the outcome of a top-down elimination process, although the selection modalities are diverse. There is currently great interest in delineation through mapping. IR and mapping are complementary in various ways. Firstly, we briefly describe the data analysis toolbox, before addressing the main bibliometric applications and a few problematic points.

Background Toolbox

The data structure of matrices in the standard bibliometric model allows scholars to mobilize the large scope of automatic clustering, factor/postfactor methods, and graph analysis. Classical methods of clustering and factor analysis continue to be used in bibliometrics, but in the last decade(s) novel methods came of age, more computer-efficient and fit for big data, an advantage for mapping science and delineating large domains. Starting with bibliometric data of the standard model and some metrics of proximity or distances, clustering and community detection methods produce groups. Elements are mapped using various dimension reduction algorithms. Factor methods produce groups through clustering applied to factor loadings, with an integrated two-dimensional (2-D) or three-dimensional (3-D) display when just two or three factors are needed in the analysis.

A major driving force of bibliometric methodology is the general network theory, which took large networks of science, especially collaboration and citation, as iconic objects [2.115–117]. Quite a few mechanisms have been proposed to explain or generate scale-free networks since *Price's* cumulative advantage model for citations [2.118] along the lines of Yule and Simon, and later studied in new terms (preferential attachment) by *Albert* and *Barabási* [2.119], see also [2.120]. These models have some common features with the Watts–Strogatz small worlds model, but also differences that are empirically testable [2.121]. Amongst other mechanisms: homophily [2.122], geographic proximity [2.123], thematic proximity inferred from linguistic or citation proximity. *Börner* et al. reviewed a few issues in science dynamics modeling [2.124]. Of great interest in bibliometrics and especially delineation, community detection algorithms exhibit a general validity beyond *real* social networks, and belong to the general toolbox of mathematical clustering and graph theory—applicable to various markers of scientific activity, document citations, words, altmetric networks, etc., see also [2.120].

Hundreds of clustering and mapping methods have been designed during one century of uninterrupted research. This section can only provide a basic overview of the main method families, in the perspective of domain delineation. More comprehensive descriptions and references, as well as a basic benchmark of various methods, applied to a sample of textual data, can be found in [2.125].

Clustering Methods. Although *hierarchical clustering* algorithms sometimes seem old-fashioned because of their computing complexity, $O(n^2)$ in the very best cases, some of them show good performances for relative small universes. For large ones, they can be coupled beforehand to data-reduction stages, classical (SAS Fastclus $O(n)$), preclustering algorithms for big data (Canopy clustering [2.126]), or sampling methods. All-science bibliometric maps use rather faster algorithms today, not without limitations however. Discipline-level maps, or simply internal clustering of the domain set at various stages of delineation may still rely on the classical techniques.

Hierarchical ascending algorithms are local, deterministic and produce hard clusters, with a few exceptions (pyramidal classification), properties favorable to dynamic representations. They do not constrain the number of clusters and provide a multiscale view through embedded partitions, with some indication of robustness of forms in scale changes. Most hierarchical descending (divisive) methods are heavier. Hierarchical methods typically rely on ultrametrics, which has downsides, see [2.125].

Amongst popular methods in bibliometrics are ascending methods: single linkage, average linkage, and

Ward. Single linkage is relatively fast and exhibits good mathematical properties in relation to spanning trees but produces disastrous chain effects which must be limited in various ways. Ward and especially group average linkage give better results. Group average linkage, advocated for bibliometric sets by *Zitt* and *Bassecoulard* [2.127] and used by *Boyack* and *Klavans* in various works [2.128], is slightly biased towards equal variance and is not too sensitive to outliers. Ward is biased towards equal size with a strong sensitivity to outliers. Properties and biases were studied especially by *Milligan* [2.129, 130] using Monte Carlo techniques.

Density methods are appealing: deterministic too, local, and as such prone to dynamic representations of publication or citation flows. DBSCAN [2.131] (density-based spatial clustering of applications with noise) is the most popular to the point of becoming synonymous with *density clustering*. The SAS clustering toolbox includes hierarchical methods with prior density estimation, with good properties towards sampling and the ability to capture elongated or irregular classes. However, this property is disputable in bibliometric uses (Sect. 2.3.2, *Shape/Properties of Clusters*). More recently, density peaks [2.132] has implemented an original and graphical semiautomatic procedure for determining the cluster seeds.

Not directly hierarchical is the venerable *K-means clustering* family, still popular, thanks both to its excellent time/memory performance and sensitivity to different cluster densities. A shortcoming of not being deterministic, they converge to local optima of their objective function, depending on their random (or supervised) initialization. In comparative analyses, they are not considered too sensitive to outliers. They optionally allow for soft/fuzzy clusters, and approximate dynamic data-flow analysis.

Factor methods are basically dimension-reduction techniques, indirectly linked to the partition problem. A quick-and-dirty heuristics for extracting a limited number k of dominant clusters from k factors consists of assigning each entity to the factor axis which maximizes the mode of its projection, subject to the constraint of a common factor sign for the majority of entities assigned to this cluster—which eliminates few of them in practice. For a more rigorous procedure, see the descending hierarchical clustering method Alceste [2.133] in the dataspace of correspondence analysis. Factor methods rely on the mathematical foundation of singular value decomposition (SVD) of data matrices for reducing dimensionality and filtering noise. The interesting metrics used by correspondence analysis (CA [2.134]) explains the attention over half a century from many scholars in relation to mapping or clustering limited to a few dominant factor dimensions. Dropping this limit, i. e., taking into account factor spaces with hundreds of dimensions [2.135], latent semantic analysis (LSA [2.136]) unleashed the potential of singular value decomposition and fostered the integration of semantics in textual applications, in a lighter but more convenient form than handmade ontologies, costly to edit and update.

Hybrid factor/clustering methods, sometimes coined *topic models*, result in representing each cluster as a local, oblique factor, with a progressive scale from core elements to peripheral ones, opened to fuzzy or overlapping interpretations or extensions. Generally powered by the expectation maximization algorithm (EM), they converge to local optima, too. Non-negative matrix factorization (NMF) and self-organizing maps (SOM) are well-known examples. Axial k-means (AKM in [2.137]) has been used in a comparative citations/words bibliometric context (Sect. 2.4).

Also known as topic models, the *probabilistic models* try to lay solid statistical foundations for their hybrid-looking representation: they produce explicit generative probabilistic models for the utterance of topics and terms [2.138]. Probabilistic LSA (pLSA in [2.139]) and latent Dirichlet allocation (LDA in [2.140]) are the best-known examples, claiming good semantic capabilities. The older fuzzy C-means method (FCM) is akin to this family, which uses the EM scheme for converging to local optima of their objective function.

The *graph clustering family*, also known as *network analysis*, or *community detection methods*, does not operate on the raw (entities $\times$ descriptors) matrix, as the previous families do, but on the square (entities $\times$ entities) similarity matrix, whose visual counterpart is a graph. Most of these methods operate directly on the graph, detecting cliques or relaxed cliques (modal classification), e.g., Louvain [2.141], InfoMap [2.142], and smart local moving algorithm (SLMA in [2.143]). Some of them operate on the reduced Laplacian space drawn from the graph (spectral clustering [2.144]). Quite a few comparative studies are available [2.145–147].

Note on Deep Neural Networks. While neural networks were somewhat in standby mode during the 1995–2005 decade, challenged by more manageable mathematical methods, several factors like the pressure of big data availability and progress in hardware (GPU, i. e., graphics processing units) triggered a renewal under the banners *deep neural nets* and *deep learning*. Allowing learning by backpropagation of errors in many layers networks, they gave form to the dream of knowledge acquisition by growing levels of abstraction: for images, extraction of local features; contours, homogeneous areas, shapes; for written language: character n-grams, words, word n-grams, expressions/phrases, sentences. Typically, they avoid heavy natural language processing (NLP) preprocessing (parsing, unification, weighting, selection...). These techniques are already widely used in supervised learning, with spectacular progress in automatic translation, face recognition, listening/oral comprehension, with important investment from the largest internet-related companies (e.g., Google, Apple, Facebook, Amazon), especially. As far as informetrics and IR are concerned, the main domain impacted so far is logically large-scale retrieval ([2.148] which uses a robust letter-trigram-based word-n-gram representation). There have also been some attempts in relation to nonsupervised processes for information retrieval [2.149].

A promising technique is neural word embeddings (NWE). Millions of texts now available online make it possible to develop vector representations of words in a semantic space in a more elaborate way than LSA—a method coined *neural word embeddings*. For example, the Word2Vec algorithm [2.150] processes raw texts so as to list billions of words-in-context occurrences (e.g., word + previous word + next word), then factorize [2.151] the word × context matrix (tens of thousands of words, a few hundreds of thousands, or millions of unique contexts) and extract some hundreds or thousands of semantic and syntactic dimensions. We will return later to the semantic capabilities of NWE.

Note on the Definition of Distances. Whether starting from a binary presence/absence matrix or from occurrence or co-occurrence counts, some methods embed a specific weighting scheme, i. e., a metric, for computing distances, or similarities between items. This is the case of probabilistic models, correspondence analysis, and axial K-means. Other methods allow for a limited and controlled choice, as aggregative hierarchical methods do. In the case of graph clustering methods, the user may freely choose his preferential distance definition prior to building the adjacency matrix, which adds an extra degree of freedom beyond the choice of the degree of nonlinearity, via a threshold value. For word-based matrices, heavier than citation-based ones, the methods of the k-means family also make it possible to choose a weighting scheme (Salton's term frequency-inverse document frequency (TF-IDF), Okapi BestMatch25 [2.152]).

Whereas factor/SVD methods combine the metrics and mapping capability, e.g., two-factor planes or 3-D displays, at the native granularity level (e.g., document × words), other mapping algorithms may operate on rectangular or on square (distance) matrices of elements or on groups from a clustering stage, or institutional aggregates (journals). Families of mapping techniques rely on various principles: equilibrium between antagonistic forces—repulsion between nodes, attraction alongside edges (e.g., the Fruchterman and Reingold algorithm [2.153], implemented in Gephi [2.154], alone or combined with clustering (Sandia VxOrd/DrL/OpenOrd [2.155], CWTS VOSviewer [2.143])); optimization of diverse functions: projection stress minimization in the case of MDS (multidimensional scaling), with Euclidean distances in the case of metric MDS, a variant of PCA (principal component analysis), and other distances or nonlinear functions of these distances in the case of nonmetric MDS, one of the nonlinear unfolding techniques; maximizing inertia in the case of Correspondence analysis, minimizing edge-cuts in a 2-D projection plane; or maximizing local edge densities [2.156].

Itemset Techniques. Itemset techniques are used for describing a data universe in terms of simple procedures, typically Boolean queries with AND, OR, and NOT operators. This may be used for building a stable procedural equivalent of data, e.g., for updating a delineation task (like probabilistic factor analyses). It may also be used for query expansion, as mentioned above in Sect. 2.3.1. The problem amounts to duplicating a reference partition in a new universe: machine learning techniques are basically fit to this problem, and, in the particular context of textual descriptions, itemset techniques. They are akin to generating Boolean queries with AND, OR, and NOT operators, for extracting approximations of the delineated domain, within precision and recall limits established in the machine learning phase [2.107, 157].

A Benchmark. To illustrate the capabilities of these various methods with an example, in the absence of a bibliometric dataset labeled with indisputable *ground truth* classes, we turned towards a reference dataset popular in the machine learning community, the Reuters 21 578 ModApté split (the corpus description is available online at http://www.daviddlewis.com/resources/testcollections/rcv1/. The website http://www.cad.zju.edu.cn/home/dengcai/Data/TextData.html has made a preprocessed version of this corpus available to the public, as supplementary material to [2.158]). The main features are:

- Source: A set of short texts: newswires from Reuters' press.
- Contents: In the six-class selection used, the number of texts (≈ 7000) and terms (≈ 4000) is sufficient with regards to text statistics.
- Class structure considered as ground truth: Built by experts, visually glaring in Fig. 2.3: two big classes,

one very dense, the other not, and four small classes, two of which are linked together. In this way, two major problems of real-life datasets are addressed: the imbalance between cluster sizes, and between cluster densities.

We challenge 17 clustering/mapping methods to retrieve this class structure. The similarity of their cluster solution to ground truth partition is measured by two indicators, adjusted Rand index (ARI [2.159]) and normalized mutual information (NMI [2.160]). The results are detailed in [2.125]. Let us summarize them in a user-oriented view, sorted by number of required parameters: the lesser the better, ideally, facing a bibliometric dataset without prior knowledge, no parameter:

- Two methods of network analysis require no internal parameterization, Louvain and InfoMap. However, the similarity matrix generally requires a threshold setting, here fixed to 0.1 in the cosine intertext similarity matrix. Infomap obtains the best result in terms of NMI (0.436 value versus 0.423), the index considered the best match for human comparison criteria. This value is rather poor, and this method does not distinguish classes 1, 2, 3, 4, and splits class 6.
- Nine methods require one parameter: The three hierarchical clusterings need a level cut parameter, possibly adjusted for 6 resulting clusters, while for CA, NMF, AKM, pLSA (probabilistic latent semantic analysis), LDA and spectral clustering, the number of desired clusters (6) has to be specified. As the latter group converges to local optima, we kept the best results in terms of their own objective function out of 20 runs. The indisputable winner is average link clustering, in both ARI (0.62) and NMI (0.71) terms. The lists of the four following challengers are contrasted: with regard to ARI, first Mac Quitty hierarchical clustering (0.50), then LDA, AKM, CA; with regard to NMI, first AKM (0.51), then Mac Quitty, CA, LDA. If one optimizes ARI over all 20 runs with prior knowledge of the six-clusters structure—a heroic hypothesis—, average link clustering still performs best (with a ten-clusters cut, ARI = 0.71, NMI = 0.64) while the followers reach, at best, ARI = 0.55 and NMI = 0.55.
- The last group of methods (ICA (independent component analysis), DBSCAN, FCM, affinity propagation, SLMA, density peaks) require at least two parameters, a handicap in the absence of prior knowledge of the corpus structure. SLMA obtains the best rating (ARI = 0.60, NMI = 0.55).

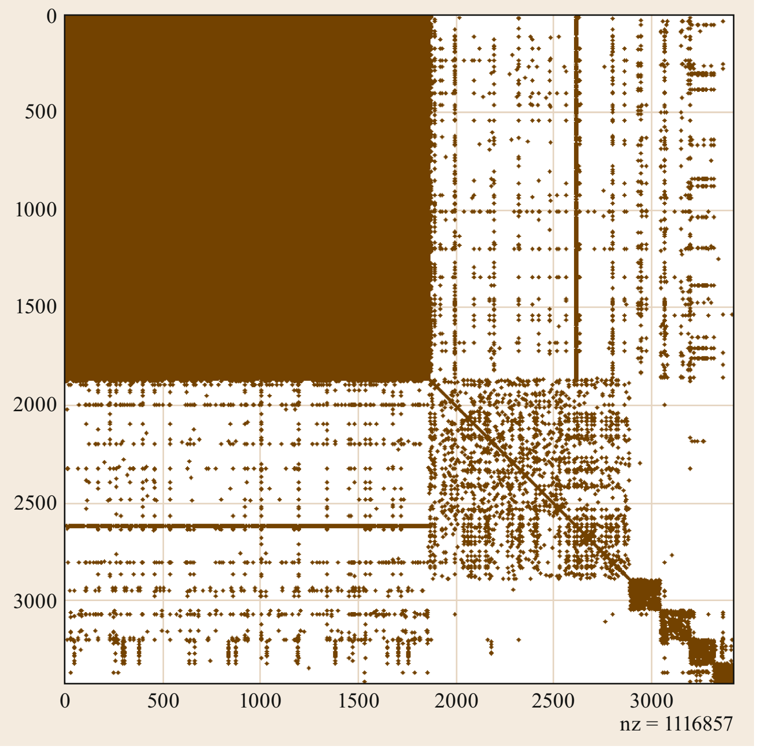


Fig. 2.3 Benchmark structure (ground truth). *Spy* plot of the cosines between document vectors of the top six classes Reuters ModApté split collection. The rows and column ordering is that of the six Reuters classes. *Black pixels* mean: cosine > 0.5

Our general conclusion is that one must be very cautious regarding domain delineation resulting from one run of one method. Multiple samplings, if necessary, and level cuts of average links as well as multiple runs of LDA, AKM, and SLMA may help determine core clusters, and possibly continuous gateways between them. Limitations of this benchmark exercise should be kept in mind. It would benefit from tests on different reference datasets: any method can be trapped in particular data structures, and the results cannot be extrapolated without caution. As advocated below, processing multiple sources (lexical, citations, authors ...) and investigating the analogies and differences in their results will always prove rewarding. A number of in-depth benchmarking studies are found for hierarchical clustering (*Milligan* [2.129, 130] not covering the last techniques), discussing the generation of test data as well as comparisons of algorithms. For community detection, usually taken as a synonym of graph-based clustering rather than clustering of true social (actors) communities, [2.145] ranked first Infomap, then Louvain and Pott's model approach [2.161]. *Leskovec* et al. [2.146] studied the behavior of algorithms with increasing graph size. *Yang* and *Leskovek* [2.147] reflect on the principles of clustering outcomes compared to institutional classifications.

Bibliometric Mapping

Classical Way. Most classical bibliometric mapping, as well as information retrieval, relies on substantive (*feature*) representations of words, word combinations, citation, indexes, and so forth. Substantive representation implies legibility and interpretation by experts or users, and a condition for bibliometricians or sociologists to check and possibly deconstruct the document linkages. It contrasts with featureless machine representation applicable for example to distances of texts (see below). In contrast, the substantive approach is deepened in semantic studies: ontologies and semantic networks suppose more elaborate investigation of term relationships. Bibliometric mapping and IR techniques are both a client of ready-made semantic resources, and providers of studies, supported by data analyses, likely to help the construction of thesauri and ontologies.

The standard bibliometric model starts from the data structure of articles, essentially a series of basic article $\times$ attributes matrices, one of these reflexive: article $\times$ cited references, where references can also stand as attributes. The derived article $\times$ article matrices (e.g., bibliographic coupling, lexical coupling) and elements $\times$ elements matrices (e.g., coword or profiles, cocitation or profiles) cover a wide range of needs. Clusters of words are candidates for conceptual representation, concepts which in turn can index the documents. Likewise, clustering of cited articles reveal intellectual structures and in turn index the citing universe. Basically, the attributes (words from title, abstract, full text; keywords list, indexes—other fields like authoring) are processed in bags of monoterms or multiterms, recognized expressions or word *n*-grams. Standard bibliometric treatments rarely go further, semantic studies do, for example by using chain modeling of the texts. All these forms allow for control and interpretation of linguistic information.

Assuming that the final purpose is to classify or delineate literature, the access is dual: direct classification of articles after their profile on the structuring elements (words, cited references), or a detour by the structuring items: word profile (especially coword), citation profile (cocitation), index (or class profile) including coclassification, when applicable. The basics of citation-based mapping were established in the 1960s and the 1970s: bibliographic coupling [2.109], chained citations [2.162], cocitation [2.101, 163], author cocitation [2.164], coclassification, etc. The lexical counterpart, with its first technical foundations in *Salton's* pioneer works [2.165], was reinvested by English and French social constructivism in the 1980s [2.166–168] with a stress on local network measures quite in line with the development of social network analysis in that period [2.169]. In bibliometrics, the true metric approach of text-based classification, Benzécri's correspondence analysis [2.134], remained confidential. For convenience reasons, many large-scale classifications relied on proximity indexes and MDS or hierarchical single-linkage (ISI cocitation). We return later to word–citation comparison and combination (Sect. 2.4).

Developments. The principles above, mutatis mutandis, are kept in further developments of citation mapping: the approach through citation exchanges, mentioned in Sect. 2.2, assumes predefined entities, journals for example. At the article level, symmetrical linkages between articles, or between structuring elements, are classical: large-scale cocitation (*CiteSpace* [2.170]). *Glänzel* and *Czerwon* [2.171] advocated bibliographic coupling. As already mentioned, direct citation linkage clustering, the first benchmark for cocitation and coupling in *Small's* princeps paper [2.101], is considered as particularly able to reflect long-period phenomena [2.92, 172, 173] but not short-term evolutions. It turns out that the time range picked and the granularity of groupings desired might suggest the choice between the three families of citation methods to reflect structure and changes in science.

From the theoretical point of view, cocitation (respectively coword) is semantically superior to coupling, by visualizing the structure of the intellectual (cognitive) base, but requires a secondary assignment of current citing literature. Coupling as such, because it by default spares the dual analysis (the cited structure; the lexical content), is semantically poor but bibliographic coupling handles immediacy better than cocitation does. However, this depends on the computer constraints and the settings: the thresholding unavoidable in cocitation analysis drastically reduces weak signals that are accounted for in coupling. The dependence of the maximum retrieval on the threshold of citation and the assignment strength (number of references), in a close field, is modeled in [2.59]. Quite a few authors compared the methods empirically [2.128] over a short time range, [2.173, 174]. These studies are not always themselves comparable in their criteria, nor are they convergent in their outcome, so that it is difficult to come to a conclusion on this basis alone.

The new data analysis toolbox (fast graph unfolding, topic modeling) gradually pervades large-scale studies. From the domain delineation perspective, a general answer in terms of single best cannot be expected. The benchmark above reminds us that classical methods, apparently outdated in the big data era, still prove to perform quite well. Let us recall a few issues in clustering/mapping for bibliometric purposes, especially delineation.

A few Clustering/Mapping Issues

As other decision-support tools, maps in bibliometrics receive contrasted interpretations. In a social constructivist view, maps are mainly viewed as tools of stimulation of sociocognitive analysis and also as supports of negotiation with/amongst actors. If technicalities are not privileged, there is clear preference for local network maps, preferably lexical or actors-based, connected to sociocognitive thinking. Bibliometricians and librarians are keener on quantitative properties and retrieval performances. Expectations as to ergonomics, granularity, robustness, clusters properties, and semantic depth, largely vary depending on the type of study.

Ergonomics. Map usage benefits from new displays with interaction facilities. A tremendous variety of mapping methods is available ([2.175] although in practice a few efficient solutions prevail). The progress in interfaces (scale zooms, bridges between attributes, interaction with users...) changed the landscape of mapping. If adding cluster features to cluster maps is trivial [2.176], the systematization of overlay maps by *Leydesdorff* and *Rafols* [2.177] is quite appealing. Since delineation tasks often deal with multidisciplinarity, multiassignments, and cluster expansion, various types of cross-representations (Sect. 2.4) including overlay maps are quite convenient tools for discussion.

Granularity. The granularity considered here is the smallest unit handled. Progress of data analysis allows large-scale work with a fine granularity. Document-level maps are now regularly proposed by *Boyack* and *Klavans* [2.91]. The classical alternative in bibliometrics uses the *journal* molecule instead of publications, with the advantages and shortcomings already discussed. Delineation tasks used to be conducted at the journal level and this convenient solution can be somewhat improved using a core–periphery scheme with multidisciplinary qualification [2.178]. The interest of journal granularity for delineation remains dependent on the specialization profile at the scale considered, so is quite field-dependent. The best fit to the journal approach is found in fields with a strong editorial focus, such as Astrophysics, but [2.179] recalls that the general rule is the superiority of document granularity. At the global science level, journals or even journal categories are an option for sketching great regions [2.177], with low precision ambitions. In favor of journals, their persistence as institutional entities with slow demography, facilitates longitudinal approaches, again at the expense of precision (Sect. 2.3.2, *Dynamic Clustering*). Granularity does not reduce to the question of journals versus document level. It can also suggest methodological choices, e.g., the family of citation method to select, depending on the objective, taxonomies of disciplines or finer level research fronts in a broad sense.

Shape/Properties of Clusters. Ex post supervision of clusters (built by unsupervised methods) is a critical stage of studies. Discussion on the cluster aggregate features, or sampled articles, is much easier if clusters are reasonably homogenous. Therefore, the ability to recover clusters of any shape (elongated, nonconvex...), which is essential in other contexts (say image analysis), may not be desirable in bibliometric mapping. A few strongly linked compact clusters is easier to assess than the equivalent elongated class. The skewness of cluster distribution is another concern, especially in citation clustering, and the inflation of microclusters with poor connections is inconvenient—an argument voiced in favor of a direct citation approach for high-level taxonomies. From this point of view, the slight tendency of average linkage towards homogeneity and the tendency of k-means towards size balance, giving a moderately skewed distribution of cluster size, may be seen as *desirable biases* (refer to [2.146] in the context of community detection) with respect to further cluster supervision. As the benchmark exercise has shown, this does not prevent average linkage from recovering heterogeneous structures.

Soft Versus Hard Clusters. For reasons of convenience and computer efficiency, hard clustering is widespread but remains a violent approximation of the complexity and intrication of community networks and semantic relations in scientific literature. Hard clustering is sometimes the first stage of a two-stage classification: Cocitation analysis usually combines hard clustering for cores in the cited universe, and assignment of the citing literature is tantamount to soft clustering of research fronts. Reciprocally, starting from hard bibliographic coupling clusters makes it possible to generate a soft image of cited clusters. The conditions of assignment parameters in the second stage determine the degree of overlap. This is true also for factor analyses more suitable for overlapping entities, especially with oblique factors, i. e., principal axes of clusters upon which any entity, in or out, has a projection. The query expansion or bibliometric expansion practiced at the cluster level also builds soft clusters from an existing hard partition on the same data, therefore enhancing the recall at the cluster level. More generally, the wide development of probabilistic clustering is consistent with fuzzy approaches of assignment of particular articles/items.

Multilevel visualization of partitions is valuable for discussing topic or domain borders, especially when obtained from techniques which do not favor cluster homogeneity, or exploring strongly multidisciplinary phenomena. For example, assuming a strong proximity of two topics A and B, it is interesting to know whether this proximity is localized—say to subclusters A1 and B1—or distributed. Local intense linkages may prefigure capture of a subcomponent or merge A1–B1. Such interpretation only makes sense with robust methodology.

In a cluster selection process for delineation, all things being equal, soft or fuzzy clusters are allowed to extend towards shared areas, and then slanted towards recall at the cluster level. This applies to the boundary clusters, with an effect on a domain's delineation. However, bibliometric use of soft clustering remains limited and does not usually depart from the holistic perspective (Sect. 2.3.2, *Semantics, Statistics, Informatics*).

Robustness and Evaluation Issues. Robustness is an essential aspect of data analysis applied to bibliometrics. Sensitivity to data issues, to the type of network, to metrics and clustering algorithms, lead to rather different solutions. Ground truth or even gold standards are generally unavailable. In empirical studies, analysts have to get along both with biased representation of panels and divergences of techniques, as well as sensitivity to settings within one technique. We already mentioned general problems of bibliometric data, especially coverage. Within a given data corpus, the skewness of informetric distributions is a powerful foundation of robustness, but many sources of instability remain. The particular question of time robustness is sketched later.

Sensitivity to the Network Weighting and Metrics. For memory's sake, some prior transformation of bibliometric networks is practised to compensate across-domain differences, such as citing behavior. In such case, the value of linkages are weighted by a function of the number of inlinks of given groups (tantamount to classical cited-side normalization) or the number of outlinks. The latter is present both in influence measures (*Pinski* and *Narin* [2.44], revival in the last decade [2.180]) and the limit case of citing-side normalization which presents original properties [2.181, 182]. Citing-side normalization of the citation network is a limit case (removing iteration) of *Pinski* and *Narin* influence weights [2.44]. It is strictly classification-free if the basic normalization unit is the paper or the journal [2.181]. It exhibits interesting properties for any basic unit making sense, e.g., domains: the dispersion of domains' impacts calculated this way with normalization at the domain level is a measure of interdisciplinarity of science in a steady state system [2.183].

A major native characteristic of bibliometric networks is the skewness of node degree distribution and resulting polarization: citations, Zipf–Mandelbrot word usage, Bradford concentration—in connection with concentration generating models recalled above in social network theory. Concentration gives tremendous selective power and at the same time, calls for corrections in IR context for information retrieval and usage, depending on the context. A vast choice of metrics or quasimetrics (similarity indexes) is available, introducing weightings with some inverse function of frequency, especially useful in a mapping context. It is common knowledge that various similarity indexes produce contrasted perspectives. Coword analysis pioneers, notably, compared the unweighted index (raw), the asymmetrical (inclusion) index, the partially weighted index (Jaccard, Ochiai among others), the strongly weighted index (p-index or affinity amenable to a similarity). After thresholding, the landscape of the transformed networks is quite different: the first two indexes tend to keep the frequent items as hubs, the last one highlights infrequent words and associations at some risk of overexposure of rare forms, amongst them typing errors.

Analogous normalizations, from the abundant repertoire of similarity indexes, are frequent for cocitation [2.184] and coauthorship analysis [2.185, 186].

Clustering algorithms build on the final network in various ways. Obviously, any delineation based on such weighted networks of structuring elements—where skew distribution is the rule—will be quite sensitive to methodology. In bibliometrics, the contrast is extreme between steep landscapes generated by raw measures, dominated by the centrality of hubs, and information-driven strongly corrected configurations, at the risk of instability and errors on very low frequencies. Intermediary options are often picked, for example Ochiai–Salton and Jaccard measure. Document coupling relations, similarly, depend on the normalization of term frequency, typically inverse frequency weighting, Hellinger, etc. built-in or not in data analysis methods (TF-IDF, χ^2 in correspondence analysis, etc.).

Asymmetrical Relations. Specific to citations, a complete model of citation exchanges requires some native or constructed aggregation with relatively stable entities (authors, journals, pre-existing categories, etc.) in order to allow both in- and out-linkages while document-level direct citation is unidirectional—with exceptions. Asymmetry at the journal level inspired the CHI classification of journals after their theoretical versus applied orientation [2.44] on the hypothesis that applied science journals tend to import knowledge and export citations, and reciprocally for basic science journals. The same phenomenon appears at the field level (cell biology versus medical research, for example).

The valuation of bilateral relations calls for methodological choices which can largely affect mapping and delineation. Take the simplest case where i and j denote two aggregates (journals, domains...) and assume the ij link is normalized on the basis of the total outflow of i and the total inflow of j, and conversely for the ji link. Let us calculate the bilateral link between i and j by the arithmetic mean, the geometric mean, and the maximum of these two unidirectional normalized flows, a simplified variant of [2.87, 187] for the sake of the example. Should these valued networks be used for delineation purposes, they would tend to produce rather different results. The multiplicative indexes trivially penalize one-way relations typical of vertical channels, and tend to group entities with balanced relations, either particularly integrated channels or basic science fields with multidisciplinarity relations, or else clients sharing methods or products. In contrast, the maximum index tends to retrieve vertical channels (say cell biology–medical research) regardless of flows dissymmetry. Additive indexes stand in intermediary position, and appear as a middle-ground choice.

Semantics, Statistics, Informatics. Scientific domains at the mesolevel represent a considerable amount of data, especially in longitudinal series. The computing requirements, even with sparse bibliometric matrixes, are high, driving towards clustering or spectral analysis algorithms with high efficiency. The trade-off between computer efficiency and semantic power is far from simple. Correspondence analysis [2.134] was amongst the first factor technique to exhibit some semantic power in textual applications, especially a robust capability to group quasisynonyms with the distributional equivalence property. In its wake, postfactor analyses keep claiming some semantic power (Sect. 2.3.2) and built-in mapping capability. In parallel, local similarity techniques associated with traditional or innovative clustering methods from network analysis privilege the native graph of proximity and elements/links groupings. In those approaches the duality (structuring elements $\times$ documents) needs assignment decisions (e.g., research front assigned to cocited core) with a semantic dissymmetry as to the internal scrutiny of clusters: while the detailed map of structuring elements is appealing for cluster evaluation (cited cores; within cluster word-map), the document coupling map, internal to a cluster, is hardly interpretable alone as stressed before.

Now, if word-maps present high potential for sociological interpretation, mere lexical associations remain semantically shallow with regard to truly semantic analyses. A common limitation to all these methods is the *bag of words* overlooking the rank of words and the structure of statements—the downside partly alleviated by multiterm treatment (noun phrases). Citations present a fuzzier relation to semantics (Sect. 2.4) but cocitation cores are nevertheless understandable for experts. Labels or lists of descriptors directly issued from cocitation or coword cores, for example a ranked list of specific terms, or indirectly rebuilt from clusters obtained by coupling, are common but limited auxiliaries for evaluating clusters. Cards might be reshuffled with new competitors to LSA such as neural word embeddings (Sect. 2.3.2). In addition to the similarity calculations in the word–context, useful for information retrieval, semantic calculations on word vectors are possible, allowing good performance in analogy tests (i. e., "Find X so as X is to A what B is to C") or inference operations on these vectors, such as `king` $-$ `man` $+$ `woman` $\rightarrow$ `queen`. This gain in semantic precision suggests that, applied to scientific corpora—now increasingly available in full text—it could allow in the future for an analyst to select the semantic dimensions relevant for delineating scientific fields and constitute crisp or overlapping groups of articles (or parts of these) in this subspace.

A recurrent problem of more traditional bibliometric representations, a counterpart of statistical simplicity and computer efficiency, is the holistic character of linkages, especially if combined with hard clustering. In document coupling techniques, either word-based or citation-based, the standard linkage measure is the weighted and normalized number of words shared. In lexical coupling, an implicit hypothesis is that the (weighted-normalized) number of shared tokens reflects the dominant semantic dimensions of the paper. For example, if very few words or references refer to methodology, this dimension will contribute less, all things being equal, to the shaping of bibliometric similarity, which can be misleading. In the opposite case, if methodology markers prevail, a transdisciplinary corpus will tend to be split between hard science literature and soft science literature on the domain, whereas mixed clusters would probably reflect the domain structure in a better way. Should the linkage between two clusters need explanation, this should be inferred from the features and given the titles of the two clusters, unless the technique includes indicators of contribution. In clusters of structuring elements (word graphs, cocitation cores) the relations are interpretable when zooming in on the fine-grained networks of words or cited articles, but without semantic characterization.

In a delineation context, a minimum of semantic break-up would make the scrutiny of the border region easier and faster. It could especially orient discussions on preferential extensions of a core zone towards neighbor clusters with shared methodology but new objects, shared object with new methods, etc. Ad hoc simple characterization of vocabulary has been successfully applied for other purposes, e.g., the level of application of biomedical research journals [2.188]. However, manual semantic tagging is quite intensive and field-specific. At the document level, many natural sciences articles can be labeled with simple semantic combinations. In computational linguistics, many works since *Teufel* et al. [2.189] (argumentative zoning) address this issue of categorization of scientific discourses and automatic annotation, applicable for example to the summarization of scientific texts. Several proposals on categorization of arguments have been made, many of them at the experimental stage. *Liakata* et al. [2.190] developed and automatized the core scientific concept (CoreSC) categorization whose first layer distinguishes 11 categories: objective (hypothesis, goal, motivation, object), approach (method, model, experiment), and outcome (observation, result, conclusion). This line of research is extremely promising for bibliometric studies, especially domain delineation, but remains for the time being limited to small universes. In the meantime, oversimplified semantic indexing would help a lot in qualifying interdocument or intercluster relations. Figure 2.4 shows a fictitious configuration where documents are naively described by semantic triplets with various degrees of kinship. The graph display could be replaced by a superimposition of three partitions, each one upon a different semantic dimension.

More intensive semantic mapping relies on sophisticated ontologies, knowledge models, and semantic networks. If such resources have not been established beforehand and published, bibliometric studies cannot generally afford such heavy developments, however see [2.191].

Directly opposed to semantic approaches are non-feature methods from computer science, which ignore the substantive representations and even more so the semantic content. In various IR/bibliometric applications (disambiguation of authors and affiliations, proximity of documents, detection of plagiarism) similarity between texts may be calculated on the basis of character n-grams [2.192] rather than *feature* word n-grams which is somewhat standard. The link to the minimal unit with semantic load, the word, is lost (almost completely for low values of n). The usual metrics can be applied to n-grams. A more radical way using the bit sequence representation with further compression, is the basis of measures like normal compression distance (NCD in [2.193]). NCD is a dissimilarity measure which is an approximation of the general Kolmogorov information distance [2.194, 195], parametrized by the compression algorithm. A *normal* compressor should satisfy four properties:

1. Idempotence
2. Monotonicity
3. Symmetry
4. Distributivity.

From the linguistic point of view the compression method is a black box. It nevertheless exhibits rather good performances for calculating text similarity with a most indirect semantic power of forms unification. The normalized Google distance (NGD in [2.196]) is the transposition to Google searches, at the word level, of the NCD, keeping the *feature* characteristics of the coword analysis and its semantic power. Its native application builds on lexical associations from millions of users.

Table 2.3 summarizes the degree of semantic ambition in the case of lexical approaches—transposable to citation attributes.

Dynamic Clustering. The delineation process has to face changes in the configuration of networks [2.124], affecting the value of a delineation solution at a particular moment. Dynamic clustering is understood in two (related) acceptations.

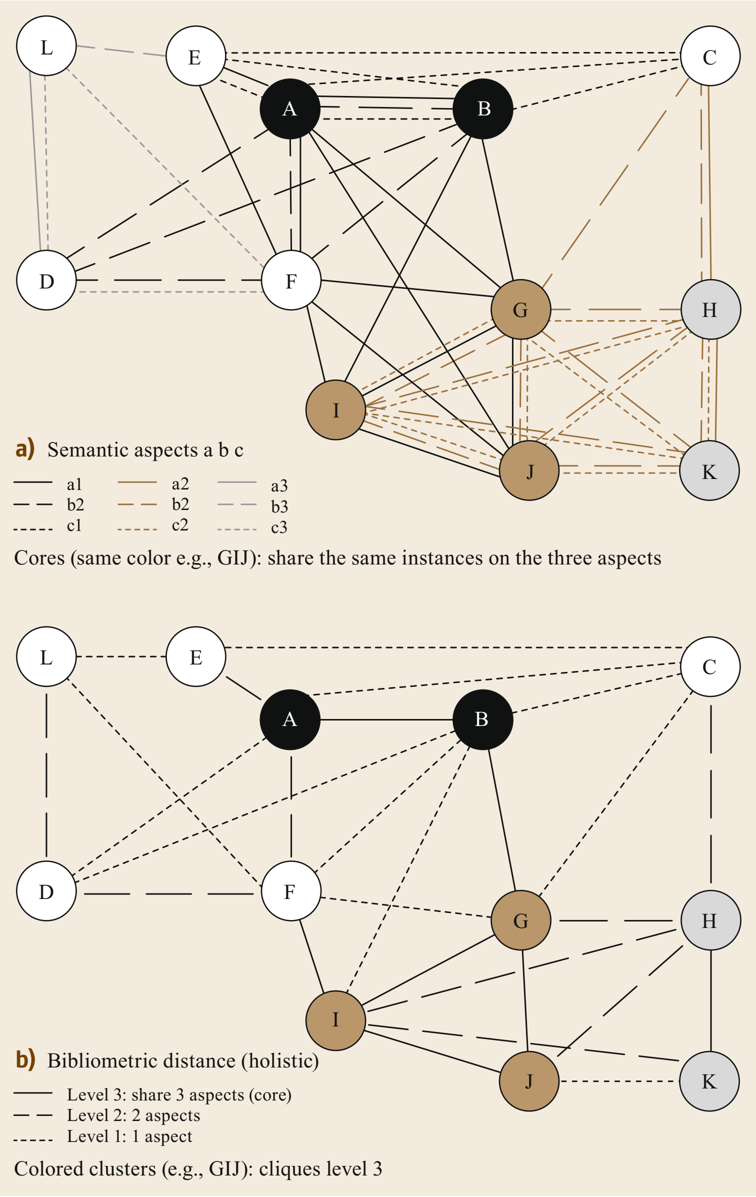

Fig. 2.4 Semantic and bibliometric linkages. This figure sketches bibliometric holistic distance versus decomposition into semantic links, with the (heroic) hypothesis of tagging with only three criteria, e.g., a = theory–hypothesis, b = experimental method, c = observation–test. For example a1, a2, a3 on the figure denote different hypotheses. The second panel represents three kinds of semantic relations. An article is described by a triplet a, b, c. For example, the documents G, I, and J are described by the same triplet {a1, b2, c2}. Documents G and I, for example, are connected by three links. The second panel aggregates information in a single type of linkages with varying degree of intensity. Here the bibliometric linkage is assumed proportional to the number of shared semantic instances, which is of course arbitrary. In the real bibliometric world, the lexical coupling linkage heavily depends on the most developed aspect(s)

Table 2.3 Semantic interpretation potential of various approaches

Structural items metrics	Document metrics (required in delineation task)	Category	Semantic interpretation versus black-box
Semantic network	Indirect through indexing/ assignment to word structures	Feature	Strong, feature
Word profile/coword	Indirect through indexing/ assignment to word clusters	Feature	Light, direct
Document profile/coupling	Direct: lexical coupling	Feature	Indirect, through indexing/assignment/labeling
–	Direct: char *n*-gram proximity	Featureless	Black-box[a]
–	Compression distance	Featureless and global	Black-box[a]

[a] Clusters of documents based on nonfeature proximity can be interpreted by going back to substantive elements, e.g., their word profile.

A first point of view is the adaptation of algorithms—and computer resources—to processing massive data streams, typically texts, an example today being online social networks. The initial k-means algorithm of *MacQueen* [2.197] was already an *online* incremental one, generating a cluster structure in one pass over the dataset—the usual iterative version, which converges to a solution independent of the presentation order of the data vectors, is due to *Forgy* [2.198]. Dynamic text stream mining is a growing topic in the machine learning and big data mining research communities. Changes in the cluster structure may reflect algorithmic artifacts as well as real phenomenona, hence ideal methodological characteristics are a) global optimum seeking and b) insensitivity to data ordering. An example of an incremental hierarchical clustering method for texts is [2.199], and a frequent itemsets dynamical clustering example is [2.200].

A second point of view focuses on the domains/topics picture and their description over time, through cluster time series, including the issue of time robustness in one-shot pictures. Again the distinction between clustering/mapping on *structuring elements* (e.g., cocited articles or lexical relations) and *direct clustering of literature* (e.g., bibliographic or lexical coupling), in techniques privileging classification in one space matters. The first family offers solutions with some durability. The repertoire of words gradually evolves. Change of the intellectual repertoire of cited literature, subject to an aging process, is usually faster but, except in emergent or revolutionary fields and in intrinsically rapid ones (e.g., computer science), it respects a mix of new and old literature. This gives some clue of robustness, in the short term, to the cluster solutions. By and large, in slow evolution processes, information cores are more persistent than peripheries. In one-shot clustering, working on pluri-annual window data reinforce the robustness of the breakdown and permit the cross-characterization of novelty (median of the cocited core) and internal growth in the span of the window (average date of front) [2.176]. Characterizing fine granularity hotspots in the network, such as local preferential attachment processes, may help to spot promising weak signals. Taxonomic applications of direct citation linkages might still benefit more from long time window settings. This would sketch, as noted earlier, a possible trend towards division of tasks between direct citation, cocitation, and bibliographic coupling in function of targeted granularity and immediacy of results.

By construction, direct clustering of documents over a time period (say the year) favors immediacy, but is not prolongable without a detour by the structuring elements and derived cluster labels. Another way consists in picking a coarser granularity, especially the journal level, at the expense of a heavy loss of precision. Short-time changes may be addressed by projecting a solution for a period on the reference solution of another period, a classical process in factor analysis applicable to other methods; an early example within bibliometrics is found in *Noyons* and *van Raan* [2.32].

A delineation process of any kind may be run on successive slices of time [2.201] of different lengths, with or without rolling averaging filters. A dynamic variant of LDA is [2.202], in which the word distributions of each topic varies in each time slice, where the number of clusters is fixed. Interesting historiographic insights accounting for cluster demography (emergence, death, splitting, merging...) are exhibited by longitudinal chaining of clusters, known since ISI's Atlas of Science, see [2.203–206]. The latter work is based on lexical series. The predictive value of such series, along with life-cycle models, remains a quite difficult issue.

Last but not least, the rendering of change is closely linked to dynamic models of science where structure emerges from local properties, for example in the preferential attachment model. In this view, over time, breakthroughs (scientific or technological) shape the citation profiles of followers, a common mechanism in (co)citation bibliometrics. Local accretions around hot papers are amongst the signs of emergence. The symmetrical question over whether the referencing (or lexical) profile of papers has some predictive value, remains open. This connects to the controversies about interdisciplinary distal transfers in the discovery process, quoted above, which echo the combinatory nature of invention and innovation stressed by Schumpeter. The intuitive but bold hypothesis stating that the more distant the knowledge transfer, the more radical the discovery or invention is, nevertheless, tricky to test (definition of scientific or technological distance from models A or B–C, scale issues). Attempts to characterize scientific breakthrough and radical inventions, with an ex ante notion, are found for example in [2.207], using both citations and patent classification [2.208], using changes in forwards and backwards citation profiles [2.209], using citation contexts of outstanding discoveries.

2.3.3 Conclusion

By and large, bibliometric mapping provides landscapes with aggregate groups (clusters; local factors, etc.) likely to be assessed, and implementation of multistep and cross points of views help to distinguish cores and border regions, the latter calling for cluster evaluation, see Sect. 2.5.2. No mapping method is superior on all criteria and many factors are at play: the bulk of data, the type of network, the nature of the problem, and the ergonomics of outcomes for an easy supervision. IR search remains an alternative or a valuable complement to mapping. The next section focuses on hybrid techniques.

2.4 Multiple Networks and Hybridization

This section addresses the multinetwork approaches. We shall especially develop the combination of textual and citation networks but most types of bibliometric (and altmetric) networks can naturally contribute where appropriate. The forms of hybridization encompass a wide scope from fully integrated approaches to parallel schemes aiming at comparison and eventual combination, with intermediate sequential schemes.

2.4.1 Multiple Networks

A given document may be accessed by search strategies pointing at all searchable fields of data or metadata. Modern IR, going beyond the direct query–document similarity, integrates, with the cluster hypothesis and later the cognitive model, the documents' multiple spaces and networks, including citations and collaborations. Bridges between lexical and citation universes were built, especially for labeling purposes (e.g., keyword-plus [2.210]).

Likewise, major streams of study in the sociology of science have coined general theories accounting for the various manifestations of scientists behavior in communities: communication, collaboration, publication, rhetoric, citation, evaluation. The networks of science, although diverse, originate in the same ground. As a result, many classes of bibliometric questions (topic identification, characterization of emergence, static and dynamic mapping, diffusion processes, knowledge flows in science and more generally in the science–technology–innovation system) can be answered by working on different networks, with respect to their specificity. The multinetwork approach to bibliometrics, both in terms of comparison and complementarity, appears as a natural mode of thought.

With the coming of age of data representation models such as entity–relationship for relational database management system (RDBMS) implementation and of network analysis methods, IR scholars and bibliometricians in the early 1990s found flexible tools for easy handling of different dimensions of publication data. In the last decades, the culture of data mining encouraged mixes between several networks for pragmatic purposes [2.211]. We recall the key role of author networks (Sect. 2.4.2) before focusing on text and citation networks (Sect. 2.4.3) and finally their hybridization (Sect. 2.4.4).

2.4.2 Networks of Actors

The first analyses of scientific communities in the 1970s led to some disappointing results as to the unambiguous assignment of particular scientists to a particular group. In a short history of domain delineation *Gläser* et al. [2.26] recall among others *Mulkay* et al.'s work [2.9] and Verspagen and Werker findings [2.212]. The archetype is the coauthorship graph. *Price* and *Beaver* [2.18], *Beaver* and *Rosen* [2.213], *Luukkonen* et al. [2.214], *Kretschmer* [2.215], and *Katz* and *Martin* [2.216] laid the first layers of collaboration studies in connection with invisible colleges. Author-based models of science are amongst the central topics in science studies and bibliometrics. Studies on scientific collaboration are out of the scope of this work, but let us recall the macrolevel studies of the determinants of cooperation in the wake of *Luukkonen* et al. [2.185], geographic proximity [2.217, 218], cultural links [2.186], and individual/collective behavior [2.219]. Those studies emphasize the importance of metrics and normalization in the interpretation. At the microlevel, proposals for mechanisms explaining the structure and dynamics of social networks were recalled in Sect. 2.3.

Networks of actors present a major theoretical interest: they stand at the crossroads of actual social networks' mathematical modeling and sociology of research, and bridge invisible colleges with cognitive structures [2.220]. They also show some drawbacks, echoing the scholars' disappointment noted above. Communities detection in practice faces the issue of names unification. For a long time, the problem has been both terribly costly and time consuming for data producers and bibliometricians, at both the institutional level and the author level, as stressed again in the name game project APE-INV (Academic Patenting in Europe Project), e.g., [2.221]. Great progress is ongoing due to the ORCID (Open Researcher and Contributor IDentifier; with the unique identifier of researchers), ISNI (International Standard Name Identifier), and GRID (Global Research Identifier Database) initiatives among others.

Another issue, especially for small topics detection, is the width of the competence spectrum of productive authors likely to produce some noise, but this shortcoming is alleviated at the level of large domains. In this case perhaps, community detection (in a narrow sense) has arguments to compete with citation or lexical clustering. However, in most practical studies multiscale vision is required: not only does the target domain matter, but also the subdomains. At this scale, the polyvalence of authors limits precision. The problem may be reduced by time-restriction filters, the link-level technique, external information, or hybridization with citation or word information. Similar issues appear in *author cocitation* versus *article cocitation* [2.164, 222]. Author cocitation opened insights in the study of invisible colleges, with connection to researchers' sociology. Topics mapping as such is better addressed by document-level cocitation.

The interplay of coauthorship, citation, and linguistic networks as a mirror of sociocognitive activity is increasingly gaining attention: relations between contents and actors' positions [2.223, 224], between citations and coauthorship, and any or both of these with texts [2.220]. Is the multiple approach a step towards more powerful models of authors and community behavior, able to unify the diverse representations? This unification would spread benefits over bibliometric analysis, including delineation tasks. Nonfeature methods have not waited for unification (see below) to mix up all types of information, but they sacrifice the substantive depth of analysis.

However, the quest for unification might be hindered by the specific features of every bibliometric network. Changing the type and parameters of the network is like observing the universe in various wavelengths. The most dense objects produce various forms of energy and tend to be retrieved albeit with diverse volume and appearance. Less-dense objects like clouds of various composition can be seen only in specific parts of the spectrum. Likewise, we may conjecture that dense and isolated objects will be retrieved from any network fit for precise analysis [2.113], especially words and citations and perhaps coauthorship clusters. Sociological investigation is expected to confirm such configurations as bounded invisible colleges. In less dense and more connected areas, each network is likely to produce nonsuperimposable images, with different sensibilities. The convergences suggest strong forms with easy sociocognitive interpretation, while the divergences ask for careful tests and investigation. The sociology of translation associated less dense areas to emergence or ultimate evaporation phases.

2.4.3 Citations and Words

Lexical and citation characterization classically used in bibliometrics are appropriate for clustering of themes and mapping at various scales, on the basis of the toolbox sketched in Sect. 2.3.

A few Analogies and Differences

General. One difference naturally lies in the nature of the original relation: direct attributes for linguistic elements, reflexive interarticles for citations, with several consequences. Firstly, the granularity: words are an ultimate attribute (in classical *feature* methods) whereas cites target the full article semantic aggregate. Then, the linguistic content of citations is not explicit, and requires a statistical detour via the text fields and the data model, to emerge (automatic labeling of clusters with their specific vocabulary, citation contexts). Secondly, the time relation, not explicit in lexical relations, directly appears in the citation link, both cited and citing article being dated. Bibliometrics makes a large use of this diachronic relation in immediacy–aging studies. In contrast, the word content of an article is readily legible, but deprived of temporal information beyond the article date of submission/publication. Going further requires statistical studies to date the word in terms of chronological profile of use. Longitudinal studies on words have to rely on time statistics of use, typically with the assumption of achronicity: constant meaning over time. This is a bold statement in some cases. Beyond classical dating of word or word linkages after their usage, determined by the obsolescence of topics, natural language analysis paved the way for analyses of word transformations in a scientific context [2.225].

With respect to these constraints, a large class of bibliometric, IR, or altmetrics issues can be addressed by the lexical method or the (generalized) citation method with the exception of specific direct chaining [2.162]. Symmetrized relations (cocitation, coupling) mitigate the diachronicity, albeit underlying time features can be invoked if required. The reformulation of the dynamic chaining research fronts [2.205] is emulated by word-based clusters [2.202, 206]. Only the former directly contains citing–cited information for immediacy characterization.

Because of limitations (indexer effect) and lack of reactivity of controlled language, modern bibliometrics moved gradually towards natural language, building on the increasing availability of full text resources and lexical treatment. In spite of progress in computational linguistics, the NLP remains tricky, a counterpart of language richness and versatility. Polysemy, metonymy, synonymy, figures of speech, metaphors, acronyms, and disciplinary jargon are well-known linguistic traps of linguistic difficulties that users, bibliometricians, and retrieval specialists have to cope with. Unification (stemming and lemmatization, synonymy detection) also benefits from clustering techniques. Unsupervised homonymy tracking is a more challenging problem, since bridges in word clusters may be rooted in concept transfers or polysemy or else simple homonymy. This issue is somewhat alleviated in small (narrow context) studies. If elaborate ontology or semantic networks are seldom off-the-shelf, useful tools for term extraction, parsing, and coword exploration are available. Stemmers (with *Porter*'s stemmer milestone [2.226]) or, a step further, lemmatizers are efficient with some risk in precision. New massive techniques, such as the above-mentioned deep learning-based or neural networks or targeted methods such as neural word embeddings, might bypass or alleviate costly preprocessing. Constraints of bibliometric studies dealing with large data universes are usually incompatible with refined semantic treatments, but the supply of large-scale statistical semantics resources might spare costly ad hoc developments. We mentioned (Sect. 2.2.4) a possible revival of controlled vocabulary supported by bibliometric treatments.

Statistical Background. The common feature is the skewness of frequency distribution found, among other disciplines, in information processes (Bradford–Lotka–Zipf trilogy, see [2.227]). The classical model to fit word distributions is the hyperbolic Zipf–Mandelbrot model. Other Paretian distributions are also used for citation frequency analogous to node degrees in the native oriented graph of citations. Similar skewed distributions are found in authors' collaboration graphs, with a distinction between scale-free distributions and small-world distributions (Sect. 2.3). The parameters of citation distributions are modulated by the citation windows, the parameters of word distribution are modulated by the type of lexical sources (title, abstract, full text...), the type of lexical unit picked, the language, and the richness of vocabulary.

Comparing the distributions of citations and words on the same corpus, some authors found that the latter appears more concentrated and less *complex* [2.33], thus less favorable in principle to precision—without forgetting the different granularity. Frequency weighting of linkages of the native word or citation networks, or similarity indexes with various types and degrees of normalization, may be implemented for retrieval or mapping purposes, for favoring information-rich elements in low and/or medium frequency. The precision of citation approaches was underlined in comparative retrieval tests, and especially the interest of cross-retrieval [2.228, 229]. As to co-occurrences, coword matrices tend to be less sparse but noisier than cocitations relations.

For the delineation work, the distribution of words or citations designs the background, with implications for interpretation, but what directly matters is the arrangement of documents after their texts or their bibliography. For this purpose, the typical approaches are the direct profile proximity on either type of structuring elements, words or references (*coupling* rationale or profile metrics in vector space), or the secondary assignment on prior classes of structuring elements such as coword, cocitation, or corresponding profiles. The distribution of node degrees in bibliographic coupling tends to be less skewed than in the original citation graph. Again normalization of distances or similarity by some function of inverse frequency can reduce the unevenness. The recall advantage of word-based techniques suggested their use in the large-scale mapping of clusters defined, beforehand, by citations [2.91]. There is some evidence in the same direction for patent–publication relations. Composite word–citation metrics are addressed in Sect. 2.4.4. Technicalities involved in term unification are also different. As information tokens, references are less difficult to match than natural language elements. Keys on cited references reveal effectivity and improve with standardization of entries, with residual difficulties in particular cases like citation analysis of patents towards science.

Sociological Background. The textual contents of an article and its bibliography are both the results of authors' choice in their community context. Both involve an intricate mix of scientific and social aspects: words and cited references are community markers and reflect the sociability of invisible colleges. A large body of literature (refer to the review [2.230]) has been devoted to citation behavior, including *Cronin's* classic work [2.231]. Whatever their determinants can be, Merton's rewards, *Small's* symbolic beacons or concept symbols [2.232], *Gilbert's* persuasion tools [2.223] or Latourian interests, the references mainly point towards the thematic groups where founding fathers, gatekeepers, and potential partners are found, which matters in science mapping. On the textual side, rhetoric and jargon expressing community habits, in addition to general words voicing interests, rejoin focused scientific terms—especially specific multiterms with medium frequency—to define topics. A substantial amount of convergence between texts and citations is therefore expected when the delineation of topics and communities are at stake. Some degree of parallelism may be found between relatively high frequency expressions (after filtering of stop-words) and highly cited articles in generic knowledge and multidisciplinary linkages. The measured convergence depends on the information unit and is likely to increase with small lexical units of citation contexts (see below).

However, the question arose as to which network is the more appropriate for describing science, at a time (the 1980s) where citation evaluation, indexing, and mapping were gaining interest. The social constructivist stream and the actor network theory mentioned above (Sect. 2.2) favored the coword networks [2.166] against citations to represent knowledge on a background of actor's interests. Texts appeared abler to depict more completely *science in action* [2.233] especially in controversial areas where social and cognitive aspects are inseparable, while citations were supposed confined to the capture of *cold science* with delays and incompleteness. The delay argument alone is less convincing for bibliographic coupling. Typical cocitation *research fronts* rely on a high-pass filter on citation or cocitation scores, favoring old articles, to reduce the data volume. Bibliographic coupling often works on the whole reference lists, letting recent and less cited references play. A residual effect of the publication cycle of the citing side nevertheless subsists. Similar delays may also occur in the use of new words or expressions qualifying a scientific technique.

In its very realm, academic science, citation analysis encountered lasting problems in quite a few disciplines, especially in a fraction of SSH, because of citation sparsity, incomplete processes of internationalization, and lack of coverage in databases. This argument is somewhat weakened nowadays because of data source progress and changing behavior of scholars confronted with science globalization and bibliometric evaluation. Citation analysis proved an appealing tool, including for the borderlines of standard literature, for example transfer documents (guidelines and even magazines and newspapers) explored in biomedicine by *translational research* for improving health system services [2.234]. See also the EUSTM website at https://eutranslationalmedicine.org. As to the coverage of technology, the transposition of citation analysis to patents was revealed to be rather successful [2.235] competing with lexical approaches [2.236]. It nevertheless requires acquaintance with specific citation rules and behavior in patent systems. The Internet produces linkages with an exploitable analogy with citations, as the Google search engine has demonstrated in the wake of Pinski and Narin's influence weights.

Citations are not without their shortcomings, stressed in voluminous literature from various horizons; see *Bornmann* and *Daniel*'s aforementioned extensive review [2.230], and for the defense, mostly, see [2.51]. For the reason stated above, citation biases are somewhat less severe in mapping applications than in citation evaluation (impact, composite indexes) which concentrate controversies. Latourian citations or rare negative citations do not add much noise to cocitation topics. Other downsides are more serious. The bandwagon effect in citation behavior tends to create spurious cliques in native cocitation networks, possibly hindering the discriminating power of citation relations. The inflation of the number of references in authors' practice, which is a long-term trend [2.237], also brings noise to conventional citation clustering. The disciplinary insertion affects the number of references (*propensity to cite*) justifying citing-side normalization approaches mentioned above.

Albeit language-dependent, textual analysis is media-free, which is valuable in fields where academic sources with standard citation behavior are not sufficient. Topics peripheral to the academic mainstream, or demanding a mix of heterogeneous data may be confined to text-based delineation.

In cases where no differential data coverage issue is faced, differences may arise between these expressions of scientists' behavior, resulting in alternative breakdowns into topics, independently from statistical properties. The expectation is that citations, albeit in a blurred and biased way, are more capable of tracking the intellectual inheritance. A single difference in the semantic mix, for example different methodology on the same category of problem, will probably better discriminate amongst microcommunities than lexical analysis, at least as long as those microcommunities do not secrete specific terminology.

Let us turn towards limit cases, special forms of particularism, especially perhaps in SSH where intellectual traditions resist globalization. Words as well as citations would distinguish between schools of thought with opposing theories, strong community preference, and distinct jargon: say in postwar period marginalist versus Marxist economists. In contrast, if the linguistic repertoire is shared by the two communities while they diverge in the intellectual base, the outcomes of the two approaches will be different. The reverse can be true, with a common recognition of the intellectual base but divergent traditions in terminology, perhaps again for reasons of national tradition. Such configurations, relatively rare, limit the generality of the conjecture stated above about local convergence of bibliometric networks in zones with high-gradient borders. Most of the time, a set of clustered papers belonging to a strong overlap of a word-based cluster and a citation-based one may be considered as a strong form, in a rationale already present in the first comparisons by *McCain* [2.228] on term versus citation indexing. The cognitive overlaps between information types was a keypoint in Ingwersen's model mentioned above.

Empirical Comparisons

The cross-check of cluster contents is a run-of-the-mill operation. For example, the enhancement of cocitation coverage by two-step expansion could be controlled by lexical means [2.127]. A few specific comparisons of the two mapping approaches on the same data are found in the literature. The scale is therefore different (subareas rather than a large domain) but the method can be applied to an overset expected to contain the targeted domain, as seen before. In an extensive study of a few promising fields in the 2000s, using bibliometric mapping, *Noyons* et al. [2.238, 239] warned about the difference of concepts: publications and keywords and concluded they were "totally different structures".

Fig. 2.5a,b Archipelago display: Nanosciences **(a)** and Genomics **(b)**. Data: Reordered cross-tabulate matrix of axial K-means clusters respectively from bibliographic and lexical coupling 50×50). Relative overlap (z-axis) measured by the Ochiai index. Reordering: ranks on 1-dim MDS, making the diagonal accumulation showing the visual convergence between the two breakdowns apparent. The line is sinuous because of discrepancies between c-cluster versus w-cluster size distribution. The visual rendering suggests superclusters at a larger scale. In the nano figure, the area of nanotubes as a whole is retrieved by both methods, but with two different breakdowns and more discriminative power on the citation side (after [2.113]) ►

An opposite conclusion was reached by *Zitt* et al. [2.240] on nanosciences and *Laurens* et al. [2.241] on genomics, previously delineated as a whole by a hybrid sequence method. They implemented a more direct comparison scheme on clusters respectively from bibliographic coupling and lexical coupling (natural language, titles–abstracts), using the same axial k-means method (AKM). Cross-tabulate cluster overlaps [2.242, 243] were reordered, giving a quasilandscape with a heavy and narrow diagonal load (Fig. 2.5). This gives evidence of a fairly good convergence of lexical and citation solutions, also confirmed by direct indicators.

On their high-level maps, *Klavans* and *Boyack* [2.244] and *Leydesdorff* and *Rafols* [2.245] also observe a reasonable degree of convergence. More general comparisons of mapping methods including textual are found in [2.173, 246, 247]. A recent exercise of mapping comparing cluster methods is reported by *Velden* et al. [2.248]. Most experiments, however, lack a ground truth reference, and techniques presented as gold standards are disputable.

More generally, suppose we built clusters of documents from several origins: lexical coupling, bibliographic coupling, fronts from cocitation, author coupling, etc. Those various cluster solutions may be individually mapped. They can also be simultaneously represented using normalized overlaps between w-clusters, c-clusters, a-clusters, with appropriate metrics. Profiles distance may be required to overcome the zero overlap between hard clusters of the same family, say w-clusters. Resulting matrices are still quite small and amenable to MDS display.

The fact that the agreement between citation and lexical approaches is good but not complete brings one more argument in favor of complementarity. One thing to keep in mind: because of the imperfect optimization of reordering and choice of the article rather than sentences or narrow contexts as the lexical unit, the global convergence tends to be underestimated.

Complementarity

Complementarity, rather than competition, already inspired the *citations in context* researches, initiated in cocitation studies [2.249, 250] which are a natural space to connect referencing, intellectual base, and linguistic aspects. In a step further than linguistic labeling entities in (co)citation analysis, the studies of *citation in context* range from simple context visualization in citation engines to investigations in the dynamics of science. They tend to reinvest research in action, associating language and communities' life. The linguistic and semantic analysis of citation contexts contribute to topics such as the citation types or motives [2.251], the classification and cross-analysis of the contents of the citing or the cited documents [2.252], the fine-grained relation of citation contexts and abstract terms [2.253], the exploration of new dimensions of scientific texts [2.254]. Some of these advances influence citation techniques in return. An example is the improvement of cocitation accuracy [2.255, 256].

As a result of multinetwork or polyrepresentation hypotheses, some issues typical of one representation can receive a solution from the other. Convergence at the local level also creates spaces for complementarity: synonyms of any kind, for example, tend to be retrieved in the same citation-based clusters. Citation techniques escape linguistic polysemy and the reverse is true, but *citation homonymy* often due to matching keys, is a less important risk.

Finally, textual information preserves its advantages of availability, intuitiveness, and interpretation, with easy transposition to concepts and topics. A major shortcoming is the complexity and ambiguity of natural language, resulting in poor precision in the case of unsupervised protocols. In spite of the composite unit handled (the full article rather than the narrow concept), citations are appealing for tracking intellectual influences and often less noisy, at the expense of lower recall in weak signal configurations.

The capability of pure lexical approaches to emulate citation-based or hybrid approaches in challenging topics such as the aforementioned description/anticipation of early stages of domain emergence, remains a challenge.

2.4.4 Hybridization Modes

Looking for optimal exploitation of these contrasting properties is the quest of hybrid techniques, in line with pragmatic mixes of dimensions in IR-type delineation for bibliometric purposes. The same pragmatism inspired mixed information classification of web

sources [2.257]. The detail of the more sophisticated techniques are not on the table: millions of Google users benefit from hybrid IR processes every day, but in spite of expansive literature devoted to the PageRank algorithm itself starting with [2.258] and published works on lexical/semantic processing [2.196], the detailed combination of multinetwork operations in the search engine is not documented. We will limit ourselves here to quite basic combinations, readily available in bibliometric literature.

The scope of hybridization is quite large: words and citations, on which we focus, may be taken either as variants of information tokens likely to be indistinctly treated under certain conditions, in a typical informetric posture; or seen as elements of quite different relations with their own fundamental properties and interpretation, suggesting their use in sequential or parallel protocols. Parallel exploitation, particularly, is *sociology-compatible* allowing for separate interpretations and comparison before final combination if necessary.

Full Hybrid

The structuring/clustering of fields using a common metric mixing citation and term distances at the finer grain level, from the start, is a promising path [2.259, 260]. *Boyack* and *Klavans* [2.128] on a large dataset, observed that even a *hybrid naive* coupling outperformed pure bibliographic coupling. Statistical differences between word and citation distribution can be reduced through a normalization of the similarity measures with different distributions ([2.261] with later simplification in [2.262]) achieving a full and flexible integration. *Koopman* et al. [2.263] established cluster similarities using a combination of tokens, for comparing clustering solutions based on direct vocabulary and indirect vocabulary associated with authors, journals, citation, etc.

Those developments remain within the framework of *feature methods* keeping the substance of information elements, words, and citations. In Sect. 2.3, we mentioned purely computational methods (character n-grams on text flow, compression) for calculating generalized text distances regardless of linguistic features. An option is to stay within the textual domain (full text, abstract, title...) or to enlarge to the full article including authors, affiliations, list of references, etc. We get a massive and blind form of hybridization, dissolving both terms and references into signals, ignoring all forms of normalization including zones length (text versus bibliography). Such black boxes are deprived of any semantic interpretation, but in our experience prove efficient for quick calculation of interdocument distances.

We have seen above (Sect. 2.3.2) that deep neural networks have proven in many areas of supervised learning, including information retrieval, their ability to do without prior weighting of the variables. Their unsupervised variants, building upon their success in very constrained fields like the Go game, should be able to do the same from an informal collection of data—such as *full hybrid* data—and so an application to domain delineation might be to consider the last layers of a network collecting the many traces of scientific activity: whatever citations, texts, and so on in the wake of present limited attempts of hybridization. Research in unsupervised deep learning, though, is still at a preliminary stage [2.264]. There is no doubt, however, that in the next few years progress—and controversy—are to be expected from deep learning's entry into the competition. These processes, however, remain black boxes, with quite difficult interpretations. Perhaps high-level semantic categorization resulting from the careful interpretation of the last layers might allow experts to select a subset of explicit dimensions in order to take into account the users' expectations of a delineation process. Whether this could reconcile cognitive classification and institutional expectations, an issue mentioned above, is another question.

Sequential Hybrid: Citations → Terms

Sequential protocols of delineation may rely on more iterations; we limit ourselves here to pointing out the basic sequences. We mentioned the tradition of completing citation objects by textual tagging above. The question of the validity of cocitation research fronts (Sect. 2.2.3) triggered further developments in terms of retrieval and recall rate and the means to foster it, possibly with the help of texts. *Braam* et al. [2.265] developed a systematic complementation of cocitation cluster coverage by lexical means, a first operational example of hybrid delineation. The citation → text sequence keeps being explored for other purposes, especially in global science maps. *Boyack* and *Klavans* [2.91] use textual metrics for display of cocitation cluster relations at the large scale where citation signals are weak.

Sequential Hybrid: Terms → Citations

Here, the perspective is reversed. The remote ancestor is a classical application of citation indexing, when title words or KeyWords Plus™ were used to query a citation index to harvest papers on a given (set of) topics. The rationale is simple: starting a multistep process with experts' help is easier with word queries. In a second step, the expansion is carried out on the citation network, where unsupervised or lightly supervised procedures are safer than on texts, with proper precautions.

General conditions for citation analysis are required, especially not too scarce reference lists. There is some analogy with the *boomerang effect* on citations [2.266]. An example of protocol is the Lex+Cite process explored in *Laurens* et al. [2.241], especially for emerging or transverse domains, where classical methods tend to fall short.

Quite a few options exist for expansion. If the seed is considered globally, literature with reference combinations present in the seed, but not in particular papers, is recalled. However, unspecific cites should be ruled out, which may require information from the whole database. Conversely, if only combinations at the paper level are allowed (strict bibliographic coupling), some broad-scope literature is missed; cluster-level enrichment, if a previous breakdown into clusters is available, stands in the middle. Besides the recall-oriented aim, these hybrid protocols may also enhance precision by submitting the core itself to bibliographic coupling constraints. Along the same lines, an elaborate strategy starting with lexical queries and query expansion, completed by journal selection and ending by collecting citing papers, is proposed in [2.267].

Parallel Design

As described above in Sect. 2.4.3, parallel design allows for comparison especially when metrics and clustering methods are identical, so that the final outcomes can be compared by factor analyses, parallel clustering–mapping, and reordered cross-tabulations. In parallel clustering, a similarity between clusters from different origins is defined after their degree of overlap, and then the intercluster matrix, of small size, is easily displayed using an MDS-type method. The cross-tabulation for example highlights strong relative overlaps with two strategies in addition to choosing either the c-cluster or the w-cluster on a topic: (a) precision-oriented: a heavy intersection between c-cluster and w-cluster suggests a strong form of topic, strategy possibly extended to superclusters (b) recall-oriented strategy, taking the union of c-cluster and w-cluster.

2.4.5 Conclusion

The various publication-linked networks, at least words and citations offer globally convergent views but not at the point that one can be happy with a single solution: sociology of citing, collaborating behavior and writing rhetorics keep some distance, and bibliometric protocols can choose to mix up all information tokens or to combine parallel approaches at the final stage only. Comparison and complementarity merit further endeavor. In practice, delineation cannot avoid supervision and actors' negotiation. Protocols of experts' guidance for evaluation purposes are desirable. Cross-validation of parallel processes, and even in some cases of sequential processes [2.241], may alleviate the burden of multistep external validation. There are strong indications that multinetwork methods improve recall and offer richer substance to expert/user discussions, but more benchmark studies against ground truth are needed.

2.5 Delineation Schemes and Conclusion

2.5.1 Delineation Schemes

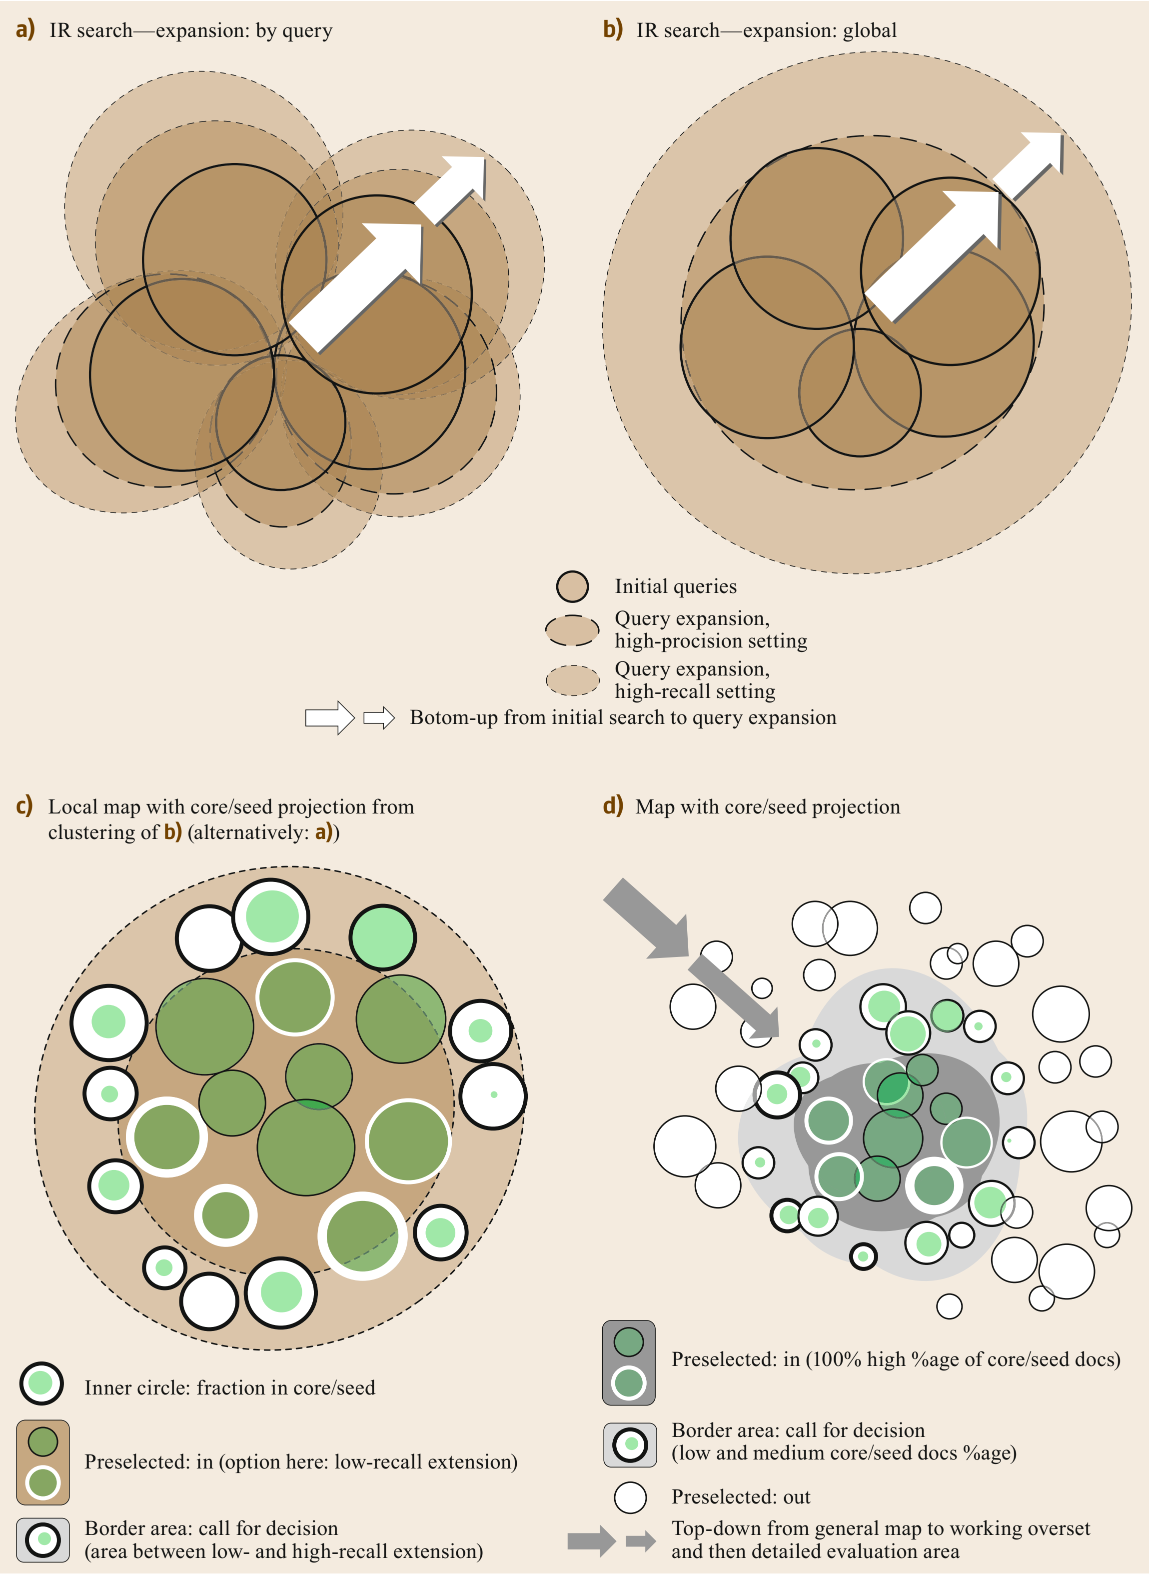
IR Search First

A scheme of a bibliometric study asking for careful delineation may be as follows:

- For memory's sake, selection of the expert/peers panel, matching the expected variety of the domain.
- Supervised IR search on specialized journals and specific vocabulary, aiming at precision, building up the core of the domain. Alternatively, use of cited cores at the article or author level. The granularity is, typically, the document level. In favorable cases, some partial query formulas are found in the literature.
- Query expansion or bibliometric expansion with citations (the latter usually requiring lighter supervision). The query expansion is conducted globally or query by query. Optionally, a round of data analysis/clustering can suggest query rephrasing or complementing (Fig. 2.6a,b).
- Evaluation of outcomes especially on the borderline. In multilevel processes, the border region typically stands between the high-precision cores/seeds (or low-recall expanded set) and the high-recall expanded set. Circles of expansion with expected relevance indexes (example in Sect. 2.4) enlighten decision-making, again optionally supported by thematic clustering/mapping.

Clustering/Mapping First

Regional overset maps are expected to contain all the target, and the decisions on border regions are typically made at the cluster level. Granularity obviously matters: we cannot expect that any high-level clustering of global or superlocal science will directly produce



a) IR search—expansion: by query
b) IR search—expansion: global
Initial queries
Query expansion, high-procision setting
Query expansion, high-recall setting
Botom-up from initial search to query expansion

Preselected: in (100% high %age of core/seed docs)
Border area: call for decision (low and medium core/seed docs %age)
Preselected: out
Top-down from general map to working overset and then detailed evaluation area

Fig. 2.6a–d IR search and mapping approaches. **(a)** IR process: bottom-up queries and expansion of individual queries. Assumed at the paper-level. **(b)** Variant of **(a)**: Expansion based on the entire set (lexical or citation-based). The border area, to be discussed, is typically determined by the region between the high-precision seed (or a low-recall expanded set) and a high-recall set. Circles of expansion in the border region, if indirect indicators or relevance are available, can drive the choice of delineation. (Optional **(c)**) Local clustering from B data (alternatively: from A data). Clusters are helpful for discussion but the border region and the decision tools may exist in A or B stages. The map is local and in the general case is not superimposable to a fraction of the global map D. A discussion on global versus local mapping is found in [2.179]. **(d)** Global mapping/clustering: top-down from global or overset map to the target; detection of border area with the help of information from projection. The example in the next panel (Fig. 2.6e) assumes no external information, it relies on clustering outcomes only to define core, periphery and outside regions ◄

a class retrieving the target domain as a whole. A lower-level breakdown yielding fine-grained delineation of the frontier will be preferred, with a number of subareas large enough to match the diversity of the domain and eventually increase precision, but small enough to make cluster-level expertise feasible. Reasonably, the granularity picked fulfils two objectives, aiding the delineation and preparing the study of the domain's subareas.

In the perspective of a cluster evaluation procedure, possibly time-consuming and costly, it is recommended that one relies on a lightly supervised preselection of the border region, located between the internal core, a priori deemed *in*, and the external zone deemed *out*. Depending on the clustering–mapping protocols chosen (see the sketch Fig. 2.6c,d), various solutions can address this preselection, for example:

- Clustering with IR search projection. For this preselection, most helpful is the simultaneous representation of a global map (or at least of an overset-map) obtained on one criterion and cluster-level properties on another criterion. The projection of local features over a large context is often used: in two-step protocols, seeds for example are projected on clusters in the expanded set [2.241] with the ratio of seed articles as the indicator for delineation. Another combination: a global map conveys a particular vision depending on the network represented and the methodological choices made, and the hits of an IR search on a lexical marker (with a generous setting for recall) alerts one to clusters of interest. In Fig. 2.2 for example, the central communities might be considered as belonging to a core, whereas distant colonies, on the borders, require evaluation. Such cases illustrate the complementarity of IR and mapping techniques for avoiding silence both on weak and strong signals, as mentioned above. An alleviated process uses the projection of specialized journal literature onto a global map [2.177]. Such processes help pinpoint clusters forming the border region as the *decision area* and/or suggest journals or groups of papers as candidates for extending a core. Clusters may also undergo a complementary stage of query expansion or bibliometric expansion, typically transforming—in a given universe—a hard partition into an overlapping structure. For the domain delineation, only the overlaps involving the border region will matter for the final outcome.
- Crossing methods. An alternative is the crossing of literature sets produced by different techniques or upon different networks. Instead of the standard core–periphery schemes, visualization may confront cognitive viewpoints, where areas of convergence (overlaps) are considered as strong forms (another form of core) and nonoverlapping parts as possible extensions to be validated. An example of crossmaps was shown in Sect. 2.4. In the limit case of Boolean formulas addressing the whole domain to delineate, this would be equivalent to running a word-based search AND/OR a citation-based search. The AND clause yields the strong form and the OR clause a possible expansion along two branches, words and citations.
  The principle can be extended in a pragmatic way, given that (a) data analysis methods are not very robust and tend to yield quite different outcomes; (b) data from different networks do not lead to identical results (polyrepresentation). Therefore the combination of methods, or the combination of networks, provides both ways to enhance precision (*strong forms* where outcomes of different reliable methods converge), and ways to enhance recall, in divergence areas, at some risk.
- Decision region and cluster evaluation (Fig. 2.6e):
  - Evaluation at the cluster level. Again, thematic clusters are understood here in a broad meaning, whatever the data analysis method used. As a rule, there is no ground truth making the evaluation of recall, precision, and F-scores or variants straightforward, so the relevance of each cluster has to be assessed by indirect indicators and/or supervision based on available cluster data. A light manual scrutiny can rely on cluster aggregate information such as label, pseudotitle recomposed from most specific

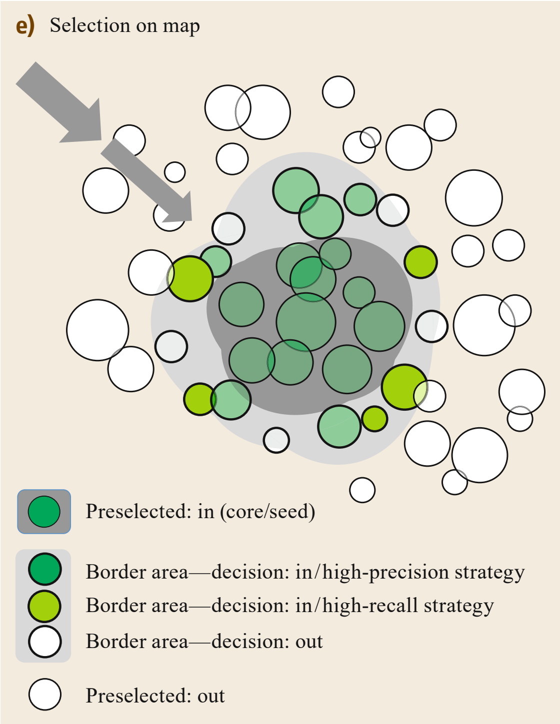

Fig. 2.6e IR search and mapping approaches. Evaluation and decision on clusters in border area. Example of direct selection of a bibliometric map on some criteria without input of other projected information

words or phrases, a ranked list of words, specific journals, cited authors/institutions, etc. Specificity of attributes is calculated by TF-IDF or other indexes. Features from a previous IR or mapping process, say ratios of expansion to core, or results from crossmaps, are particularly helpful. Map displays using pleasant interfaces make the task easier.

- Evaluation at a finer granularity level. Finer-grained information can be available from the delineation protocol: IR projections of good quality onto a map; cluster crossings from hybrid methods; combination with zones of bibliometric expansion, etc. In such cases the border region may be treated at the infracluster or the document level. In pure mapping exercises, the cluster level may simply reveal too coarse, with exceedingly large or heterogeneous groupings. In this case, one has to go deeper into cluster content, through sampling for detailed analysis or further breakdown, at a cost.

The driving of evaluation is conditioned by the mastering of methodological effects and biases, likely to yield very different outputs. A particular attention, at the domain level, should be brought to the tendency of metrics and methods to favor particular semantic dimensions: To what extent can a domain be extended towards its intellectual base, especially theoretical foundations? Towards its tools and techniques? Towards its objects and products? Decision rules, in absence of a IR standard, will be based on quantitative indicators of the process, for example the intensity of bibliometric linkages in expansion stages, and experts' advices in terms of subjective precision, recall, and their balance (tantamount to variants of F-score). The convergence of experts' preferences, with the help of self-rating, may be taken into account.

2.5.2 To Conclude

Delineation at the mesolevel deals with intermediary objects. Models in Price's tradition cast some light on the dynamics of the whole scientific system, whereas network theory proposes, at the microlevel, various mechanic models explaining emergence of mesostructures. The connection with practical solutions for topic and domain delineation, a rather multidisciplinary issue, will stimulate many research projects.

In practical studies, delineation operations should respect the proportionality principle. In simple cases, specialized and mature fields, the domain can be defined by using ready-made resources: official classifications, databases schemes. The complex cases which typically justify scientometric field studies—multidisciplinary, generic and emerging/unsettled domains—are precisely those where delineation and expertise are the more challenging. Coarse-grained approaches (journal-level) are easier to implement, but again hindered by a locally complex network and abundance of nonspecific media.

Bibliometrics both exploits and feeds science classification resources, literature searching and mapping models and human skill. Validation procedures include cross-analyses and direct supervision. The delineation tasks pull together multiple strands of bibliometrics and IR. They inherit progress in data and network analysis, as well as common limitations in data coverage, robustness issues, ergonomy challenges with respect to supervision and discussions with sponsors. Bibliometrics cannot pretend to operationalize in a standard manner all questions from decision-makers nor, in cognitive applications, all questions from sociologists of science and other scholars.

Within the scope where *bibliometric hypothesis* applies, a horizon of delineation is the comparison and combination of solutions from the networks which reflect scientific activity, essentially actors and institutions, citations and texts. Taking advantage of all available facets of data is a pragmatic choice, to which the concept of polyrepresentation has given a theoretical support. The cross-study of the three main universes associated to documents is also gaining attention in bibliometrics and sociology of research, supported by social network analysis. The theoretical profusion around models of growth and decline of communities is perhaps not settled now, but is very promising for understanding the invisible colleges in its various aspects. Will this multinetwork research track converge towards unified hypotheses? There is little doubt that progress in this matter will enlighten the delineation issue especially in emerging areas. Meanwhile, the question remains whether networks should be fully hybridized with more or less radical techniques—substantive or featureless—or various network solutions be conducted in parallel with final synthesis. In the background, the tremendous potential of deep learning on big science data is likely to reshuffle the cards in retrieval and classification methods. The prospects are unclear right now, as their lack of explainability is a serious drawback in the bibliometric delineation context.

The management of supervision is central to the feasibility of bibliometric studies and their delineation tasks. Configurations are diverse, one cannot compare simple problems requiring light supervision, with large studies on controversial areas. In the latter case, the operators of the study deal with a possibly complex managerial organization, with steering committees and expert panels mixing policy makers, stakeholders, and scientists, possibly with multiple roles. The selection of data sources and the methods of supervision, and finally the perimeter of the domain, will reflect those social stakes. The definition of fields or disciplines is particularly sensitive to academic interests, epistemic convictions and border issues, likely to create conflictual visions, sometimes between external observers and established players. The panel composition, to be efficient, should match the diversity of the domain, both in terms of thematic specialization and social stakes, with possibly some help from a few high-level generalists. In the mediation role, bibliometrics is also a social practice.

Bibliometric studies, if commissioned by administrations or institutions, enter a complex landscape of decision–help procedures where quantitative proposals are elements of discussion and decision among others. The question is vaster, however. *Gläser* et al. [2.26] underline the differences between operational definitions (say method outputs), pragmatic definitions (for clients and sponsors), and theoretical definitions (talking to science studies) of topics or domains. The notion of scientific domains is mobilized for a wide scope of purposes, labeling, information, and evaluation in scientific institutions, science administrations, IR databases of any kinds, laboratory life, scientists' self-positioning, and last but not least the reflexive work of scientometricians and social scientists on understanding the mechanisms of scientific activity.

Michel Zitt

Lereco Lab (retired)
National Institute for Agronomic Research (INRA), Dept SAE2
Nantes, France
mzitt@numericable.fr

Michel Zitt received a PhD in Management (1979) and a Doctorate in Economics (1991). He mainly published on various aspects of bibliometrics and evaluation: citation measurement and normalization, science thematic mapping, hybrid word-citation techniques, and internationalization of science. Several works stress the limitations of indicators, dependence on data coverage, scale of observation and diversity of science. He was awarded the Price Medal in 2009.

Alain Lelu

ELLIADD (retired)
Université de Franche-Comté
Besançon, France
alelu@orange.fr

Alain Lelu received a PhD in Statistics and Computer science (1993). He published on Information Science, mainly on neural models applied to textual data, clustering, factor methods and intrinsic dimensions of data tables and graphs. He also wrote prospective papers on social impacts of telecommunications and data analysis.

Martine Cadot

Knowledge and Language Management
LORIA (Laboratory in Computer Science and its Applications)
Villers-lès-Nancy, France
martine.cadot@loria.fr

Martine Cadot received a MS in Economics (1995) and a PhD in Computer Science (2006). She taught Mathematics, Statistics and Computer Science. Her present research at LORIA focuses on building statistically robust models for real data, in collaboration with scientists of various domains. She participated in international knowledge discovery challenges (3rd place at KDD Cup 2002, 1st place at DEFT 2011).

Guillaume Cabanac

Computer Science Department
University of Toulouse
Toulouse, France
guillaume.cabanac@univ-tlse3.fr

Guillaume Cabanac is an Associate Professor at the University of Toulouse, France. He received a PhD (2008) and a habilitation degree (2016) in Computer Science. His research lies at the crossroads between Information Retrieval, Digital Libraries, and Scientometrics. He co-chairs the Bibliometric-enhanced Information Retrieval (BIR) workshop series and he serves on the editorial board of *JASIST* and *Scientometrics*.

3. Knowledge Integration: Its Meaning and Measurement

Ronald Rousseau, Lin Zhang, Xiaojun Hu

Interdisciplinary research depends on research traditions and fields originating from different research teams, different countries and regions. Its essence is knowledge integration. As a dynamic and interactive process it continuously pushes the structure of science to become a complex diverse system.

In this chapter, we provide a systematic review of interdisciplinary research. Starting from a definition of interdisciplinary research, its elements, and its role for scientific progress, we particularly focus on how to identify the activity of interdisciplinary research, how to measure it and point out the limitations of existing approaches. Stating that one can measure knowledge integration implies that this notion refers to a continuum, beginning from no integration (disciplinary research) to a large degree of integration (highly interdisciplinary).

Following Stirling, Rafols and Meyer we show that knowledge integration can be measured by two main factors: a diversity factor and a network coherence factor. The diversity factor itself consists of three aspects: variety (number of categories taken into account), evenness and similarity between categories. In accordance with the Jost–Leinster–Cobbold approach we prefer a so-called true diversity measure.

As an illustration, we provide a simple example of a study on interdisciplinarity in the field of synthetic biology, using the true diversity measure derived from the Rao–Stirling measure. Finally, we include some suggestions for future research.

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_3

3.1 Interdisciplinarity

Interdisciplinary research is generally seen as a source of creativity and innovativeness [3.1]. As a consequence, measures of interdisciplinarity serve as indicators for policymakers, research managers, evaluators and sociologists of science [3.2]. In order to simplify the notation we will often abbreviate the term *interdisciplinary research* by IDR and the term *interdisciplinarity* as well as *interdisciplinary* by ID. Although present research policy often implicitly assumes that IDR can readily be identified and tracked, this is far from true.

Providing policy makers with maps and measures that capture the intensity of ID or of knowledge integration is a scientific task of high practical importance, yet fraught with difficulties, see [3.2] for a review, or also [3.3].

As an example to show how official institutes talk about ID we mention the European Research Council's (ERC) grants aiming to support so-called frontier research, which describe frontier research as research of an interdisciplinary nature which crosses boundaries between different fields of research, addresses new and emerging fields and introduces unconventional, innovative approaches [3.4, p. 6].

It is important to be able to identify interdisciplinary activity, to know where it occurs and ensure it is properly assessed. However it should be recognized that these are actually three separate goals. It seems highly unlikely that each of these goals can be reached using the exact same methodology. Should indicators be adapted to the target group, i. e., policymakers, research managers, funding bodies, evaluators or sociologists of science, or is this not feasible in practice?

Adams et al. [3.5] mention that key policy topics—they looked at mental health and climate change—are supported by research drawn from a wide range of disciplines and conclude that this observation provides evidence to counter the view that only a few key disciplines are required to solve the grand challenges of our time. It seems common sense that major problems benefit from multiple perspectives. Yet, only when the degree of ID can be determined does it become possible to find out if they lead to the real *novel* results aimed for by governments and funders. How do we link *interdisciplinary research* and *novel research*? One surely needs precise indicators—or as precise as humanly possible—to support experts from the targeted scientific/technological fields.

Our work is based in large part on [3.2, 6–9]. We focus on quantitative approaches; qualitative approaches are mentioned only in passing.

3.2 Definitions

IDR can mean different things to different people. According to the National Academies of Sciences of the USA [3.10, p. 2] interdisciplinary research is:

> A mode of research by teams or individuals that integrates information, data, techniques, tools, perspectives, concepts and/or theories from two or more disciplines or bodies of specialized knowledge to advance fundamental understanding or to solve problems whose solutions are beyond the scope of a single discipline or area of research practice.

In this definition the key concept is knowledge integration. Knowledge integration may be realized by integrating knowledge originating from different disciplines (interdisciplinarity in the pure sense), but it may also happen that knowledge originating from different research traditions, different regions, from different ages or from different schools of thought is brought together. The more an article, or any other item under investigation, integrates different sources, the more it is interdisciplinary. Keeping these different integrative processes in mind we will, from now on, nevertheless focus on interdisciplinarity in the pure sense. Although some researchers make a distinction between the terms interdisciplinary, multidisciplinary, transdisciplinary and cross-disciplinary research [3.11] in empirical studies one finds a continuum which makes it difficult to distinguish among these modes [3.8]. Hence, we will use the term interdisciplinary as a general term, comprising the terms transdisciplinary and cross-disciplinary. We do see *multidisciplinary* as a separate term, referring in particular to journals which publish articles on different topics such as *Nature* and *Science*, which are typical multidisciplinary journals.

IDR is a phenomenon that emerges within and because of the dynamics of a larger knowledge system that includes external drivers, such as the need to solve complex problems and dependence on funding priorities [3.2, 12]. *Molas-Gallart* et al. [3.13] point out that there is a variety of IDR and that various processes through which research is defined, funded, conducted and applied have an effect on the extent and type of impact, social or otherwise, resulting from IDR. They state that IDR is often associated with problem-oriented research, as societal problems seldom conform to disciplinary boundaries, and with interactions that go beyond academia. Yet they admit that, on the one hand, there exist forms of IDR that do not address societal issues and do not interact with potential non-academic beneficiaries, as e. g., in biophysics. On the other hand they state that impact processes through which IDR can yield socio-economic benefits need not be unique to IDR.

It is obvious that one cannot use the term IDR if one does not first define the term discipline. Hence the term discipline logically precedes the term ID [3.14]. In this contribution we will use the term discipline as a synonym for research specialty, field or knowledge domain. Disciplinary structure can be captured using statistical tools, e. g., by applying a cluster algorithm, as in [3.15–17]; as a philosophical result (as the categories used in the universal decimal classification (UDC) or in the Dewey classification) or a practice-based categorization, supported by statistics, such as the subject categories of the *Journal Citation Reports* (JCR) [3.18, 19]. Once a categorization, with possibly arbitrary delimitations between disciplines, has been applied this might result in rigid boundaries which tend to hinder accurate descriptions of the dynamics of science. This inevitable tension between the use of rigid boundaries and the description of the dynamics of science is particularly acute in emergent fields [3.8]. This is one of the reasons why *Rafols* and *Meyer*, the authors of [3.8], try out a second, complementary network perspective that does not rely on pre-existing classifications. In this context using existing categories is referred to as a top-down approach, while starting from the data, leading to a network approach, is referred to as the bottom-up approach.

We further note that it was already included in the National Academies of Sciences' definition that knowledge integration can be realized by a single person. *Porter* et al. [3.20] define IDR as requiring an integration of concepts, techniques and/or data from different fields of established research, but do not presume the formation of teams. Knowledge integration is the focal point. Hence collaboration issues are of secondary importance in IDR studies. Yet, in the majority of practical cases IDR implies the collaboration of different persons, even of different teams. *Rafols* and *Meyer* [3.8] provide the example of a biophysics and a biochemistry lab collaborating in the field of bionanoscience. For this reason we will further assume that IDR implies a research team or the collaboration of two or more research teams. Moreover, we already mention that in our opinion collaboration is a strong form of knowledge integration and, most of the time, also of knowledge diffusion (in case one or more members of the team teach or explain to others what they know to advance the joint work) (Sect. 3.11).

IDR can be studied on the level of inputs, processes, outputs, and outcomes (Sect. 3.4). Yet in [3.21] the authors note that most observers do not specify which aspects or components they focus on. Besides on inputs, processes, outputs, and outcomes one may also focus on people, objectives, activities, and impacts.

Clearly, it is not possible to define a unique and absolute measure of IDR. For this reason several proxy indicators have been created. Each proxy indicator delivers different insights about the interdisciplinary nature of the research under study. *Adams* et al. [3.21] note that the same project may be indexed as interdisciplinary for one parameter (e. g., departmental affiliations or universities) and not for another (diversity of references). Hence, it is not surprising that different indicators may deliver inconsistent and even contradictory results. Considering diversity, of whatever type (see further), as a proxy of ID it is, however, always true that smaller diversity points to more specialized research, while larger diversity points to more integrative research.

For this reason *Adams* et al. [3.21] point out that it is essential to consider a framework for analysis, drawing on multiple indicators, rather than expecting any simplistic (their words) index to produce an informative outcome on its own. The main objective of [3.21] was to compare the consistency of indicators for ID and, if possible, identify a preferred methodology. Their study revealed that choice of data, methodology and indicators (their precise mathematical formulas) can produce seriously inconsistent results despite being applied to a common set of disciplines or countries. Their results highlight issues about the link (and how to clarify it) between any quantitative proxy indicator and the assumed target of the research about IDR. *Adams* et al. [3.21] even seem to imply that IDR almost always implies a policy target. Yet, we do not agree with this assumption which, in our opinion, seems to go too far.

We also note that when studying ID, cognitive differences among scientists working together may play an important practical role. For this reason we include in this chapter a section on measuring cognitive distance (Sect. 3.15).

Rafols and *Meyer* [3.8] use a concept of integration that reflects two aspects of knowledge systems:

(a) Diversity, itself consisting of three aspects, namely species diversity, evenness and disparity (explained and discussed further on)
(b) Coherence or the extent to which specific topics, concepts, tools and data used in a research process are related [3.2, 14].

For practical reasons disciplines are often operationalized as Web of Science (WoS) subject categories. Yet, it is well known that the delineation of WoS categories is far from ideal [3.22]. These categories are, moreover, overlapping, which is generally considered to be a disadvantage. This is one of the reasons why there is no all-preferred choice to represent disciplines, and other classifications besides the WoS subject categories are used. The classification scheme of the essential science indicators (ESI) contains 22 non-overlapping broad fields and was, for that reason, used in [3.23]. *Bromham* et al. [3.24] used field of research codes (FoR) as jointly developed by the Australian Bureau of Statistics and Statistics New Zealand in 2008. *Zhang* et al. [3.25] use Leuven-Budapest (ECOOM) classes [3.18] on two levels, namely that of its 16 major subject fields and that of its 68 subfields. One may also use categories which are not related to bibliometrics, such as medical subject headings (MeSH) categories [3.26, 27], the mathematics subject classification (MSC) [3.28, 29], the physics and astronomy classification scheme (PACS) [3.30, 31] or the international patent classification (IPC classes) [3.32, 33]. *Rafols* [3.9] points out that using practice-oriented categories might be especially helpful when analyzing the social impact of research, or the influence of one subfield on another [3.31]. He notes, however, that MeSH maps could not be matched with global maps of science, indicating that the underlying cognitive structure and metrics are different. With *Adams* et al. [3.34] we note that the degree of ID depends on how finely or coarsely categories are defined. The narrower the boundaries of disciplines are defined, the more likely it becomes that a piece of literature crosses borders between disciplines.

3.3 Drivers and Arguments in Favor of Interdisciplinary Research

Molas-Gallart et al. [3.13] distinguish four main aspects in which differences in IDR emerge:

(a) The primary objectives driving the research; here the authors make a distinction between challenge driven or societal challenges, and scientific/academic driven
(b) Cognitive distance between the bodies of knowledge bridged, or designed to bridge, through IDR
(c) The extent of integration among these bodies of knowledge (pre-existing or brought about by IDR)
(d) Practices by which researchers conduct IDR.

Interdisciplinary research teams consisting of several collaborating colleagues may lead to a combination of diverse perspectives, interpretations and models, and hence avoid ignorance (about certain aspects of the topic of research or about necessary technical skills) and lock-ins (doing what *everyone has always done*). In many cases specific scientific or technical skills must be combined with knowledge on human behaviour as, for instance, otherwise epidemics may never be conquered or new products may not reach those who might benefit. According to *Yegros-Yegros* et al. [3.35] the rationale for IDR is particularly strong and convincing in scientific programs addressing grand societal issues or challenges such as climate change, epidemics (AIDS, Ebola, Zika, SARS), and the preservation of ecological diversity. According to this line of thinking, project leaders with a mind-set belonging to *Stokes'* quadrant [3.36] in which Pasteur is placed, namely the quadrant combining fundamental understanding and practical use, are said to be the natural leaders of successful interdisciplinary work.

When it comes to practice an important question is about the kind of learning that is important in ID teams and the kind of information and knowledge exchange that occurs. Stated otherwise: *What kinds of exchanges form the basis of collaboration in ID groups?*. This has been studied in [3.37]. In this article Haythornthwaite asked members of teams what they thought the others learned from them. In this way she found that learning was not just about factual knowledge, but included learning about processes and methods, engaging jointly in research, learning about technology, generating new ideas, socialization into the profession, accessing a network of contacts, and administrative work. Obviously, more than just domain knowledge is shared in IDR. Distributions of these relations showed that there is more sharing of similar than of different kinds of knowledge, suggesting that knowledge may flow across disciplinary boundaries following lines of practice. Simply receiving information or observing materials without engaging with them is not sufficient for learning. It is the interaction with others that makes knowledge exchange particularly useful. In this, there may or may not be reciprocity.

It is also well-known that IDR entails costs [3.38]. In this contribution we will not go into details about these costs, but just mention that there are different kinds: those associated with team building and the coordination costs associated with it, and those associated with the lack of appreciation of IDR, in the sense that academic structures are still largely based on monodisciplinary structures. For this reason scientists performing IDR often encounter problems in getting tenure or other academic rewards. Besides lack of institutional appreciation we also mention a general bias in evaluation as evaluation standards are often disciplinary based [3.39, 40]. *Bromham* et al. [3.24] found that whatever the general perception, IDR was less funded than non-ID research. Recently *Leahey* et al. [3.41] found another *penalty* for doing IDR, namely lower productivity, yet combined with increased citations (more detailed information on a possible increase in citations is provided in Sect. 3.14). They conclude that IDR is a high-risk, high-reward endeavor.

3.4 Different Aspects of Interdisciplinary Work

The aspects reviewed in this section refer mainly to inputs, processes, outputs and outcomes of interdisciplinary work.

3.4.1 Inputs

Inputs for IDR projects, whether or not they start as such or become ID during their development, include antecedents (what exists before the project starts), such as teams, team building capacities of the project leader and other personal factors of researchers within a research group. The physical environment, as well as bureaucratic and structural issues such as existing policy documents can also be considered as inputs to IDR [3.42]. In the initial stage of an IDR project team building and team expansion are important parts which can be described in a qualitative way.

When IDR is about providing practical solutions for concrete problems of a local community, i. e., a local community is the final targeted beneficiary, then representatives of this community should be included from the start [3.43], and as such should be considered as part of the input.

When planning/starting an ID project several aspects must be taken into account, among which required skills and needed equipment are two essential ones. Hiring new researchers and technicians with specific skills may be necessary, as is reaching out to another team to join forces (for skills and/or equipment). Yet, many projects not initially conceived as such evolve to become IDR when it is realized that more insight into the research question is required.

3.4.2 The Process Itself

Knowledge integration is a process. Like any other process it has inputs, outputs and outcomes. Yet, here we consider the integration activity itself. This activity can be described when it happens or can be reconstructed afterward. Both forms are qualitative and often participative. *Sanz-Menéndez* et al. [3.44] used a survey technique to reach what they refer to as a comprehensive insight in the degree of interdisciplinarity in three research areas:

- Pharmacology and pharmacy
- Cardiovascular systems
- Materials science.

Their survey included questions related to socioprofessional features of individual researchers, the cognitive context of references, team features and external collaboration. They concluded that during IDR the aspects of specialization, fragmentation and hybridization all come together.

Smith [3.45] wrote that citations can be seen as historic remains left by interactions of different ideas related to the object of study. For this reason we claim that article references are remnant signs of the process of knowledge integration as it has happened during investigations. Hence, studying ID can be done through a study of article references.

3.4.3 Outputs

There is no special output format which is typical for IDR; articles in journals and edited books, monographs, and patents can all be used. Yet, an edited book or a special issue of a journal could be mentioned here, when contributions are written and edited as the result of an ID project. This observation holds in particular if editors have, more than usual, taken care that the contents of chapters are highly integrated and each chapter presents unique aspects of integrative work.

Several outcomes are highly desired and typical, be it not unique, for IDR. These are discussed next.

3.4.4 Outcomes

The outcomes we describe can be reached through single-authored work, a mono-disciplinary team in one department or through multidisciplinary work. Yet, we mention them here as they are often described (when evaluating IDR) or are aimed for in IDR. These outcomes may have a direct or an indirect impact on academia and/or society:

- Dissemination of project results reaching the intended audience(s).
- Advising policy makers.
- Citations in the general literature, especially when these occur in a variety of disciplines (knowledge diffusion, Sect. 3.11). New knowledge injected into other fields is one possible outcome of IDR. This aspect can be studied using diffusion indicators. In medical studies the desired outcome is often an increase in public health. An intermediary outcome could be the influence on medical advisory committees and in medical guidelines [3.46].
- Setting up websites as information tools.
- Dedicated meetings with stakeholders.
- The ability to work across the academic/non-academic boundary can be seen as a capacity-building impact.
- Successful translational research in which findings from basic science really enhance human health and well-being through life saving point-of-care patient applications; or the reverse direction in which clinical findings lead to new basic insights.
- Innovative ideas resulting from ID reflections, see Sect. 3.16.
- Being able and prepared to respond to support excellence and respond to new opportunities. According to [3.47] this ability comes from:
  - Diversity in research fields: A broad range of disciplines supports exceptional levels of research excellence.
  - Diversity in support which gives flexibility of research support to allow a mix of long and short terms responses and includes strategic and responsive awards. Diverse funding mechanisms are required to enable curiosity-driven research and evolving targeted programs of high policy priority or scientific need.
  - Diversity of research organizations, where mission-led units complement large and small universities with regional as well as international engagement. *Robert May* [3.48] showed that research economies with a strong university research base performed consistently better than those committed to narrow, mission-led research institutes.
- Supporting emerging new fields (such as synthetic biology, translational medicine).

3.5 Quantitative Measures: Introduction

In this section we begin our discussion on how to measure the degree of interdisciplinarity. Stating that one can measure the degree of ID implies that this notion refers to a continuum, beginning from no disciplinary research to a high degree of ID. Before going into details, we mention here that in this section we will not cover the evaluation of IDR. As we consider this a totally different issue, we will discuss the evaluation of IDR in another section (Sect. 3.13).

Which databases are best used in IDR? The WoS and its sub-databases Science Citation Index (SCI), Social Sciences Citation Index (SSCI) and Arts & Humanities Citation Index (A&HCI) are often employed. Yet, this use can be considered as an historical path dependency, in the sense that colleagues tend to collect data from the same databases as their predecessors. If IDR involves a large-scale study then databases that provide support for bulk download or include metadata that support IDR analysis are preferred [3.2]. We note, though, that not all studies of IDR are large-scale studies; for instance *Rafols* and *Meyer* [3.8] performed a detailed study of some case studies in one particular field (bionanoscience).

Wagner et al. [3.2] make another distinction, namely between approaches that account for the larger system and those that do not. Those that do, do so by viewing the science system as a whole. They use statistical relationships among key aspects of relevant or desired data to measure desired characteristics of aggregation of authors, articles or journals.

3.5.1 Top-Down (Classification-Based) and Bottom-Up Approaches

Most current bibliometric-based measures of IDR input and processes rely on the journal categories established by the Institute for Scientific Information (ISI). However, the use of journal categories for measuring IDR has some obvious limitations because of the dependence upon a predefined taxonomy or category structure. Classification-based measures can be useful as a first start, especially when used to compare large areas of science with large amounts of data (an application of big data analytics). Nevertheless, issues around the use of underlying taxonomies or classification schemes as the basis for IDR measures makes this approach problematic. With no consensus on the best categorization and considerable evidence that various measures of IDR yield quite different results depending on the classification system chosen for analysis, it is apparent that problems remain for any IDR measure based on a predefined classification scheme [3.2]. To these objections we like to add that ID should be studied on the article level: journals are, in general, not an appropriate unit.

Bottom-up approaches based on network clusters formed by articles, using co-citation, co-word or bibliographic coupling analysis, can capture knowledge integration in the making evidenced by people working on new problems [3.2]. We note that this statement implies a time aspect, see further Sect. 3.17. We also note that the statement about "knowledge integration in the making" is certainly not true for co-citation analysis, as it takes too much time to gather enough citations to lead to a meaningful timely analysis.

Cassi et al. [3.49] calculate the degree of interdisciplinarity of an institution. As such they need to combine ID values of individual articles published by members of the institute with the ID value of the institute as a whole. Is the ID of an institute the average of the ID of its articles, or should ID be measured directly from the set of all articles published by the institute? To answer this question they applied a decomposition of the Rao–Stirling measure (this measure is explained further on). This means that the diversity of a research institute is the sum of the diversities within each article it published, plus the diversity between articles. This decomposition is performed in terms of inertia of sets of points. These authors further provide an interpretation of their results by comparing with a benchmark, namely the value of their index calculated for the world production in the same field and the same period of time. They then perform a statistical test to decide whether a difference is significant or not.

Wagner et al. [3.2] make a distinction between two approaches: The structural approach and the spatial approach. In the next section we first consider the structural approach, leaving the spatial approach to Sect. 3.7.

3.6 Structural Approach

According to [3.2] the structural approach is better at capturing emerging developments that do not fit into existing categories, while the classification-based approach might be useful at large-scale explorations such as the disciplinary breadth of universities. In a time where many universities strive to be *of world class*, studying the disciplinary breadth, combined with ID aspects, is an interesting idea that should be elaborated further.

As *Zitt* [3.50] points out, the literature does not converge on a universally accepted methodology or basis from which to uncover the structure of science, let alone how that structure may reveal IDR. Structural diversity is the diversity of disciplines, institutions and support mechanisms. It is a property of a research base that has the capacity to address the challenges of tomorrow, and to do this in a flexible and responsive way [3.47]. It is distinct from social diversity, i. e., diversity in gender, nationality, and ethnicity.

Most ID studies apply citation analysis. Yet, methods of text analysis and hybrid methods are other options [3.51]. *Rafols* and *Meyer* [3.8] note that the percentage of references outside the discipline of the citing paper is a simple and often used indicator of IDR. This method was used e. g., in [3.52, 53]. This is also the method suggested by *Garfield* et al. [3.54]. When studying the ID of a set of documents, such as the publication output of an institute or research group, one may focus on the publications themselves and their distribution over categories, or one may examine article references or one can take into account the categories of articles citing the articles under study [3.49]. We think, however, that considering citing articles is an aspect of diffusion and not of knowledge integration.

Citation analysis privileges publications as the major outcome of IDR. This is the most important limitation of this approach. This leads to the question [3.2]: in relying on quantitative, publication based measures, what information about IDR impact is lost?

Any measure that includes citations/references has to deal with the problem of *why does one cite?*, including preferences for certain journals and/or languages. Citation analysis is, moreover, complicated by the fact that disciplines are not sharply defined and are vastly different in size. For this reason relative measures, applying normalization, are needed. But when applying normalization the properties of various normalization techniques must be understood, explained and taken into account, which is not a sinecure. Studying disjoint units makes measures clear and precise. Although this is a clear advantage it is a fact that IDR is about overlap between fields; hence overlapping study units, and not disjoint ones, seem unavoidable when studying IDR.

Zitt [3.50] offers a cross-scale perspective to address the aggregation problem in order to make indicators more comparable across fields, while [3.55] presents a macro-approach to IDR at the article level to test the impact of the level of aggregation (measured by the number of citations to a unit of output). The authors of [3.25], too, include a comparison with respect to levels of aggregation.

Analysis of IDR at the journal (citation) level is performed by placing journals into disciplinary categories and then viewing the extent to which they have relationships with journals outside that disciplinary category. In this context [3.56] and [3.57] make a clear distinction between the cited and the citing side: measuring IDR at the journal level as either an input (from the cited side, measuring its contribution to or impact on other journals/disciplines) or an output (from the citing side, measuring its uptake or use of information from other journals/disciples). The set of relationships between journals can be represented in tables or in an abstract space based on vector analysis, showing similarities or linkages and differences or variations. This process brings our discussion to the point of considering a metaphorical knowledge space in which to conduct IDR analysis, see Sect. 3.7.

If one knew the field/discipline of each author, then co-authorship could be used to describe IDR. In this approach, as mentioned in [3.58], the problem of interdisciplinary recognition shifts from the semantic analysis of an article or the scientific classification of cited (or citing, in the case of diffusion) papers to the identification of its authors' specialization. A practical way of determining an author's field is through their departmental or institutional affiliation. Yet, departments or institutes are organizational units, not disciplinary ones. Another obvious problem is the case of interdisciplinary institutes not focusing on one particular field. *Abramo* et al. [3.58] had the exceptional advantage that in Italy each academic scientist classifies him/herself in one and only one scientific field, 370 in all. These fields are grouped into 14 disciplinary areas. Also [3.12] used the distribution of researchers over a set of subdisciplines. Clearly, as long as scientists regularly update their field (if necessary) this looks like an ideal situation for studying IDR.

3.7 IDR in the Research Landscape

A second approach to using bibliometrics is a methodology that describes a landscape or space within which science operates [3.59]. *Wagner* et al. [3.2] note that spatial distance as a measure to analyze and visualize IDR was already suggested in [3.54]. The practical usefulness of this approach has been enhanced by recent developments in computing and algorithms that can be used to standardize the analysis and to bring into view the underlying dynamics of the relationships among and across disciplines. Programs such as Pajek [3.60] and VOSviewer [3.61, 62] have important applications in ID studies. Visualization in overlay maps is a way of providing a description of diversity and coherence without the need to collapse the data into a single figure [3.9].

A classical method is to use factor analysis in which each factor can be labeled as a category or discipline. Then the elements of the matrix that load multiple factors above some preset threshold are considered the most interdisciplinary [3.63, 64]. Factor analysis is an example of an approach that defines an emergent structure from data based on a set of distances, rather than a pre-imposed structure.

3.8 Concrete Measurements

In this section we come to mathematical formulas to measure ID. We will focus on the measurement of diversity, through its three components:

1. Variety
2. Balance
3. Disparity.

Wagner et al. [3.2] discuss concrete measurements but do not provide precise mathematical formulas, hence cannot explain why some indicators are, for logical reasons, better than others. With *Jost* [3.65] we stress that one must not confound a concept (here interdisciplinarity and diversity) with an index that measures it.

Morillo et al. [3.66, 67] attempt to establish a tentative typology of disciplines according to their degree of interdisciplinarity measured through multi-assignation of journals to WoS subject categories by which the assignment of a journal to more than one category indicates the existence of cognitive links between disciplines, which can result in interdisciplinary research. Note that the word *can* is of importance here, since such links may also be the result of the multidisciplinarity of these journals.

Several papers suggest combining similarity and distance measures to build an indicator. In a seminal paper *Porter* et al. [3.20] developed measures of integration and specialization of research outputs to understand where IDR is situated within the system of science. Their integration indicator measures cognitive distance among the subject categories in which a body of research is published. Somewhat similarly, [3.68] suggests a diversity index as a way to incorporate multiple measures of IDR. Their index measures how particular research articles integrate research fields, based on the assignation of the journals they cite to WoS subject categories. The line of thought that began in [3.20] was taken up again in [3.8], which we will discuss in more detail. Measures using similarity and variation are also used to compute network properties such as betweenness centrality, an application of which was proposed in [3.56].

After having reviewed a wide range of documents on diversity measurement *Stirling* [3.69] concluded that diversity consists of three basic concepts: variety, balance and disparity, each of them being a necessary but insufficient property of diversity as a whole. Species in ecology, WoS categories in informetrics or forms of energy (another example considered by *Stirling* [3.69]) are not independent entities, but they are shaped by patterns of common development or ancestry leading to proximities (or the opposite: disparities) between units. The key of an acceptable integration score is that it captures not only the number of disciplines cited by a paper and their degree of concentration but also provides a measure of how disparate these disciplines are. In order to do so, it relies on a specific metric of distances or similarities between pairs of disciplines. *Stirling* [3.69] concludes that the Rao–Stirling measure, which can be interpreted as a distance-weighted Simpson diversity, is such an acceptable measure. It is defined as

$$D = \sum_{\substack{i,j \\ i \neq j}} (d_{ij})^{\alpha} (p_i p_j)^{\beta} \; . \tag{3.1}$$

Here d_{ij} denotes the dissimilarity (disparity) between category i and category j, and p_i and p_j denote the proportions of the total number of items under study in category i and category j, respectively; finally α and β are parameters that adjust the importance given to distances among categories (α) and proportions (β).

Next we provide a short overview of elements taken into account in IDR studies.

Here, the systems or units of analysis can be university departments, an emergent topic represented by a set of articles (hence from different departments all over the world), researchers, research teams or a funded project.

Elements can include articles, monographs, dissertations, projects or funding proposals.

Elements must be classified into categories. The most straightforward way of assigning bibliographic elements, such as articles or references to categories, is to rely on the categories provided by databases providers. The most widely used classification is Clarivate Analytics' (formerly ISI and later Thomson Reuters) Web of Science categories which is journal-based (not article-based) and very problematic, as articles published in the same journal do not necessarily share a similar topic or research perspective [3.9]. An alternative is to use a bottom-up approach in which investigators themselves carry out a clustering of articles based on citation patterns. This may lead to disjoint categories corresponding with research practices. A probably better approach is to cluster articles based on keywords. In this way it becomes possible to obtain clusters which include emergent topics and fields. Yet, it is obvious that such clusters change in a dynamic way (they are born, die, divide) [3.70] and hence such investigations may be difficult to replicate, especially if underlying data may not be made public.

Providing an estimate of the cognitive distance, the d_{ij}-values in the disparity component, between categories is challenging. Global maps of science as developed in [3.19, 22, 26, 57, 71–76] may be useful here. Yet, as suggested in [3.77] we think that a direct measurement is better than an indirect measurement via these maps of science. In our opinion, such maps should be used only as visual illustrations.

A table showing examples of different choices of systems, elements, categories and metrics to measure diversity is provided in [3.9].

3.9 Entropy is not the Same as Diversity or Interdisciplinarity

As the notion of entropy is often used in the context of IDR [3.12] and of measuring diversity we take some time to explain this concept and its difference with the notion of diversity. Entropy is a mathematical concept drawn from statistical thermodynamics (Clausius being the originator), statistical mechanics (Boltzmann) and information theory (Shannon). It is a measure of disorder or uncertainty in a system, in this case the system of science. The entropy measure is a particular case of a measure used in practice to describe diversity [3.8, 69, 78].

Jost [3.65], however, makes a strong point showing that entropy and diversity are different notions which should not be confounded. We repeat his arguments but instead of a biological context we embed them in an ID context. Concretely, we want to measure ID by considering references and the spread of references over disciplines. Consider an article with A references originating from E equally cited disciplines. Hence each discipline is used A/E times. It is then reasonable to say that this article has an interdisciplinarity of E disciplines. If now these A references originate from $2E$ equally cited disciplines, then this article has an interdisciplinarity of $2E$. If all cited disciplines are equally common then ID is proportional to the number of cited disciplines. It is, moreover, natural to set the proportionality constant equal to one. Considering now the entropy measure

$$H = -\sum_{j=1}^{N} p_j \log_b(p_j) \;, \tag{3.2}$$

where p_j denotes the fraction of items assigned to category or cell j. If $N = E = 4$ and taking $b = 2$ yields

$$-\sum_{j=1}^{4} \frac{1}{4} \log_2\left(\frac{1}{4}\right) = 2 \;, \tag{3.3}$$

for the first case and

$$-\sum_{j=1}^{8} \frac{1}{8} \log_2\left(\frac{1}{8}\right) = 3 \;, \tag{3.4}$$

in the second case. Hence, one would conclude that ID has not doubled. The reason is that entropy is related to the uncertainty of finding a discipline in the sample, not to the number of disciplines. Similar counterexamples can be obtained for other indicators such as the Gini index. Each ID index creates equivalence classes in the set of all study objects, here reference lists. All reference lists leading to the same value of the indicator are considered to be equivalent. In each equivalence class there is exactly one case where all disciplines are equally common (admitting any real number as the number of disciplines). Hence, finding the ID of a reference list, starting from any ID measure reduces to the problem of finding an equivalent reference list composed of equally common disciplines. Recall that if there are E equally common disciplines, then each occurs with a relative frequency of $1/E$.

Given an article with differently cited disciplines with proportions $(p_j)_j$, its entropy value H_0 is

$$-\sum_{j=1}^{S} p_j \ln(p_j) \;. \tag{3.5}$$

The problem is now to find the number E (the number of equally common disciplines) for which the entropy value, denoted as $H(E)$ is equal to H_0. Now

$$H(E) = -\sum_{j=1}^{E} \frac{1}{E} \ln\left(\frac{1}{E}\right) = \ln(E) \;. \tag{3.6}$$

Hence

$$\ln(E) = H_0 \text{ or } E = \mathrm{e}^{-\sum_{j=1}^{S} p_j \ln(p_j)} \;. \tag{3.7}$$

This E is the so-called true interdisciplinarity for the article with different cited disciplines with proportions $(p_j)_j$. It is now clear that there is a considerable advantage in using ID measures which coincide with their true interdisciplinarity. Indeed, only then one may rightly say that a value $2y$ refers to a double ID as the value y.

We conclude that there is nothing wrong with the idea of using entropy for diversity measurement, but instead of the classical Shannon entropy measure, one should use its true ID analogue.

3.10 The Rafols–Meyer Framework

The main purpose of the article written by *Rafols* and *Meyer* [3.8] was to investigate if, indeed, more ID leads to better research. In order to answer this question two other questions must be answered. The first is to define scientific performance, i. e., excellence in scientific research, while the second is to define interdisciplinarity, more precisely the intensity of IDR, as this is not a yes-no question. *Rafols* and *Meyer* [3.8] do not study the first question but propose a methodology to answer the second one. After mentioning that the key concept is knowledge integration, they come to the conclusion that two aspects must be investigated: diversity and coherence. In this context the term diversity relates to high cognitive heterogeneity, while coherence relates to a process in which previously different and disconnected bodies of research become related. Coherence emphasizes how different bodies of research are consistently articulated and form a meaningful constellation [3.8]. Diversity in this context is disciplinary diversity while coherence is a network property. Following [3.69] the notion of diversity consists of three aspects:

- Variety: The number of distinctive categories, here disciplines
- Balance or evenness in the distribution of categories
- Disparity (or its opposite: Similarity): The degree to which categories are different/similar.

All these notions must be operationalized and a concrete measure must be chosen. In a first step Rafols and Meyer choose the unit of investigation, namely separate articles. This means that they want to investigate to what extent (recall that they study the intensity of IDR) an article can be said to be ID. The next choice is to consider the references of this article. This means that, as stated above, they consider these references as the remnants of the knowledge integration process that has taken place during the research reported in the article.

Diversity and coherence are related to the stage of a research field. They can be combined, leading to four possible combinations [3.8], see Fig. 3.1:

- Low diversity and high coherence: All the references are from the same discipline and are highly related. This is the case of specialized disciplinary research.
- Low diversity and low coherence: The investigated article studies distant research specialties within the same discipline.
- High diversity and high coherence: References come from many disciplines, but are similar. This suggests that the article is the result of a completed interdisciplinary effort. Although it is highly interdisciplinary there is no new knowledge integration.
- High diversity and low coherence: References originating from many disciplines that were hitherto unrelated. This is from our point of view the most interesting case, as it indicates potential new knowledge integration.

Knowledge integration increases if diversity and coherence increase, or at least one of the two increases and the other stays invariant. Now further steps in the operationalization process must be taken. As disciplines, Rafols and Meyer use WoS subject categories (SCs) of

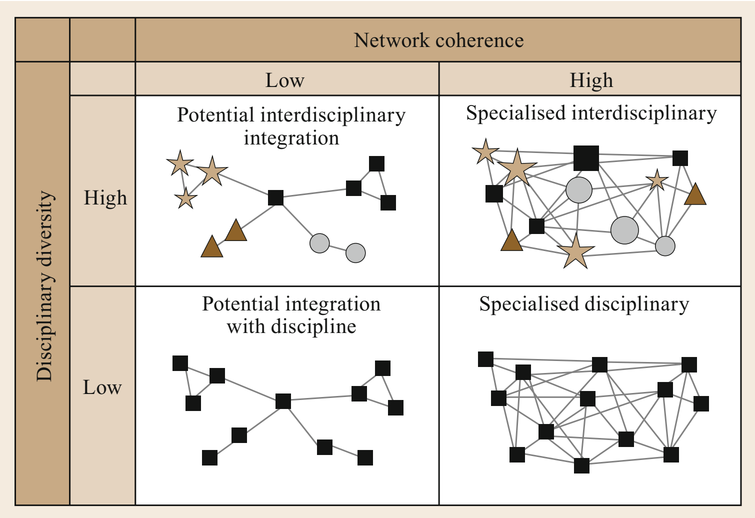

Fig. 3.1 Symbolic relation between diversity and coherence (after [3.8])

the references of references, but they note that if the initial set is large enough diversity can be computed directly from the SCs of the references. Coherence is operationalized through the bibliographic coupling network of the references. This allows the network relationship to reveal the structural consistency, or lack thereof, of the reference network. These choices imply a top-down approach for diversity as the items are classified according to a given categorization, and a bottom-up approach for coherence as the network is constructed from the data.

The final step is the choice of indicators. Rafols and Meyer calculate variety, the Shannon entropy, the Simpson and the Rao–Stirling measure as diversity measures. They decide on the Rao–Stirling measure as their final choice, as this measure takes disparity into account. We recall that the general Rao–Stirling measure is defined as shown in (3.1). In case one lacks empirical reasons to adjust α and β, they are often taken equal to one, which is also done by *Rafols* and *Meyer* [3.8]. Moreover, if two categories are identical or near-identical (distance zero or almost zero) then the sum of their separate contributions to the final diversity value is (almost) the same as the contribution of the single category consisting of the union of the two. This is a good property as it protects, at least partially, against misclassification.

Coherence is calculated as mean linkage strength, i. e., the mean degree centrality normalized by network size, and mean path length, i. e., the mean of the closeness centrality after dichotomizing similarities. These two measures turn out to be highly correlated. The authors decide on mean linkage strength as their final choice. This leads to two indicator values for each article under study. Values for each article are shown on a two-dimensional map, illustrating the uniqueness of each result. Yet, values of diversity as measured through the Rao–Stirling measure are rather similar in their case studies.

The framework used by *Rafols* and *Meyer* [3.8] separately analyzes the two key concepts necessary for the definition of knowledge integration. Diversity, on the one hand, describes the existing differences in the bodies of knowledge that are integrated, and coherence, on the other hand, describes the intensity of the relations between these bodies of knowledge [3.9]. *Rafols* and *Meyer* [3.8] suggest that the combination of these two approaches may be useful for comparative studies of emergent scientific and technological fields where new and controversial categorizations are accompanied by equally contested claims of novelty and interdisciplinarity [3.79]. In [3.9] the author proposes to subdivide the notion of coherence into three aspects: density, intensity and disparity. We are, however, not convinced about the added value or even feasibility of this approach and will not include this aspect in our investigations. We leave an in-depth investigation of this problem for others.

The Rafols–Meyer approach can be extended to patents, using global maps of technology and related measures of diversity. Moreover, the framework can also be applied to the integration of organizations, cities or countries [3.80]. Besides applying this framework to cognitive distance, one may try to apply it to the other four proximities discussed by *Boschma* [3.6] (see Sect. 3.15 for details). Extending this framework to other dimensions, it would be possible to investigate how knowledge integration is mediated by geographical, organizational, institutional and social networks [3.81].

3.11 Knowledge Diffusion as the Mirror Image of Knowledge Integration

We already mentioned that new knowledge injected into other fields is one of the possible outcomes of IDR. In this section we delve somewhat deeper into this diffusion aspect.

Since collaboration implies a direct form of knowledge sharing it can be considered a strong method of knowledge diffusion [3.82]. Knowledge sharing, and hence diffusion, through collaboration takes less time than knowledge diffusion through reading and citing. During collaboration, knowledge diffusion is nearly instantaneous, since during the joint work authors share knowledge and expertise. This happens even before a paper has been written. The knowledge shared between authors diffuses over the research groups, departments, institutes and countries to which the collaborating authors belong. This type of knowledge diffusion can be placed in the ID process, and consequently influences outputs and outcomes.

3.11.1 Knowledge Diffusion as a Property of One Article

Contrary to the case of knowledge integration, knowledge diffusion with respect to one article is largely determined by outsiders [3.14]. In [3.14] the diffusion process and related measurement has been described in some detail. The authors introduce the concept of an intermediary (IM) set. This is a set placed between the objects of inquiry, e. g., articles and objects characterizing the type of diffusion under study. Concretely, this may be disciplines when studying diffusion over disciplines, characterized by WoS subject categories; or journals, when studying diffusion over journals, etc. For the knowledge integration case studied in [3.8], the object of inquiry was an article; their aim was to study knowledge integration (interdisciplinarity) characterized by WoS subject categories and the IM was the set of references-of-references. If one wants to study how the knowledge contained in one article is diffused over journals, then the IM consists of citing authors acting through citing articles, which are each mapped to the journal in which the citing article has been published.

3.11.2 Interdisciplinary Knowledge Diffusion as a Property of a Set of Related Articles

Everything we have discussed so far about single articles also applies—with some adaptations—to groups of articles. However, changing the focus from one article to a group of related articles leads to an interesting new aspect.

The act of publishing subsequent research, e. g., written by the same research group, leads to a form of diffusion by publication. This has been pointed out in [3.23]. In this context diffusion as described above may be described as citation diffusion, i. e., diffusion by being cited. If a group publishes in different journals, or even different (sub)fields this may or may not be a token of knowledge integration. Whether knowledge integration has taken place must be determined by the methods described above: there is integration if the publication pattern is diverse and coherent, but not if the diversity is not articulated as a coherent body of research. This latter case is what occurs in multidisciplinary contexts, for example in centers that put diverse scientific groups under the same roof without achieving links between them—or in multidisciplinary journals such as *Nature* and *Science*.

As diffusion through citations is determined by citing articles it is a measure of reach [3.14]. If one is interested in a measure determined completely by outsiders, self-citations must be removed. Diffusion is largely determined by factors outside the original set of articles (or book, etc.). Superficially, the notion of knowledge diffusion has little to do with the article itself (or articles themselves), as it is more concerned with the question of how this article is received by the scientific community. Yet, the reason or reasons why an article is highly diffused has to do with intrinsic properties (intellectual and other) of the article itself. Publication diffusion is determined by the group of authors under study but is different from knowledge diffusion.

Diversity can be understood in the same way for knowledge integration as for knowledge diffusion. Coherence, however, has another interpretation when considered in the context of integration or in the context of diffusion. More coherence means more integration, but it may mean less diffusion, in the sense that the knowledge is spread over more but related topics. If diversity increases then clearly knowledge diffusion took place. For the relation between coherence and knowledge diffusion the answer is less clear.

3.12 Other Network Measures

Leydesdorff [3.56] suggested that betweenness centrality can be used as a measure of interdisciplinarity at the journal level. Using network measures in studies of IDR often means focusing on the intermediation role of certain actors, say some specific scientific contributions. *Rafols* et al. [3.83] developed intermediation as a framework, complementary to the diversity-coherence framework.

Using factor analysis, *Leydesdorff* and *Rafols* [3.19] analyzed the full set of ISI subject categories to find that it can be decomposed into 14 factors or macro-disciplines (as a name or an interpretation). Each of these macro-disciplines can be clustered, with the clusters providing spaces of high population (density) amidst open spaces. In their vision, links across these spaces show the interdisciplinary character of the populated spaces. This system-wide mapping of population spaces and their links provides a basis for determining the extent to which different fields are more or less interdisciplinary in character. Yet, the problem with this approach is that it depends on the classification used (WoS categories), though it has been shown [3.73] that most global mapping studies agree on the core structure of science. This suggests that although at the fine level the specific science map may be dependent on the classification, at a coarser level these differences are not relevant.

3.13 Evaluating Interdisciplinary Work

Klein [3.7] emphasizes that appropriate evaluation of IDR evolves through a dialogue between conventional and a new, expanding group of indicators for quality. According to Klein, traditional methodology and statistics have a role to play, but they are not sufficient to fully reveal the underlying dynamics. Describing time-dependence through dynamical aspects is, in her view, essential for an appropriate evaluation of IDR.

In [3.7] *Klein* considers seven generic principles, which we will review next, providing a coherent framework for thinking about the evaluation of interdisciplinary work:

1. Variability of goals. It must be accepted that IDR is performed with different goals in mind. Some teams focus on workability and social impact, while others seek simplicity or predictive power. Still others want to reach new levels of comprehensiveness or empirical grounding.
2. Variability of criteria and indicators. One set of criteria consists of conventional metrics, such as number of publications, citations or patents. Yet, another set emphasizes feedback to multiple fields, expanded expertise and tool sets, and the ability of researchers to work in more than one discipline, and as such being able to co-mentor students in other than their original field of expertise.
3. Leveraging of integration. In IDR evaluation one not only calls attention to outcomes but also to the quality of the process. Klein mentions that the Harvard project [3.84] highlighted the epistemic criterion of balance in weaving perspectives into a coherent whole. Recall that coherence is one of the two main aspects studied in [3.8].
4. Interaction of social and cognitive factors in collaboration. Clearly IDR is a special type of social process, one leading to knowledge production and integration. During collaborations, differences in opinion or in approaches to attack problems must be negotiated to avoid misunderstandings and to strengthen conditions leading to a consensual mode of work. Hence, communication and negotiation are important points in the formative evaluation of research projects. In this context we mention that having an open communication and management structure is one of the points in the evaluation procedure for gauging the performance of key labs in China [3.85]. ID teams form a network, but they still stay connected to the networks they belonged to before the team was formed. While the out-team connections may help in bringing new information into the network, they may also compete for individuals' time and attention. This suggests that out-team as well as in-team connections should be examined when assessing team dynamics and performance [3.37].
5. Management, leadership and coaching. Competence, especially of IDR leaders, is at least in part defined in terms of how well the management of projects and programs implements consensus building and integration. Leaders must perform cognitive, structural and process-oriented tasks and act as coaches, a task related to the topic of team building.
6. Iteration in a comprehensive and transparent system. Feedback must lead to new and improved methods and models. Transparency requires that evaluators as well as participants in IDR are from the outset informed about evaluation criteria.
7. Effectiveness and impact. Unintended (positive) consequences and unforeseen long-term impacts cannot be captured by a priori criteria. *Boix-Mansilla* et al. [3.84] mention that interdisciplinary impacts are often diffused, delayed in time and dispersed across diverse areas. This implies that a full evaluation of an IDR project may need a broad perspective of more than one decade.

Point 7 brings us to the question of whether IDR always leads to more citation impact.

3.14 Does Interdisciplinary Research Have More Impact?

First we point out that having an impact is different from receiving many citations. *Meagher* and *Martin* [3.86] point out that the impact of a field like mathematics—outside its own field—is largely realized through active collaboration with colleagues from other departments, i. e., through interdisciplinary research. That said, we next consider the topic of citation impact.

Molas-Gallart et al. [3.13] point out that increasing impact and increasing interdisciplinarity are not systematically positively correlated, a point already made in [3.53]. Also [3.35] warns against the idea that higher citations may reflect all benefits of IDR. They mention that, for instance, the aspect of opening up perspectives is not directly measured by high numbers of citations. Also the aspect of problem solving as a result of IDR may be underestimated, in particular when these solutions are associated with practical applications [3.87].

The question of whether articles that show a higher degree of knowledge integration are more cited is a complex question. In the context of interdisciplinarity, the answer seems to be heavily dependent on the definitions and measures used to gauge ID, and the field normalization used to count citations. Clearly the answer is certainly not a straightforward yes [3.35, 53, 88, 89].

Standard indicators may not be adequate to reflect the impact of IDR. For instance on the institutional level, journal rankings, being mostly discipline-oriented, can disadvantage diverse, interdisciplinary research in research evaluations [3.83]. On the country level, we note that high average citation impact hides a mix of peaks and troughs. More consistent performance, i. e., greater evenness in relative citation impact, avoids the risk of missing key areas [3.47].

Yegros-Yegros et al. [3.35] studied the difference on impact of proximal and distal interdisciplinarity. Citation impact is operationalized in terms of number of citations after field-normalization. In their work interdisciplinarity is measured by variety, balance and disparity of references. They use a tobit regression model to examine effects on citation impact, controlling for other variables such as number of authors and organizations. They observe an inverted U-shape relationship between degree of interdisciplinarity and citation impact. Variety has a positive effect on impact, while balance and disparity have a negative effect. These results indicate that the most-cited publications are those with a clear disciplinary focus, but that nevertheless give small proportions of references (the low balance) to many proximal (low disparity) disciplinary categories.

These findings can be interpreted in two different ways. First, while combining multiple fields has a positive effect on knowledge creation, successful research is better achieved through research efforts that draw on a relatively proximal range of fields, as distal interdisciplinary research might be too risky and more likely to fail. Yet, a second possible conclusion is that scientific audiences are reluctant to cite unorthodox papers that mix highly disparate bodies of knowledge. This would put publications that are too ground-breaking or challenging at a disadvantage.

Also *Wang* et al. [3.89] studied the influence of variety, balance and disparity separately. They found that long-term (13 year) citations increase at an increasing rate with variety, decrease with balance, and increase at a decreasing rate with disparity. Furthermore, although variety and disparity have positive effects on long-term citations, they have negative effects on short-term (3 year) citations, and although balance has a negative effect on long-term citations, its negative effect is insignificant in the short run.

3.15 Measuring Cognitive Distance

The capacity of sharing knowledge, possibly leading to new discoveries, depends on the cognitive distance between members of a team. *Broström* and *Mc Kelvey* [3.90] describe cognitive distance as an inverse characterization of the degree of overlap between two nodes in a semantic network in terms of knowledge bases, values, norms and the heuristics of attribution and decision making. *Boschma* [3.6] sees cognitive proximity, the opposite of cognitive distance, as one of the factors that facilitate effective collaboration between different actors in translational research. Clearly, when cognitive distance is either too large or too small, this might be a hindrance to learning and innovation. *Boschma* [3.6] considers five types of proximity in the context of firms. We take the liberty of re-interpreting them in the context of collaborating research teams with a different disciplinary background.

3.15.1 Cognitive Proximity

Effective transfer of knowledge requires absorptive capacity to identify, interpret and exploit new knowledge. As a rule, researchers have a tendency to perform research in close proximity to their existing knowledge base. Yet, this sets constraints to further improvement. For each new step there exists a minimum level of knowledge under which teams are incapable of bridging the knowledge gap. That is, a team's cognitive base should be close enough to a collaborating team's knowledge base in order to successfully communicate, understand and process what the other team has to offer. Cognitive proximity facilitates communication, but too much cognitive proximity is detrimental to new learning and innovation. On the one hand, effective IDR needs a limited cognitive overlap, while on the other hand there must be sufficient cognitive overlap for the sake of communication. We note, though, that the act of collaborating itself increases cognitive proximity.

3.15.2 Organizational Proximity

Organizational practices are very relevant to the issue of IDR. Although a common knowledge and competence base is a prerequisite for bringing teams together, knowledge creation also depends on the capacity to coordinate the exchange of complementary pieces of knowledge owned by a variety of actors. Too much organizational proximity leads to a lack of flexibility, while too little organizational proximity leads to a lack of control and possible opportunistic behaviour (collaborators that mainly take, i. e., learn new techniques, and hardly share information and skills).

3.15.3 Social Proximity

Research is embedded in a social context. Social proximity leads to trust based on acquaintanceship, maybe even friendship and joint experiences. Social proximity reduces the risk of opportunistic behaviour. Too little social distance may weaken IDR due to an overload of trust (not all experiments or statistical analyses are redone or checked as far as possible by a member of the other team). Too little social proximity may lead to lack of trust and commitment to the joint project.

3.15.4 Institutional Proximity

Social proximity is understood in terms of individual scientists, while institutional proximity is related to the general institutional framework. Institutional proximity refers to norms and values of conduct. These may differ between departments and on a larger scale between universities and countries. These norms may be derived from legal laws and rules, but also from cultural norms and habits. A culture of shared trust is a basis for IDR. New experiences, leading to innovative research, are more easily transmitted in a sphere of cultural proximity and a common language. As such, institutional proximity provides stable underlying conditions for IDR. The cultural dimension of institutional proximity is related to geographical proximity, discussed next.

3.15.5 Geographical or Spatial Proximity

When co-workers are co-located it goes without saying that probably the other forms of proximity are also high. Yet, it may happen that two universities situated in the same city have quite different goals. Being geographically close may, however, lead to IDR that otherwise would not have taken place. Once teams are formed, geographical proximity may stimulate all other forms of proximity as face-to-face contact may easily increase. Moreover, geographic proximity may be a cost-reducing factor, as collaboration and face-to-face discussion may occur without incurring travel costs.

3.15.6 More on Cognitive Distance

Cognitive distance between research groups and members of an evaluation panel has been measured in [3.77, 91] based on researchers' publication portfolios. In these investigations, categories are either WoS subject categories or journals in which articles have been published. In the calculation of cognitive distance similarity between these categories or journals was taken into account.

Wang and *Sandström* [3.92] provide a methodology for the measurement of cognitive distance between researchers and study its role in peer review. Scientists holding the mainstream view of their field may not be able to give a fair review regarding new or alternative research. This is in particular the case for IDR. These authors developed a strategy that combines measuring research experience and content to obtain a measure for the cognitive distance between applicants and referees in a grant reviewing exercise. Note that grant reviewing panels are organized for a longer period of time, which is quite different from a one-off panel. In the first approach the authors use cited references as a researcher's knowledge base. Hence, the more references two researchers have in common the smaller their cognitive distance. This implies that the first method proposed in [3.92] is a form of author-bibliographic coupling. Based on the obtained author-reference matrix they calculate the Salton cosine measure between authors (practically: an applicant for a grant and a panel member). Cognitive distance is then defined as "one minus the cosine value" (where the cosine value was always positive in this application). It is not clear, however, what is a *good* outcome as values for a cognitive distance of zero or one are both undesirable. Similarly, in the second approach *Wang* and *Sandström* [3.92] analyze actual research contents, restricted to titles and abstracts and form an author-topic matrix. Again, they calculate a cosine measure between authors. In their discussion they mention that when it is desired to have industry representatives in a panel, their approach may not work, as these representatives typically have none or very few academic publications.

3.16 Identification of Interdisciplinary Ideas

The process of creating an innovative product starts with research activities based on a new idea. Decision makers would like to obtain estimations about the innovative potential of an idea before work on its realization starts. As estimating the interdisciplinarity of an idea can be done beforehand, interdisciplinarity is used as a proxy for innovative potential. The work of *Thorleuchter* and *Van den Poel* [3.93–95] aims at identifying the innovative potential of a new idea using texts (in theory one could also use auditory or visual information). In this way they hope to improve the performance of the innovation process. Innovation tends to occur between two or more technologies or two or more scientific fields that are not yet related. For this reason innovations can be said to be interdisciplinary products. An idea has two parts: a means (how) and a purpose (what). When an idea is represented as a text phrase the authors try to identify interdisciplinary ideas as cases where means and purpose are assigned to different not-yet-related technologies or scientific disciplines.

Their general approach is a form of text mining referred to as idea mining. In a first step, idea mining identifies means and ends (purposes) from textual information describing a problem. In a second step, it searches in new information sources for textual patterns that contain either a means or an end from the problem description and that also contain corresponding new means or new ends. This leads to a pattern of a *new* means leading to an *old* end; or vice versa. Idea mining usually identifies a large number of possible solutions. Next, possible solutions are classified and clustered. Relationships of these clusters to disciplines are determined to find out if an idea is of interdisciplinary nature or not. In this step one needs a description of fields or disciplines. *Thorleuchter* and *Van den Poel* [3.93] use the scope notes of the WoS subject categories for this purpose. As these scope notes are manually created, the authors claim that they are of good quality and up to date. To present the ideas in a comprehensible way to human experts, a text phrase is built for each idea. Then human experts evaluate the ideas shown to see if they can be put into practice. This approach is closely related to *Swanson*'s idea of literature-based discovery [3.96, 97].

3.17 Time Aspects

The fact that knowledge integration and diffusion themselves are dynamic processes has consequences for their measurement [3.23]. What is currently thought of as a highly interdisciplinary field is a point-in-time perception of how far apart the present constituent categories were at an earlier time, suggesting that a measure of the distance between two topics or between fields of science should be based on the analysis of large amounts of data over time. Moreover, interdisciplinary practices can be assumed to differ across disciplines. A medical researcher using basic statistics is not performing interdisciplinary work; yet, using statistics that requires a skilled statistician in the team, is. This shows the influence of basic education in a field (what is included in basic teachings and what is not) on the notion of IDR.

For these reasons, IDR can be considered as part of an evolution, rather than a state, thereby requiring that researchers must portray its development over time. In fact, given the consensus that a central concept of IDR is a process of knowledge integration, this in itself suggests a dynamic process leading from less to more integration. Yet, established fields may have subfields that start diverging [3.98]. Stated otherwise, on the micro level one might see knowledge integration but on the macro level of fields or subfields one may observe divergence. While an existing field might be characterized by a static IDR measure as *highly integrated*, in the process of evolving to its highly integrated state, it may have lost much of its novelty and breakthrough value. Hence being highly integrated is not a desirable state, as already mentioned in Sect. 3.10 (high diversity and high coherence). Insofar as current IDR measurement is often static, using a finite time window, this most certainly is not an optimal state of affairs.

3.18 Limitations of Existing Approaches

Existing databases have a number of limitations that raise questions about their usefulness in developing bibliometric-based measures of interdisciplinary research. Funding agencies often seek to support research that addresses complex scientific and social problems. They claim that doing so requires the integrated contributions of varied fields of knowledge. This clearly implies that the humanities and social sciences must play an important role in such investigations. Yet, this aspect has often been neglected when applying ideas, concepts and measuring techniques conceived for the natural sciences and the life sciences. Emphasis on products from Clarivate Analytics, such as the JCR, or Elsevier's Scopus, may well hinder developments in the study of IDR. Reliable data to assess developments in the SS&H do not exist on an international level because the international databases only partially cover books, book chapters and especially regional non-English journals. This implies that a full-scope IDR study can only be done when incorporating regional databases. *Wagner* et al. [3.2] write that, given the limits of bibliometrics, we may be missing the most socially relevant IDR interactions because of limitations in the current contents of bibliographic databases, or, stated otherwise, because researchers who study IDR take the easy way-out and only use these databases in their studies.

3.19 An Example Within the Rafols–Meyer Framework

In this section we provide a simple example of a study on interdisciplinarity, applying the methodology suggested in [3.8]. Fourteen articles in the field of synthetic biology [3.99–112], a field in which we have some prior experience [3.113], were chosen as illustration. All these articles were published in the year 2000.

There is one important difference with [3.8] though: we use the true diversity measure derived from the Rao–Stirling measure instead of the classical one [3.25, 114, 115]. Concretely, as diversity measure we use Z, defined as

$$Z = \frac{1}{1-D}\,, \tag{3.8}$$

where D is the Rao–Stirling measure. Coherence is calculated as mean linkage strength for the network of normalized (using Salton's cosine) bibliographic coupling strength [3.8], between references included in the Web of Science.

Concretely, if an article P has ten references, among which five are items not included in the WoS, e. g., articles in journals not covered in the WoS, books, an unpublished doctoral thesis, then these items are discarded. Taken over the 14 articles studied as an illustration, the percentage of discarded items is about 30%.

The remaining normalized bibliographic coupling matrix $\mathbf{M}_\mathrm{P}$ may be of the form shown below, where the diagonal values play no role and are indicated by a hyphen

$$\mathbf{M}_\mathrm{P} = \begin{pmatrix} - & 0.25 & 0.05 & 0.10 & 0.00 \\ 0.25 & - & 0.30 & 0.02 & 0.00 \\ 0.05 & 0.30 & - & 0.01 & 0.00 \\ 0.10 & 0.02 & 0.01 & - & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & - \end{pmatrix},$$

where the normalized bibliographic coupling values between each two references were calculated based on the Salton cosine measure as follows: if *shared* refers to the number of shared references between Ref 1 and Ref 2 and $T1$, resp. $T2$, refer to the number of references in Ref 1, resp. Ref 2, then the Salton cosine measure is

$$\frac{\text{shared}}{\sqrt{T1 * T2}}\,.$$

Here, the *number of references in Ref k* $k = 1, 2$, refers only to those included in the WoS.

The mean linkage strength is the average of all non-diagonal values. In this example, the coherence value for article B is

$$\begin{aligned}\text{Coherence} &= \frac{\text{sum of all elements in } \mathbf{M}_\mathrm{P}}{20} \\ &= 0.073\,.\end{aligned}$$

The final results in terms of diversity and coherence for each article in the example set are shown in Fig. 3.2.

Figure 3.3 illustrates the differences in network structure associated with increasing values for coherence, for 4 articles in the sample.

Figure 3.4 illustrates the disciplinary mix of article E's reference set by locating the WoS subject categories where references were published. Note that the same reference may be assigned to different subject categories.

These examples illustrate not only the methodology used to study interdisciplinarity, but also the interaction of fields leading to studies in synthetic biology.

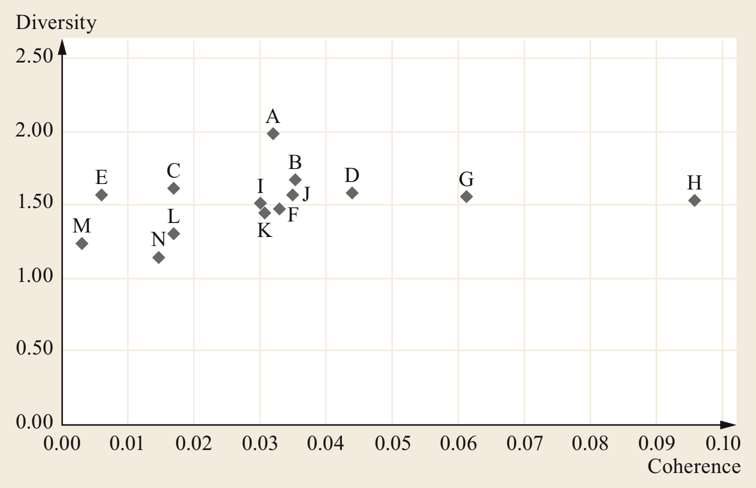

Fig. 3.2 Diversity and coherence for 14 articles in the field of synthetic biology: Coherence on the horizontal axis; diversity (Z) on the vertical axis. *Letter symbols A–N* refer to references [3.99–112], in that order

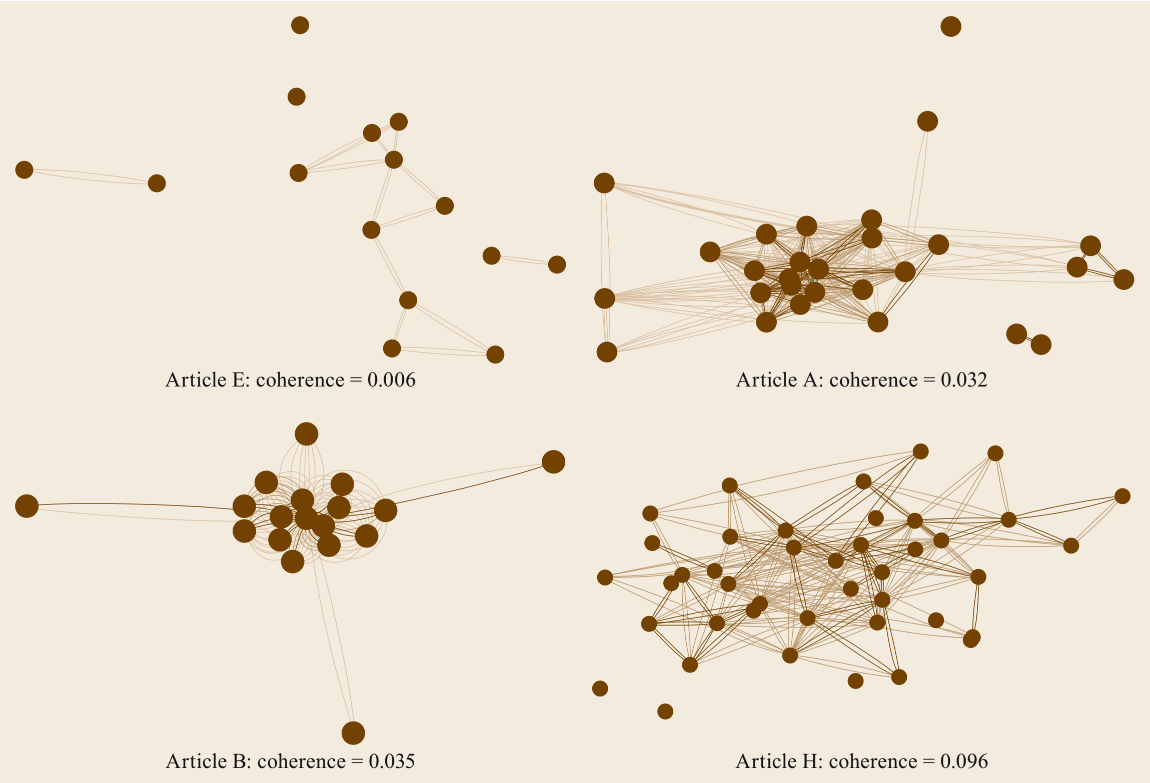

Fig. 3.3 Bibliographic coupling networks for the reference set of various articles. The figures are ordered from lower to higher network coherence (from *top left* to *bottom right*); *thicker lines* indicate greater similarity. Also here, *letter symbols A–N* refer to references [3.99–112], in that order

Fig. 3.4 Distribution of WoS subject categories for the reference set of article E [3.103] in bibliographic coupling networks. *Black nodes* indicates the references published in a given subject category (shown under each tile). *Brown nodes* indicate the references published in other subject categories (different from the given one as indicated by the *black nodes*)

3.20 Conclusions and Suggestions for Further Research

Following the definition of IDR according to the National Academies of Sciences of the USA, the essence of IDR is knowledge integration. Yet, besides integration of knowledge originating in different disciplines, we pointed out that knowledge may also originate from different research traditions, different regions and different ages.

As there does not exist a definition of the term *discipline* accepted by the majority of scientists, one must measure ID based on some operationalization. Often the choice goes to WoS categories, although it is well-known that such a choice is far from optimal.

We discussed inputs, outcomes and the process of IDR itself. IDR normally involves collaboration by scientists with a different background. This leads to different perspectives on the research that is performed and avoids lock-ins. We further discussed, be it briefly, some costs associated with doing IDR, such as lack of appreciation and being less funded.

On the one hand, quantitative measurement of IDR often implies the use of references (the citing side of the article or group of articles on which the measurement is performed). Diffusion studies, on the other hand, consider the cited side. *Rafols* and *Meyer* [3.8] used a top-down approach for measuring diversity among references and a bottom-up approach for coherence.

Once a measure of ID has been determined, one may answer the question if more ID research receives more citations. Investigations trying to answer this question indicated that the answer is no. The most-cited publications are those with a clear disciplinary focus, but that nevertheless give small proportions of references to many proximal disciplinary categories.

Evaluation of IDR itself has been described following [3.7] while different types of proximities have been described following [3.6].

This review shows that knowledge integration and diffusion are essentially dynamical processes in scientific evolution. Involving different disciplines, different regions, and different countries, these processes constitute the main motors of creativity and innovativeness, leading to new scientific structures of science, but based on the traditional fields as foundation.

Measuring or studying interdisciplinarity and, more generally, knowledge integration and diffusion, are always subjective actions, depending on several choices. Indeed, as long as there is no generally accepted definition of a discipline, ID cannot be but an artificial construct, open to diverse interpretations.

Following [3.2] we saw that assessment of interdisciplinary research inputs, processes, outputs and outcomes is still a work in progress. There are, for instance, few studies that link inputs to outputs, let alone outcomes.

The authors of [3.47] write that scrutiny reveals the limitations of an obsession with performance (especially as measured through evaluation assessments such as the Research Excellence Framework in the UK). Structural diversity is a necessary complement to research excellence. At the university level, a department focusing on high-impact journals may not be in the best position to address interdisciplinary policy challenges. At the country level, the research base with the highest average citation impact does not necessarily have the best long-term portfolio. They further write that because of humans' uncertainty about the future we need an agile and responsive research base, leading to the question of finding a measure of *agility*. Probably such a research base must, much more than now, include the social sciences and humanities.

When multiple studies have determined the degree of ID, the next step can be set with confidence; that is, studying whether investigations with a high degree of ID are the ones that have the most impact, leading to the real *novel* results aimed for by governments and funders. Further research will have to determine the links between *interdisciplinary research* and *novel research*. During this step experts from the targeted scientific/technology fields must play a decisive role.

When it comes to studying how IDR reaches the general public, alternative metrics may constitute an obvious point of departure.

In view of *Stirling*'s work [3.69] and that of others [3.8, 116] we come to the conclusion that, ideally, measures of diversity:

(a) Satisfy reasonable axioms, as pointed out in [3.69] and studied in detail by *Leinster* and *Cobbold* [3.114].
(b) Are parametrized to produce diversity profiles [3.114]; concretely, next to Z as used in the example, one must also consider the family

$$Z^q = \left(\sum_{i=1}^{N} p_i \left(\sum_{j=1}^{N} s_{ij} p_j \right)^{q-1} \right)^{\frac{1}{1-q}} , \tag{3.9}$$

where q is a parameter ranging from zero to infinity (the cases $q = 1$ and $q = \infty$ are obtained as limits); $\mathbf{S} = (s_{ij})_{ij}$ is a similarity matrix; the corresponding disparity matrix $\mathbf{D}$ is obtained as $d_{ij} = 1 - s_{ij}$; Z is the case $q = 2$.
(c) Come with an effective number to simplify interpretation: this means that the result can be interpreted

for a community of equally abundant, totally dissimilar species [3.65, 114, 117].
(d) Have (unbiased) estimators to apply to real data.

The first three points fall within the framework of this chapter, while we leave the discussion of the statistical point (d), to specialists such as [3.116].

Which measures are most appropriate for addressing particular questions concerning the interdisciplinary content of research output, at what levels of aggregation and with what degree of validity and reliability, is still a huge research question and a topic of further discussion [3.2].

Structural diversity should be placed into an analytical framework that provides acceptable general measures, relevant to policy and meaningful to stakeholders. The results of such measures would be compared with models of desirable outcomes. Only then is it possible to show where diversity has been of value and track where this valuable diversity might be lost, and hence take steps to safeguard these strengths [3.47].

Most existing approaches to measure interdisciplinarity are just drawing up the *shape* of an interdisciplinary field, and are less interested in the effect generated by interdisciplinary work. This important perspective is suggested for future studies.

Although investment must support current policy priorities, it must be accepted that without curiosity-driven research identified by researchers themselves, one would soon be mining worn-out seams [3.47]. Consequently, we conclude that mono-disciplinary and interdisciplinary work and projects both have their place in producing research that has an impact on other fields and on society.

In this review we did not discuss specific case studies published in the literature, leaving that to another occasion. Yet, we do draw the reader's attention to [3.118]. This article discusses IDR which aims at integrating the social and natural sciences, a particularly ambitious endeavor. *Roessner* et al. [3.119] investigated how features of IDR are accurately reflected in bibliometric measures of scholarly publications, concretely the Rao–Stirling integration score, over time, focusing on the entire portfolio of a well-known researcher who was active in different fields. In their mapping study *Boyack* et al. [3.71] found that biochemistry was the most interdisciplinary discipline in science.

Xiaojun Hu is a Professor in Medical Informatics at Zhejiang University School of Medicine. She received a PhD in Public Administration from Zhejiang University. Her main interest lies in interdisciplinary research between scientometrics and biomedical informatics, including patent-metrics, and biological and disease networks. As a Principal Investigator, she has finished and undertaken research projects supported by the National Natural Science Foundation of China and Zhejiang Association for Science and Technology.

4. Google Scholar as a Data Source for Research Assessment

Emilio Delgado López-Cózar, Enrique Orduña-Malea, Alberto Martín-Martín

The launch of Google Scholar (GS) marked the beginning of a revolution in the scientific information market. This search engine, unlike traditional databases, automatically indexes information from the academic web. Its ease of use, together with its wide coverage and fast indexing speed, have made it the first tool most scientists currently turn to when they need to carry out a literature search. Additionally, the fact that its search results were accompanied from the beginning by citation counts, as well as the later development of secondary products that leverage this citation data (such as Google Scholar Metrics and Google Scholar Citations), made many scientists wonder about its potential as a source of data for bibliometric analyses. The goal of this chapter is to lay the foundations for the use of GS as a supplementary source (and in some disciplines, arguably the best alternative) for scientific evaluation. First, we present a general overview of how GS works. Second, we present empirical evidences about its main characteristics (size, coverage, and growth rate). Third, we carry out a systematic analysis of the main limitations this search engine presents as a tool for the evaluation of scientific performance. Lastly, we discuss the main differences between GS and other more traditional bibliographic databases in light of the correlations found between their citation data. We conclude that GS presents a broader view of the academic world because it has brought to light a great amount of sources that were not previously visible.

4.1 The Origins of Google Scholar

The development of the field of bibliometrics has always been reliant on the availability of large-scale sources of metadata about scientific publications, which are ultimately the raw materials used by bibliometricians to carry out their analyses [4.1]. The creation of the first citation indexes by Eugene Garfield (Science Citation Index in 1964, Social Science Citation Index in 1973, and the Arts and Humanities Citation Index in 1978) turned out to be a crucial turning point that enabled the development of modern bibliometric studies. His novel approach to bibliographic information systems opened the way to a completely new way of assessing scientific performance [4.2].

By indexing not only the articles published in scientific journals, but also the bibliographic references included in these articles, it was possible for the first time to track the relationships between scientists, journals, and institutions through the main tangible outputs these entities produce: scientific documents. Thus, the

Electronic supplementary material The online version of this chapter (https://doi.org/10.1007/978-3-030-02511-3_4) contains supplementary material, which is available to authorized users.

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_4

databases of the Institute for Scientific Information (now part of Clarivate's Web of Science; WoS) became the first, and for a long time the only available sources of data for bibliometric analyses, exercising an almost absolute monopoly in this field. The use of other specialized databases (such as MEDLINE, Chemical Abstracts, Inspec, or Biosis) for bibliometric purposes was testimonial, since they did not offer citation data nor other fields (e. g., full affiliations of the authors), which are vital to produce useful bibliometric reports.

It was not until the first decade of the twenty-first century that this monopoly was seriously challenged. Elsevier launched its Scopus citation database on November 3rd, 2004. Just a few weeks later (November 18th) GS was also launched. Scopus was conceived as a traditional subscription-based bibliographic database (which indexed a specific set of journals and conference proceedings) and was clearly a direct competitor of WoS. GS departed entirely from this approach, following instead the path of its big brother, the Google search engine, a decision that greatly impacted its design and coverage.

Simply put, GS is a specialized search engine that only indexes academic documents [4.3, 4]. GS's spiders constantly crawl the websites of universities, scientific publishers, topic and institutional repositories, databases, aggregators, library catalogues, and any other web spaces where they might find academic-like materials, regardless of their subject or language. GS indexes documents from the whole range of academic document types (books, book chapters, journal and conference articles, teaching materials, theses, posters, presentations, reports, patents, etc.). Unlike the cumulative and selective nature of WoS and Scopus, GS is dynamic; it reflects the state of the web as it is visible to its search robots and to the majority of users at a specific moment in time. Documents that for any reason become unavailable on the web will eventually disappear from GS too, as will the citations they provided to other documents [4.5].

GS, like the Google search engine before it, achieved instant success among users worldwide. The reason is easy to understand: GS finds most of the scientific information that circulates around the web in an easy and fast manner. Perhaps most importantly, it is free, unlike most of the bibliographic databases that existed before it, which are often only accessible through costly national or university-level subscriptions.

GS is currently the tool most users first turn to when they need to carry out a literature search. This has been evidenced by numerous studies [4.6–11]. *Bosman* and *Kramer*'s study [4.7] is the most recent and large-scale study on the matter. They conducted a survey on the changing landscape of scholarly communication between May 2015 and February 2016, obtaining more than 20 000 responses from researchers, university students, librarians, and other members of the scholarly community. With respect to the question *What tools do you use to search literature?* GS emerged as the preferred option, selected by 89% of the respondents, followed at a great distance by WoS (41%), Pubmed (40%), others (36%), and Scopus (26%).

Since its launch in 2004, GS's interface has gone through several renovations, but the really important changes (updates to its algorithms, coverage) usually happened under the hood, unbeknownst to most users. Some developments, however, did not go unnoticed. We are referring, of course, to the creation of its two secondary products: Google Scholar Citations (GSC) and Google Scholar Metrics (GSM). GSC was launched in July 2011 and provided a platform in which users could easily create an academic profile by pulling their publications from the data available in GS. Most interestingly, these profiles also displayed several author-level bibliometric indicators [4.12]. GSM was born on April 2012 as a ranking of scholarly publications according to their h-index calculated from GS data. This tool provides an easy way to identify the most influential publications (journals, proceedings, and repositories) and articles published in recent years [4.13].

Although these two tools never lose sight of GS's main purpose (they are intended to serve as search tools, one to find relevant researchers, the other to find influential articles and publications), they use bibliometric indicators as an evidence of relevance. For the first time, the GS team decided to put the citation data available in GS to other uses. Until the creation of those products, citation counts were only used as one of the parameters to rank documents in a search and a search aid for users (*Cited by* links in GS).

The availability of citation data in GS and its secondary products GSC and GSM has attracted the attention of some bibliometricians, and even scientists from other fields, who have realized that the data available in GS provides a much more comprehensive insight into the impact publications have on their respective academic communities than the data available in other citation databases. However, the use of GS for bibliometric purposes was never one of the applications GS's developers intended for this product, and so an exhaustive critical evaluation that analyzes its suitability for bibliometric analyses is necessary.

In order to do this, this chapter first presents a general overview of how GS and its secondary products GSC and GSM work, their inclusion policies, and how they respond (results offered) when specific stimuli (user queries) are applied. Second, we present empirical evidences regarding its size, evolution (growth rate, indexing speed), coverage (publishers, repositories, bibliographic databases, catalogues), and diversity (subjects, languages, document types). Third, we carry out a systematic analysis of the main limitations this search engine presents as a tool for the evaluation of scientific performance. Lastly, we discuss the main differences between GS and other traditional bibliographic databases in light of the correlations found between their citation data at the level of authors, documents, and journals.

The online version of this chapter is complemented by electronic supplementary material (ESM) in which the sources of the empirical analyses are made available, and further documents illustrating the findings on GS are provided [4.14].

4.2 Basic Functioning of Google Scholar

In this section, we first present a concise but accurate description of how the GS search engine works. Secondly, we describe its main inclusion criteria (both for sources and, especially, for documents). Lastly, we will briefly outline GSC and GSM.

4.2.1 The Academic Search Engine

Classic bibliographic databases usually work on the principle of whitelists. They first generate a whitelist of sources that meet some specific criteria (quality, subject scope, ...) and then index all the publications that appear in these sources. The historical tendency to select some specific sources (mainly journals) and not other channels for the dissemination of academic results (conference proceedings, books, reports, etc.) responds mainly for two reasons. First, it is a question of efficiency, usually referred to as Bradford's law of scattering [4.15], thanks to which we know that for any given topic, a small core of journals provides most of the articles on that topic. When faced with technological and economic constraints, maximizing returns by selecting only the core of journals that will be most useful for a given purpose seems a logical and natural response. The other reason has to do with the evaluative use of these databases. Due to their visibility and prestige, most authors want to publish their articles in these core journals, increasing the competition to get a manuscript accepted in these journals. The limited space for publication of the printing era, as well as the higher standards to which articles are held in these journals are what help project their image of prestige. To publish an article in a core journal is a difficult task, something that only the best researchers manage to do. In the same way, receiving a citation from an article published in a core journal also lends prestige to the cited article and its authors. This is the road to research excellence.

It goes without saying that this traditional approach (which prioritizes the optimization of resources and excellence) is not without its merits and has played an important role up until now. However, the irruption of GS represents a break from this paradigm. Unlike traditional bibliographic databases, which are selective by nature, GS parses the entire academic web, indexing every scholarly document it finds, regardless of its quality, and it does not differentiate between peer-reviewed and non-peer-reviewed content. GS is, rather, an academic search engine [4.3] with a bibliographic database that grows in a (mostly) unsupervised manner, and which has one clear purpose: facilitating the discovery of academic literature for everyone worldwide.

This unsupervised indexing process is possible thanks to the automated bots (sometimes also called spiders) that GS deploys throughout the web, similarly to how the Google search engine crawls the web as well. In GS, these bots are trained to locate academic resources, index their full texts (whenever possible), and extract their bibliographic descriptions (metadata). The process ends with the automated creation of a bibliographic record that is ready to be included in a search engine results page (SERP) when it is deemed relevant for a particular query. In order for a particular academic website to be successfully indexed in GS, certain technical requirements must be met, i. e., bots must be allowed to enter the website, there must be an easy-to-follow route to the article pages, and certain metadata must be available on these article pages. More detailed information can be found on the GS help pages [4.16].

When GS's bots are able to access the full text of the documents (either because the resource is openly available on the web, or thanks to the special agreements GS has with most commercial publishers), they also extract the list of cited references from each document. Thus, they are able to link citing and cited documents, which is how they can calculate citation counts.

When a list of cited references is parsed and processed, GS tries to find matches to those documents in its database. If it finds a match, it links the citing and cited document, and the cited document will have one more citation. However, if it does not find a match for a particular cited reference, the system will create a new bibliographic record of the type *[CITATION]*, to which the citing document will be linked. These records are also displayed in SERPs, although it is possible to exclude them, as their bibliographic information is often incomplete, and users will not be able to access their full text. A *[CITATION]* record can become a full-fledged record if GS finds another version of the document on the web (because someone deposits it on a repository, or it becomes available from a publisher, etc.), and merges the two versions. Needless to say, this entire process is also completely automated.

Lastly, GS considers a wide range of parameters for ranking documents in the SERPs, such as

> weighing the full text of each document, where it was published, who it was written by, as well as how often and how recently it has been cited in other scholarly literature. [4.17]

However, the detailed set of parameters and the weight each of them has in the ranking algorithm is not publicly available.

4.2.2 What Sources Does Google Scholar Index?

The previous section makes clear the distinction between GS and traditional bibliographic databases. In their own words, "we index papers, not journals" [4.18]. However, this statement is only partially true. We would rather define GS as a database that indexes web sources. Moreover, it deliberately includes some document collections (e. g., patents, court opinions, and *[CITATION]* type records).

GS crawls a wide variety of web sources and indexes everything from those sources that it identifies as academic documents. That is why GS includes all documents regardless of subject, language, country, or year of publication, and document type. The procedure GS follows to index new documents can be summarized in three steps, which are described below.

Step 1: Compilation of Sources

Over the years, GS has compiled a huge list of sources, ranging from websites of academic institutions (higher education institutions, national research councils, commercial publishers, private companies, professional societies, non-governmental organizations, etc.), to other discovery tools (bibliographic databases, catalogues, directories, repositories, other search engines) available across the web. These sources, which are the most likely to host academic content, are the ones that shape the academic web. Once they add a source to their private master list, GS's spiders will visit it periodically to check whether new documents have been added and also to verify that the documents indexed in the past are still available.

Besides the already mentioned academic sources, anyone can request that their website be considered for inclusion in GS. They are prepared to index websites that run in most of the common repository platforms (DSpace, EPrints, ...), journal platforms (OJS—open journal systems), and also simple personal websites.

Since GS's main objective is to facilitate content discovery, the sources must not require users to install additional applications, to log in, use Flash, JavaScript, form-based navigation, or any other kind of unreasonable methods to access the documents. In addition to that, the website should not display popups, interstitial ads, or disclaimers. They specifically state that

> all those websites that show log-in pages, error pages, or bare bibliographic data without abstracts will not be considered for inclusion and may be removed from GS.

Step 2: Document Types

The next step is to index the academic documents available in each source. GS does not index all the documents in a source, only those that are academic in nature.

GS states that they cover mostly "scholarly articles, journal papers, conference papers, technical reports, or their drafts, dissertations, pre-prints, post-prints, or abstracts". However, content such as "news or magazine articles, book reviews, and editorials" is not considered appropriate for GS. However, appropriateness is not really a constraint, and the documentation also states that "shorter articles, such as book reviews, news sections, editorials, announcements and letters, may or may not be included".

These ambiguous declarations are a consequence of the automated way in which the system operates. Let us see a practical example:

The University of Oxford's official website (http://ox.ac.uk) can be considered a reliable source of academic information. GS has added this web domain to its master list of indexable sources (like it does with most universities). However, not all documents hosted in ox.ac.uk are of an academic nature. GS needs to automatically differentiate academic documents from all the rest. To do this, the system applies two approaches:

1. The parser approach: GS uses full-text parsers to identify the structure of documents. Taking advantage of the fact that many academic documents tend to present a fairly standardized structure (title, author names, abstract, body of the article, references, ...), detecting whether or not a document is academic is often possible, although errors do occur.

2. The location approach: GS automatically indexes all the documents hosted in specific locations where it is reasonable to expect that all documents will have an academic nature, i. e., institutional repositories.

For this reason, despite what is stated in GS's documentation, it is possible to find a great range of document types in GS. Documents are usually stored in the HTML or PDF format. Parsing the structure from these documents is not enough to detect their specific typology (article, book chapter, conference paper, etc.) when additional metadata is not available. Moreover, once it has been decided that all content from a given source will be indexed, the actual document type stops mattering. For example, in GS we can find many book reviews, a document type that is explicitly considered inappropriate (Fig. 4.1).

Step 3: Documents

Lastly, documents themselves must also follow certain guidelines in order to be successfully indexed in GS. Some of them are compulsory, and others are only optional. Failure to comply with these rules may provoke an incorrect indexing of the documents, or, more likely, a complete exclusion from the search engine.

The system requires one URL per document (one intellectual work should not be divided into different files, while one URL should not contain various independent works). Additionally, the size of the files must not exceed 5 MB. Although documents of a larger size can appear in GS, their full text (including cited references) will be excluded if they do not comply with this rule.

HTML and PDF are the recommended file types. Other document types such as DOC, PS, or PPT are also indexed, but they are a very small minority and they might not be processed as effectively as the others. Additionally, PDFs must follow two important rules. First, all PDF files must have searchable text. If the PDFs are just scanned images, the full texts (including the cited references) will not be processed, since GS's crawlers are unable to parse images. Second, all URLs pointing to PDF files must end with the '.pdf' file extension.

There are also rules regarding the description of the articles through metadata. Some fields are compulsory for all documents (title, authors, and publication date), while others are specific to each document type. GS supports HTML meta tags in various formats: Highwire Press, Eprints, BE Press, PRISM, and Dublin Core (the last one as a last resort, since there are no specific fields for journal title, volume, issue, and page numbers in this format). If no metadata is readily available in the HTML meta tags of the page describing the article, GS will try to extract bibliographic information by parsing the full text of the document directly. For this reason, GS also makes recommendations regarding the layout of the full texts:

- The title, authors, and abstract should all be on the first page of the text file.

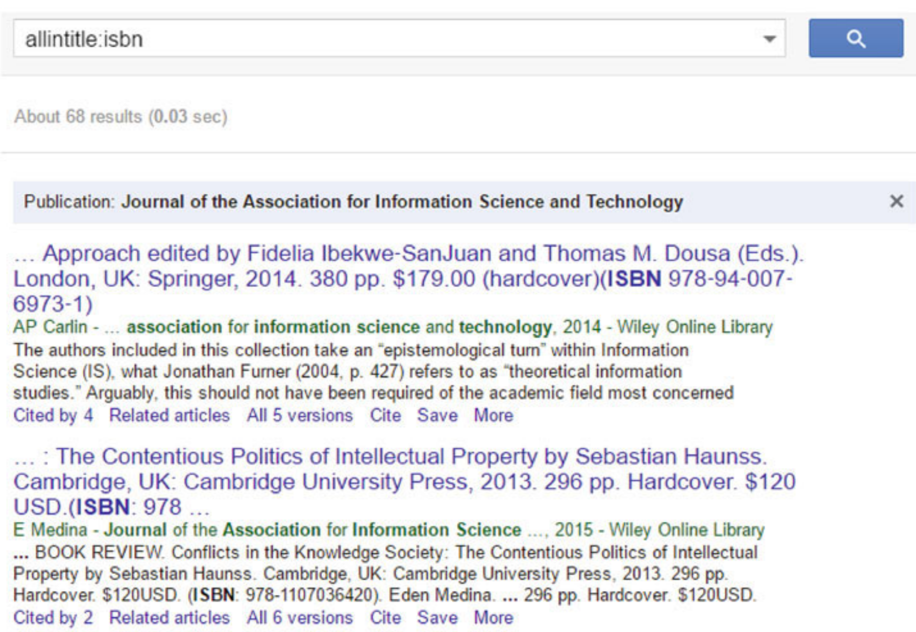

Fig. 4.1 Book reviews published in the *Journal of the Association for Information Science and Technology* (JASIST) and indexed in GS

- The title should be the first content in the document and no other text should be displayed with a larger font size.
- The list of authors should be listed below the title, in smaller font size, but larger than the font size used for the normal text.
- At the end of the document, there should be a separate section called *References* or *Bibliography*, containing a list of numbered references.

Lastly, the abstract of the document should be visible to all users that visit the article page (regardless of whether or not they have access to the full text of the document) without needing to click on any additional links or to log in. If this requisite is not met, it is likely that the document will not be indexed in GS.

4.2.3 Google Scholar's Official Bibliometric Products

GS has developed two secondary products that make use of both the bibliographic and citation data available in its core database. The first one (GSC) focuses on researchers, while the second one (GSM) focuses on journals and articles. This section describes each product briefly and discusses the bibliometric indicators they provide.

Google Scholar Citations

GSC was officially launched on November 16th, 2011. This tool is an academic profile service meant to help researchers maintain an up-to-date list of their publications without much effort (it is updated automatically), and it also facilitates searches of people (rather than documents) who are experts in any given academic topic.

First, GSC profiles contain structured personal information (name of the researcher, affiliation, and research interests). Second, the profiles show a list of all the publications written by the researcher. For each of the publications, both bibliographic (authors, title, source, year of publication) and citation data (number of citations and link to the list of citing documents) are offered. By default, documents are sorted decreasingly by number of citations, although they can also be sorted by year of publication or by title. Third, the profile also provides several author-level indicators (Table 4.1). These indicators are calculated considering two different time frames: first, without any time restriction (which is useful for comparisons of senior scholars), and second, considering only citations received in the last 5 years (which is useful for comparisons of early-career researchers). It is important to keep in mind that these indicators are calculated automatically from the data in the publication list, without any sort of human supervision.

In GSC, users have access to a document search tool that enables them to find their publications by means of author name searches (it is possible to search as many name variants as necessary), or by known document searches (usually title searches). After all documents have been found, researches may merge versions of the same document that GS has not been able to detect and fix bibliographic errors manually. All these operations only affect the researcher's profile and not other co-authors' profiles or the results in the GS search.

The platform also offers additional services, such as personalized alerts, lists of co-authors, areas of interests, list of authors by institution, etc. Therefore, authors can track the impact of their papers and other researchers' papers according to the data available in GS and be instantly informed of new papers published by other authors. All these features make GSC a powerful and free research monitoring system.

This product may be viewed as a first step in the transition from an uncontrolled database to a better-structured system where authors, journals, institutions, and areas of interest go through human filters. Nevertheless, the platform still lacks some essential features, like the identification of document types. This information can be defined by the owner of the profile on the document edit page, but it is not visible to other users visiting the profile. Another important issue is that author affiliations are not available at the level of documents. Although the affiliation field of the profile can be modified, it is only possible to display one affiliation at a time. However, researchers may change affiliations, and it would not be fair to ascribe all documents by a researcher to only one institution, if some of them were published while that researcher was working at other

Table 4.1 GSC's author-level metrics

Metrics	All	Last 5 years
Citations	Number of cites an author has received	Number of cites an author has received in the last 5 complete calendar years
h-Index	The largest number h such that h publications have at least h citations	The largest number h such that h publications have at least h new citations in the last 5 years
i10-Index	Number of publications with at least 10 citations	Number of publications with at least 10 citations in the last 5 years

institutions. Limitations like these diminish the usefulness of the platform for bibliometric studies (for more limitations, please see ESM, Appendix VI).

Google Scholar Metrics

GSM was launched on April 1st, 2012 and can be defined as a hybrid between a bibliographic and bibliometric product that presents a ranking of journals according to bibliometric indicators calculated using citation data from recently published articles in those journals. If GS represented a paradigm shift in the market of bibliographic databases, GSM accomplished something similar with respect to journal rankings, especially when compared to products like journal citation reports (JCR), the SCImago journal and country rank (SJR), or journal metrics [4.19]. GSM is an original product for various reasons:

- *Inclusion policies*: GSM only covers journals that have published at least 100 articles in the last 5 years and which have received at least one citation for any of those articles.
- *Coverage*: Apart from journals, GSM also covers some conference proceedings from computer science and electrical engineering, and preprint repositories. Other typologies like court opinions, books, and dissertations are explicitly excluded.
- *Sorting criteria*: Sources are sorted by their h5-index (h-index for articles published in a given 5-year period). The use of an h-index variant instead of a formula similar to the journal impact factor (JCR), SJR, SNIP (source normalized impact per paper), or CiteScore (journal metrics) is probably one of the most distinct features of this product. A description of the indicators available in GSM is presented in Table 4.2. For each journal, only the articles that contribute to the h5-index are displayed (h5-core). These articles are also accompanied by their citation counts, and the list of citing documents to each article is also available.
- *Categorization of sources*: The first variable of categorization is the language of publication. In the version available at the time of writing (launched in summer 2016, covering the period 2011–2015), the following languages were covered: English, Chinese, Portuguese, Spanish, German, Russian, French, Japanese, Korean, Polish, Ukrainian, and Indonesian. For each of these languages, except for English, the ranking displays the top 100 sources according to their h5-index. For English sources, a subject classification is also provided (Table 4.3).

Table 4.2 Google Scholar Metrics

Metrics	All
h5-Index	The largest number h such that at least h articles in that publication were cited at least h times each in the last 5 years
h5-Core	The set of articles from a journal with a citation count above the h5-index threshold
h5-Median	Median of the distribution of citations to the articles in the h5-core.

Table 4.3 Categories and number of subcategories in GSM

Categories	Number of subcategories
Business, economics, and management	16
Chemical and materials science	18
Engineering and computer science	58
Health and medical science	69
Humanities, literature, and arts	26
Life sciences and earth sciences	39
Physics and mathematics	24
Social sciences	52

  The classification scheme is made of 8 main categories and 302 subcategories. In each of the categories and subcategories, the number of results displayed is limited to the top 20 journals according to their h5-index.
  It should be pointed out that some subcategories are included in several categories (library and information science, for example, is included both in engineering and computer science, and in social sciences), and that one source may be included in more than one subcategory.
- *Search tool*: The platform also provides an internal search box, which enables users to locate journals that are not included in any of the general rankings. Users can carry out keyword queries, which will return sources with names that match the query. Each response to a query contains a maximum of 20 sources, also sorted according to their h5-index.

The peculiar features of this journal ranking have been tested, and numerous limitations found, such as a lack of name standardization, irreproducible data, and a questionable mix of publication typologies [4.20]. Nevertheless, the product has improved since its first editions, revealing itself as a potential source for the evaluation of journals in the areas of humanities and social sciences [4.21, 22].

4.3 Radiographing a *Big Data* Bibliographic Source

The goal of this section is to provide empirical data about the bibliographic properties of GS as a database. Three aspects will be discussed: size, coverage, and growth rate.

4.3.1 Size

One of the most crucial aspects that make us consider GS a *big data* source is the issue of determining its size. Unlike Scopus or WoS, highly controlled databases where finding out the total number of records only requires a simple query, GS is a search engine that presents what is available in the academic web at a specific moment in time. However, the web is not only dynamic, but also unstable and uncontrollable.

Therefore, the methodological difficulties of ascertaining the size of search engines are related to stability problems [4.23, 24], precision of the results obtained [4.25, 26], and the degree of permanence and persistence of the resources [4.27–29]. The high unstability of search results and the lack of precise search commands have led experts interested in finding the size of a search engine to use methods based on the extrapolation of frequencies of documents available in external sources [4.30].

As regards GS, there are two types of methods to calculate its size: direct methods (based on the execution of queries in the search engine) and indirect methods (estimations based on comparisons with external sources for which more information is known). Among the direct methods, three strategies are worth mentioning:

1. Web domain queries [4.31–33]
2. Year queries [4.3]
3. The so-called *absurd* queries [4.34].

Among the indirect methods, the capture/recapture method [4.35] and the proportion of documents in English respect to the total [4.34] have been attempted. For these last two methods, additional information must be known about the databases used as a reference. To date, these studies find that direct methods based on web domain queries and absurd queries are the ones that yield higher figures, which are similar in both cases.

Before discussing the calculation of the size of GS, it is appropriate to describe the characteristics of its coverage, since this is the key aspect to understanding the results. GS is currently made of two separate document collections: articles and case laws. The analysis of the latter is outside the scope of this chapter. The article collection is, in turn, divided into source documents and cited references (documents that GS's crawlers have only been able to find as references inside other source documents or certain metadata-only bibliographic databases). Cited references are marked with the text *[CITATION]* in SERPs and can also accrue citations of their own, which are displayed in the same way as for source documents. There is a last document type to which GS gives special attention in its interface: patents.

The integration of source documents and cited references in the same list of results breaks from the way WoS and Scopus handle these types of records, where each collection is displayed separately. In WoS, cited references are accessible from a completely separate search system (cited reference search), while in Scopus, cited references are also displayed separately as *secondary documents*.

There are two types of *[CITATION]* records: *Linked citations* (documents for which only basic bibliographic information—but no access to full-text—has been found in some library catalogue or metadata-only database) and *unlinked citations* (documents that have been cited in source documents and which the system has not been able to find anywhere else on the web).

Table 4.4 shows a compilation of the studies that have provided estimations of the size of GS. As can

Table 4.4 Compilation of studies on the size of GS

Authors	Date	Method	Coverage	Language	Size
Aguillo [4.32]	August 2010	Direct-domains	Articles + citations + patents	All	86 million
Ortega [4.3]	December 2012	Direct-date query	Articles + citations + patents	All	95 million
Khabsa and *Giles* [4.35]	January 2013	Indirect-cap/recap	N/A	English	99 million
Orduna-Malea et al. [4.34]	May 2014	Indirect-empirical studies	N/A	All	171 million
		Direct-date query	Articles + citations + patents	All	100 million
		Direct-absurd query	Articles + citations + patents	All	170 million
Aguillo [4.33]	January 2017	Direct-domains	Articles + citations + patents	All	194 million
Orduna-Malea et al. [4.36]	March 2017	Direct-absurd query	Articles + citations + patents	All	331 million
		–	Articles	All	184 million
		Direct-domains	Articles	All	197 million

N/A: not available

be expected, the results are affected by the estimation method, date of data collection, languages covered, and specific parameters of the searchers (inclusion or exclusion of cited references and patents).

Aiming to offer results as updated as possible, we replicated the absurd query in March 2017. A series of year queries, combined with the command 'fsdfsdgsdh.info' were carried out, and the number of hits each search yielded was collected. Through this simple procedure, we obtained a total of 184 001 450 source documents. Together with cited references (134 160 570) and patents (13 742 920), bringing the total to 330 804 940 documents.

Figure 4.2 offers a comparison of the size of GS, WoS core collection, and Scopus at two moments in time: 2011 and 2016. According to the most recent data, the coverage of GS seems to be almost three times as large as that of WoScc (2.8 : 1) and Scopus (2.7 : 1).

In order to test the robustness of the results, we compared the results returned by various types of queries to GS, carried out at different moments in time (Table 4.5). A high correlation was found among the results found for each year for all queries, regardless of whether or not cited references and patents were excluded.

Obviously, all these results are merely approximations of the size of GS. Its exact size cannot be ascertained with precision. Given the magnitude of the numbers the system returns (millions of documents), estimations are the best that we can expect when working with academic search engines.

Although the size of GS is clearly larger than that of other databases, the coverage by years can show us which database has a higher coverage in specific years. Figure 4.3 shows the number of documents by publication year that GS, WoS, and Scopus covered at the time of writing this.

As Fig. 4.3 shows, GS covers many more source documents than the other two databases, both for old material (first half of the nineteenth century) and recent

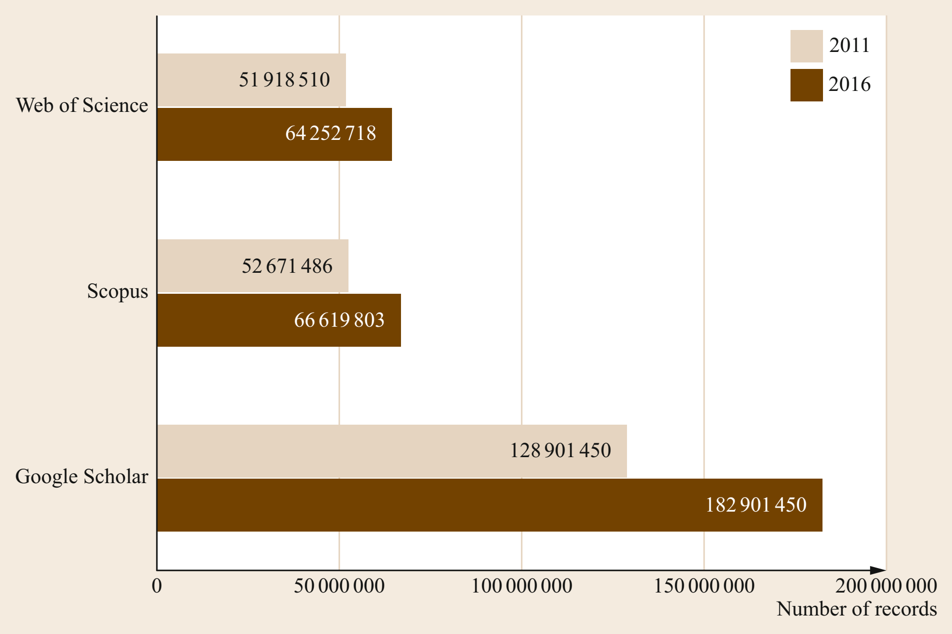

Fig. 4.2 Sectional coverage of GS, WoScc, and Scopus (from origin to 2016, included)

Table 4.5 Correlation among different queries (1800–2013)

Queries	Absurd pure (2017)	Date pure (2017)	Absurd full (2017)	Absurd full (2014)	Date full (2014)
Absurd-pure (2017)	1	0.997	0.992	0.978	0.976
Date-pure (2017)	0.997	1	0.994	0.984	0.983
Absurd-full (2017)	0.992	0.994	1	0.990	0.990
Absurd-full (2014)	0.978	0.984	0.990	1	0.995
Date-full (2014)	0.976	0.983	0.990	0.995	1

Pure: Excluding citations and patents
Full: Including citations and patents

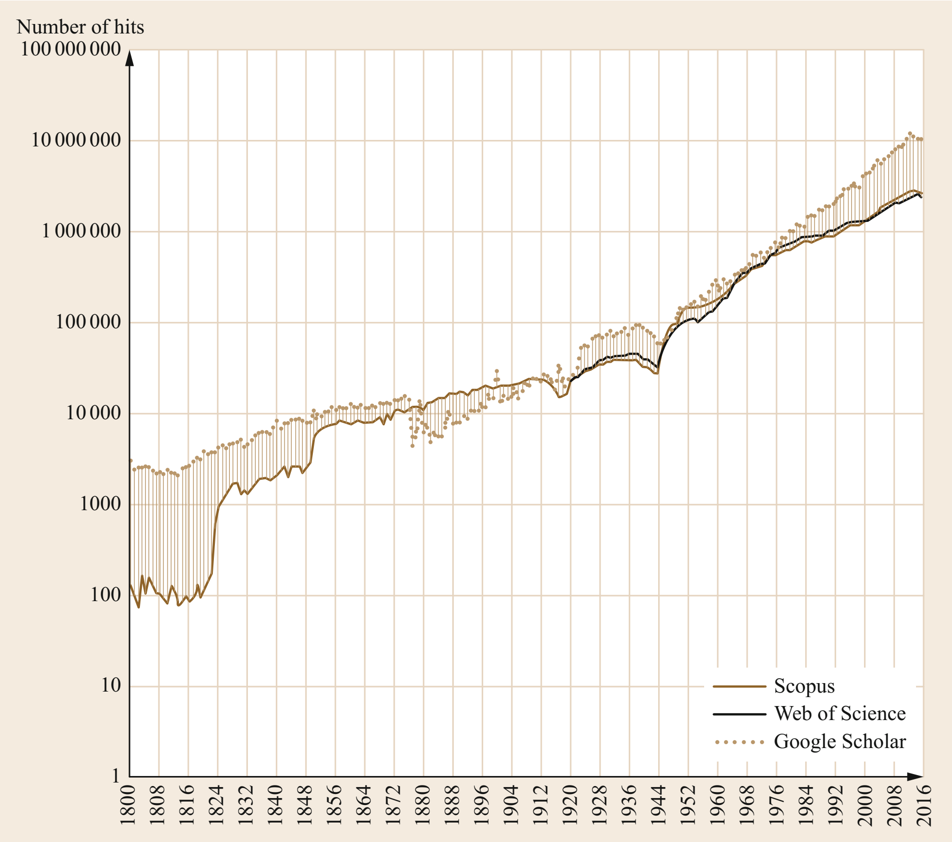

Fig. 4.3 Size of GS, WoScc, and Scopus (1800–2016). Note: The size of GS with respect to citing sources, eliminating cited references, in order to make GS comparable with the remaining databases

material (from the beginning of the twenty-first century onwards). The vast majority of the content covered by these databases was published in the current century (70.4% of all documents).

Up to this point, we have analyzed the size of GS by studying its source documents. However, it is also possible to approach this issue by studying the relationships between documents, that is, the citations themselves. As was previously said, an indirect method to find out the size of GS is to use other databases as a benchmark. Differences in citation counts in documents that are covered both by GS and the database used as a reference can be considered an indication of the underlying differences of their document bases: If a database has been able to find more citations than another database for a particular set of documents, its document base must be bigger (assuming the citation tracking mechanisms of the databases under comparison have roughly the same effectiveness).

Numerous studies have been published on this issue, most of them comparing GS to WoS and/or Scopus. The units of measurement used in these studies are varied:

1. Number of publications
2. Number of citations
3. h-indexes
4. Percentage of unique citations in each database.

A simple summary of these empirical results can reveal to which degree the size of GS's document base is bigger than that of the traditional databases, and how these differences have changed over time.

A table with a list of 63 empirical studies that address the issue of the size of GS as compared to WoS and/or Scopus is available in the electronic supplementary material [4.14, see Appendixes I, III, and IV]. For each study, the sample, discipline studied, unit of measurement used, results obtained, and ratio between the results for GS and the other databases are given. The results must be interpreted with caution, because the ratios depend to a large degree on the disciplines studied, the geographic scope (international or national), and the linguistic scope. Moreover, they can also be affected by the size of the samples (which, in general, tended to be very small).

From this meta-analysis, we can confirm several facts:

- To date, there are few studies that compare GS, WoS, and Scopus at the same time. The most frequent comparison is between GS and WoS.
- The vast majority of studies make comparisons on the basis of citations (54), way ahead of those that use documents—usually articles—(24), or indicators like the h-index (12).
- Out of the 63 studies, only 8 yielded results where WoS and/or Scopus surpassed GS in terms of size. All these studies analyzed STEM (science, technology, engineering and mathematics) fields, like chemistry. The majority of studies show that, for any given set of documents covered both by GS and WoS/Scopus, the first is able to find a higher number of citations.
- The greatest differences in favor of GS are found in the humanities and the social sciences. As regards STEM disciplines, GS is still able to find more citations, but the differences are less marked.
- The differences are greater when comparisons are made on the basis documents written in languages other than English.
- The differences between GS and the other databases seem to increase in the more recent studies, which might indicate an even broader coverage in GS respect to the other databases in recent years.
- Ratios of GS indicators to indicators from other databases are lower when comparisons are made on the basis of the h-index or the number of publications, and they are higher when citations are used instead. Ratios are even more in favor of GS when only unique citations are analyzed (citations found in one database and not in the others). These unique citations in GS, that is, its ability to find citations that no other database is able to find (not limiting itself to strictly scientific sources, but covering all the academic and professional sources it can find), are what make GS truly unique.

So as to provide a broader and more updated perspective on this issue, we have analyzed two large samples of documents covered both by GS and WoS. The results are consistent with the previous studies.

According to the samples analyzed in Table 4.6, the ratio of GS citations to WoS citations ranges from 1.54 (for a sample of 2.32 million articles and reviews published in 2009 or 2014) to 1.80 (for a sample of 69 261 highly-cited documents).

4.3.2 Coverage

After studying the size of GS, this section will focus on the characterisation of its content. To this end, its source, geographic, linguistic, discipline, and document type coverage will be discussed.

Source Coverage

Unfortunately, neither GS nor its secondary products (GSM and GSC) provide a master list of sources. As previously said, GS is not a journal database, but a service that indexes academic documents from many web domains. For this reason, efforts to determine its sources should try to identify these web domains first.

The first exhaustive study of the sources covered by GS based on web domains was carried out by *Aguillo* [4.32], who concluded that the most frequent geographic country code top-level domain (ccTLD) was '.cn' (China), and that Harvard University was the higher education institution that contributed more content to GS. *Ortega* [4.3] went a step further by estimating the proportion of content provided by several types of content providers:

1. Publishers (41.6%)
2. Other Google products (22.5%)
3. Subject repositories (16.9%)
4. Institutional repositories (11.8%).

Martín-Martín et al. [4.37] analyzed the sources of the primary versions of a set of 64 000 highly-cited documents in GS, finding close to 6000 content providers, among which the US National Institutes of Health (nih.gov), ResearchGate (http://researchgate.net), and Harvard University (harvard.edu) were the main providers of highly-cited documents. This study also found that generic top-level domains (TLDs) like

Table 4.6 Compilation of self-elaborated materials on GS/WoS citation ratios at the document level

Source	Date of data collection	Description	*N*	GS citations	WoS citations	Ratio GS/WoS
Self-elaborated. Publication forthcoming	June–October 2016	Articles and reviews with a DOI covered by WoS, published in 2009 or 2014. WoS data extracted from web interface	2.32 million	42.6 million	27.6 million	1.54
Self-elaborated for this chapter	February 2017	Highly-cited documents in master sample. WoS data extracted only from GS/WoS integration	69 261	80.8 million	44.9 million	1.80

'.edu', '.org', and '.com' were more frequent that geographic TLDs. Lastly, *Jamali* and *Nabavi* [4.38], based on a series of topic queries, used GS to estimate the sources (http://researchgate.net, http://nih.gov) and top-level domains ('.edu' and '.org') with a higher proportion of open-access documents.

Aiming to offer more updated results, we carried out a series of *site* queries in GS to find out the number hits returned for each of a list of 268 TLDs (251 geographic domains and 17 first-generation generic domains). The searches were carried out in March 2017. Publication year restrictions were not used, and cited references and patents were excluded.

Table 4.7 shows the main providers of documents according to their TLD. China is first among the geographic TLDs (12.12% of the total content), and commercial companies (.com) lead the list of generic domains (45.39% of the total content).

The sum of the results obtained for these 268 domains comes to 197 194 092 source documents, which is similar both to the one we obtained with the absurd query method in the previous section (184 001 450), and the one obtained by *Aguillo* [4.33], who used the same methodology (193 824 176). This reinforces the notion that the real number of source documents (excluding cited references) lies at around 200 million records. This figure is, however, a gross estimate, because there may be many duplicates, which will provoke an overestimation. At the same time, the fact that site command only counts primary versions would cause an infra-estimation if the web domain of the primary version does not match the web domain queried with the site search command.

Otherwise, the results indicate that most of the content is hosted on websites with generic (not geographic) TLDs (69.7%), undoubtedly because of the weight of journal publishers, standalone journals, and American universities (.edu).

For the purpose of delving deeper into the issue of source typologies, we proceeded to calculate the size of five types of web domains. We wanted to illustrate the diversity and weight of the different types of sources from which GS feeds: digital libraries and bibliographic information systems (Table 4.8), publishers (Table 4.9), learned and professional societies (Table 4.10), US government agencies and international organizations (Table 4.11), and universities (Table 4.12). These tables present the number of results found for each element, both including and excluding cited references. The goal of these tables is to enable us to observe which sources generate a higher quantity of bibliographic records in GS. Lastly, it is worth remembering that these results only consider the primary versions of the documents (those GS has selected as primary versions), and, therefore, these tables should not be understood as a ranking of sources sorted by size, but rather, a list that shows the diversity of sources available in GS.

The results in Tables 4.8–4.12 illustrate the main sources from which GS feeds: big bibliographic information systems, including databases (Pubmed, Europe

Table 4.7 Top 20 domain sources of GS (2017)

Rank	TLD	%	HCE	Description	Type
1	.com	45.39	89 500 000	Commercial	Generic
2	.org	16.38	32 300 000	Noncommercial	Generic
3	.cn	12.12	23 900 000	China	Country
4	.edu	3.55	7 010 000	US accredited postsecondary institutions	Generic
5	.jp	3.40	6 700 000	Japan	Country
6	.net	2.06	4 070 000	Network services	Generic
7	.ru	1.72	3 400 000	Russian Federation	Country
8	.gov	1.69	3 340 000	US Government	Generic

Pubmed Central, ADS), big commercial publishers (Elsevier, Springer and Wiley in particular), other academic search engines (Semantic Scholar, Citeseer, ...), subject repositories (arXiv.org), social platforms (ResearchGate, Academia.edu), as well as Google's own book platform (Google Books). It additionally includes, research government agencies (like the Japanese National Institute of Informatics and the Japan Science and Technology Agency), professional associations (IEEE), and universities (Harvard University is still leads this group). It should be noted that the results of some institutions (especially universities) are influenced by the existence of bibliographic products that are hosted within these universities' domains (Dialnet at the University of La Rioja, CiteseerX at Pennsylvania State University, AGRIS in FAO, ERIC in the US Department of Education, etc.).

However, these results should be interpreted with caution, because the methodology used to collect the data has several limitations: All hit counts displayed by GS (and Google, for that matter) are only approximations, not exact figures. What is more, the *site*: command is not exhaustive either; it only works with the primary versions of the documents in GS. GS implements a procedure to group together all the versions of a same document that may be available on the web [4.39]: subject and institutional repositories, the author's personal website, a social platform, and the official *version of record* available in a journal or on publisher's website. From all the versions found by the search engine, one of them (usually the publisher version, if there is one) is selected as the primary version. The rest of the versions can be found under the *All x versions* link available below each record.

This means that when a search containing the site: command is carried out, the system will only return the records in which the source of the primary version matches the searched source, even though there may be many more records from that source that have not been considered primary versions. If we focus on the case of ResearchGate, we can see that the 2 020 000 documents found (Table 4.8) are very far from the over 100 million documents the company claimed to cover in March 2017 [4.40]. This difference can be explained in part by the documents that are covered as secondary and not primary versions. For these reasons, the results in Tables 4.8–4.12 are most likely an underestimation of the real coverage, although it provides important clues as to the main sources it indexes.

Geographic Coverage

The geographic coverage of the documents covered by GS is also difficult to analyze, because the system is not designed to carry out searches based on authors' institutional affiliations. Therefore, like with the source coverage, a possible, although biased, approach is to analyze the distribution of geographic domains. *Orduna-Malea* and *Delgado López-Cózar*, using this methodology [4.41], found that the domains for the United States, China, and Japan were the ones that yielded the highest hit counts estimates (HCE), which is consistent with the results obtained by *Aguillo* [4.32]. Table 4.13 shows the top ten geographic domains according to their HCE, and their evolution in the last 6 years [4.32, 41].

This strategy, however, is imprecise, because it does not consider generic TLDs like '.com' and '.org', which are precisely the ones that are most used. This explains why the United States are clearly under-represented, since a great proportion of '.com' domains belong to institutions from this country [4.42].

There are few studies on the geographic distribution of documents in GS, and those few that have been published focus on the geographical origin of the journals indexed in GSM, and the comparison of these journals with the ones covered by WoS and Scopus in specific disciplines like communication [4.43], nursing [4.44], and library and information science [4.45] (Fig. 4.4). GS and GSM seem to get closer to the actual distribution of scientific journals by country of publication than the other databases.

Similar results were found in a study of over 9000 arts, humanities, and social sciences journals indexed in GSM, where GSM not only covers journals from more countries, but the English-language bias is clearly less pronounced than in Scopus and WoS (Fig. 4.5).

Linguistic Coverage

It is also difficult to find out the language distribution of the documents covered by GS, because the

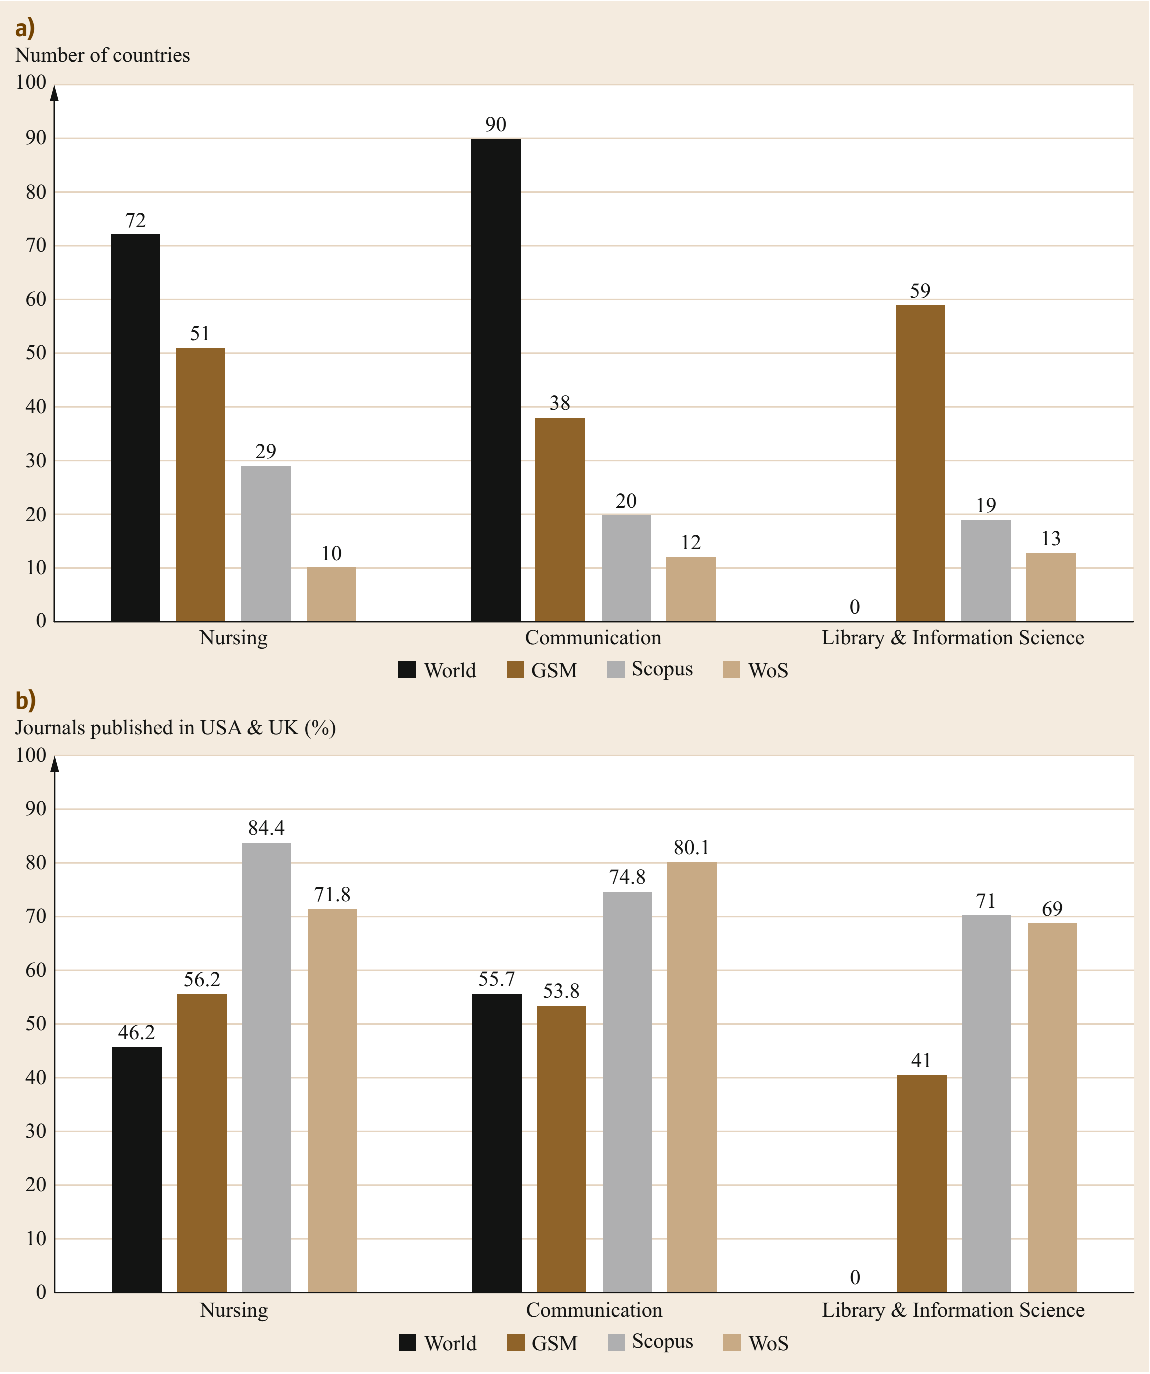

Fig. 4.4 Nursing, communication, and library and information science journals published according to GSM, Scopus, and WoS data **(a)**. Number of countries where the journals are published **(b)**. Percentage of journals that are published in the USA or UK. Note: In the case of library and information science journals, GS is used instead of GSM; and no data is available for the world category

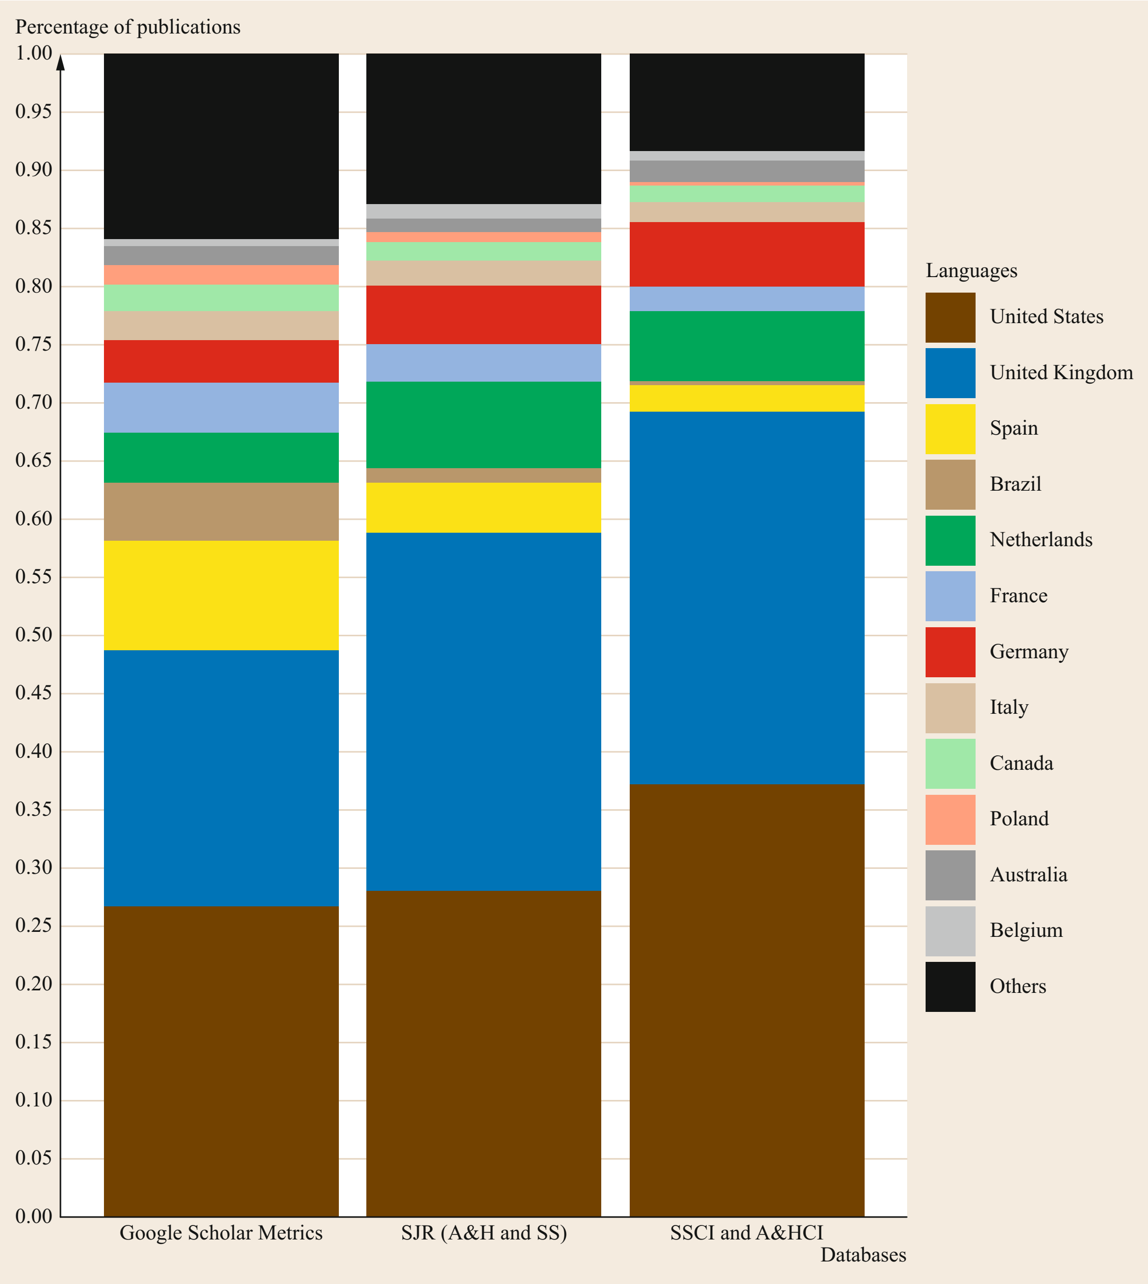

Fig. 4.5 Distribution of countries of publication in arts, humanities, and social sciences journals covered by GSM, SJR (Scopus), and JCR (WoS)

options the interface offers to filter by language are very limited. Users can limit search results to one or several of the following languages: Chinese (simplified and traditional), Dutch, English, French, German, Italian, Japanese, Korean, Polish, Portuguese, Spanish, and Turkish. However, users have to navigate to the settings page to find these options; they are not available from the main search interface.

In a study carried out by *Orduna-Malea* and *Delgado López-Cózar* [4.41], which analyzed the quantity of records by language in WoS, Scopus, and GS, a very high percentage of documents written in English was found in the first two databases (90%), while GS offered a higher linguistic diversity, because it covered other languages (especially Italian, Spanish, French, and Japanese). A year later, *Orduna-Malea* et al. [4.34], based on an analysis of the empirical studies on this topic, estimated that documents in the English language represented approximately 65% of all documents in GS.

Studies on the publication languages of journals available in GSM, as compared to those available in WoS or Scopus, reach the same conclusions. Both in communication journals [4.43], nursing journals [4.44], as well as in library and information science journals [4.45], GSM is closer to the actual distribution of languages used in scientific journals around the world, thus overcoming the bias towards English-language sources that prevails in Scopus and WoS (Table 4.14). While in the latter two, the proportion of English-language sources ranges from 80 to 93% of all sources, in GSM this figure is much lower: between 61 and 65% (Table 4.15).

An analysis of the arts, humanities, and social sciences journals available in the 2010–2014 edition of GSM yields similar results: GSM not only covers journals written in more languages, but its English-language bias is also lower than in the other two databases (Fig. 4.6), in spite of the fact that the study focused only on journals with titles written in Latin characters. GSM, because of its inclusion criteria, does not cover many journals for which articles are available in GS.

Aiming to obtain additional empirical data about the linguistic distribution of the content available in GS, we carried out a series of searches in GS. For each of the 12 languages that GS allows users to choose from to limit the search results (simplified Chinese, traditional Chinese, Dutch, English, French, German, Italian, Japanese, Korean, Polish, Portuguese, Spanish, and Turkish), 67 keyword-free, publication year queries were carried out, one for each publication year for the period 1950–2016 (871 queries in total).

Table 4.14 Number of different languages in nursing and communication journals indexed in GSM, Scopus, and WoS

Discipline	World	GSM	Scopus	WoS
Nursing	33	20	13	6
Communication	23	14	7	6

Table 4.15 Percentage of journals published in English in nursing and communication, and indexed in GSM, Scopus, and WoS

Discipline	World	GSM	Scopus	WoS
Nursing	57.2	61.9	81.2	92.7
Communication	70	65.3	91.6	87.8

Table 4.16 shows the distribution of results by language (excluding cited references and patents). As can be seen, English-language results make up half of the total amount of results (49.8%), followed by the sum of simplified and traditional Chinese results (33.7%). These results are consistent with the figures on geographic coverage through the analysis of web domains presented previously and confirm the preeminence of the United States and China in GS's coverage.

Even considering the disproportionately huge amount of English and Chinese results (which are clearly influenced by the sources from which GS extracts data), the distribution of the other languages is unquestionably more varied than the distribution presented by other databases. Figure 4.7 shows the relative distribution of languages in GS, Scopus, and WoS.

While the percentage of documents published in English in WoS and Scopus is of 90 and 80%, respectively, in GS the percentage is closer to 50%, and therefore the rest of languages are noticeably better represented.

Again, we would like to warn that the results obtained must be interpreted in the context of a search engine, and not a bibliographic database. GS automatically identifies the language of a document from certain parameters. However, a document might contain text in several languages. Therefore, the same document might be classified in various languages. Additionally, in some cases, the fact that a document is hosted in a geographic domain can help GS identify its language (for example, '.cn' is associated with the Chinese language), even if sometimes the documents are not written in the expected language [4.46]. For those reasons, the number of results might be an overestimation.

Table 4.16 Distribution of languages in GS results (cited references and patents excluded)

Language	Documents	(%)
English	90 932 140	49.76
Chinese	61 545 203	33.70

Total	182 716 450	100

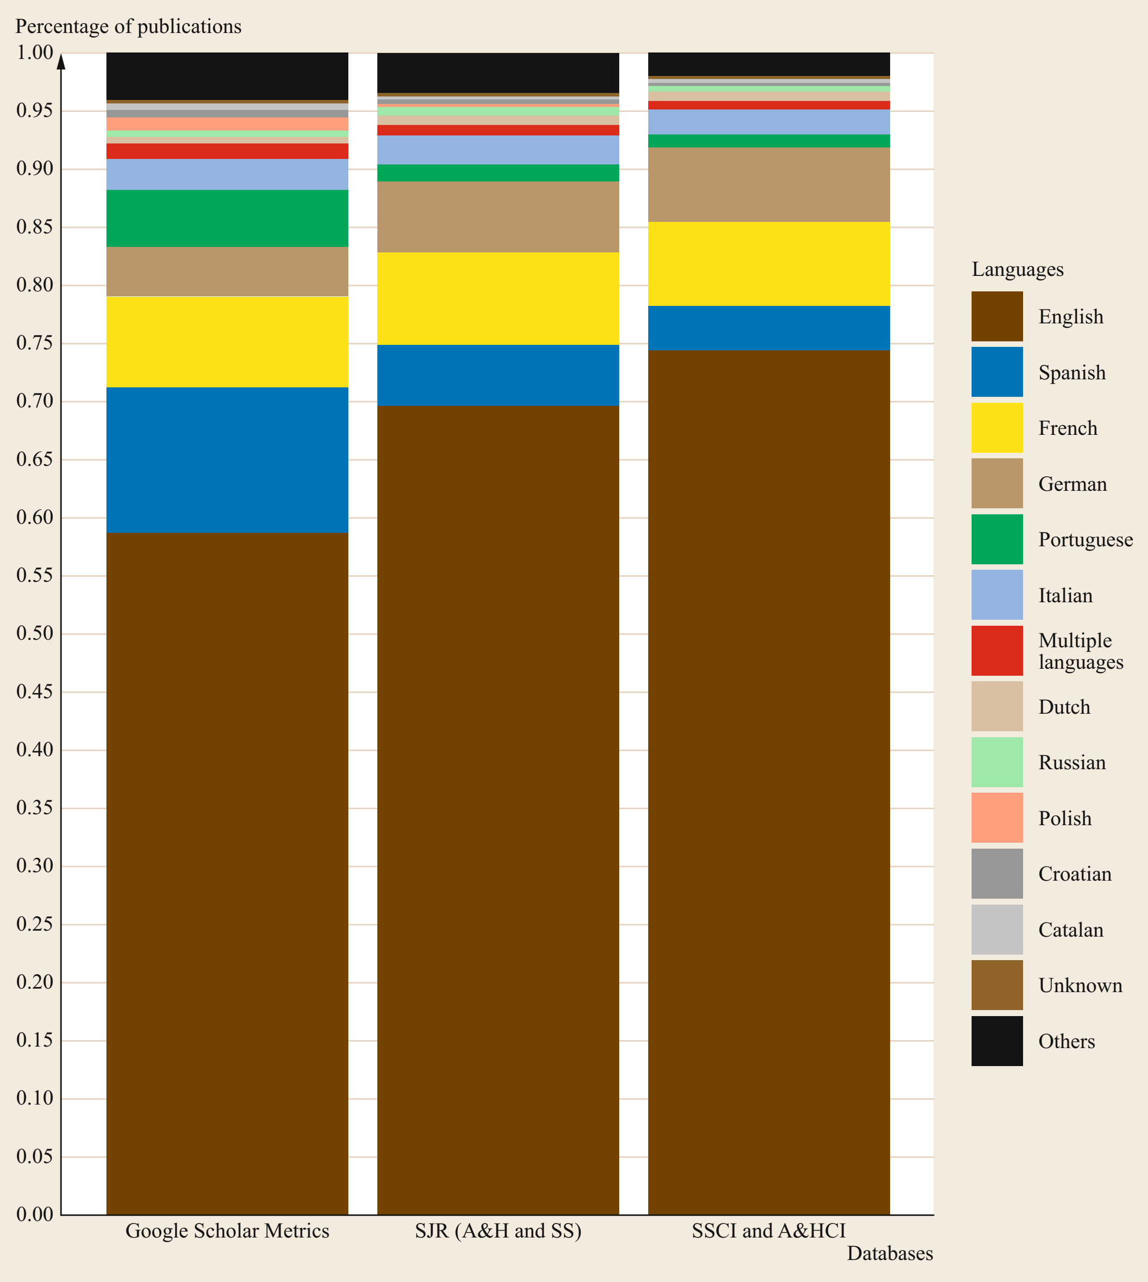

Fig. 4.6 Distribution of arts, humanities, and social sciences journals indexed in GSM (2010–2014) as compared to SCImago journal Rank (arts and humanities (A&H) and social sciences (SS) only), and journal citation reports (SSCI and A&HCI (Arts and Humanities Citation Index))

Discipline Coverage

Discipline coverage is another crucial aspect of the analysis of a bibliographic database. However, studies published to date mostly deal with journal coverage in GS as regards specific disciplines and countries.

From the data available about Spanish journals in the areas of social sciences, covered by GS and GSM in the year 2011 [4.47], and the data available in IN-RECS [4.48], a ranking of Spanish journals in disciplines related to the social sciences, a very informative table about the coverage of GS and GSM was developed (Table 4.17). Of the 1090 Spanish journals studied in IN-RECS, 95.2% (1038) were covered by GS. What is more, for some disciplines, GS covered even more

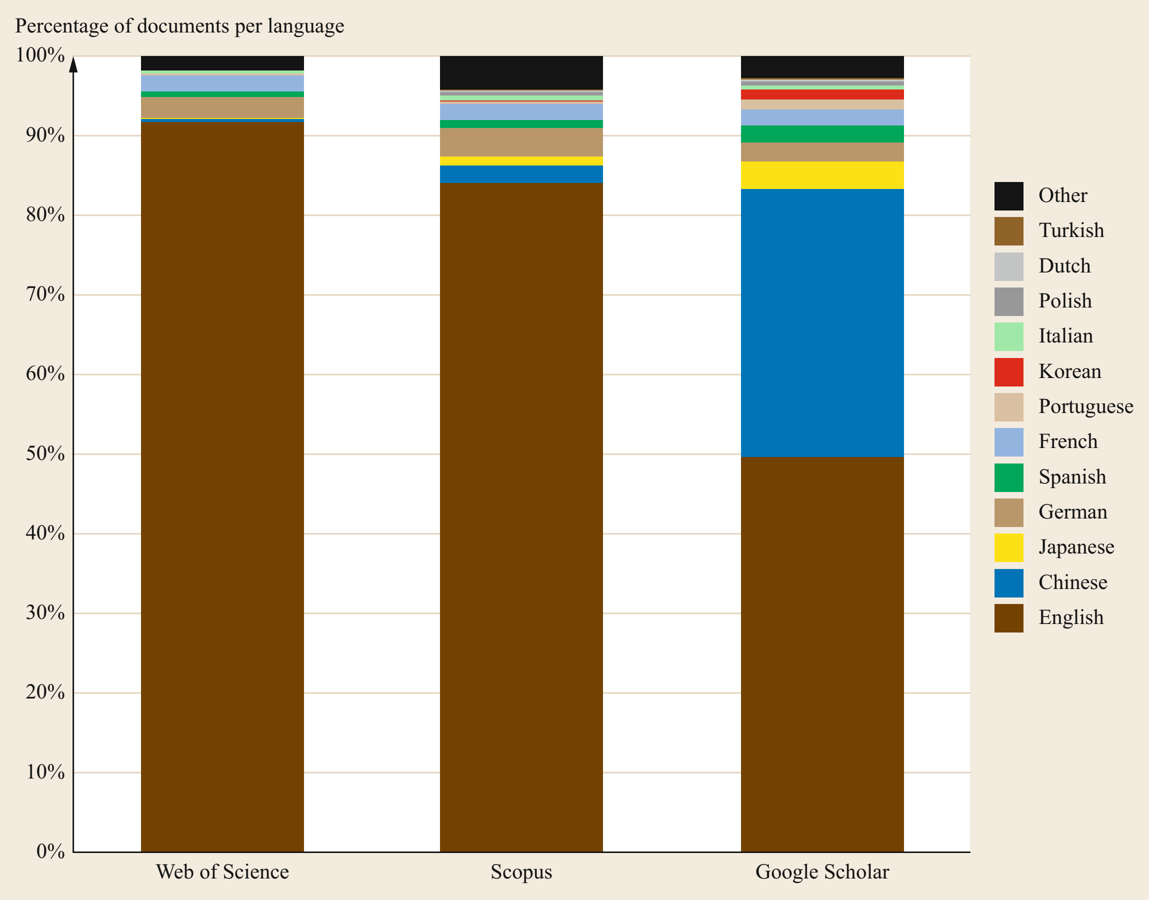

Fig. 4.7 Distribution of the languages of documents indexed in GS, Scopus, and WoS (1800–2016)

Table 4.17 Coverage of Spanish journals by discipline in IN-RECS, GS, and GSM

Discipline	IN-RECS	GS		GSM	
	Year (2010)	Year (2011)	Coverage (%)	Year (2011)	Coverage (%)
Law	341	251	74	110	43.8
Education	166	157	95	69	43.9
Economy	136	137	101	55	40.1
Psychology	108	109	101	42	38.5
Sociology	82	87	106	25	28.7
Political science and administration	60	56	93	21	37.5
Geography	51	54	106	15	27.8
Anthropology	46	46	100	10	21.7
Sport	N/A	42	N/A	14	33.3
Urban studies	43	39	91	15	38.5
Library and information science	33	36	109	15	41.7
Communication	24	24	100	12	50.0
Total	1090	1038	95	403	37.0

journals than IN-RECS. If we extrapolate those results, we can estimate that GS is very close to covering all active scientific journals. Of course, this hypothesis would require a more varied sample of journals to be tested.

On the other hand, GSM covers just over a third of all active Spanish social sciences journals (36.97%). This is most likely caused by the inclusion criteria enforced by the system (journals must have published

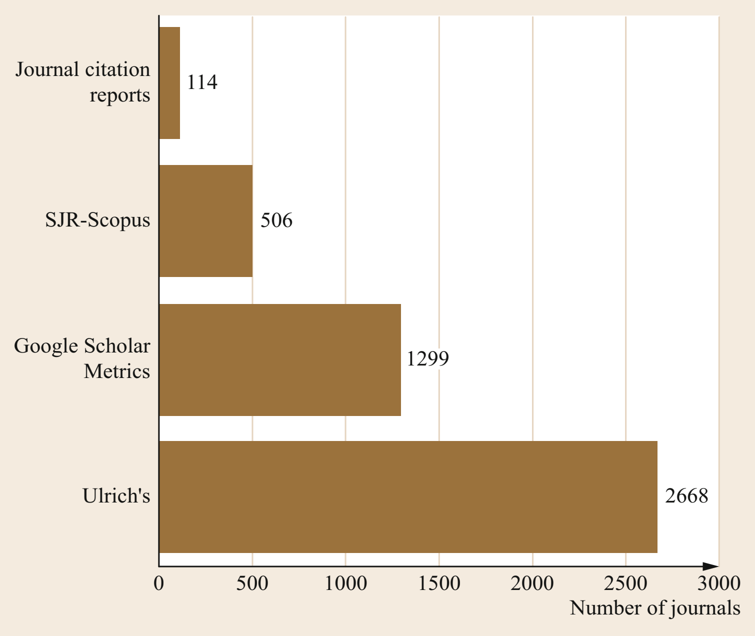

Fig. 4.8 Number of Spanish scientific journals covered by journal citation reports, Scopus, GSM, and Ulrich's directory

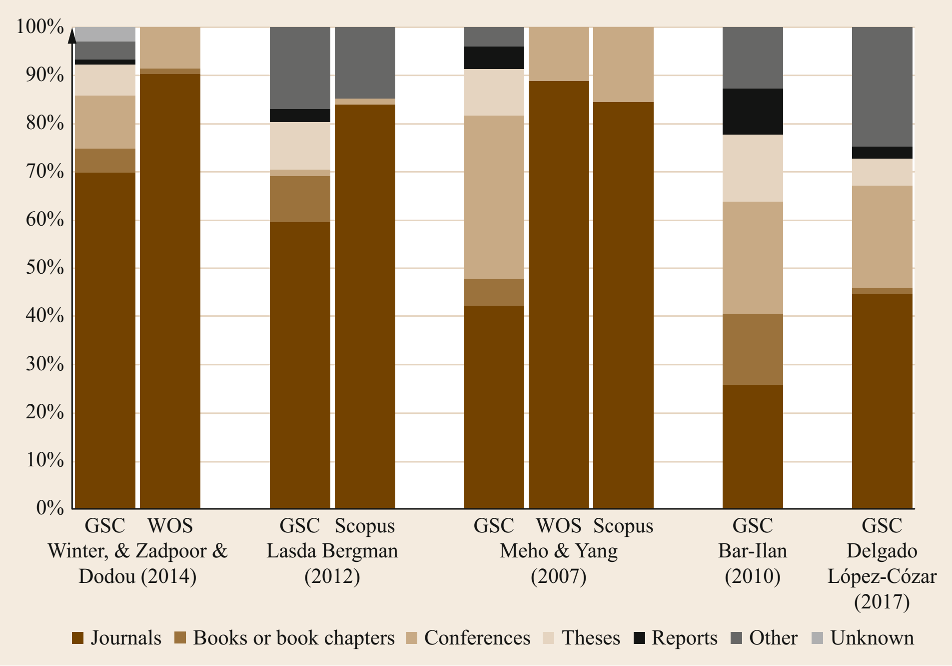

Fig. 4.9 Comparison of the document type distributions in GS, WoS, and Scopus as found in several studies

at least 100 articles in the last 5 years and have received at least one citation). Nevertheless, even with those limitations, GSM still covers many more journals than traditional databases (WoS and Scopus), and, therefore, is able to display a much broader spectrum of disciplines, better representing the scientific landscape.

In a study focused on the quantity of Spanish journals indexed in GSM, as compared with the total number of active Spanish journals, which according to the Ulrich's directory is around 2668 journals [4.49], similar results are obtained. Only 48.7% (1299) of Spanish journals were found in GSM (Fig. 4.8), but if this result is compared to the traditional journal rankings, we find that, in spite of its inclusion criteria, GSM covers twice the amount of journals than SJR (Scopus data), and ten times more than the journal citations reports (WoS data). However, there are studies that yield different results. *Gu* and *Blackmore* [4.50] find that, of a sample of 41 787 refereed academic journals from all disciplines covered by the Ulrich's directory, only 20.8% (10 354) were to be found in GSM, a lower amount than those that were found in SJR (32%, 15 911).

An additional method to quantify the number of publications covered by databases is to analyze the number of citations received by a sample of documents in a specific scientific discipline. With this approach, we can find studies focused on journals [4.51, 52] and researchers [4.53–56]. There is one other approach, based on the characterization of the documents returned by GS to sets of topic queries [4.38].

Important disciplinary differences can be observed in the list of studies that offer empirical evidences on the functioning of GS. While in the social sciences, the humanities, and engineering (especially in computer science) the ratio of citations in GS to citations in other sources is very high, the differences are much lower when STEM fields are analyzed. As was previously commented, the field of chemistry was initially covered poorly in GS, mostly due to the refusal of the American Chemical Society and other important publishers to be indexed by the search engine. These problems have already been solved [4.53, 57].

Document Type Coverage

Lastly, the last aspect of the coverage of GS has to do with document typologies. In order to learn about the wealth and diversity of document sources from which GS extracts data, we must summarize the results offered by the studies that have analyzed the distribution of citing documents according to their typology in several databases (Fig. 4.9). The main feature of GS is that it indexes more diverse document typologies. Indeed, it is the database where journal articles constitute a lower percentage of the total documents (from 28 to 70% depending on the samples). Conversely, in WoS and Scopus, journal articles make up 90% of the documents, which means there is a very limited coverage of conference communications and books.

Aiming to obtain more updated and representative results, a total of 871 queries (by language and year of publication) were carried out (including cited references and patents in the search), extracting the 1000 search results available for each query. There were 861 843 documents extracted [4.58].

Given that GS does not provide information about the typology of the documents that are displayed in

Table 4.18 Distribution of document typologies in GS ($N = 861\,839$ documents)

SERPs, document type identification becomes a rather complex task. By means of matching techniques to other data sources (WoS, CrossRef), and by applying a set of heuristics to extract more metadata from the websites that hosted the documents, the typology of 53.8% of the documents in the sample was ascertained (398 549). Table 4.18 shows the number of documents by typology and language.

If we focus only on the documents for which the typology could be identified, articles (65.3%) and books (30.2%) are the most frequent typologies, followed at a distance by doctoral theses and conference communications. However, we must bear in mind the limitations of the sample. The search strategy used (keyword-free searches which were only limited by year and language of publication), combined with GS's limitations (a maximum of 1000 results per query, sorted by GS's relevance ranking algorithm), result in a sample biased towards highly-cited documents, because the number of citations is the parameter that weighs the most in these types of queries [4.58].

In order to illustrate the bibliographic diversity in GS, Table 4.19 provides a list of the document types analyzed in the empirical studies that have addressed this issue.

Table 4.19 Document typologies found in GS

Clearly, GS's bibliographic wealth is due to the manner in which it indexes information: The search engine indexes any document that is hosted on the academic web, providing it meets certain technical and structural criteria. The consequence, at any rate, is that the presence of full text conference proceedings, book chapters, reports, patents, presentation slides (either from university courses, conferences, or other events), and especially monographs and doctoral theses make of GS a unique tool not only to find information, but also to find citation data that is not available anywhere else.

4.3.3 Growth Rate

Although Sect. 4.3.1 already presented some results as to this search engine's growth rate (even comparing it to Scopus and WoS), a sectional approach such as the one represented in Fig. 4.2 misses the main properties of GS, such as its dynamic nature. All content (both source documents and their citations, new or old) in GS is updated automatically.

As regards longitudinal analyses, *Harzing* [4.53, 59] studied the growth of citations to 20 Nobel Prize winners in 4 disciplines, detecting a growth of 4.6% from April 2012 to April 2013. A similar result (4.4%) was found by *Harzing* and *Alakangas* [4.54], where 146 senior researchers from the University of Melbourne were analyzed.

Retroactive growth (that is, the inclusion of documents published a long time ago) was addressed in part by *De Winter* et al. [4.52], who analyzed the relative difference between citation counts to a classic article up to mid-2005 measured in mid-2005 and citation counts up to mid-2005 measured in April 2013.

The speed with which GS indexes new source documents (and finds more citations to documents already in its document base) was addressed by *Moed* et al. [4.56]. The authors compute the indexing speed of GS for 12 journals in 6 different disciplines, and compare the results to those found in Scopus. Although there are differences among disciplines, and results are affected by the open-access policies of big publishers, the authors find that "the median difference in delay between GS and Scopus of indexing documents in Scopus-covered journals is about 2 months." The latest study on this issue to date was written by *Thelwall* and *Kousha* [4.60], which focuses on early citations to journal articles. They selected a sample of articles published in library and information science (LIS) journals between January 2016 and March 2017. The results in GS are compared to those in WoS, Scopus, and ResearchGate. The results in this study show that GS clearly outperforms all the other databases in terms of finding early citations,

[a] Not indexed in Scopus because they are book reviews
N/A: Not available

although ResearchGate's data is quickly becoming an interesting source for citation data as well.

What follows is a small-scale analysis that aims to illustrate this phenomenon, which has consequences not only for document searches, but on the speed with which citations are detected in the system. Articles accepted by the *Journal of the Association for Information Science and Technology* (JASIST) and made available as advance online publications between January 1st and March 25th, 2017 were identified, noting the specific date when they were made available online. Secondly, those articles were searched in GS, and, in the cases when they were found, the exact date of indexing was saved (this information is available when documents are sorted by date). Knowing these two dates, we were able to compute the speed of indexing (number of days since the article was first available online, until GS picked it up). Results are displayed in Table 4.20.

On the date of data collection (March 26th) GS had indexed 13 out of 24 of the articles analyzed from the publisher's website, although in 4 cases the date of indexing in GS was not available, because these documents were previously available in GS as preprints. What is more, out of the 11 articles GS had still not picked up from the publisher's website, 9 were available from other sources (mainly subject or institutional repositories). Only the two most recent articles (available on the publisher's website only 1 day before the analysis was carried out) were not available in GS in any form. As regards the indexing speed, it ranges from 1 to 3 days. It is worth taking into account that there is a ± 2 day margin of error, because we know the date of indexing but not the exact hour. According to these data, it seems that it only takes around 2 days for documents published in JASIST to be indexed in GS, although a larger sample would need to be analyzed to confirm this for sure.

If we compare these results to the coverage of these documents in other databases, we can observe that Scopus had indexed the documents that had been made available up to March 13th. Although the exact date of indexing in Scopus is unknown, it was necessarily below 13, a very respectable speed considering it is a controlled database. However, these documents are classified as *in press* in the platform, and Scopus does not compute citations to documents until they are formally published in a journal issue, something that can take months. WoS does not index documents until they have been formally published, and therefore does not cover any of the documents in the sample.

4.4 Google Scholar's Data for Scientometric Analyses

Lastly, this chapter would not be complete without addressing the limitations of this search engine as a source of data for bibliometric analyses.

It is important to differentiate between the limitations from which this platform suffers by design for a specific purpose, and the various kinds of errors that the search engine makes when it processes data from the academic web. Errors are deviations from the expected or normal functioning of the tool (like, for example, the existence of duplicate citations, versions of the same document that have not been merged, incorrect or incomplete attribution of authorship, etc.). Limitations, on the other hand, refer to the characteristics that can compromise the suitability of the tool for a specific purpose, especially if it is not the original purpose for which the tool was first developed (like, for example, using GS as a source of data for bibliometric analyses, instead of as a search tool).

4.4.1 Errors in Google Scholar

The studies that have been published on the topic of errors found in GS are rather disorganized and superficial. There are few empirical evidences, and they often lack proper systematic study backed by representative samples. Most of the time, only anecdotal evidence is presented, without addressing the important issue of the degree of pervasiveness of the errors (how often the errors occur throughout the document base). The results in these studies are difficult to summarize and compare, and they become obsolete very quickly, because GS is constantly being updated and introduces improvements to its algorithms regularly.

Following in the footsteps of the numerous and sharp studies carried out by *Jacsó* [4.12, 31, 54–69], below we present a taxonomy of the types of errors made by GS. We propose to divide errors into four broad groups (search-related errors, parsing-related errors, matching errors, and source-related errors), as described in Table 4.21. These errors can affect bibliographic records (authorship, source or year of publication, etc.) and citations themselves. A more in-depth discussion of the errors that can be found in GS was recently published by *Orduna-Malea* et al. [4.36].

4.4.2 Google Scholar Limitations

After describing the most common type of errors in the database, this section describes the main limitations for the use of GS as a source for bibliometric studies and research performance evaluation. To this end, we have prepared three descriptive sheets listing the limitations of GS search, GSC, and GSM, because although some limitations are present in all three products, some of them are particular to only some of them.

Each descriptive sheet contains several sections:

1. Coverage
2. Search and results interface

Table 4.21 Types of errors in GS

Type of error	Description
Search-related	Those related to the process of searching information
Parsing-related	Related to the process of identifying and extracting bibliographic information about documents from websites or full texts (including cited references)
Matching	Those related to the process of identifying different versions of a same document in order to remove duplicates
Source-related	Which affect the links that lead to the source in which the document has been found

Table 4.22 GS descriptive sheet

GS ***Coverage***
Lack of transparency in its coverage[a]: ● There is no public master list of the sources GS indexes (publishers, repositories, catalogues, bibliographic databases and repertoires, aggregators, ...). ● There is no public master list of journals indexed in the platform.
Non-scientific and non-academic documents are also occasionally covered: course syllabi, library guides, tweets, ...
There is no accurate method to estimate the size of GS.
Data is not stable. GS is dynamic and reflects the state of the academic web at a certain moment in time, ... The irregularity and unpredictability of GS's indexing speed may bias some bibliometric analyses if it is not taken into consideration.
Full text files that exceed 5 MB can be found on GS, but their full text will not be indexed (cited references will not be analyzed).
Easy to manipulate: Anyone can obtain a fully or partially fabricated document indexed in GS by uploading it to a university domain or public academic repository.

Table 4.22 (continued)

GS ***Search and results interface***
The advanced search form is limited to four search dimensions: keywords (with assisted Boolean operators, and the possibility to search only in the title of the document, or anywhere in the article), authors, source of publication (journal, conference, ...), and year of publication.
The number of records displayed in each results page is 10 by default. It can be increased to 20 on the settings page. In the past, however, it was possible to increase this number up to 100.
Only the first 1000 results for any query can be displayed. Similarly, even if a document has received more than 1000 citations, only the first 1000 can be displayed when clicking the *Cited by* link.
Results can only be sorted by relevance or by date of publication: • Relevance: This is the default method. Although the specific parameters that are taken into consideration for this sorting method have not been publicly disclosed, it has been found that the number of citations received by documents, as well as the language of the document in relation to the user's preferred language, both weigh heavily in the relevance sorting algorithm. • Publication date: limits the search to documents published in the current year.
There are only three result filtering options once a search has been made: • By document type, limited to three categories: case laws, patents, and articles. The latter category includes journal articles, books or book chapters, conference proceedings, technical reports, theses ... • By type of record: users are given the option to remove cited references (documents GS has only been able to find in the reference lists of other documents) from the search results. By default, cited references are included in the search results. • By year: it is possible to limit results to documents published in a given year, or a range of years.
It does not offer any features to analyze results or compute bibliometric indicators.
Quality of the data
In each search result, *authors* are displayed in the second line: below the title and next to the source of publication (usually a journal), the date of publication, and the name of the publisher or web domain where the document was found. The space allocated to the author data in this line is limited (usually between 30 and 40 characters), and, therefore, only the first three or four authors can be displayed, depending on the length of their names. In this line, authors are mentioned only by the initials of their first and second names and their surname. If these authors have created a public GSC profile and verified it with their institutional email, their name will contain a link to their public GSC profile. For more complete author data, users can click on the Cite button, and there, export the record to BibTeX (or another reference manager format). The BibTeX record will display the full name of up to 10 authors of the document.
No data regarding *institutional affiliation* of the authors of the documents is available (institution, country). Therefore, it is not possible to carry out studies on geographic and institutional production and collaboration.
There is no information available about the *language* in which documents are written, even though internally they must have this information, because users can choose to limit results to documents written in one or more of the following languages: simplified Chinese, traditional Chinese, Dutch, English, French, German, Italian, Japanese, Korean, Polish, Portuguese, Spanish, and Turkish.
The *typology of each document* is not clear (book, journal article, conference communication, thesis, report, ...). Only books are marked as such, usually when they have been found on Google Books.
Not all documents have an *abstract*
Author-supplied keywords are not available. The same happens with the descriptors used by the databases where the records are found.
The *list of cited references* in each article is not available either (even though they definitely have that information, since they need it to compute citations), making it difficult to carry out studies that require cited reference analysis.
Errors in the parsing routine can lead to numerous problems. There still is no conclusive study about the type and degree of occurrence of these errors, but among them we can find: • Poor bibliographic description of documents: incorrect or missing titles, authors, source of publication, date of publication, ... • Duplicate records, when GS is not able to match two or more records that actually refer to the same document. This can also lead to split citation counts, since some of the citations will be attributed to one of the versions of the document, and some to the other versions.
GS does not rely in any kind of controlled vocabulary for author names, journals, publishers, institutions, ... that facilitates the identification of the different name variants for these entities.
These last two limitations make it more difficult to carry out large-scale studies using GS data, since the data would have to go through important cleaning and normalization processes prior to the analysis.

Table 4.22 (continued)

GS
Data reuse and exporting capabilities
Users can copy citations for single records, in a variety of formats, by clicking on the *Cite* button below every record.
Records can be exported to reference managers manually one by one, also by clicking on the *Cite* button. The available formats are BibTeX, EndNote, RefMan, and RefWorks. Alternatively, users can also save records to the *My library* feature by clicking on the *Save* button (for which it is necessary to be logged in to a Gmail account). *My library* allows users to export up to 20 records in one go, in BibTeX, EndNote, RefMan, or CSV format. The abstract is never included as part of the exported records.
GS does not offer, nor is it planned to offer (at least in the near future), any kind of public application programming interface (API) to enable users to access and export data from GS in bulk.
A strict CAPTCHA system is in place to discourage users from making too many queries to the platform too quickly. Users (or bots) that go over a certain (undisclosed) number of queries in a certain time are asked to solve a CAPTCHA of some sort before they are able to continue their searches. Sometimes, if the system detects too many searches made from the same IP, that IP can get blocked temporarily.

[a] This limitation also affects GS citations and GSM

3. Quality of the data
4. Data reuse and exporting capabilities.

The information included has been taken from the authors' own observations and empirical tests. Due to length of the sheets, the sheet that describes the limitations of GS is given in Table 4.22, and the tables that list the limitations of GS citations and GSM can be found in the electronic supplementary material [4.14, see Appendix VI].

4.5 The Expanded Academic World of Google Scholar

The results of the analysis of the size, coverage, growth rate, and speed of indexing of GS fully justify considering this platform as a big data bibliographic tool (Fig. 4.10).

The empirical evidence described throughout this chapter allow us to affirm that GS is an all-inclusive tool, capable of bringing together not only the scientific world stricto sensu (that which is represented by WoS and Scopus as well), but the entire academic and professional world in a broad sense, thus providing a much broader picture of academic activity [4.37]. Its coverage is the most well balanced of the commonly used multidisciplinary databases in terms of countries of publication, languages (no English bias), and document typologies (not only scientific articles), something which is crucial when analyzing fields where it is common to use channels of communication other than journal articles published in English, such as disciplines

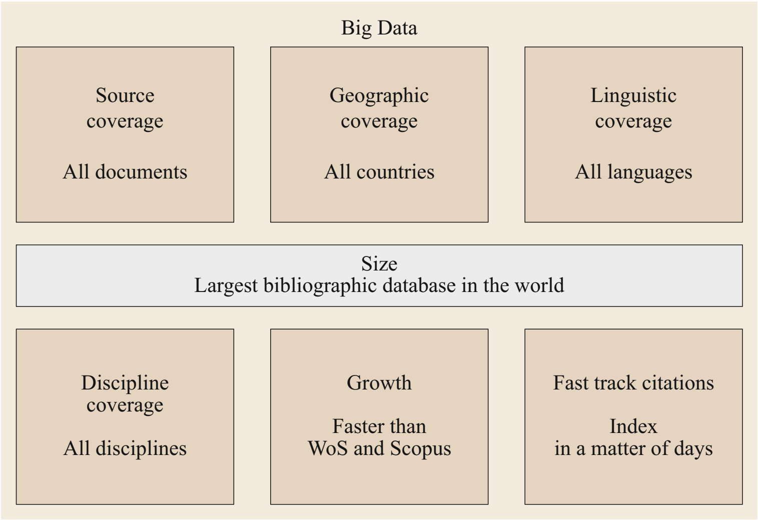

Fig. 4.10 GS, a big data bibliometric tool

in the arts, humanities, social sciences, and engineering. In this sense, Fig. 4.10 tries to convey the idea that GS covers all knowledge territories and all communities (scientific, educational, and professional), while WoS and Scopus only deal with scientific knowledge in the strict sense, and its communities.

The most important change over the previous paradigm, however, is GS's inclusion policy. WoS and Scopus have very exclusive and restrictive source inclusion policies. These sources are usually journals, which also place the prospective manuscripts researchers send to them under a rigorous evaluation processes (peer review). Contrary to this traditional model, GS works in a completely automated manner, without exercising any kind of selection process based on quality. Curated content from traditional journals and studies that have not gone through any kind of screening both coexist. GS automatically crawls, finds, and indexes any document that follows an academic structure and is hosted in an academic domain, even if it has not undergone any external quality control and is there only by decision of its authors. This breaks completely from the traditional controls to which all academic content had to be subjected prior to its public dissemination (peer review). For better or for worse, this is the distinguishing feature of GS: its ability to bring together reviewed and non-reviewed content, scientific and academic content (Fig. 4.11).

It should be pointed out that one of the main features shown in Fig. 4.11 is GS's nature as a receptacle. All the prestigious publications covered by WoS and Scopus are also covered by GS. When we observe the sources from which GS feeds, we can be sure, based on the empirical evidence on its size and coverage presented in the previous sections, that all the content covered by WoS and Scopus is also covered by GS. But of course, apart from the scientific elite, GS covers many other sources. We do not dispute that some of them may be of a lower quality, but others are of the same quality, if not higher, especially in certain disciplines (mainly doctoral theses, conference articles, working papers, and books).

Although it is true that GS covers sources that have not gone through a validation process like peer review (keynote conferences, syllabi, book reviews, technical reports, ...), these sources provide evidence of other kinds of impact beside the scientific impact, and could help put in a new light the work of researchers whose work is relevant to these communities and not the ones who publish in traditional databases.

Of course, the mixture of all these source documents (especially when considering that all of them are considered for computing citations) has been the object of important discussions in the bibliometric community [4.4]. To date, the main method to validate

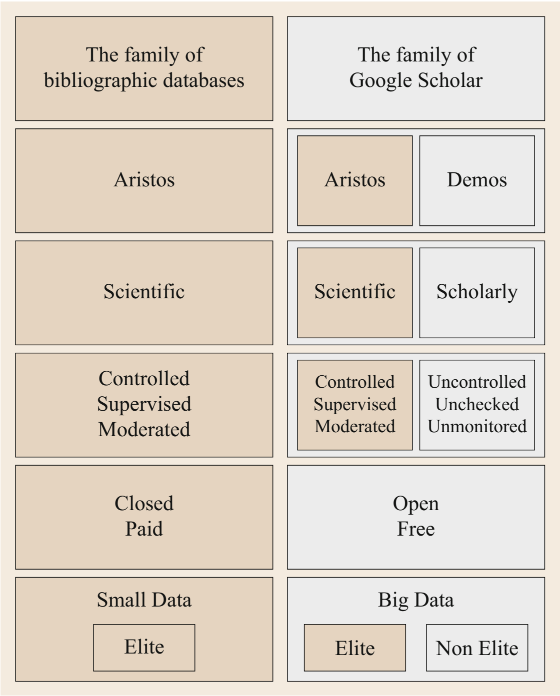

Fig. 4.11 GS versus traditional bibliographic databases

measurements made with data from GS has been to calculate their correlation with other well-established indicators. Many studies, which have been recently compiled by *Thelwall* and *Kousha* [4.70], have analyzed correlations between the number of citations according to GS and other databases (mainly WoS and Scopus), either at the level of journals or at the level of authors, as a way to evaluate its suitability as a source of data bibliometric studies.

The electronic supplementary material [4.14] offers a revised and updated list of these studies (see Appendixes II, III, and IV). Studies are grouped according to their unit of analysis (authors, citations, and average h-index). Although caution is advised for interpreting these results, because the nature of the samples are very different in terms of their size, time frames analyzed, and time when the studies were carried out, we can extract the following observations:

- The average correlation between GS and WoS (from 51 observations) is 0.76, and 0.81 when GS is compared to Scopus (28 observations).
- Out of all the studies, only in 2 are the correlations found to be below 0.50 (0.39 and 0.43 in Scopus, and 0.48 and 0.50 in WoS). All of them refer to correlations in the humanities and social sciences. On the other hand, there are numerous studies where the correlations found are above 0.9

(1 with GS/WoS comparisons and 7 with GS/Scopus comparisons).

- The highest correlations are found among STEM fields, and the lowest ones are usually found for fields in the humanities and social sciences.
- The differences between GS and the other databases seem to have increased in the more recent studies, which might indicate an even broader coverage in GS with respect to the other databases in recent years.
- No significative differences are found among studies with different units of analysis.

It also seems that multidisciplinary studies of international scope, and with very high sample sizes, achieve very high correlations, but that these become moderate by restricting the focus and emerging the intrinsic properties of each discipline. However, it should be borne in mind that correlations may have been calculated using different techniques (Pearson, Spearman, etc.), although values are reported independently, which may have a slight influence on the results.

To date, the largest sample studied for these purposes is the one used by *Martín-Martín* et al. [4.71], who used a sample of 64 000 highly-cited documents in GS, of which 51% were also covered by WoS and had at least one citation. Most of the documents covered by both databases were journal articles, and the rest were monographs, theses, and conference articles. The R-squared (Spearman) found for the number of citations received by documents covered by both databases was $R^2 = 0.73$.

For this chapter, we decided to replicate the previous study, using the sample of 861 843 highly-cited documents in 13 languages (see Appendix V in the electronic supplementary material for further details about this dataset) [4.14, 58]. Out of these documents, 69 279 (8%) of them were covered by WoS and had received at least one citation. The Spearman correlation between the number of citations according to GS and according to WoS for these documents was $R_s = 0.9$. Figure 4.12 presents a scatter plot based on these data.

As Fig. 4.12 shows, the correlation between the number of citations these documents have received according to the two databases is evident. Additionally, an important number of observations seem to have received many more citations from GS than from WoS. This means that, even though the correlation is very high in general terms, GS is usually able to find many more citations than WoS for the same documents.

4.6 Final Remarks

GS is a prodigious mine of academic information that covers all fields of knowledge. Thanks to GS we now have access to previously unexplored territories of knowledge which, even if only roughly, allow us to form a broader mental picture of academic activity. This platform sheds light where previously there was only darkness. GS can definitely help to open the academic Pandora's box [4.4]. Opening this box will bring to light document typologies (especially monographs, theses, reports, conference communications, and book chapters) from the scientific core and periphery, which were previously invisible and unaccessible. The bibliographic features of these documents will probably change certain axioms and prejudices of academic evaluation. Previously undervalued researchers, clearly harmed (or outright forgotten) by the policies of traditional databases, will come to light, because there will be evidence of the impact of their work. Conversely, it will also confirm the poor performance of other researchers, until now protected by the lack of proper tools to evaluate them.

Perhaps all this will finally lead to a redesign of certain assessment and promotion systems, funding programs, and even research policies and structures. The report *The metric tide* [4.72] already gives a glimpse of this changing trend from an institutional position, and not merely as an intellectual exercise advocated by a few and confined to research publications, with varying degrees of scientific impact, but without an actual practical impact.

That said, we cannot belittle the limitations of GS for bibliometric analyses. To begin with, the data exporting limitations (a maximum of 1000 results per query, and no easy way to export them). These obstacles are a hindrance when massive amounts of data are necessary for an analysis. The lack of an API in GS forces us to use third party applications (like Harzing's Publish or Perish) or download results manually. This results in very slow and costly data collection processes, which must be followed by a thorough cleaning of the raw data [4.63, 73, 74].

Additionally, GS does not provide vital information in its records, like the institutional affiliation of the authors, the language, and the document types. Not to mention the difficulties that normalizing the bibliographic information collected from so many varied sources entails. On the other hand, we do not believe that the errors from which some records suffer are

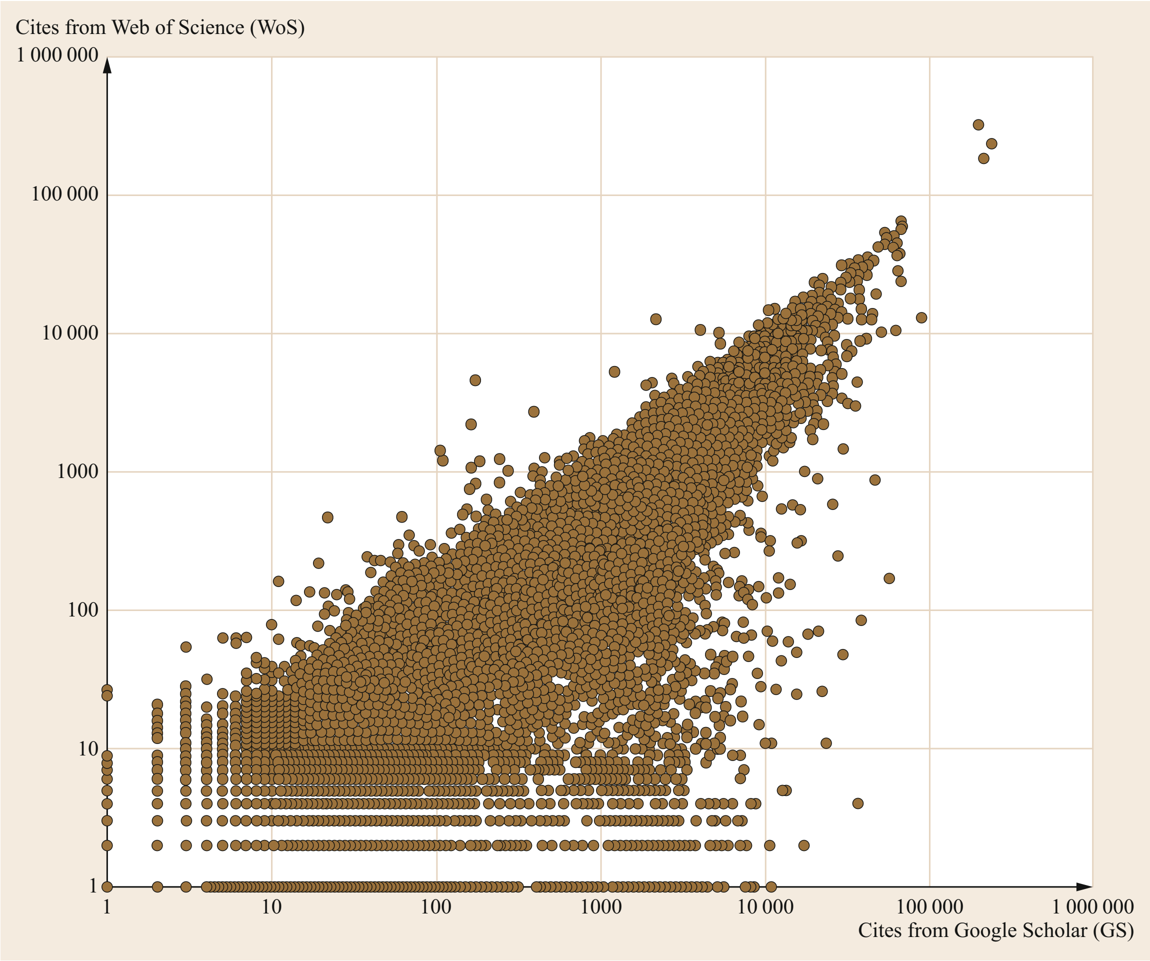

Fig. 4.12 Scatter plot of citations of highly-cited documents according to GS and WoS ($N = 69\,279$)

a major obstacle to the use of GS for bibliometric purposes. In a big data tool such as this, these errors are diluted and have no consequence on the big picture. These errors rarely affect individuals, journals, or other aggregates, as has been referred to by some studies already [4.75].

At any rate, the more dangerous limitations do not have to do with the methodological and technical problems previously discussed, but with the obscurity of the system, and, most of all, with the possibility of publication or citation manipulation, caused by the lack of quality control in the indexation of documents, which has been empirically proven by various studies [4.20, 76, 77]. Likewise, one of the main criticisms that is directed at GS is the lack of transparency, both regarding its coverage (what sources it indexes) and updating mechanisms, and regarding its algorithm for ranking results after a query.

Lastly, we hope that this study will help readers understand the inner workings of GS and become aware of its enormous potential. We always tried to offer empirical evidence of its strengths (*contra data non argumenta*), without forgetting about the important dangers that its abuse could lead to. We hope to make the scientific community question assumed truths of an academic world of which only the tip of the iceberg has been visible until now. Let us explore its depths, let us observe and describe these new landscapes, and then let us decide if we would rather remain on the surface.

Emilio Delgado López-Cózar

Información y Documentación
Universidad de Granada
Granada, Spain
edelgado@ugr.es

Emilio Delgado López-Cózar is a Professor at the Facultad de Comunicación y Documentación of the Universidad de Granada. He holds a PhD in Library & Information Science. His research interests are focused on the analysis of the new sources of information and scientific evaluation (e.g., search engines like Google Scholar) and of the new metrics used to measure the visibility and the impact of scientific activity (Altmetrics).

Enrique Orduna-Malea

Audiovisual Communication,
Documentation, and History of Art
Universitat Politècnica de València
Valencia, Spain
enorma@upv.es

Enrique Orduna-Malea is Assistant Professor at the Polytechnic University of Valencia. He holds a PhD in Webometrics, a Master Degree in Management of Multichannel Contents, and MA in Library & Information Science. His research interests focus on the study of contents and users in the Web and the design of methods and models of analysis. He has co-authored 3 books, and 40+ articles included in JCR (Journal Citation Reports).

Alberto Martín Martín

Información y Documentación
Universidad de Granada
Granada, Spain
albertomartin@ugr.es

Alberto Martín Martín is a fourth-year PhD candidate at the University of Granada, thanks to a Doctoral Fellowship granted by the Ministerio de Educación, Cultura y Deporte in Spain. For his thesis project, he is studying the potential of the data available in Google Scholar for bibliometric analyses.

5. Disentangling Gold Open Access

Daniel Torres-Salinas, Nicolas Robinson-García, Henk F. Moed

This chapter focuses on the analysis of current publication trends in gold Open Access (OA). The purpose of the chapter is to develop a full understanding of country patterns, OA journal characteristics and citation differences between gold OA and non-gold OA publications. For this, we will first review current literature regarding Open Access and its ostensible citation advantage. Starting with a chronological perspective we will describe its development, how different countries are promoting OA publishing, and its effects on the journal publishing industry. We will deepen the analysis by investigating the research output produced by different units of analysis. First, we will focus on the production of countries with a special emphasis on citation and disciplinary differences. A point of interest will be identification of national idiosyncrasies and the relation between OA publication and research of local interest. This will lead to our second unit of analysis, OA journals indexed in Web of Science. Here we will focus on journal characteristics and publisher types to clearly identify factors which may affect citation differences between OA and traditional journals which may not necessarily be derived from the OA factor. Gold OA publishing, as opposed to green OA, is being encouraged in many countries. This chapter aims at fully understanding how it affects researchers' publication patterns and whether it ensures an alleged citation advantage as opposed to non-gold OA publications.

5.1 Open Access and Scholarly Communication

Almost 30 years have gone by since the emergence of ArXiV, the revolutionary open access launched in a pre-Internet era in the early 1990s [5.1]. This event established the first landmark of the open access (OA) movement, a revolution in the way scholarly works are disseminated which would not have been possible without the technological advancements that preceded it. The spread of OA has always been surrounded by controversy with regard to its motivations, and its effects and the benefits for those providing open access. Among others, *Kurtz* and *Brody* [5.2] have pointed out the *increasing access* to scientific information, identifying OA as a natural step in today's ever more rapid communication processes. Contrarily, *Beall* [5.3] sees OA publishing as a threat to the scholarly communication system, and argues that "authors, rather than libraries, are the customers of open access publishers, so a powerful incentive to maintain quality has been removed".

The current expansion of OA can be explained partially by the serial breakdown [5.4], a scholarly publishing crisis derived from the shift to online scientific publishing and the concentration of journals among a few publishers, who obliged libraries to subscribe to fixed collections of journals at unsustainable prices through *big deals* [5.5], limiting access to scientific literature. However, OA publishing is now handled by a few publishers who negotiate country-wide licenses for article processing charges (APC) through deals which share many similarities with the *big deal* subscription access agreements [5.6]. *PLOS One*, *Scientific Reports* and *Nature Communications*, the three most

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_5

prolific mega-journals, already represent 62.2% of all gold OA publications between 2012 and 2016 (data extracted from Clarivate Analytics InCites). In the same vein, PLOS itself generates more than $40 million annually (https://www.plos.org/financial-overview). It is safe to state therefore, that OA is no longer just an ideological movement, but also a multimillion business.

The OA movement took shape in the Budapest Open Access Initiative (http://www.budapestopenaccessinitiative.org/) in 2002 seeking to unite:

> [A]n old tradition and a new technology [which had] converged to make possible an unprecedented public good .... [T]he willingness of scientists and scholars to publish the fruits of their research in scholarly journals without payment, for the sake of inquiry and knowledge.

Still, traditional publishers have constantly resisted modifying their subscription-based business model, leading to boycotts from scientists [5.7] and calls to defy publishers' copyright privileges [5.8]. While some concessions have been made, and most journals nowadays allow preprint versions of papers to be uploaded in repositories, such defiance to break paywalls still remains, either through legal [5.9] or illegal means [5.10].

Many studies and reviews have been devoted to defining the characteristics and implications of OA [5.11–13], the state of OA [5.14–17], how much of the scientific literature OA represents [5.18], benefits derived from it [5.19, 20] or its relation with citation impact [5.21–24] and other related topics. Still, there are many questions and misunderstandings that need to be addressed to better comprehend and assess the mechanisms that are being put in place to make OA possible.

In this chapter, we focus on gold OA, that is, publications from OA journals, and analyze differences in production and impact between countries by using normalized citation scores to better characterize the phenomenon of OA publishing. Long gone is the debate questioning the viability of an OA publishing model [5.25]. Many OA journals are now well-known and well-established journals, and authors have accepted the APC model and are willing to pay journal publication fees. However, there are important sectors of the scientific community who still raise concerns as to the quality of these journals and the potential threats they pose to the scientific communication system [5.26–28].

5.2 What is Open Access?

The Budapest Open Access Initiative (BOAI) was the first to coin the term *open access* [5.19]. In their founding document, they offered the following definition of OA:

> [Research literature which is] free[ly] availab[le] on the public internet, permitting any users to read, download, copy, distribute, print, search, or link to the full texts of these articles, crawl them for indexing, pass them as data to software, or use them for any other lawful purpose, without financial, legal, or technical barriers other than those inseparable from gaining access to the internet itself. The only constraint on reproduction and distribution and the only role for copyright in this domain should be to give authors control over the integrity of their work and the right to be properly acknowledged and cited.

The Berlin Declaration on Open Access to Knowledge in the Sciences and Humanities (BDOA) of 2003 (https://openaccess.mpg.de/Berlin-Declaration) added further specifications to this definition. First, it defined research literature as:

> Original scientific research results, raw data and metadata, source materials, digital representations of pictorial and graphical materials and scholarly multimedia material.

Second, it established that OA contributions must comply with two conditions:

1. The concession of copyrights to access, use, distribute and modify freely and worldwide such documents as long as the author(s) is acknowledged.
2. That the document is deposited in an online repository which complies with certain technical standards.

But the implementation of OA led to situations which were not originally contemplated by these definitions. One of them has to do with the appearance of multiple versions of the same document [5.29]. As a document can be uploaded to a repository and also submitted to a journal, various versions of a paper can be available at the same time (pre-submitted manuscript, peer-reviewed manuscript and journal formatted version). This situation can create a level of uncertainty, as there could be substantial differences between these different versions. It must be noted that in many cases the version uploaded to a repository is a so-called author copy of the manuscript published in the journal, i. e., the version accepted for publication by the journal, but not subjected to the copy-editing process conducted by the publisher. This practice ensures that the scientific contents of the preprint and published version are identical.

Also, the use of relaxed notions of OA influence the perception researchers have as to what OA is and what it is not. There is a tendency to consider OA and free access as synonyms. OA was formally defined more than ten years after the practice had begun. Issues such as copyrights or how to make documents accessible were not even considered at this early stage [5.25]. It is plausible to speculate that the retroactive definition of OA has helped resolve this misconception of OA. For instance, a recent report commissioned by the European Commission claimed that more than half of the publications were in OA, but defined OA as "freely available online to all (no money had to be paid, no registration to a service or website had to be made)" [5.18]. This was later noted by a news story published in Nature which had to emphasize that [5.30]:

> Although free to read, [articles] may not meet formal definitions of open access because, for example, they do not include details on whether readers can freely reuse the material.

Although free access can still be perceived as positive, the fact that authors are uploading their publications to private corporations such as ResearchGate, Mendeley, figshare or Academia instead of OA repositories, raises concerns as to the future sustainability of the OA movement [5.6].

Originally, two routes to OA were envisioned to provide a middle ground that offers room to new business models while promoting sustainable and universal access to scientific literature. These are known as the green and golden routes [5.16]: two non-mutually exclusive models to reach OA while conceding space to journals to make a profit. The green route designates scientists as those to be held responsible for permitting OA to their publications. They are expected to upload their works to repositories maintained by university libraries following the model set by *Ginsparg* and ArXiV [5.14, 31]. In principle, this solution leaves the journal as an accessory element which ceases to be at the core of the scientific communication system. Still, journals influence authors' decisions on making their work accessible, as they hold the copyrights of the manuscripts they publish [5.19].

The golden route maintains journals as the core of academic communication. Journals are the ones which should provide OA. This means abandoning the subscription-based business model. *Laakso* et al. [5.17] describe three types of OA journals: direct OA, delayed OA or hybrid OA. Direct OA journals are those which offer their full contents in OA. While most of these publishers adopt an author-pays model, including article processing charges (APC), this is not a prerequisite for direct OA journals and, in fact, many journals are maintained by public institutions without incorporating any fee for authors. Delayed OA journals, on the other hand, maintain a subscription-based model but offer OA to all their contents after a given period. Hybrid OA journals are the most restrictive of the three types. In fact, many argue that they are not true OA journals, as they provide OA only to those publications for which the authors have paid an OA clause, the rest of their contents remaining behind paywalls.

Since these two routes were defined, other types of OA have been described in the literature. We must note that some of these denominations are controversial and are not even considered by some authors as truly OA, as they do not fit the general definition provided by the Budapest Open Access Initiative. For instance, *Suber* [5.32] makes the distinction between Gratis and Libre OA. He defines the former as that which offers rights only to *read* articles, whereas the latter extends rights to reuse articles. Another proposed type of OA is that named as Black OA [5.33], which is defined as that in which articles are illegally distributed through pirate sites such as Sci-Hub and LibGen, something considered by many as not real OA. Finally, it is worth discussing bronze OA [5.34]. While not truly OA, articles falling under this category are those which are freely distributed by publishers through their websites, without including any type of open access license. Articles falling under this category respond to forms of delayed OA (that is, journals making their archives accessible), from journals not listed in the *Directory of Open Access Journals* (DOAJ), or articles which are temporarily offered freely by journals to promote their contents.

One of the main concerns of OA advocates has been to learn how much of the scientific literature is already in open access and how this number is growing in respect to the overall growth of scientific literature. *Björk* et al. [5.15] established that 20.4% (up to 24% of articles in hybrid journals are included) of the literature was already OA in 2008, 8.5% being gold OA. *Gargouri* et al. [5.35] found similar figures when analyzing its growth and differences by discipline. They reported that an average of 24% of the literature was in OA between 2005 and 2010. Contrarily to Björk and his team, they found out that only 2% of the OA literature was gold OA, with biomedical research being the field with the highest share of gold OA (8%). A more recent study [5.34] reported that up to 28% of the literature was accessible via OA, bronze OA being the most common form of OA (16.2%) followed by green OA (4.8%), hybrid OA (3.6%) and, lastly, gold OA (3.2%).

First studies analyzing publication and citation trends in OA tended to focus on green OA [5.22–24], as in many cases the authors of these studies were themselves advocating for green OA [5.36]. But journals' embargo requirements and OA release delays have pushed others to considered gold OA as a more promising venue [5.37], leading to new studies focused specifically on OA journals. Since the beginning of the 2000s the number of OA journals has grown exponentially, going from fewer than 750 journals in 2000 to more than 6500 in 2011 [5.38]. The types of journals have also diversified, and we can now differentiate between OA journals with or without an APC model, born versus converted OA journals and between small and mega-journals.

5.3 Disentangling Gold Open Access

One of the first issues studies on OA journals encountered was the difficulty to find a comprehensive list of all OA journals [5.29, 36]. Recently, both Scopus and Web of Science (WoS) have provided the ability to identify OA journals within their databases. Data and figures displayed in this chapter are retrieved from Web of Science InCites and hence some discrepancies could be found with OA journal lists provided elsewhere. According to Clarivate, OA journals in InCites are based on the DOAJ open access status [5.39]. This must be considered when interpreting the findings displayed.

The success of OA publishing is intimately related to the expansion of digital distribution and the consequent abandonment of printed materials. According to *Björk* and *Solomon* [5.40] we can distinguish four waves that took place almost simultaneously in the latter half of the 1990s and the beginning of the new century. The first wave is characterized by the launch of new OA journals by individual scientists, exemplified by the *Journal of Medical Internet Research*, currently a world leading journal in its field. The second wave consists of the adoption of an OA model by established subscription journals. Here a pioneering journal was British Journal of Medicine (BMJ), first offering OA in 2000. A more ambitious initiative, in the sense of the magnitude of journals converting to OA, is the launch of Scielo in 1997, a publicly subsidized South American portal, which gives OA to hundreds of journals at no costs to publishers.

A game changer in OA publishing was the launch of *BioMed Central* (BMC, currently owned by Springer) and *PLOS* in 1998 and 2000 respectively. These two OA-born journals are the first ones to adopt an APC model, envisioned by BMC founder, Vitek Tracz. The fourth and last wave is that representing the reaction of established publishing firms to OA by proposing the hybrid model. That is, subscription-based publishers implementing an OA option at the level of individual articles, such as Springer's *Open Choice*, thus making journals hybrid in terms of the financing model.

The APC model is seen by many as the most sustainable solution for maintaining journals as a profitable business while ensuring universal access to scientific literature. Supranational and national organizations, such as the European Union, the US National Institutes of Health or the British Wellcome Trust, include OA policy mandates ensuring that all publicly funded research findings are preserved and publicly accessible. In most cases, they promote both the gold and green routes, considering that the APC model allows "savings of up to 30%" [5.39] compared with journal subscriptions. While it can be claimed that gold OA ensures the publication of peer-reviewed papers and hence the credibility of research, others have questioned if an author-pays model really ensures the quality of the work published [5.28]. As authors become essential to the business model of these journals, quality levels may drop or cease to exist, leaving room for *predatory journals* which will publish anything as long as profits keep rising [5.3]. This phenomenon, which is not directly related with gold OA but with the APC model, has caused many researchers to perceive gold OA publications as research of a lesser quality [5.26].

In the late 2000s a debate emerged in the literature with regard to a perceived OA citation advantage [5.22–24, 41, 42]. Green OA advocates promoted the idea that researchers who made their publications OA had a citation advantage, as opposed to those who did not, due to the higher accessibility and visibility of their work. While this perception was confirmed by most studies [5.43], some authors pointed out that this perception could be more of an acceleration of the number of citations rather than an advantage due to an *early view* bias that favored OA papers [5.24]. In the case of gold OA the story is rather the opposite: "open access has multiplied that underclass of journals, and the number of papers they publish" [5.28]. The pernicious effect of *predatory publishers* and the low barriers set by many OA peer-reviewed journals have led opponents of OA to state that "[t]he open-access movement has been a blessing to anyone who has unscientific ideas and wants to get these ideas into print" [5.27].

Björk and *Solomon* [5.40] argue that OA journals are not of a lesser quality than traditional ones, but are younger. In fact, OA journals in fields such as biomedicine, or those with an APC model indexed in Web of Science, have citation rates similar to those of subscription-based journals [5.44]. This is also corroborated by *Gumpenberger* et al. [5.36], who indicate that there is an "overall positive impact trend for top Gold Open Access journals".

5.3.1 Gold OA Output and Impact of Countries and Scientific Fields

In this section, we will examine such arguments by analyzing the most recent trends in OA publishing for the period 2007–2016. In contrast to the study by *Björk* and *Solomon* [5.40], we do not distinguish between OA funded by article processing charges (APC) and other, mainly subsidized, forms of OA. In addition, rather than categorizing journals according to the *country of the publisher*, and calculating journal impact factor-like citation rates for a journal as a whole, the current study also presents analyzes on the *article production of countries in OA journals*, as expressed in the affiliations of publishing authors, and so called *category normalized citation rates*, comparing the citation impact of an entity—e. g., the total collection of articles published in OA papers, or the OA articles published by authors from a particular country—to the world citation average in the subject field in which the entity is active.

Table 5.1A provides insight into the global development of gold OA publishing. The table shows a steady increase of this percentage over the years, from 3.24% in 2007 to 12.09% in 2016. For the period 2012–2016 this percentage amounts to 10.5%. The last column gives the category normalized citation impact of the OA articles published in the various years, correcting for differences not only in citation practices between subject fields, but also between document types and publication years. A value of 1.0 means that gold OA articles are cited on average as frequently as an average article (either gold OA or non-gold OA). The

Table 5.1 Overview of gold OA publications: Evolution and distribution by research fields. 2007–2016 period

A. Evolution of gold OA				
Publication year	**Articles WoS**	**OA Articles WoS**	**% OA Articles WoS**	**Category normalized citation impact**
2007	1 071 782	34 752	3.24	0.81

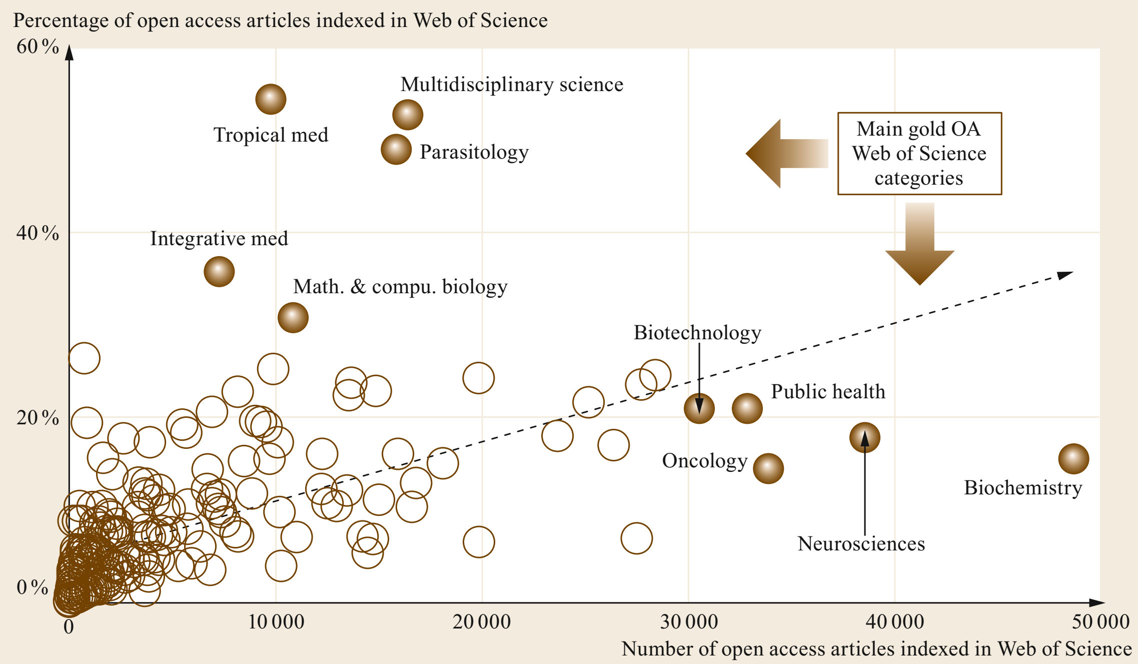
category normalized citation impact of gold OA articles ranges over the years between 0.73 and 0.89. There is no clear trend in the data. Aggregating data into two 5 year periods, the scores in the two periods are statistically similar: 0.81 versus 0.83. In short, gold OA articles are cited some 15% less often than an average article (either gold OA or non-gold OA article).

Table 5.1B presents a breakdown of the gold OA articles and their impact by scientific field. 41.1% of OA articles are published in journals assigned to the natural sciences discipline. Relative to the total number of articles in this subject field, the share of gold OA articles is 10.25%, which is near the overall average of 10.5 indicated in Table 5.1. This is also the field with the largest normalized citation score (0.97), which is somewhat higher than the value of 0.83 obtained for the total set of all gold OA articles in the database from all disciplines.

Figure 5.1 delves into these areas by showing the total number of gold OA publications by WoS subject category and the percentage which gold OA represents within each subject category. Biochemistry is the field with the highest number of gold OA publications, followed by neurosciences, oncology and public health. However, it is in the subject categories of multidisciplinary sciences, tropical medicine and parasitology where gold OA represents half of the overall number of publications. The explanation of such a large share in the multidisciplinary fields is due the presence of OA mega-journals such as *PLOS One* and *Scientific Reports*. In the case of *tropical medicine and parasitology*, journals from big OA publishers are still present (e. g., *PLOS Neglected Tropical Diseases*, *PLOS Pathogens* or *Malaria Journal*, which belongs to BMC), but there are also national journals which do not publish in the English language. Interestingly, these are mostly Brazilian journals such as *Memorias Do Instituto Oswaldo Cruz*, *Revista da Sociedade Brasileira de Medicina Tropical* or *Revista Brasileira de Parasitologia Veterinaria*. This is reasonable when considering that these subject categories have a heavy local component and that South America and Brazil, in particular, are regions where these subject categories are more relevant in comparison with regions such as North America and Europe.

The ranking of countries according to their number of gold OA publications differs substantially from that based on total publication output (Fig. 5.2). Some top countries in terms of gold OA make a much smaller contribution to the total global output. For instance, Brazil, which occupies the 14th position of most pro-



Technical Note Dataset: InCites dataset; schema: OECD; document type: article; time period: 2007–2016

Fig. 5.1 Total number and share of gold OA publications by WoS subject category. 2012–2016 period ductive countries within the 2007–2016 period according to the Web of Science, is actually the fourth country in terms of the absolute number of OA publications. Similarly, Spain, the ninth country with the largest number of publications within the same period, goes up to the seventh position when one considers only gold OA publications. Another example is Mexico, which falls from the 23rd position according to their contribution to OA publishing, to the 31st position when looking at their global figures.

The case of Brazil is particularly interesting, as it is by far the country with the largest share of OA publications from its overall output (almost 30%), a consequence of the gold OA proactive policy undertaken by the Brazilian government through the promotion of the SciELO platform, an initiative followed by other Latin American and Caribbean countries, which provides OA to journals from these countries [5.45]. In the case of Spain, the share of OA publications based on its overall output is not as large as that of Brazil, but, as noted elsewhere [5.46], Spain has increased its share of gold OA output at a higher rate than the world average over the last decade.

While for all countries the category normalized impact of OA publications is lower than the overall value of their normalized impact, the gap between these two figures differs greatly by country. Differences in the case of the United States, United Kingdom, Japan, Switzerland and Austria are almost non-existent. This is not the case for China, Brazil, Spain, France or Canada, for which the impact of gold OA publications is substantially lower than their overall impact level. This difference can be partly explained by the disciplinary profiles of these countries.

Figure 5.3 shows the five most productive countries of gold OA publications by six scientific fields as defined by the Organization for Economic Co-operation and Development (OECD). Colors represent the value of the category normalized citation impact of each country-field combination. As observed, countries with higher normalized impact tend to publish most of their output in the medical and health sciences, the natural sciences, and social sciences. In these fields, most of the countries in the top five positions reach an overall impact equal to or above the world average (category normalized citation impact ≥ 1.0).

This is not the case in agricultural sciences, engineering and technology and humanities. All countries—except the USA in engineering and technology and in the humanities—have lower values of normalized impact than the world average. Also, these are the only fields where the United States is not the largest con-

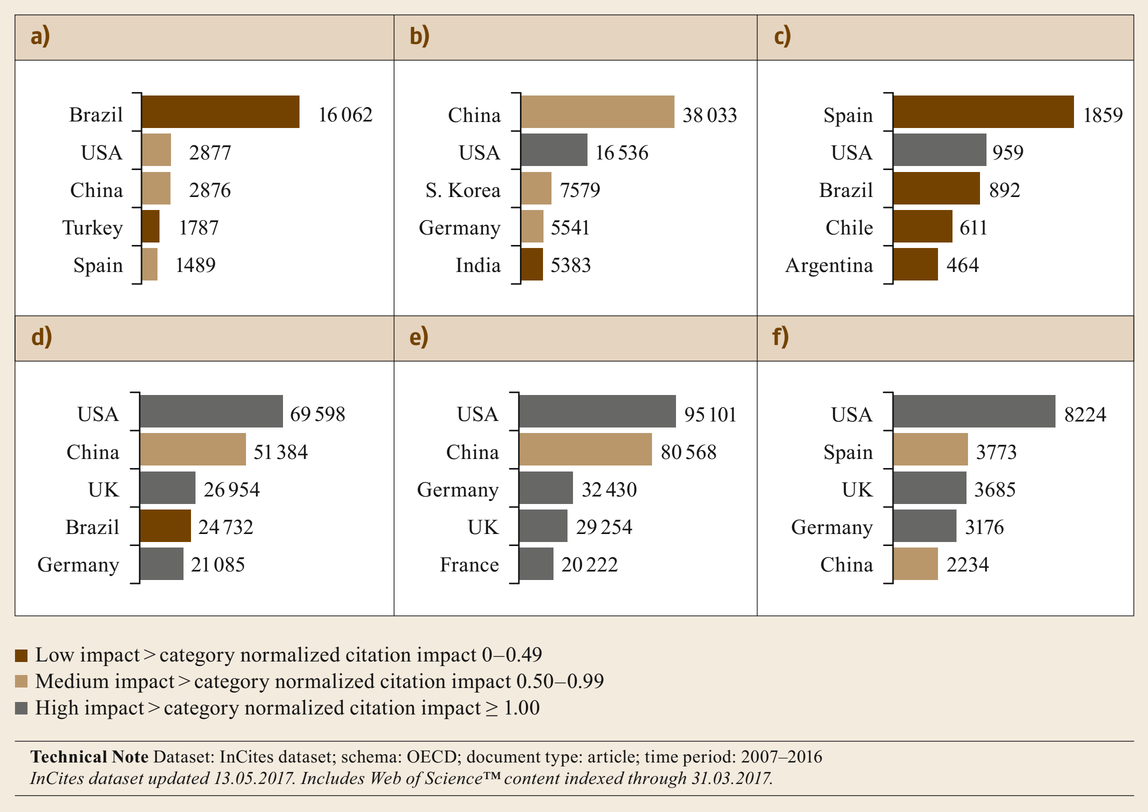

Fig. 5.3a–f Top five most productive countries in open access journals by field: **(a)** agricultural sciences; **(b)** engineering and technology; **(c)** humanities; **(d)** medical and health sciences; **(e)** natural sciences; **(f)** social sciences

tributor. Brazil, for instance, is the country with by far the largest number of publications in agricultural sciences. A closer examination in this field shows that six of the top ten journals producing most of the publications are Brazilian, all of which exhibit low impact factor values under 0.6. China is number one in the case of engineering and technology, and Spain in the case of the humanities. It is also worth noticing the asymmetry of the share of publications in Fig. 5.3a,b, where there is a large difference between the number of publications of the first country with respect to the rest.

These figures suggest that the differences in impact between gold OA papers and a country's total publication output, shown in Fig. 5.2, are largely due to the gold OA disciplinary profile of each country and the characteristics of OA journals in these different fields. This idea is reinforced by *McVeigh* [5.47], who indicated that high impact OA journals are unevenly distributed among countries and research fields. Furthermore, the large presence of Central and South American journals [5.48] could explain the large proportion of OA publications with low impact from countries such as Brazil, Spain, Chile or Argentina. Considering that there is an English-language positive bias and a Portuguese as well as Spanish-language negative bias in the citation impact scores of OA journals [5.49], it is appropriate to conclude that [5.46]:

> [T]he reasons behind [the] poor performance [of these countries] may be due to the national factor as well as to the large share of gold OA papers [compared to that of other] countries.

5.3.2 Characterizing OA Journals by Country and Field

Our next analysis focuses on the country of origin of gold OA journals. The purpose is to examine the characteristics of OA journals and illustrate how the relation between gold OA impact, countries and fields is intimately related or closely linked with the presence of national OA journals from these countries and fields. The issue between countries' output and the country

	Journals	WoS docs	Avg impact factor	St dev impact factor	Avg CNCI	St dev CNCI
Non-open access	10 194	6 554 091	1.96	3.02	0.85	1.07
Open access	1025	844 036	1.94	2.22	0.62	0.59
Total general	11 219	7 398 127	1.96	2.95	0.83	1.04

Technical Note. Dataset: InCites dataset; schema: OECD; document type: article; time period: 2007–2016
InCites dataset updated 13.05.2017. Includes Web of Science™ content indexed through 31.03.2017

of origin of journals has been widely examined when studying the phenomenon of *predatory journals* in OA publishing. *Bohannon* [5.28] published a controversial experiment in Science magazine where he submitted hundreds of fake manuscripts to journals indexed in the *Directory of Open Access Journals* (DOAJ) and Bealls' List of Predatory Journals [5.3]. His experiment criticized the lack of peer review of many of the journals to which he submitted his bogus papers which were, in many cases, accepted. This paper was seen by many as an attack upon the gold OA movement [5.50]. Studies were rapidly undertaken analyzing the extent to which 'predatory journals' were affecting the whole gold OA publishing enterprise. One of the most significant findings was that most of their actions were geographically restricted to India and Nigeria [5.50, 51].

Moreover, South America is the continent with the largest share of gold OA publications (up to 74%) [5.52], but its presence in predatory journals represents barely 0.5% [5.51]. These findings demonstrate that gold OA publications are not necessarily of a lesser quality. Following what we observed in Figs. 5.1 and 5.2, we could hypothesize that national differences in gold OA impact are affected by disciplinary biases and the types of publishers of journals from these countries. *Ennas* and *Di Guardo* [5.49] already point out that "journals owned by UK and US publishers have a very strong and positive relation to the [positioning in the SCImago Journal Rank] ranking" and that "journals adopting a business model requiring a form of payment to publish tend to become top rated more than others". Similarly, *Laakso* and *Björk* [5.38] highlight the diversity of types of journal publishers, geographical regions and scientific disciplines.

Table 5.2 compares the average journal impact factor and category normalized citation impact (CNCI) of gold OA journals, non-gold OA journals and the total collection of journals. Interestingly, while there are no significant differences in the average journal impact factor, gold OA journals have on average a much lower category normalized citation impact than non-gold OA journals (0.62 against 0.85).

Figure 5.4a,b compare the citation impact of gold OA journals with that of other journals, broken down by discipline. They also indicate the absolute number of gold OA journals in a discipline. Figure 5.4a shows results based on the journal impact factor, and Fig. 5.4b on the category normalized citation impact. While Fig. 5.4a shows that in natural sciences and in humanities gold OA journals have on average higher impact factor values than other journals have, and lower values in the other disciplines, Fig. 5.4b reveals that CNCI values of gold OA sources are below those of other journals in *all* disciplines, the difference being largest for social sciences and humanities. Note that the lower number of OA journals in the humanities is largely due to the fact that WoS does not calculate the impact factor of journals indexed in the arts and humanities citation index.

Figure 5.5 further analyzes the CNCI of gold OA journals as a function of the country of the publisher of the journals. It reveals large differences in average CNCI between publishing countries. In the set of countries publishing more than 10 gold OA journals, those published from The Netherlands, Germany, USA and England tend to have high CNCI values. These countries host large international publishing houses. Typical examples of countries with relatively low CNCI values and at least five gold OA journals are Colombia, Mexico, Serbia, India and Brazil. This evidence further strengthens the suggestion that the relation between impact and gold OA could be related more to other factors such as type of publisher, country of the journal and the field of scope of the journal, rather than with the fact that they are OA journals. Indeed, this perception aligns well with the findings provided by *Chavarro* et al. [5.53] who showed that, in the case of Colombia, publishing in what they refer to as non-mainstream journals is not only common, but that these journals are different in purpose than other journals, as they tend to publish research findings in subjects related to local knowledge or as a means to bridge the international community and local communities.

5.3.3 The Effect of OA Mega-Journals in the Publishing Ecosystem

It is impossible to discuss gold OA without taking some time to analyze the phenomenon of so-called OA mega-journals (OAMJs). Defined as [5.54]:

> Not only potentially disruptive in terms of altering the way research findings are assessed and communicated; [but] also disrupting academic culture itself

OAMJs have become, along with the rise of academic social media platforms [5.6], one of the major side-effects of gold OA in the publishing industry. These journals have not only impacted the scientific publishing culture due to the large number of papers they publish, but have also changed, or at least influenced, the ground rules of peer review by which a paper is considered to be worthy of publication.

According to *Wakeling* et al. [5.55], OAMJs are defined by two main characteristics:

1. They are broad in scope, covering many scientific areas
2. They set the peer review bar based on the technical soundness of manuscripts, not considering within their selection criteria the novelty of the publication or its significance and contribution to the field.

This has been seen by many as a lowering of the publication standards, and partially explains the perception by many researchers that these journals are of a lesser quality. What is more, big publishers have now introduced their own mega-journals (e. g., *Nature Communications*, *Scientific Reports* and *BMJ Open*). This move has been seen by some as a way "to tap into the stream of rejected manuscripts from their more selective top journals, in a system described as *cascading reviews*" [5.56]. Still, such malicious thinking does not seem supported by the data, which actually shows that, in terms of citations, both OAMJs and traditional journals show similar patterns [5.56].

Indeed, when examining the number of papers *PLOS One* publishes every year, the share they represent from the gold OA world output and its citation impact indicators, the numbers are quite revealing. Table 5.3 shows the publication trend of *PLOS One* for the 2009–2016 period. Starting with 4400 articles in the analyzed period, *PLOS One* reached its highest peak of articles published by year in 2013, when it produced more than 30 000 publications. This number was relatively stable in the two subsequent years with a decrease to 22 000 publications in 2016. *PLOS One* represented during the 2012–2014 period around 20% of all gold OA publications, decreasing in the later years. This was due to the decrease of publications, but also to the increase of publications from *Scientific Reports*, which went from over 3900 articles in 2014 to more than 10 700 articles in 2015 and up to 20 470 published papers in 2016.

A different issue is that related to the disruptive effect OAMJs have in scientific communities. According to *Beall* [5.27], a strong opponent of gold OA, "[t]hese journals, many of them now editorless, are losing the cohesion, soul, and community-binding roles that scholarly journals once had". Traditionally, scientific journals have been considered as niches which tie together and represent scientific communities, playing also a social role. OAMJs blur such communities, as contents of different areas and communities are published in the same place. However, where some

see a problem, others see an opportunity. *MacCallum* [5.57], acknowledges such a problem, but frames it from a different angle. OA means targeting not only scientists, but also policy makers, health managers, etc. OAMJs do not necessarily threaten the cohesion of scientific communities, but force publishers and information providers to rethink how to structure the increasing amount of literature produced by OAMJs, not only:

> To cater to different communities, but also to satisfy the needs of each individual and even enable them to generate new questions or discover novel avenues of research.

This is probably a somewhat opportunistic response to this issue, but one which reflects the disruptive effect OAMJs have had not only on the production of scientific literature, but also in its consumption.

5.4 Conclusions and Future Prospects

Despite the large number of studies devoted to defining, characterizing, analyzing and discussing OA, its integration into the scholarly communication system is still a grand challenge which leaves room for further debate and discussion. More than 25 years of OA have elapsed since the launch of ArXiv. Since then, topics under discussion have shifted many times. In the 1990s, studies tended to question copyright ownership [5.58] and explain the possibilities of making research findings more accessible [5.1]. The 2000s saw the expansion of OA, with many papers advocating for it [5.8, 13, 25, 59], explaining the different routes to OA [5.16] and debating about whether OA gave greater visibility to research literature [5.24, 41, 60, 61], in many cases arguing in favor of a citation advantage [5.21, 22, 42, 62, 63].

In the last decade, new topics have been added to this ongoing conversation. The settlement and growth of OA publishers, the emergence of OAMJs and of *predatory journals*, and the launch of academic social media platforms have led to more reflexive discussions as to the way OA is being integrated within the scientific communication system. Growing concerns as to how OA business models are affecting the quality of published research have been constantly present in the last few years [5.27, 28, 40]. This chapter intends to provide further insights as to the diversity of gold OA and its citation impact in comparison with non-gold OA. In this regard, the work of *Björk* and colleagues [5.15, 17, 38, 40, 44] already provides great in-depth analyses as to the heterogeneity of gold OA journals and the many factors that could be affecting the negative view OA journals seem to provoke within a large sector of the scientific community [5.26].

Building from their findings, we can relate the following comments. Regarding the overall number of gold OA publications and how much they represent from the overall number of publications, *Björk* et al. [5.15] indicated that "8.5% of all scholarly journal volume for 2008 is available through some form of Gold OA". The current study focused only on journal articles and it is based on data from Clarivate's InCites. We have obtained for 2008 a value of 4.37%, and for the year 2016 a value of 12.1%. This outcome illustrates that the overall share of gold OA output is still increasing with the emergence of new players, such as *Scientific Reports* and *Nature Communications*.

Björk and *Solomon* [5.40] concluded in their 2012 study that:

> OA journals indexed in Web of Science and/or Scopus are approaching the same scientific impact and quality as subscription journals, particularly in biomedicine and for journals funded by article processing charges.

In the current study, in which the category normalized citation impact (CNCI) of gold OA articles is compared to that of all other articles, a moderate increase is found in the ratio of the impact of gold OA and other types of articles. The question as to whether OA articles have a higher citation impact than non-OA papers has been addressed during the past 15 years in many studies analyzing the large multi-disciplinary citation indexes WoS and Scopus. *Laakso* et al. [5.17], *Björk* et al. [5.15], and *Björk* and *Solomon* [5.40] present reviews of these studies. To the best of the current authors' knowledge, the analysis presented in this chapter is one of the first to use the category normalized citation impact indicators at a large scale. The results show that gold OA articles have in the 2012–2016 period on average a citation impact that is some 15% lower than the world average impact in the gold OA articles' subject fields. It must be noted that this world average is based on all articles, both OA and non-OA.

The results presented in this chapter illustrate the heterogeneity in gold OA publishing, and the skewness of the underlying publication output and citation impact distributions. A limited number of gold OA journals accounts for a large percentage of the global gold OA output, and the effects of these journals upon overall scores can be assumed to be substantial.

These outcomes illustrate how cautious one should be in drawing generalized conclusions about gold OA publishing. The results obtained in the current study confirm the conclusions by *Björk* and *Solomon* [5.40] that:

> Gold OA publishing is rapidly increasing its share of the overall volume of peer-reviewed journal publishing, and there is no reason for authors not to choose to publish in OA journals just because of the 'OA' label, as long as they carefully check the quality standards of the journal they consider.

The relationship between access modality and citation impact is complex, and does not allow for simple, general conclusions. One should be cautious with generalizing statements such as *OA journals have higher (or lower) impact than subscription-based serials*. Based on the findings presented here, we have observed three models of gold OA production at the national level. These are shown in Table 5.4. The first model is that of countries like the USA, the United Kingdom, Germany and the Nordic countries, which publish in OA journals from big publishing firms with high impact factor, in many cases in OA mega-journals. The second model is exemplified in countries such as Brazil or India. These countries tend to have a large output in OA journals edited from their own countries. These journals tend to belong to specific fields (e.g., agricultural sciences in the case of Brazil), reinforcing the idea that they may be serving as bridging communities or focusing on topics of local or national interest [5.53]. The last model is represented by countries like Spain and Poland, which show a mixed combination of publishing in high impact OA mega-journals from big publishers, as well as publishing in nationally oriented OA journals from their own countries.

These results illustrate the many factors that could affect the final citation impact of OA publishing, and question statements against or in favor of OA publishing. Discussions related to gold OA are not independent of other factors such as the disciplinary profile of countries' output, national characteristics or types of publishers.

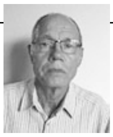
Daniel Torres-Salinas
EC3metrics SL y Medialab-UGR
Universidad de Granada
Granada, Spain
torressalinas@ugr.es

Daniel Torres-Salinas holds a PhD in scientific documentation. He currently works as a bibliometrician at the Universities of Granada and Navarra. He is a researcher in the EC3 Research Group (Evaluación de la Ciencia y de la Comunicación Científica) and focuses on bibliometric topics. In addition, Daniel Torres-Salinas is CEO of the EC3metrics spin-off. He is co-author of various evaluation tools and has published more than 50 scientific.

Nicolas Robinson-García
School of Public Policy
Georgia Institute of Technology
Atlanta, GA, USA
elrobinster@gmail.com

Nicolas Robinson-García is a Postdoctoral Researcher at the School of Public Policy of the Georgia Institute of Technology in the United States. He holds a PhD in Social Sciences from the University of Granada (Spain). He is currently interested in the development of quantitative methods to analyze scientific mobility flows as well as the analysis of new data sources and methods to trace societal engagement of researchers.

Henk F. Moed
Amsterdam, The Netherlands
hf.moed@gmail.com



Henk F. Moed obtained a PhD in Science Studies at the University of Leiden in 1989 and was a senior staff member at the Centre for Science and Technology Studies (CWTS) at Leiden University between 1981 and 2010. From 2010 to 2014 he was Senior Scientific Advisor at the international publishing company Elsevier, Amsterdam, The Netherlands. He has been active in numerous research topics in the fields of bibliometric research and assessment of research performance
Henk Moed has published over 100 research articles in international, peer-reviewed journals, has been program chair of numerous international conferences in the field, and is a member of the Editorial Boards of several journals in his field. He is currently an independent scientific advisor and Visiting Professor at the Sapienza University of Rome and the University of Granada.

6. Science Forecasts: Modeling and Communicating Developments in Science, Technology, and Innovation

Katy Börner, Staša Milojević

In a knowledge-based economy, science and technology are omnipresent, and their importance is undisputed. Equally evident is the need to allocate resources, both monetary and human, in an effective way to foster innovation [6.1, 2]. In the preceding decades, science policy has embraced data mining and metrics to gain insights into the structure and evolution of science and to devise metrics and indicators [6.3], but it has not invested significant efforts into mathematical, statistical, and computational models that can predict future developments in science, technology, and innovation (STI) in support of data-driven decision making.

Recent advances in computational power combined with the unprecedented volume and variety of data concerning science and technology developments (e.g., publications, patents, funding, clinical trials, and stock market and social media data) yielded ideal conditions for the advancement of computational modeling approaches that can be not only empirically validated, but used to simulate and understand the structure and dynamics of STI in support of improved human decision making.

In this chapter, we review and demonstrate the power of computational models for simulating and predicting possible STI developments and futures. In addition, we discuss novel means to visualize and broadcast STI forecasts to make them more accessible to general audiences.

6.1 Models and Visualizations

Science, technology, and innovation are crucial for the prosperity of nations, and are a driving force of human civilization. After World War II, science entered a phase of accelerated growth, reflected in the exponential rise in the number of active scientists and an increase of scientific output [6.4]. Science itself is undergoing a transformation, with most researchers engaging in collaborative or team work [6.5, 6]. In order to create effective science policies and maximize the returns on our society's investments in STI, we must understand STI as a complex and dynamic system that emerges from interdependences and interactions of different actors at different levels of aggregation.

Models of STI aim to inform policy decision making in many fields, including education, energy, healthcare, security, and others [6.7, 8]. These models do not replace—but rather empower—experts to make better informed decisions when selecting reviewers, picking the best proposals for funding, or when making resource allocation decisions. They are a new kind of

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_6

'macroscope tool' [6.9] that help derive key insights from big data in support of evidence-based policy.

Some existing models of STI are optimized to make recommendations. IBM's *Watson*, for example, can suggest reviewers for a set of proposals without much information on the type of match or the matching process. Other models aim to capture the true structure and dynamics of complex STI systems, simulating the diffusion of ideas and experts, estimating the impact of population explosion and aging, or communicating the probable outcomes of different policy decisions. Still others help answer either resource allocation or multifaceted strategic questions, the latter of which are often used in a team setting where small multidisciplinary groups investigate and debate alternative futures together.

Computational models are well established in many fields: meteorology, where they are used to predict weather and storms; epidemiology, to predict and prevent pandemics; and climate, to predict future scenarios and set carbon prices. In industry (hereafter used as a general term to indicate the various industrial sectors, such as retail, IT, car manufacturing, etc.), computational models are used to optimize operations, management, production, distribution, and marketing. Early adopters of data-driven decision making (most notably Target, Walmart, and Amazon) now dominate their sectors. Those who were slow to invest and then did so in isolated aspects of the organization (most notably Sears and Kmart) are headed towards bankruptcy.

Interactive data visualizations that show probable futures in response to different policy decisions or external events can help stakeholders discuss model assumptions, designs, and outputs. Ideally, stakeholders get to "drive the future before it is implemented" [6.10, 11]; they can quickly explore different policy options and discard those that lead to undesired consequences [6.2, 12]. However, designing effective interfaces that let different stakeholders communicate and explore different scenarios is a nontrivial endeavor.

6.2 Models and Modeling

While our world is infinitely complex, our ability to sense, understand, and act within that world is finite. To capture and interpret the structures and dynamics of a complex system such as STI, scientists build models, which are simplified representations of a system [6.13]. Models bring conceptual unity to what is otherwise too complex to understand and manage. Regardless of the approach, the goal of any model is to simplify thinking "while still retaining some ability to illuminate reality" [6.14, p. 11]. In order to understand and predict different aspects of the world, models reduce the world to a subset of elements and laws that govern the behavior of those elements. Such simplification allows researchers to focus on and elucidate only the specific elements of a system that concern them. While every model is bounded by its initial framework, this does not mean that it cannot increase our understanding of the phenomenon at hand.

Complex systems research, however, challenges the notion that by perfectly understanding the behavior of each component of a system, we will understand the system as a whole. While there is no agreed upon definition of complex systems, the combination of various definitions leads to the following characteristics that a system needs to have in order to be considered complex [6.15, 16]. Two major components of a system are its entities and the interactions among those entities, with a much heavier emphasis on the interactions than on the entities.

A complex system usually has a large number of entities that mainly respond to local information (i. e., each element of the system is ignorant of the behavior of the system as a whole). The interactions these entities have can be: nonlinear (small changes in system variables that can have disproportionate outcomes); dynamic (changes over time); rife with feedback loops (both positive and negative, which can lead to distributions such as a power law); fairly rich (any element in the system influences and is influenced by quite a few others); and fairly short range. So far as the system as a whole is concerned, it is open (i. e., interacts with its environment); requires nonequilibrium conditions (there needs to be a constant flow of energy to ensure the survival of the system); and has a history (not only does it evolve through time, but its past is coresponsible for the present behavior).

Computational models consist of input (theories translated first into mathematical equations, and then into algorithms with different parameter values) and output (structures, or the behavior of the model over time). A dynamic system is one which by its very nature changes its state in ways that can be modeled by an application of an evolution law (a set of rules that describe what phase space configuration the system will occupy in the next moment). In the case of complex systems, these rules—though often very simple—can lead to so-called *emergent behavior*, a phenomenon in which "individual, localized behavior aggregates into global behavior" [6.14, p. 44]. When modeling the evolution of dynamic complex systems, researchers must remember that the resultant model represents one configuration in a phase space, given at time t [6.17], and as the models aim to capture system dynamics, output at time t often serves as input for computing time $t+1$.

Typically, the accuracy of simulations increases with both the ease of repetition and the number of simulations run (i. e., the number of possible futures obtained). Running simulations multiple times allows for better estimates concerning the sensitivity of outcomes to initial conditions, as well as the probabilities associated with those outcomes.

Computer modeling is gaining traction as an acceptable approach to doing science in a wide range of fields, from astronomy to economics [6.18]. Computational models use simulations to study the behavior of a system, and these simulations pose new questions regarding the scientific method, the nature of evidence, theory and theory building, and the role of data [6.19]. Outside pressures have forced researchers in climatology—a field heavily dependent on computer models—to be at the forefront of deeply critical thinking regarding the capabilities and limitations of computer modeling [6.20]. In this way, climatology exemplifies how community-lead, large-scale endeavors to gather, model, and visualize data can lead to significant infrastructure building.

Using simulations in the social sciences is a more recent phenomenon; however, a number of excellent resources showcase the benefits of broad usage cases [6.21] and provide practical guidance [6.22, 23]. Computational models can be used both to advance theory via conceptual models, and as tools to enhance decision making via predictions. In both cases, modeling is an iterative process that includes both induction and deduction [6.14] to revise and improve an initial set of assumptions, often leading to better results.

Recent developments in machine learning have dramatically improved researchers' capabilities to identify structures and patterns in data to aid with decision making [6.24, 25]. *Jon Kleinberg* and colleagues [6.26] provide a great overview of what they call "prediction policy problems" ranging from the medical field (predicting which surgeries will be futile) to criminal justice (deciding on whether to detain or release an arrestee).

6.3 Modeling Science

The book *Models of Science Dynamics* [6.8] provides a unique review of major model classes—from population dynamics models to complex network models—accessible to science policy researchers and practitioners. Two special issues in *Scientometrics* entitled *Modeling Science: Studying the Structure and Dynamics of Science* [6.27] and *Simulating the Processes of Science, Technology, and Innovation* [6.28] feature research, applications, and validations of exemplary STI models.

Models capturing the structure and evolution of scientific endeavor fall into one of two categories: descriptive and predictive [6.29]. Descriptive models include maps, and aim to describe the major features of static datasets. Predictive (or process) models aim to capture the mechanisms and temporal dynamics by which real-world systems evolve, focusing on the identification of elementary mechanisms that lead to the emergence of specific structures or dynamics. Ultimately, process models seek to simulate, statistically describe, or formally reproduce statistical characteristics of interest.

Computational models have been developed to enhance our knowledge of fundamental generating processes regarding citing, publishing, careers, rewards, funding, team formation, problem selection, and research areas dynamics. They gained traction in recent years because of their power to simulate processes leading to particular outcomes. Particularly important were findings that identified universal patterns, that is, patterns holding across majority of scientific fields, such as citations dynamics and timing of major discoveries.

A number of scientific models draw from complexity theory. Modern notions of complexity have their roots in theories of chaos, complex systems, fractal geometry, nonlinear dynamics, and self-organizing criticality. Complexity theory has been influential in physical science, technology, and mathematics for some time. This influence is newer and less developed in social science [6.30]. This is unsurprising, since models of complex systems work best with homogeneous elements where there is little or no difference between the individual elements of the system (e. g., atoms and molecules). Using the tools of complexity theory to cover the richness of both entities and their relationships within social systems proves to be a harder task.

The *natural* and *self-organizing* development of science towards more interdisciplinary activities is comparable with ecological systems that exhibit growth and emergent behavior [6.31, 32]. *Anthony van Raan* [6.33] expanded on this idea, portraying science not only as an interdisciplinary, complex, and self-organizing system, but as an amalgam of "cognitive regions" derived from the parts of pre-established disciplines. Such disciplines represent research fields that originated from earlier interdisciplinary developments.

In this model, science itself is a living, complex and dynamic system consisting of several ever-growing subsystems, each of which unfolds further into a myriad of different fields and subfields. A variation of the so-called "epidemics model" [6.34] was used in the 1960s to develop an epidemic theory on the diffusion of ideas and the growth of scientific specialties [6.35]. By using mast cell research as a case study, William Goffman demonstrated that it was possible to see growth and development as sequences of overlapping epidemics.

A wide range of studies used network-based models of citations to understand different aspects of science. A number of studies focused on understanding the dynamics of citation accumulation, starting from the identification of cumulative advantage/preferential attachment as the driving mechanism behind the power-law distribution of citations [6.36, 37]. *Filippo Radicchi* et al. [6.38] found that citation distributions are universal across fields by replacing the raw number of citations with relative ones. More advanced models of citation dynamics have focused on features such as the obsolescence of knowledge, which leads to a decrease in the number of citations as a function of time [6.39, 40].

Dashun Wang et al. [6.41] have developed this idea the furthest, developing a generative model that takes into account three parameters (the number of previous citations, obsolescence, and fitness) to predict citation dynamics of individual papers. Such network approaches are also used to identify communities of research papers that frequently cite one another [6.42], a task of enormous importance for policy and evaluation. These citation networks were also used to trace the usage of words and phrases to determine whether the usage of such words corresponds to the emergence of new paradigms [6.43].

While most network models focus on a single type of node at a time, some combine a number of different types of nodes. For example, work by *Feng Shi* et al. [6.44] aims to understand how choices at the microlevel (e. g., an individual scientist's choice of topics) may constrain the development and advancement of knowledge at the macrolevel, making incremental advances/improvements to the things that are already known, rather than huge leaps to unconnected—and therefore still unimagined—futures.

A number of models focus on scientific careers. For example, *Alexander Petersen* et al. [6.45] developed a generative model showing the detrimental effect policy decisions related to the increased availability of short-term positions have on researchers' productivity levels. Work by *Albert-László Barabási* and his team uses a stochastic model to show that the timing of one's most important contribution is not the result of (academic) age, but can occur at any stage of one's career, and is a function of productivity [6.46].

Agent-based models can reveal the microprocesses of individuals that lead to particular macrolevel patterns. These models focus on the relations and interactions among entities rather than the characteristics of the entities themselves. *Nicholas Payette* [6.47] provides an excellent overview of agent-based models in the context of studying science. *Nigel Gilbert* introduced the first agent-based model to study science focused on papers (rather than authors) as agents and managed to reproduce Lotka's law of productivity, as well as the rise and decline of specializations [6.48].

Katy Börner et al. [6.49] developed a more nuanced model called TARL (topics, aging, and recursive linking), in which they simulate the simultaneous coevolution of networks of papers and authors driven by the "rich-get-richer" phenomenon [6.37, 50, 51]. *Xiaoling Sun* et al. [6.52] revisited the topic of the growth and decline of disciplines, proposing an agent-based model in which the evolution of disciplines is guided mainly by social interactions of scientists writing papers together. The disciplines thus rise and fall through the splitting and merging of communities of collaborators.

A key insight to be drawn from existing model results is that science is complex, and therefore the study of science is also complex. This complexity comes from the fact that not only are communication processes under study multilayered, but that both the data and the latent structures within the data are evolving over time. Furthermore, it is now obvious that the intricate relationships between social, conceptual, cognitive, and institutional forces need to be taken into account to fully understand the organization of science.

Despite great advances towards expanding our understanding of science, there are definite limitations in terms of predicting the emergence of a new field [6.53]. These deficiencies are due to the fact that 'normal science' is much easier to predict than 'radical innovations'. External forces (new policies, wars, etc.) have a major impact on the development of science, while data access and model development are both limited.

Current work focuses on the expansion of data sources from the traditional output of research in the forms of bibliographic data on publications, grants, and patents to the analysis of full text of those resources, grant applications (both successful and unsuccessful), mentorship (formal and informal), conferences, employment data, social media, etc. [6.53]. In parallel, algorithm development aims to capture not only strong associations but also causation [6.53, 54]. One step in that direction is using counterfactual scenarios to assess how well models perform [6.26, 55–57].

6.4 Exemplary Models of Science

This section discusses two science models in more detail. The first example describes how teams in various fields have evolved over time, and what it is they contribute to contemporary science. The second example proposes radical changes to the current funding system. Both of these models have been empirically validated, and reveal a high correlation between the simulated datasets and the structures/dynamics found in publication and funding data.

6.4.1 The Importance of Small Teams in the Big Science Era

Contemporary science is a collaborative effort within an intricate network of people, institutions, concepts, and technology. Many projects are of such complexity and scope that they require the joint efforts of many individuals with diverse expertise, culminating in teams of hundreds. Furthermore, studies suggest that large, interdisciplinary teams are more likely to produce high-impact work.

Yet only 50 years ago, the situation was very different. Most papers were written by single authors, and the largest coauthor teams did not exceed ten members. How did this change in the production of knowledge occur? How do science teams form, and what processes lead to their expansion? Perhaps most importantly, what makes a successful team?

Considering these questions, team size distribution lies at the heart of our understanding of collaborative practices and research productivity. As Fig. 6.1 shows, knowledge production today is qualitatively different from that of earlier times: *little science* performed by individuals or small groups of researchers is largely superseded by *big science* efforts conducted by large teams that span disciplinary, institutional, and national boundaries.

In Fig. 6.1, we see a change in the distribution of research team sizes in physics from a Poisson distribution to one dominated by a fat tail (a power law). In 1941–1945, for each paper with five authors, there were one thousand single-authored papers (blue). In 2006–2009, there were as many papers with five authors as there were single authored papers (red), and very large teams were not uncommon. Such a distribution (Fig. 6.1) can be reproduced using the model developed by *Staša Milojević* [6.5], which demonstrated how teams emerge, grow, and would evolve in the future.

Vitally, Milojević's model shows that team formation was, and remains, a Poisson process resulting in relatively small core teams (including single-investigator teams) carrying out certain types of research. The model also simulates the emergence of larger teams over the last 50 years in all fields of science, albeit with varying pace and magnitude of change.

According to the Milojević model, every big team originates from a small team; while some small teams do not change in size, others quickly accumulate additional members proportionally to the past productivity

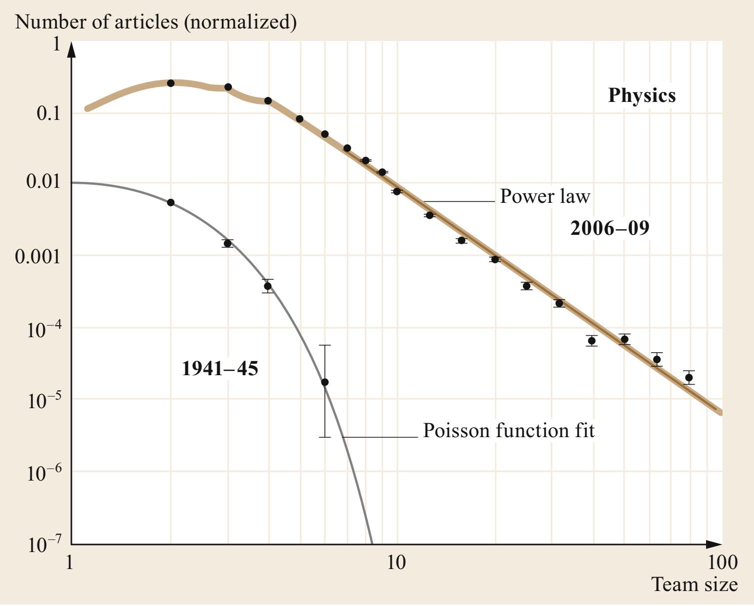


Fig. 6.1 Change in the distribution of team sizes

of preexisting team members, eventually allowing small teams to grow into big teams.

Furthermore, Milojević's model shows that relatively small teams dominate knowledge production in most fields; cumulatively, small teams still contribute more new knowledge than large teams. These findings are of key importance to policy, because they show that increased funding emphasis on large teams may undermine the very process by which large, successful teams emerge.

6.4.2 Crowdsourcing Funding Allocation

As funding agencies consume resources that could be more productively used to conduct and finance research, *Johan Bollen* et al. [6.58] argue that scholars "invest an extraordinary amount of time, energy and effort into the writing and reviewing of research proposals". In their 2014 paper, they used National Science Foundation (NSF) and Taulbee Survey data to calculate the return on investment for scholars in computer science. This calculation reveals a negative return on investment.

Given a computer and information science and engineering (CISE) funding rate of 21%, four professors working full-time for four weeks on a proposal submission with labor costs of about \$35 000, five submission-review cycles may be required, resulting in a total expected labor cost of \$175 000.

The average NSF grant is \$164 526 per year, to which US universities charge about 50% of their overhead, leaving roughly \$109 684 for research. Consequently, the four professors in question lose \$65 316 of paid research time by obtaining a grant. US universities might even forbid professors to apply for grants—if they can afford to forgo the indirect dollars. Note that this simple calculation does not cover any time spent by scholars to review proposals. In 2015 alone, NSF conducted 231 000 proposal reviews to evaluate 49 600 proposals.

Bollen et al. [6.58] then go on to propose a *FundRank* model to (partially) replace the current process of government research funding allocation by expert-based crowdsourcing. In this new FundRank system, each eligible scholar (e. g., all eligible to submit NSF and National Institutes of Health (NIH) grants today) receives a certain dollar amount each year—let's say \$100 000. She then needs to give a certain fraction (e. g., 50%) to colleagues that are most deserving by logging into a centralized website and entering names and amounts. In this way, scholars collectively assess each other's merit and *fund-rank* one another, with high ranking scholars receiving the most funding.

Instead of spending weeks writing and reviewing proposals, scholars are now incentivized to spend time communicating the value and impact of their past, current, and planned work so that others can judge their contributions. Using a fully digital system, conflicts of interest could be easily identified and honored; networks of mutual favors could be detected automatically, and results shared publicly.

FundRank was implemented using the recursive PageRank algorithm pioneered by *Page* and *Brin* [6.59]. Using PageRank, the "importance" (here consisting of reputation, value, and impact) of a scholar depends not only on the number of scholars that vote for her, but also their importance. The more important the scholars that link to a person, the more important the person must be. The FundRank model was validated using citation data from 37 million papers over 20 years as a proxy for how each scientist might distribute funds within the proposed system. Simulation results show funding patterns that have a similar distribution compared to NSF and NIH funding for the past decade—at a fraction of the cost required by the current system.

6.5 Challenges

Using mathematical, statistical, and computational models of STI in decision making poses a new and diverse set of challenges, many of which can be viewed as opportunities. Such challenges/opportunities are related to fundamental research, applied research, cyberinfrastructure, education, and outreach.

6.5.1 Fundamental Research

Research concerning STI is conducted across a wide range of disciplines, including (but not limited to): economics, social sciences, information sciences, science policy, scientometrics/bibliometrics, and physics. Researchers in these disciplines develop mathematical, statistical, and computational models of different types (stochastic, agent-based, epidemics, game-theoretic, network, etc.) to address the questions they are interested in.

One of the factors impeding the advancement of fundamental research is lack of free access to high-quality data. Such access would significantly reduce data curation efforts currently being done by each individual team, and as a consequence, would enable reproducibility. An additional challenge facing this type of research is the lack of obvious sources offering continuous funding.

Furthermore, researchers exploring STI modeling tend to publish in a wide range of venues, often addressing vastly different audiences. Current research efforts and the results of said efforts are not universally known to the researchers, let alone policy makers. Such a widespread state of ignorance slows scientific progress and can even lead to unnecessary reinventions of the wheel. Scientific events that foster interactions among intellectually diverse communities and shed new light on problems by forcing researchers and practitioners to think and talk about their own research in new ways would help address this issue.

In the meantime, to arrive at policy-relevant solutions, researchers and analysts must pose good questions rather than focus solely on outcomes. Moving from descriptive to normative theories seems desirable. One major research challenge concerns the development of multiscale models—covering the micro (individual) to macro (population) levels—and understanding the appropriateness of particular models for particular scales. Ultimately, STI modeling experts should keep an open mind, and aim to learn from other branches of science (e. g., physics, economics, medicine) that are actively working on systems-science approaches.

6.5.2 Applied Research

One of the main reasons for the relatively low adoption rates of STI models is that these models are developed within different government institutions/agencies, and as a consequence often lack wider exposure. Relationships between model builders and users/stakeholders are often strained by poor communication at all stages of development, from the initial design (what question is being asked, what assumptions are being made, what measures and metrics are being used, etc.) to the interpretation and application of the results to real-world problems. This strain is further exasperated by an inherently opaque modeling process that neither creates nor maintains a sense of *buy-in* from the very beginning of a project.

For those interested in further reading, there are a few case studies that provide insights into the possibilities and challenges of carrying out applied research using modeling [6.60]: *Charles Phelps* et al., for example, implemented a tool for the measurement of the importance of vaccines—*SMART Vaccines*—which was then used by decision makers rather than model builders [6.61].

6.5.3 Cyberinfrastructure

As with many other disciplines, a robust cyberinfrastructure (e. g., data and model repositories, computing and visualization infrastructures) will greatly benefit STI modeling efforts. Many of the sciences have already setup billion-dollar international data infrastructures, and distributed computing systems in close collaboration with their government and industry partners, with impressive effect. Such synergy can be seen in the fields of meteorology (e. g., weather forecasts and hurricane and tornado prediction), epidemiology (e. g., predicting the next pandemic and identifying the best intervention strategies), climate research (e. g., predicting future scenarios and setting carbon prices), and financial engineering (e. g., stock trading and pricing predictions).

Sadly, no such universal infrastructure yet exists for the study and management of STI modeling, leading to up to 80% of project efforts being commonly spent on the acquisition, cleaning, interlinkage, and preprocessing of relevant data. Despite great benefits of building common infrastructure that we've witnessed in the natural sciences—where building a general infrastructure of commonly used data available to all has led to major advances (e. g., climate studies, astronomy, etc.)—STI modeling resources have been largely spent on individual project levels. Such a model of funding is unconducive to quick advancement of this area; successful STI modeling requires validation, iterative improvement, and a community of users, all of which could be provided via appropriate cyberinfrastructure. However, building such an infrastructure will require active partnerships among academia, government, and industry.

6.5.4 Education and Outreach

Advancing science, technology, and innovation requires extensive education and training. Recent studies show that data visualization literacy—the ability to read and write data visualizations—is relatively low [6.62]. Going forward, introducing computational modeling into formal and informal education will prove vital. More proactive and involved partnerships between stakeholders and modelers will allow for simpler models that can be understood and validated more easily. Such active partnerships will in turn help modelers deliver a timely and effective product, while also helping stakeholders determine their usefulness. At the same time, there is an urgent need for researchers, model builders and other users to enhance their communication and visualization skills.

Modeling results also need to be communicated effectively to different types of stakeholders. Storytelling and the art of communicating major results and recommendations in a clear and simple message is vital. Recent reports by the US National Academy of Sciences [6.63] and the National Academies of Sciences, Engineering, and Medicine [6.64] emphasize the importance of communication with nonscientists, and provide excellent examples of how such communication can be achieved.

6.6 Insights and Opportunities

As we have made clear, computational models of STI are deeply complex, and special effort is required to communicate not only their inner workings, but the implications of their results to relevant stakeholders. With this in mind, visualizations of data quality, data analysis, model parameter effects, and near real-time forecasts of STI developments can substantially increase the adoption rate and utility of modeling efforts.

6.6.1 Modeling Needs and Implementation

Modeling research and development strongly depend on understanding the problem at hand, as well as the range of actions a decision maker can take in response to that problem. If the wrong problem is modeled, or if suggested actions are infeasible (e. g., doubling the US R&D funding budget), then model utility as a consequence will be low.

Furthermore, there is a major difference between statistical significance and *business relevance*. For example, models used by PayPal need to avoid causing substantial costs via *false positives* (unidentified malicious users that cost PayPal money) but also via *false negatives* (valued customers with blocked accounts that cost PayPal reputation and might lead to bad press).

Model validation is of paramount importance. Ideally, different types of models can be applied to capture the structure and dynamics of that very same complex system and only if multiple models predict the same results should these results be used to make informed decisions.

Experts will need to work across disciplinary and institutional boundaries to exploit synergies, and to arrive at modeling results that are greater than the sum of their parts. There is a need for—and advantage to be gained from—combining basic and applied contract work [6.65]. Model developers (e. g., in academia and industry) should aim to *room in* with model users (policy and other decision makers) in an effort to foster active relationships.

Computational models also need to be vetted by experts, and as a consequence earn the trust of the scientific policymaking community before many start using them in practice. Key to building trust is the dogged pursuit of transparency, and also engaging stakeholders in the design and application of STI models. Easy-to-use, simple models that answer real-world questions are more readily adopted by decision makers than complex models with many parameter values.

Different policy offices have different abilities to absorb and implement models. Resistance to the adoption of new tools and approaches in general is unavoidable; the United States Federal Government, perhaps most notoriously, is the largest and most complex organization in the world, yet remains poorly understood and continues to use outdated decision support tools and processes. Models could be extremely useful when making resource allocation decisions, whether promoting agency missions, or managing international crises. Systems dynamic modeling is considered the best option, and yet not much has changed over the last decade since these approaches were first suggested. This can be attributed—simply, and frustratingly—to the human unwillingness to adapt and change.

6.6.2 Data Infrastructure

High-quality and high-coverage data is an imperative ingredient in high-quality modeling results. Currently, multiple teams are overlapping their efforts in cleaning, interlinking, and processing the same data (e. g., publication or patent data), and as a consequence are reducing the total amount of resources that could be spent on model research or validation. What's worse is that such data is preprocessed in slightly different ways across teams, making it hard or impossible to replicate results across sites.

While having so-called *big data* regarding science and technology dynamics is important to answer certain questions, having *more data* is not—and should not be—the answer to modeling questions. Though a large number of modelers use unstructured data, structured data boasts unique values, and as it becomes increasingly available [6.66] should also be explored. Given that many high-quality datasets are held by various sectors of industry (e. g., Web of Science and Scopus publication data, LinkedIn expertise profile data, Twitter or Instagram data, etc.) it appears highly desirable to work closely with them. Going forward, data sharing, data repositories, and joint data curation efforts should be explored as universal practices.

6.6.3 Code Repository and Standards

Efficient means by which to share STI model code are essential, not only to ensure replicability and reproducibility of model results, but also to support model comparisons and effective teaching. While some teams actively use the repository GitHub.com to share code and documentation, STI models remain difficult to locate among the millions of open-source code projects stored there.

The time is ripe to focus the energies and resources of researchers on building a cyberinfrastructure and a research community to support both systematic research and development efforts. Instead of creating a new repository, it would be most efficient to build upon and extend/interlink existing model repositories. Existing data repositories can be broken into three categories: academic, government, and industry.

Academic Repositories

Academic repositories are typically associated with a tool. For example:

- *Agent Modeling Platform* (AMP) project provides "extensible frameworks and exemplary tools for representing, editing, generating, executing and visualizing agent-based models (ABMs) and any other domain requiring spatial, behavioral and functional features." (http://www.eclipse.org/amp)
- *GAMA* is a "modeling and simulation development environment for building spatially explicit agent-based simulations." (https://github.com/gama-platform)
- *NetLogo* is a "multi-agent programmable modeling environment. It is used by tens of thousands of students, teachers and researchers worldwide. It also powers HubNet participatory simulations." (http://ccl.northwestern.edu/netlogo)
- *MASON* is a "fast discrete-event multi-agent simulation library core in Java, designed to be the foundation for large custom-purpose Java simulations, and also to provide more than enough functionality for many lightweight simulation needs. MASON contains both a model library and an optional suite of visualization tools in 2D and 3D." (http://cs.gmu.edu/~eclab/projects/mason)
- The *Repast Suite* is a "family of advanced, free, and open source agent-based modeling and simulation platforms that have collectively been under continuous development for over 15 years." (http://repast.sourceforge.net)

Repositories might also be created for specific research projects. For example, SIMIAN (http://www.simian.ac.uk) funded by the Economic and Social Research Council to promote and develop social simulation in the UK, uses the SKIN model (https://github.com/InnovationNetworks/skin). Another example is OpenABM (https://www.openabm.org) that provides a growing collection of tutorials and FAQs on agent-based modeling as part of the CoMSES Network.

Government Institutions

Government institutions aim to support sharing of datasets or tools. NSF's *SciSIP* program maintains a listing of "Datasets, Graphics & Tools" pertinent to the *Science of Science Policy* (SOSP) community at http://www.scienceofsciencepolicy.net/datasets_tools.

The *Interagency Modeling and Analysis Group* (IMAG) (https://www.imagwiki.nibib.nih.gov) and the Multiscale Modeling Consortium aim to grow the field of multiscale modeling in biomedical, biological and behavioral systems, to promote model sharing and the development of reusable multiscale models, and disseminate the models and insights gained from the models to the larger biomedical, biological, and behavioral research community, among others.

The *Predictive Model Index* lists over 100 reusable, sharable models in support of reproducible science (https://www.imagwiki.nibib.nih.gov/model-indexing). The *Centers for Disease Control and Prevention* (CDC) made the "H1N1 Flu (Swine Flu): Preparedness Tools for Professionals" software available at http://www.cdc.gov/h1n1flu/tools. The page was developed during the 2009–2010 H1N1 pandemic, but it has not been updated, and is being archived for historic and reference purposes only.

Publishers typically aim to ensure replicability of work by asking authors to submit datasets and models. Examples are The *Journal of Artificial Societies and Social Simulation* (JASSS, http://jasss.soc.surrey.ac.uk/JASSS.html), an interdisciplinary journal for the exploration and understanding of social processes by means of computer simulation; published since 1998, *JASSS* recommends authors upload model code and associated documentation to the CoMSES Net Computational Model Library (https://www.comses.net/codebases/). As of June 2016, the CoMSES library featured 352 agent-based models.

Industry

Industry has long embraced big data and advanced data mining, modeling, and visualization algorithms. Computational models are widely used in online recommendation services (e. g., those provided by Amazon or Netflix), and by financial and insurance companies (e. g., to detect credit card fraud and estimate fees). Many companies use models internally to support strategic decision making, and to guide investment decisions. While code is typically proprietary, close industry-academia-government collaborations are likely beneficial for all parties involved.

6.6.4 Visualization and Communication of Modeling Results

Global operation rooms that provide visualizations of current data and predictions of possible futures (already commonplace in the fields of meteorology, finance, epidemiology, and defense) might soon be commonplace in support of funding, strategic intelligence, or policy decision making.

William Rouse has been pioneering "policy flight simulators" that let decision makers fly the future before they write the check [6.10]. His team uses a combination of commercial off-the-shelf tools (e. g., AnyLogic, D-3, Excel, R, Simio, Tableau, and Vensim) rather than writing software from scratch. This practice can enable creation of a prototype interactive environment within a week or two, which in turn allows rapid user feedback and easy midcourse corrections.

Meanwhile, *Ben Shneiderman* and his team developed EventFlow, a novel tool for event sequence analytics that includes a timeline display showing all individual records, their point and interval events, as well as an aggregated view of all the sequences in the dataset (http://hcil.umd.edu/eventflow) [6.67]. Among others, the tool supports the examination of data quality before any type of data analysis is conducted or visualizations are rendered—blind usage of data is dangerous.

Storytelling in particular provides a powerful means to communicate data analysis and modeling results [6.63, 68]. Merging data with narrative, especially when communicating the value of research, is a primary way to connect to policymakers.

Katy Börner and her team are developing and prototyping *Science Forecasts*; a news show that communicates local and global developments in science, technology, and innovation to a general audience. In Spring 2015, a pilot episode was recorded featuring a moderator that explained trends using an animated map of science, analogous to a weather forecast. Zeroing in on specific research results using Twitter for detecting episodes of depression, the information was presented by Johan Bollen and Fred Cate, both faculty at Indiana University. A still image of the news can be seen in Fig. 6.2.

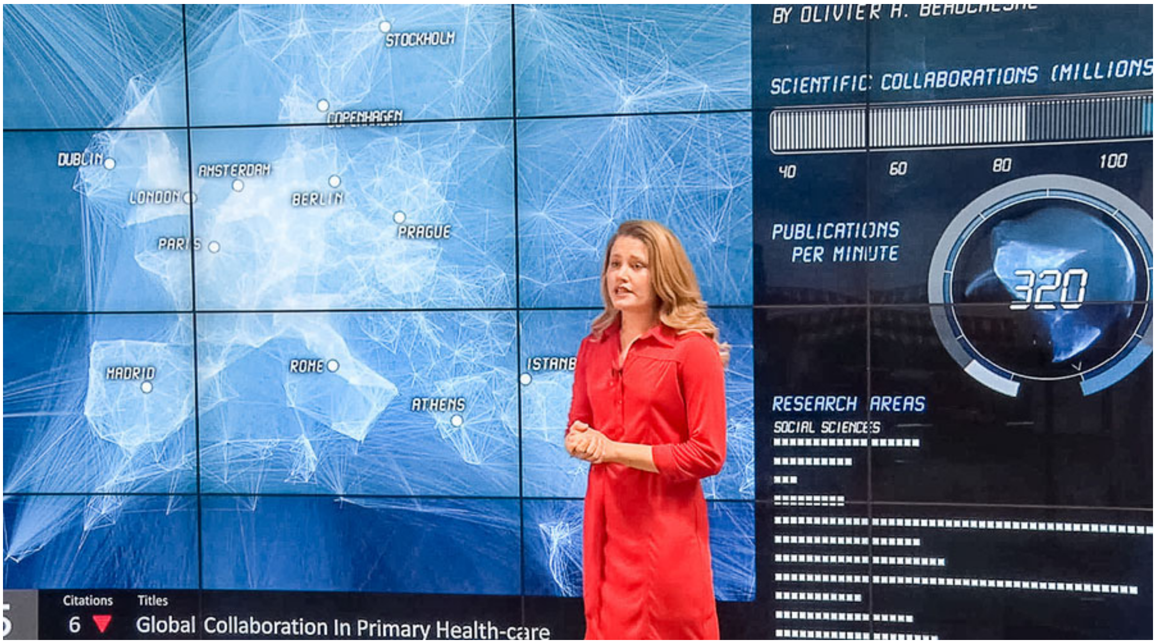

Fig. 6.2 *Science Forecast*, recorded at Indiana University, presents interviews and animated maps of scientific activity in a manner similar to weather forecasts. The program demonstrates the power of data and visual analytics to provide up-to-date stories on science trends and developments

6.7 Outlook

In 2007, *Issues in Science and Technology* published *The Promise of Data-Driven Policymaking* by *Daniel Esty* and *Reece Rushing* [6.69]. In 2016, the same magazine published "Data-Driven Science Policy" [6.7]. The articles both point out that in the corporate sector, a wide variety of data-driven approaches are used to boost profits, including systems that improve performance and reliability, evaluate the success of advertising campaigns, and determine optimal pricing. Both articles argue for the need for—and discuss the premise of—data-driven decision making and policy making in STI using large-scale, high-quality datasets, and computational means to inform human decision makers.

Today, in 2019, a wide range of mathematical, statistical, and computational models exist that were developed and implemented in a variety of settings to increase our collective understanding of the structure and dynamics of STI and to support human decision making. While academic researchers typically focus on work that can be published, there is a growing emphasis by researchers and practitioners on the power of models to advance future decision making, and to communicate the usefulness of models to simulate, explain, and communicate the past, present, and future.

Acknowledgments. Bloomington, IN, USA
katy@indiana.edu

Katy Börner is Victor H. Yngve Distinguished Professor of Engineering and Information Science in the School of Informatics, Computing, and Engineering, Adjunct Professor at the Department of Statistics in the College of Arts and Sciences, Core Faculty of Cognitive Science at Indiana University. She holds an MS in Electrical Engineering from the University of Technology in Leipzig (1991) and a PhD in Computer Science from the University of Kaiserslautern (1997).

Staša Milojević

School of Informatics, Computing, and Engineering
Indiana University
Bloomington, IN, USA
smilojev@indiana.edu

Staša Milojević is an Associate Professor of Informatics in the Center for Complex Network and Systems Research in the School of Informatics, Computing, and Engineering at Indiana University. Her work covers a range of topics within the "science of science": dynamics of research teams, collaborative networks, formation and evolution of scientific fields, and research metrics. She received a PhD in Information Studies from the University of California, Los Angeles.

7. Science Mapping Analysis Software Tools: A Review

Jose A. Moral-Munoz, Antonio G. López-Herrera, Enrique Herrera-Viedma, Manuel J. Cobo

Scientific articles are one of the most important types of output of a researcher. In that sense, bibliometrics is an essential tool for assessing and analyzing academic research output contributing to the progress of science in many different ways. It provides objective criteria to assess research developed by researchers, being increasingly valued as a tool for measuring scholarly quality and productivity. Science mapping is a bibliometric tool to analyze and mine scientific output. The aim of this chapter is to present a thorough review of science mapping software tools, showing strengths and limitations. Six software tools that meet the criteria of being free, full, and allowing the whole analysis to be performed are analyzed:

- BibExcel
- CiteSpace II
- CitNetExplorer
- SciMAT
- Sci^2 Tool
- VOSviewer.

This analysis describes aspects related to data processing, analysis options, and visualization. The particular properties of each tool that allows us to analyze the science are presented, the choice of a particular tool one depends on the type of actor to be analyzed and the output expected.

7.1 Science Mapping Analysis

According to *Price* [7.1], science, in a concise definition, is determined as that which is published in scientific publications, and the researcher is the person who collaborated in writing some of these publications. Therefore, it is clear that the publication is the mean by which research is evaluated, validated, and transferred. With respect to the set of scientific publications, attention is mainly focused on documents published on academic journals, but there are also other kinds of publications, such as proceedings, patents, books, etc. As mentioned in the above definition, academic articles published by researchers have developed at quick pace. Moreover, nowadays there are many global bibliographic databases, indexing millions of scientific documents. For example, the Web of Science (WoS) core collection indexes more than 12 000 journals, and Scopus indexes around 18 000 journals. These kinds of databases offer a wealth of information (such as authors, titles, journals, keywords, institutions, citations, etc.) to be analyzed, and consequently, generate new knowledge in relation to different aspects of the science.

In order to analyze and evaluate scientific activity, a huge amount of data is needed. Thus, the analysis of this data is performed using intelligent techniques and tools. In this sense, bibliometrics is an important tool for assessing and analyzing the scientific production contributing to the advance of science in a wide range of ways [7.2, 3]. Furthermore, it gives objective criteria to evaluate a researcher's production, being progressively valued as a tool for assessing academic

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_7

quality and productivity [7.4]. It is a useful approach to assess and analyze the different actors that produce research [7.5]:

1. Countries
2. Universities
3. Research centers
4. Research groups
5. Journals
6. Researchers.

On the other hand, it should be noted that bibliometrics has been used for quantitative production evaluation, but in the last decades it has been starting to be used as a research tool in its own right [7.6, 7]. The approaches employed to perform the bibliometric analyses can be used to explore the impact of a research area, a set of researchers, or a particular article [7.8]. In addition, the analysis output could help to optimize research allocation, reorient funding, rationalize organizations, and restrict or increase productivity in other areas [7.9].

In relation to bibliometrics, it can be divided into two main areas [7.10]: performance analysis and science mapping analysis. The former assesses the different scientific producers using the bibliographic data and applying bibliometric indexes (e. g., *H*-index [7.11], HG-index [7.12], etc.). The latter is dedicated to showing the structural and dynamic aspects of a research field, and how it evolves through time [7.13–15]. Particularly, it tries to find a representation of the intellectual connections and its evolution in a knowledge area [7.16].

In order to perform a science mapping analysis, a great variety of software tools can be used. Among the available tools, some have a generic aim and come from the field of statistics or social network analysis. Nevertheless, in 2011, *Cobo* et al. [7.17] described the main software tools developed specifically for this task. Since then, new software tools have appeared, and new versions of the previously described tools have been released. Thus, an updated review of the available software is given in this chapter. The tools that meet the following criteria have been taken into account:

1. They are freely available.
2. The software is complete in itself.
3. They allow to perform the whole analysis to be performed.

Nevertheless, there are other interesting options to cover different necessities or preferences.

Regarding generic software, Pajek [7.18] and Gephi [7.19] are the most remarkable options. They allow analysis of different aspects related to networks and offer several visualization modes. Nonetheless, they do not have preprocessing tools that allow to perform some transformations from the retrieved data. In other words, the user may use the final network file.

Among the APIs (application programming interface), there are also different alternatives available, such as Bibliometrix [7.20], Citan [7.21], Sciento-text [7.22], and BiblioTools [7.23]. The three first tools are based on R packages and BiblioTools in Python. They offer different analysis options to perform different analyses but have the inconvenience using non-bibliometric full software.

Other available tools are those based on a relational database model in which the user can perform some Structured Query Language (SQL) queries [7.24, 25]. These kinds of tools are designed to perform science mapping analysis, extracting different indicators.

Furthermore, there are others tools focused on preprocessing step, such as Software Tool for Improving and Converting Citation Indices (STICCI) [7.26]. It performs several dataset format conversions, corrects mistakes, duplications, misspellings, name variants, etc. Thus, it is an interesting tool for preparing the database.

On the other hand, it is worth highlighting a commercial option, VantagePoint [7.27]. This is a tool for discovering knowledge in relation to patent and academic databases.

In addition to software focused on science mapping analysis, there are other tools that allow performing other kinds of bibliometric studies, such as CRExplorer [7.28]. This is focused on detecting the main production of a field, based on the referenced publication years spectroscopy (RPYS) method [7.29].

The chapter is structured in four main sections. In the first section, the main characteristics of the bibliometric networks are described. In the second section, each software tool is thoroughly described, highlighting the distinctive features of each one. In the third section, a comparative analysis among the software is shown. In the last section, some conclusions from the review performed are made. Thereupon, the aim of this chapter is to introduce readers to the science mapping analysis tools available.

7.2 Bibliographic Networks

An important feature in relation to the available science mapping analysis software is the possibility of building several networks according to the different units of analysis. In other words, the software capacity to extract different bibliometric networks is of central importance.

Different bibliographic or bibliometric networks are available in the scientific literature [7.30, 31]. The main characteristic of these types of networks is that they are composed of nodes and edges. Nodes represent publications, journals, researchers, or words. Edges show relations between two nodes. Bibliometric networks used are weighted, and the most common are based on relations of citations, keyword co-occurrence, and co-authorship. In the networks, the edges not only indicate the relation between the nodes, also the strength of the relation. In the following paragraphs, the co-citation, bibliographic coupling, keywords co-occurrences, and co-authorship networks will be briefly described. Table 7.1 shows the characteristics of the main bibliometric networks [7.17]:

1. Bibliometric techniques
2. Units of analysis
3. Type of relations analyzed by these techniques:

- Co-citation networks: According to the definition of co-citation [7.32], two publications can be considered as being co-cited if a third publication cites both of them. The strength of the co-citation relation will depend on the number of publications that cites both publications together. Thus, the higher the number of co-citations, the stronger the co-citation relation.
- Bibliographic coupling networks: In this case, two publications are bibliographically coupled if a third publication is cited by both publications [7.33]. A higher number of references shared by two publications indicates a stronger bibliographic coupling relation between them.
- Co-authorship networks: In this kind of bibliometric network, the different actors (researchers, institutions, or countries) are linked to each other according to the number of publications that they have authored together [7.34].
- Word co-occurrences networks: In order to build this kind of network, terms are extracted from the title and abstract of a set of publications, as well as from the keywords listed by the author when the document was submitted. The number of co-occurrences of two keywords depends on the number of documents where both appear together in the title, abstract, or author's keyword list [7.35].

Table 7.1 Bibliometric networks types

Bibliometric techniques		Units of analysis	Relations
Co-citation	Author	Author's reference	Co-cited author
	Document	Reference	Co-cited documents
	Journal	Journal's reference	Co-cited journal
Bibliographic coupling	Author	Author's oeuvres	References among author's oeuvres
	Document	Document	References among documents
	Journal	Journal's oeuvres	References among journal's oeuvres
Co-author	Author	Author's name	Authors' co-occurrence
	Country	Country from affiliation	Countries' co-occurrence
	Institution	Institution from affiliation	Institutions' co-occurrence
Co-word		Keyword or term extracted from title, abstract or document's body	Terms' co-occurrence

7.3 Science Mapping Software

Several software tools have been specifically developed to analyze scientific domains by means of science mapping. In this chapter, the tools that meet the following criteria have been analyzed:

1. Freely available tools
2. Full software tools (APIs were excluded)
3. Tools that allow the whole analysis to be performed.

Therefore, we present six representative software that allow us to analyze different aspects in relation to science:

1. BibExcel [7.36]
2. CiteSpace II [7.37]
3. CitNetExplorer [7.38]
4. SciMAT [7.39]
5. Sci^2 Tool [7.40]
6. VOSviewer [7.41].

In Table 7.2, general information about the software analyzed is shown. Nevertheless, it should be taken into account that the software tools analyzed are still being developed, and, therefore, there will be new releases incorporating new features.

In the following sections, the main characteristics of these tools are depicted. Aspects related to data processing, analysis options, and visualization will be described for each tool.

7.3.1 BibExcel

BibExcel [7.36] is intended to help users analyze bibliographic information or any information of a textual nature formatted in a comparable manner. The idea is to create data files that can be imported to Excel or any program that takes tabbed data records (such as Statistical Package for the Social Sciences (SPSS), UCINET [7.42] or Pajek [7.18]) for further handling. It was developed by Olle Persson at the University of Umeå, Sweden.

This software incorporates various tools, some of them visible in the window and others hidden behind the menus. Many of the tools can be used as a part of mix to accomplish the desired outcome. The main characteristic of this software is its flexibility, but for this reason, it could be initially perceived as difficult to use by new users.

Furthermore, if we take a look to the recent research literature, several applied studies can be found. For instance, some of the latest studies carried out with BibExcel are focused in different thematic areas, such as:

1. Transport geography research [7.43]
2. Space research [7.44]
3. Intelligent transportation systems [7.45]
4. Scientific production on open access [7.46]
5. Ebola research [7.47]
6. Project management success [7.48].

Therefore, although this software does not offer the possibility to obtain a visualization without using a different tool, as has been observed, it is a tool frequently used in bibliometric studies.

Table 7.2 Software tools general information

Software tool	Analyzed version	Year	Developed by
BibExcel	2016-02-20	2016	University of Umeå (Sweden)
CiteSpace II	5.0.R4 SE	2017	Drexel University (USA)
CitNetExplorer	1.0.0	2014	Leiden University (The Netherlands)
SciMAT	1.1.04	2016	University of Granada (Spain)
Sci^2 Tool	1.2	2015	Cyberinfrastructure for Network Science Center (USA)
VOSviewer	1.6.5	2016	Leiden University (The Netherlands)

Data Processing

BibExcel can read information retrieved from various bibliographic sources, for example, WoS, Scopus, and the ProCite export format. Nevertheless, if the user has learned the typical BibExcel file structure, different types of documents can be formatted in order to be analyzed.

On the other hand, it allows us to submit the textual data to different preprocessing tasks, such as an English word stemmer, document deduplication, and text transformation (keeping authors' first initials, converting comma-delimited addresses, etc.). Besides, BibExcel empowers the deletion of low recurrence items and keeps just the strongest links. On the other hand, it provides different options to extract data (publication year, author name, etc.) and to remove it (DOI, reprint author, first column, etc.).

Analysis Options

Different bibliometric networks can be obtained using the parameters offered by this tool. The main networks are:

1. Co-citation
2. Bibliographic coupling
3. Co-author
4. Co-word.

Moreover, it is possible to create different co-occurrence matrices taking any document's field or combining some of them. Then, these matrices can be submitted to a normalization process using three measures:

1. Salton's cosine [7.49]
2. Jaccard's index [7.50]
3. Vladutz and Cook measures [7.51].

Once the data has been normalized, the user can apply a clustering algorithm or prepare a matrix to perform multidimensional scaling (MDS) using an external tool.

Visualization

In relation to the visualization, it does not present a specific tool for the output representation. It incorporates different export options that allow us to visualize the data using external software like Pajek [7.53], UCINET [7.42], SPSS, or VOSviewer [7.38]. The type of visualization selection will depend on the nature of the unit of analysis. Nevertheless, it offers the possibility of obtaining data files for interesting visualizations, such as the Google Maps (Fig. 7.1).

7.3.2 CiteSpace II

CiteSpace [7.37] is a Java application that allows the analysis and visualization of trends and patterns in a research area. The main goal of this tool is to facilitate the analysis of emerging trends in a knowledge domain. It was developed at Drexel University, USA.

This tool offers several options to understand and interpret network and historical patterns, such as the growth of a topic area, the main citations in the knowledge base, the automatic labeling of the different clusters using terms from citing articles, geospatial collaboration network, and international collaboration.

It is interesting to note that a previous version of this tool existed. It is now designed as CiteSpace II due to the major improvements performed. The main features that characterize this version are:

1. Burst detection
2. Betweenness centrality
3. Heterogeneous networks.

In order to show the great variety of studies performed with this tool, some of the latest research publications have been retrieved. The thematic areas studied are varied, such as:

1. Global rice [7.54]
2. Sustainable development [7.55]
3. Nonpoint source pollution [7.56]

Fig. 7.1 Google maps visualization using BibExcel data (from [7.52])

4. Molecular modeling in cyclodextrins [7.57]
5. Hospitality research [7.58].

In view of these publications, it is reasonable to think that this software is important and highly used in the applied scientific literature.

Data Processing

CiteSpace is able to work with different bibliographic formats, such as WoS, PubMed, arXiv, and the SAO/-NASA Astrophysics Data System (ADS). Moreover, analysis about grants and patents can be performed through National Science Foundation (NSF) awards and Derwent Innovations Index data.

In relation to data retrieval, CiteSpace allows us to obtain bibliographic records from PubMed directly from the tool. This function can be set to obtain a maximum of records. It is necessary to consider that these records do not include information on cited references, so it is not possible to perform a citation analysis. However, this data can be used to perform analyses about networks of collaboration, terms, keywords, and categories.

Analysis Options

According to the scientific literature [7.37], the CiteSpace workflow is briefly described in the following phases:

1. *Knowledge domain detection*. It is important to use the broadest possible term in order to cover the main available research in relation to an area.
2. *Data collection*. As stated above, this tool is able to use several bibliographic records.
3. *Extract research front terms*. It collects the terms from titles, abstracts, descriptors and identifiers of citing articles in datasets.
4. *Time slicing*. In this step, the user has to specify a specific time period in the whole interval and the length of the time slice selected.
5. *Threshold selection*. This threshold is based on three sets of levels for citation counts, co-citation counts, and co-citation coefficients.
6. *Pruning and merging*. By default, this tool use pathfinder network scaling [7.59]. Users can choose whether to apply this operation to individual networks. CiteSpace II implements a version of this algorithm that reduces the overall waiting time [7.37].
7. *Layout*. It supports a standard graph view an a timezone view.
8. *Visual inspection*. The tool allows the users to interact with the visualization in several ways. Some parameters can be controlled, such as attributes and labels.
9. *Pivotal points verification*. This step may be performed by an expert. The importance of the marked pivotal points has to be confirmed in order to obtain a correct final output.

Using CiteSpace, different types of bibliometrics networks can be obtained. The following networks can be constructed from the entered data:

1. Co-author [7.60, 61]
2. Co-author institutions
3. Co-author countries
4. Co-grants
5. Subject categories co-occurrence
6. Co-word [7.6, 35, 62]
7. Documents co-citation
8. Author co-citation
9. Journal co-citation [7.32, 63]
10. Documents bibliographic coupling [7.33, 64, 65].

On the other hand, the networks, or graphs obtained, can be analyzed by applying different time periods in order to detect the evolution of the domain studied. Moreover, the most important items from the network can be filtered by the analyst (e. g., the 50 most cited items for each time span). The matrices are normalized using three different measures:

1. Salton's cosine [7.49]
2. Dice [7.66]
3. The Jaccard index [7.50].

Furthermore, a burst-detection algorithm [7.67] is adapted to identify emergent research-font concepts. In order to highlight the potential pivotal points, Freeman's betweenness centrality metric [7.68] is used.

Visualization

CiteSpace II offers several possibilities to visualize and perform analysis from the networks built. The user obtains a visualization where the pivotal points are shown in relation to their betweenness centrality. They are highlighted in the software window with a ring surrounded by a tree ring (Fig. 7.2). This ring represents the citation history of an article. The color determines the time of corresponding citations, the thickness is proportional to the number of citations in a time slice, and finally, the number next to the node center is the number of citations received during the whole time period. In Fig. 7.3, an applied visualization in the scientometric area is shown.

Before obtaining the visualization, some characteristics can be selected, such as the static or animated mode

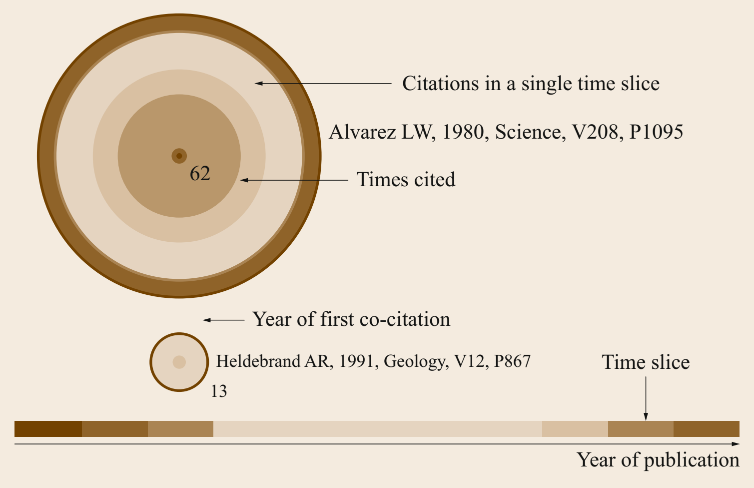

Fig. 7.2 CiteSpace II tree ring visualization (from [7.37])

and the type of networks. By default, it only shows the merged network, but it is possible to obtain the networks of all the time slices. These networks are opened in several extra windows. Once the visualization is shown, the user can interact, changing some features. For example, a persistent label can be set to a node, or two different nodes can be merged using the alias function.

Finally, it is interesting to highlight the geographical visualization option. Authors' geographic locations can be mapped as a geospatial map in keyhole markup language (KML). To obtain this representation, the Google Earth interface can be used (Fig. 7.4). Then, it is possible to explore authors' locations and links to their collaborators, and also to redirect to the original articles directly within Google Earth.

7.3.3 CitNetExplorer

CitNetExplorer is a software tool for visualizing and analyzing citation networks, based on the algorithmic historiography designed by *Garfield* [7.70]. In the networks obtained by CitNetExplorer, each node represents a publication. Each edge represents a citation relation between two publications. It was developed by the Centre for Science and Technology Studies (CWTS) at Leiden University, The Netherlands.

This software can be used for different purposes, such as analyzing the development of a research field over time, identifying the literature on a research topic, exploring the publication oeuvre of a researcher, or supporting literature reviewing [7.38]. Furthermore, not only does it focus on scientific publications, it may also be used to analyze other types of citation networks, such as patents.

In order to know the application of this software to carry out an analysis in different research areas, a search was conducted on the main bibliographic databases. CitNetExplorer has been used to analyze different areas in some recent publications:

1. Theme evolution of electrochemical energy storage research [7.71]
2. The journal *Nature of Nanotechnology* [7.72]
3. Successful aging [7.73]
4. Tribology [7.74]
5. Emerging induced pluripotent stem cell-based therapies for age-related macular degeneration [7.75].

Data Processing

The information to construct citation networks is collected directly from the WoS database. However, it is not restricted to this database, *Scopus* data could equally be analyzed. Then, CitNetExplorer is able to deal with large citation networks, including millions of publications and tens of millions of citation relations. Once the citation network has been formed, it can be exported into Pajek file format [7.53].

In order to construct the citation networks, CitNetExplorer uses two different approaches. One approach consists in providing both data from publications and data from citation relations among publications. The other approach consists in adding the data directly downloaded from WoS. In this case, in order to obtain the citation relations, CitNetExplorer is able to perform citation matching. There are two different citation matching functionality ways:

1. Based on DOI matching, but this data often is not available.
2. Based on first author's name, publication year, volume number, and page number. A perfect match is needed for each element.

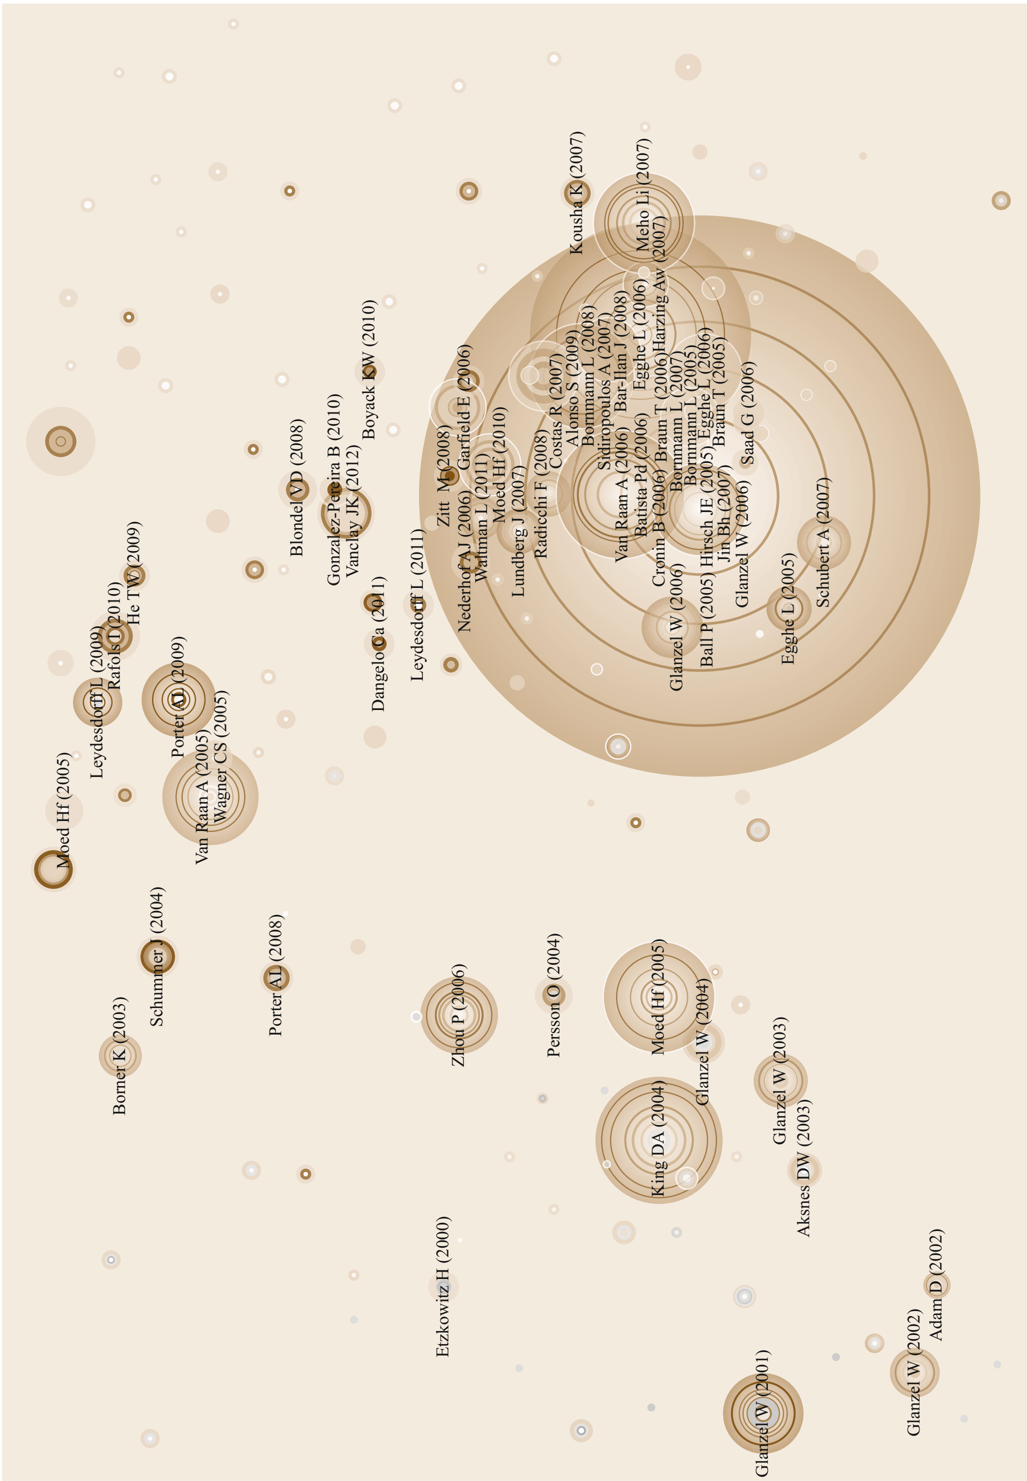

Fig. 7.3 CiteSpace visualization example

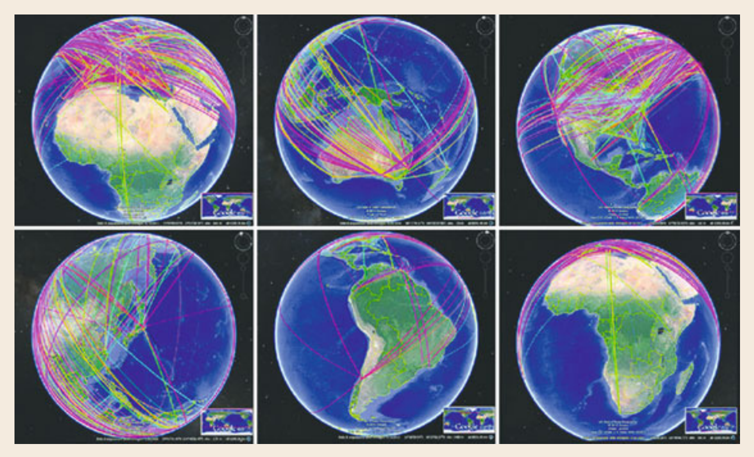

Fig. 7.4 CiteSpace visualization in Google Earth (from [7.69])

CitNetExplorer does not use the title data, because in many cases is not written in a consistent way [7.38], which makes a perfect match between citing and the cited document impossible.

Analysis Options

CitNetExplorer presents three remarkable functionalities:

1. The capability of select publications
2. Drill-down and expand functionalities
3. Different algorithms to generate the network.

When the network obtained contains many citation relations, CitNetExplorer offers the option of using *transitive reduction* to display only a selection. This selection consists in removing all non-essential citation relations from the network. In other words, "a citation relation from publication A to publication B is considered non-essential if other paths from publication A to publication B exist" [7.38]. Although the number of citation relations is lower, it ensures that any pair of publications is still connected in any path.

On the other hand, the *drill-down* function allows us to identify a specific topic inside the research area analyzed. Using this function, only the selected publications will be displayed. This functionality is divided into two steps: publication selection from the current network and network update (including only the documents selected). The network obtained after drilling down is called the current network. Furthermore, there are three different approaches to select documents:

- Select all the documents in a defined time period.
- Select the publications assigned to a group.
- Mark one or more documents in the current network to obtain a new network (default).

Another important functionality is the *expansion*, it could be considered as the opposite to *drill-down*. It consists on add publications to the current network that are closely linked to the publications that compose the network. It is useful when the user wants to expand the subnetwork (current network after drill-down) to include publications that are not directly about the topic but are related to it.

In relation to these functionalities, several consecutive drill-downs and expansions could be performed using CitNetExplorer. It allows to obtain different subnetworks composed by the documents that form an specific topic or subtopic.

In relation to the analysis options offered by CitNetExplore, four different options are provided:

1. Extract connected components
2. Cluster publications
3. Identify core publications
4. Find the shortest or the longest path from a publication to another.

Through the clustering process, each publication that is comprised in the network is classified in a cluster, according to the closeness among the different items. Thus, clusters are composed by publications strongly connected by means of their citation relations. Each cluster is then considered as a topic in the research area studied. The publications are assigned by *maximizing* [7.76].

Another analysis option is the identification of core publications. By means of the concept of *k-cores* [7.77], CitNetExplorer identifies publications that compose the core of a network. This allows us to disregard unimportant publications in the periphery of the network obtained. The user can establish the minimum number of citation relations (incoming or outcoming) that a publication should have to be considered as a core publication.

Visualization

The visualization interface allows us to interact with the generated network in different ways. These interactions are useful in order to explore and obtain a deeper insight of the information offered. It allows us to explore the network units using the zoom and scroll functionality and incorporates a smart labeling algorithm to avoid overlapping; if the mouse cursor is put over a node, the citation subnetwork is highlighted. On the other hand, not only the direct citation relations are visible, but the visualization can be set to show higher-order indirect citation relations.

In order to create the network visualization, each document is represented in horizontal and vertical dimensions (Fig. 7.5). To do this kind of visualization, CitNetExplorer follows the research literature on hierarchical graph drawing [7.78]. Documents are placed in vertical dimension based on the publication year. All documents published in the same year are assigned to the same layer, unless the number of publications exceeds the maximum (10 by default). This process is accomplished using a simple heuristic algorithm that minimizes the number of layers. On the other hand, documents are placed in horizontal dimension based on their closeness to each other in the network. The horizontal location is determined by *minimizing* [7.79].

7.3.4 SciMAT

SciMAT (science mapping analysis software tool) is an open source (General Public License (GPLv3)) science mapping software tool designed to assist all the steps in the science mapping workflow, incorporating all the necessary elements (methods, algorithms, and measures) to obtain the different analyses and visualizations. SciMAT was developed by the SECABA Lab at University of Granada, Spain.

SciMAT is based on a longitudinal science mapping approach that establishes the following four steps [7.10]:

1. Research theme detection
2. Low-dimensional space layout of research themes
3. Discovery of thematic areas
4. Performance analysis.

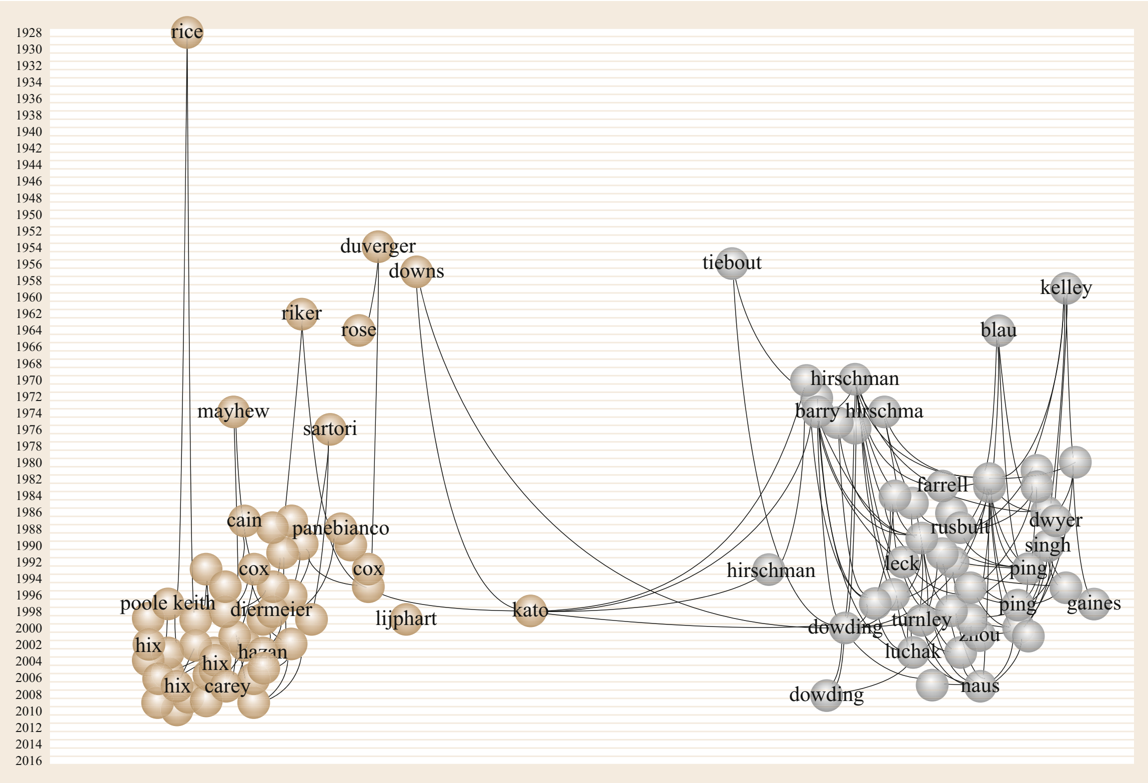

Fig. 7.5 CiteNetExplorer visualization example

Moreover, it has some remarkable characteristics:

- It incorporates all modules to perform all the steps of the science mapping workflow. It supports the analyst in carrying out all the different steps, from the data loading to the visualization and interpretation of the output.
- It incorporates the majority of methods to build bibliometric networks, different similarity measures, and several visualization techniques.
- It allows us to perform different preprocessing tasks, such as detecting duplicate and misspelled items, time slicing, and data and network reduction.
- The analysis is performed in a longitudinal framework in order to analyze and track the conceptual, intellectual, or social evolution of a research field through consecutive time periods.
- The science maps obtained are enriched with bibliometric measures based on citations, such as the sum, maximum, minimum, and average citations. Moreover, it uses advanced bibliometric indexes such as the *H*-index [7.11, 80], *G*-index [7.81], HG-index [7.12], and q^2-index [7.82].

As can be found in bibliographic databases, SciMAT has been used to perform different applied analyses in several thematic areas. Some of the recent publications were focused on:

1. Social work [7.83, 84]
2. Intelligent techniques in health systems [7.85]
3. Virtual and remote labs in education [7.86]
4. Software product lines [7.86]
5. Animal science [7.87]
6. The *Knowledge-Based Systems* journal [7.88]
7. Qualitative marketing [7.89]
8. Integrative and complementary medicine [7.90]
9. Intelligent transportation systems [7.91, 92].

In view of the many applied studies, it can be considered as a useful tool to perform science mapping analyses.

Data Processing

SciMAT allows users to add files in WoS and RIS (research information systems) formats. It then incorporates a preprocessing module where de-duplicating (manual, by plural or by Levenshtein distance, or importing from a XML (extensible markup language) file), time-slicing, data reduction, and network reduction can be performed.

When the files are added to SciMAT, it generates a knowledge base composed of 16 entities:

1. Affiliation
2. Author
3. Author group
4. Author reference
5. Author reference group
6. Document
7. Journal
8. Publication date
9. Period
10. Reference
11. Reference group
12. Reference source
13. Reference source group
14. Subject category
15. Word
16. Word group.

From these entities, five can be used as a unit of analysis in the science mapping analysis carried out by SciMAT:

1. Author
2. Word
3. Reference
4. Author reference
5. Source reference.

Thus, the entities involved in the analysis should be carefully preprocessed, paying attention to the misspelling and de-duplicating process. The de-duplicating process joins the similar items, so only one of them remains. When two items are joined, only one of them is kept in the knowledge base, and it is impossible to know the initial item joined. For this reason, SciMAT incorporates the concept of group for each unit of analysis. A group is a set of items that represents the same entity.

Analysis Options

According to the literature published on SciMAT [7.39], it divides the analysis process into four main stages:

1. *Build the dataset*. The user configures the periods of time used in the analysis, the aspects to analyze (author group, author reference group, source reference group, reference group, or word group) and the portion of data used (minimum frequency as a threshold).
2. *Create and normalize the network*. The network is built using co-occurrence or coupling relations or, indeed, aggregating coupling. Then, the network is filtered to keep only the most representative items.

Finally, a normalization process is performed using a similarity measure.

3. *Apply a clustering algorithm to obtain the map and its associated clusters or subnetworks*. Different cluster algorithms to build the map are available in SciMAT, such as a simple center algorithm [7.7, 17], single linkage [7.93], and variants such as complete linkage, average linkage, and sum linkage.
4. *Apply a set of analyses*. In this last step, different analyses can be performed on the generated map (network, performance, and longitudinal analyses).

Visualization

Different visualization techniques are available in SciMAT, such as strategic diagrams, cluster networks, evolution maps, and overlapping maps. In the following paragraphs, some characteristics of the different visualization techniques are described.

The strategic diagram represents the detected clusters of each period in two-dimensional (2-D) space and categorizes them according to their Callon density and centrality measures. Each cluster shown in the strategic diagram can be enriched by the previously selected bibliometric data measured (Fig. 7.6, extracted from *Moral-Munoz* et al. [7.90]). Furthermore, the associated network for each cluster is also obtained (Fig. 7.7).

Moreover, the results of the temporal or longitudinal analyses are shown using an evolution map and an overlapping-items graph. In Fig. 7.8, the evolution map obtained by *Moral-Munoz* et al. [7.90] is shown.

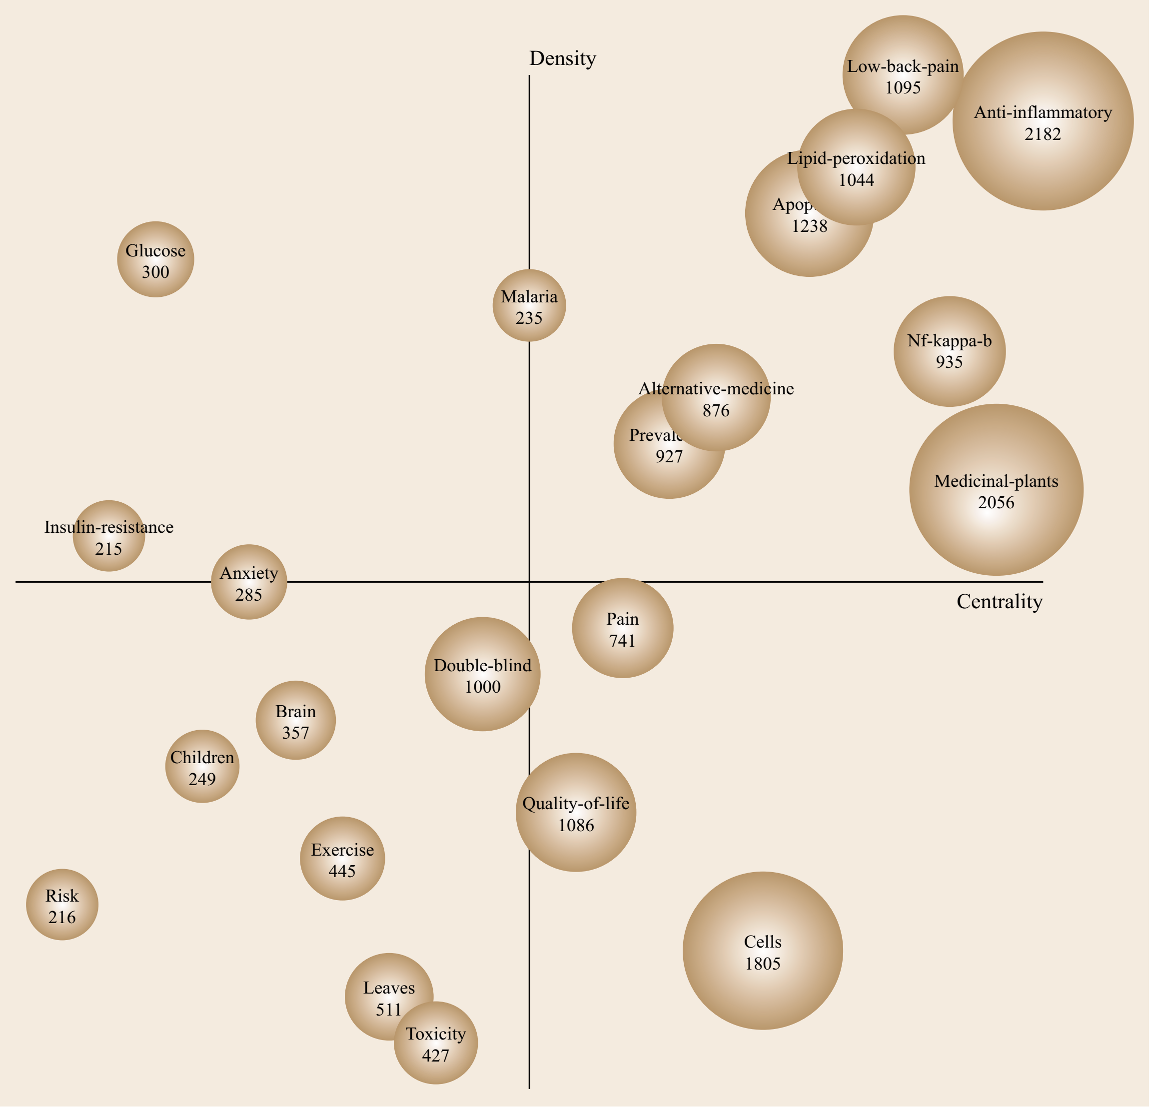

Fig. 7.6 SciMAT strategic diagram [7.90]

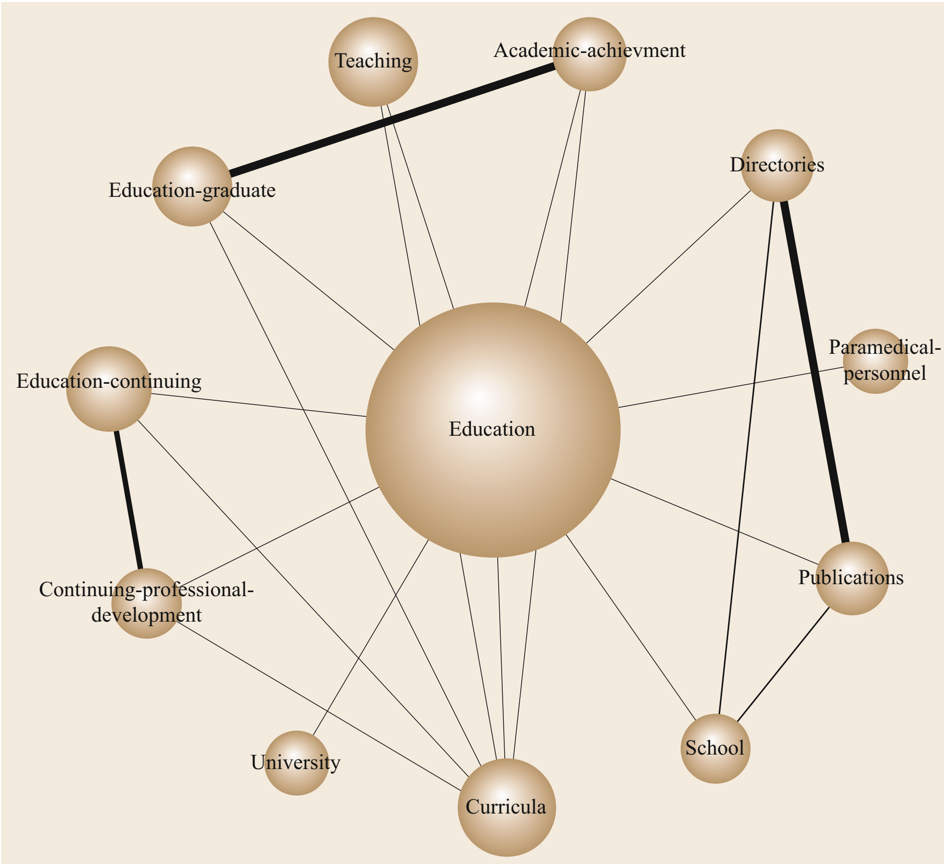

Fig. 7.7 SciMAT cluster network

Furthermore, in Fig. 7.9, the overlapping-items graph across the three consecutive periods is shown. It represents the periods and their number of associated items. Arrows represent the number of items shared by both periods, the number of new items, and the items that come out of the following period.

Finally, it is interesting to remark that the visualization module can build a report in HTML (hypertext markup language) or LaTeX format. The images (strategic diagrams, overlapping-items map, etc.) are exported in PNG (portable network graphics) and SVG (scalable vector graphics) formats, so the user can edit them easily. Furthermore, the cluster networks and evolution maps are exported in Pajek format.

7.3.5 Sci^2 Tool

Sci^2 Tool [7.40] is a modular toolset that is particularly intended for the research of science. It supports temporal, geospatial, topical, and network analysis and the representation of datasets at the micro (individual), meso (local), and macro (global) levels. It was developed by the Cyberinfrastructure for Network Science Center at Indiana University, USA.

Sci^2 Tool specifically focused on scientific documents, and it incorporates algorithms to treat this type of analyses. The main characteristic of this tool is the modular configuration, which allows preparation of the data to submit it to a posterior analysis. Furthermore, some plugins can be added to perform different tasks.

Several applied studies have been published using the Science of Science (Sci^2) tool. Some recent publications have focused on the following thematic areas:

1. Social innovation research [7.94]
2. Twitter conversations [7.95]
3. Engineering education [7.96]
4. Global positioning system [7.97]
5. Innovation systems [7.98]
6. Scholarly publications [7.99]
7. Project management [7.100].

In view of this production, it worth considering it an adequate tool to perform science mapping analyses.

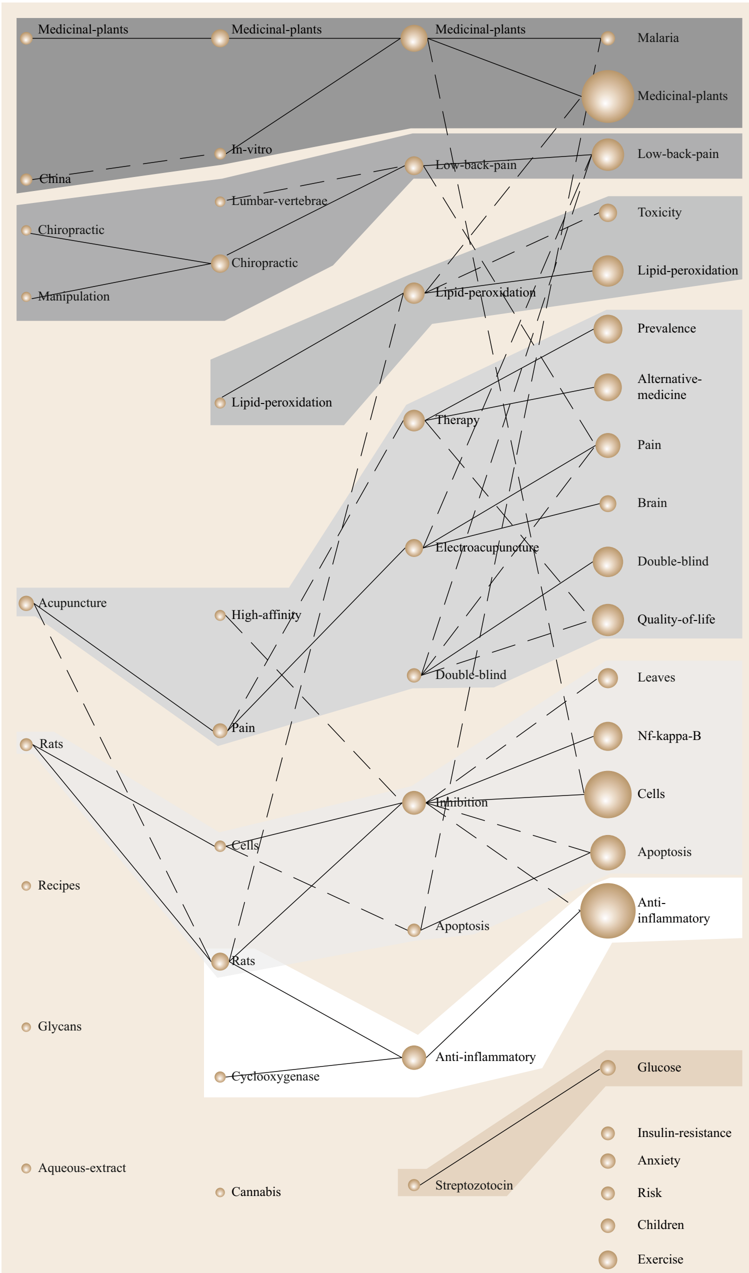

Fig. 7.8 SciMAT evolution map example [7.90]

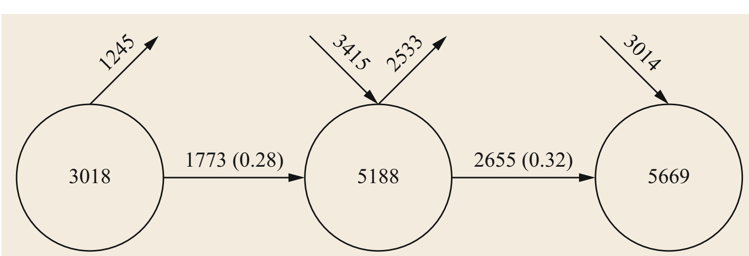

Fig. 7.9 SciMAT overlapping map

Data Processing

Sci^2 Tool is able to read several bibliographic data formats, such as WoS, Scopus, Google Scholar, Bibtex, and the exportation data format of EndNote. Furthermore, it can analyze data information from social media such as Facebook, research funding from the NSF and the National Institutes of Health, as well as other academic data in CSV (comma-separated values) format. As can be observed, this tool supports a wide variety of information sources.

Once the data has been added to this tool, it offers the possibility to submit this data to several preprocessing tasks. They depend on the type of analysis the user wants to perform:

1. In temporal analysis, a slice by time can be performed.
2. In geospatial analysis, the ZIP code can be extracted.
3. In topical analysis, different words and transformations are allowed (lowercase, tokenize, stem, and stopwords).
4. In network analysis, there are several options, such as to extract top nodes, delete isolates, or apply the Pathfinder algorithm.

Analysis Options

The Sci^2 Tool workflow is based on the typical science study [7.13, 40]:

1. Data acquisition and processing
2. Data analysis
3. Modeling
4. Layout.

Finally, the results obtained need to be checked in collaboration with domain experts.

This tool allows extraction of different types of networks and performing several analysis (temporal, geospatial, textual, and networks). Mainly, Sci^2 Tool obtains the following bibliometric networks:

1. Co-author
2. Co-PI (principal investigator)
3. Document co-citation
4. Journal co-citation
5. Author co-citation
6. Bibliographic coupling
7. Author bibliographic coupling
8. Journal bibliographic coupling.

Likewise, this tool allows building direct link networks, such as author references, document references, journal references, and author document networks.

Visualization

In order to represent the networks obtained, Sci^2 Tool applies several algorithms to map and analyze them. As stated above, there are four types of analysis, and consequently, different visualizations can be obtained.

Some characteristics in relation to the different visualizations are briefly described below:

1. *Temporal visualization* (Fig. 7.10, extracted from Sci^2 Tool documentation [7.40]). Through data slicing, the user can evaluate the evolution of the network. The result is presented as a horizontal bar graph. In this type of visualization, the *x*-axis is time, and the *y*-axis is amount. Moreover, the visualization output consists of bars with labels and colors than correspond to the different units of analysis.
2. *Geospatial visualization*. Using the ZIP code extraction, the user can build a geospatial map where an author's location is presented. Sci^2 Tool offers two geospatial options: the choropleth map and the proportional symbol map:

   - The choropleth map (Fig. 7.11): This presents color countries of the world or states of the US in proportion to numerical data. The user can also scale each individual dimension logarithmically or exponentially and add legends for each visualization dimension.
   - Proportional symbol map: This shows the geospatial information associated to three numerical attributes, which are visualized as symbols overlaid on a world or US base map. The size and colors are proportional to the attributes' values. As in the above case, each individual dimension can be scaled logarithmically or exponentially, and a legend for each dimension can be added.

3. *Topical visualization* (Fig. 7.12). Through the word co-occurrence network, a representation about how the concepts or terms are related is obtained. Then, the map of science represents the subdiscipline nodes that are aggregated to different main disciplines of the area studied. Each discipline has a different color and is labeled. Circles are proportional to the number of records. The lines represent the relations among nodes.
4. *Network visualization* (Fig. 7.13). In this kind of visualization, authors, institutions, and countries, as well as words, papers, journals, patents, and funding are represented as nodes, and their complex relationships as edges. Sci^2 Tool uses the GUESS (the Graph Exploration system) window to show the visualization, and the element attributes of the network can be modified.

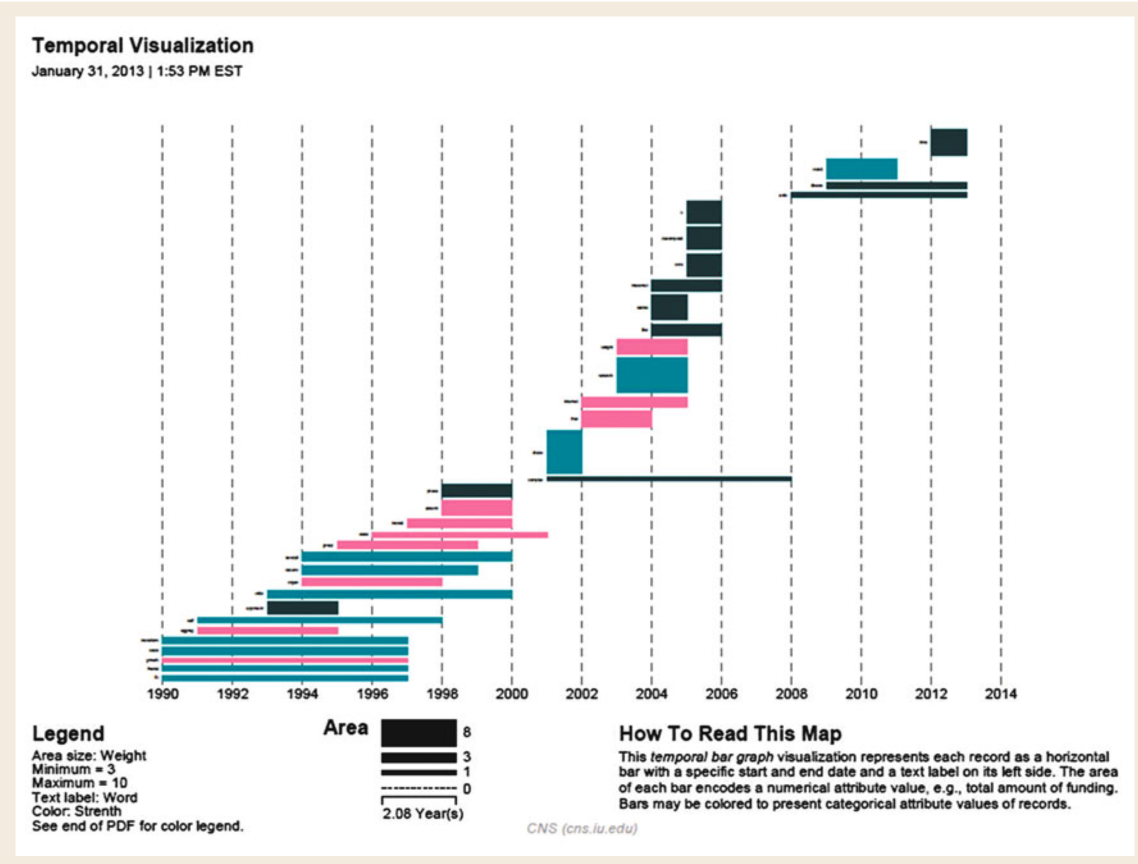

Fig. 7.10 The Sci^2 Tool: temporal visualization [7.40]

In light of the different visualization options presented, it is evident that this tool offers a great and adequate number of possibilities to represent the different aspects of science. It covers the main network visualizations present in the scientific literature.

7.3.6 VOSviewer

VOSviewer [7.38] is a software tool designed for constructing and visualizing bibliometric networks, with journals, researchers, or individual publications as actors, and based on co-citation, bibliographic coupling, or co-authorship relations. It also offers the possibility of building co-occurrence networks of important terms extracted from a corpus of scientific literature, using a text mining functionality. It was developed by the CWTS at Leiden University, The Netherlands.

It is important to highlight that VOSviewer specially focuses attention on the graphical representation of bibliometric maps. Thus, it is helpful for interpretation of a large bibliometric network in an easy way by means of the different visualization options. It allows use of different functionalities, such as zooming, scrolling, and searching.

VOSviewer counts with a large path in the field of science analysis. With the aim of showing the different applications of this software to specific research areas, a search has been conducted. Only in 2016, VOSviewer was used to analyze:

1. The concept of international competitiveness [7.102]
2. Thermal spray [7.103]
3. Triple negative breast cancer [7.104]
4. Antioxidative herbal medicines in type 2 diabetes mellitus [7.105]
5. Space research [7.44]
6. Autism spectrum disorders [7.106]
7. Probiotics in pediatrics [7.107]
8. Spinal tuberculosis [7.108]
9. Iranian papers on reproductive medicine [7.109]
10. Zebrafish in Brazilian science [7.110]
11. Production on open access [7.46]
12. Evidence-based antioxidative herbal medicines in the management of diabetic nephropathy [7.111]

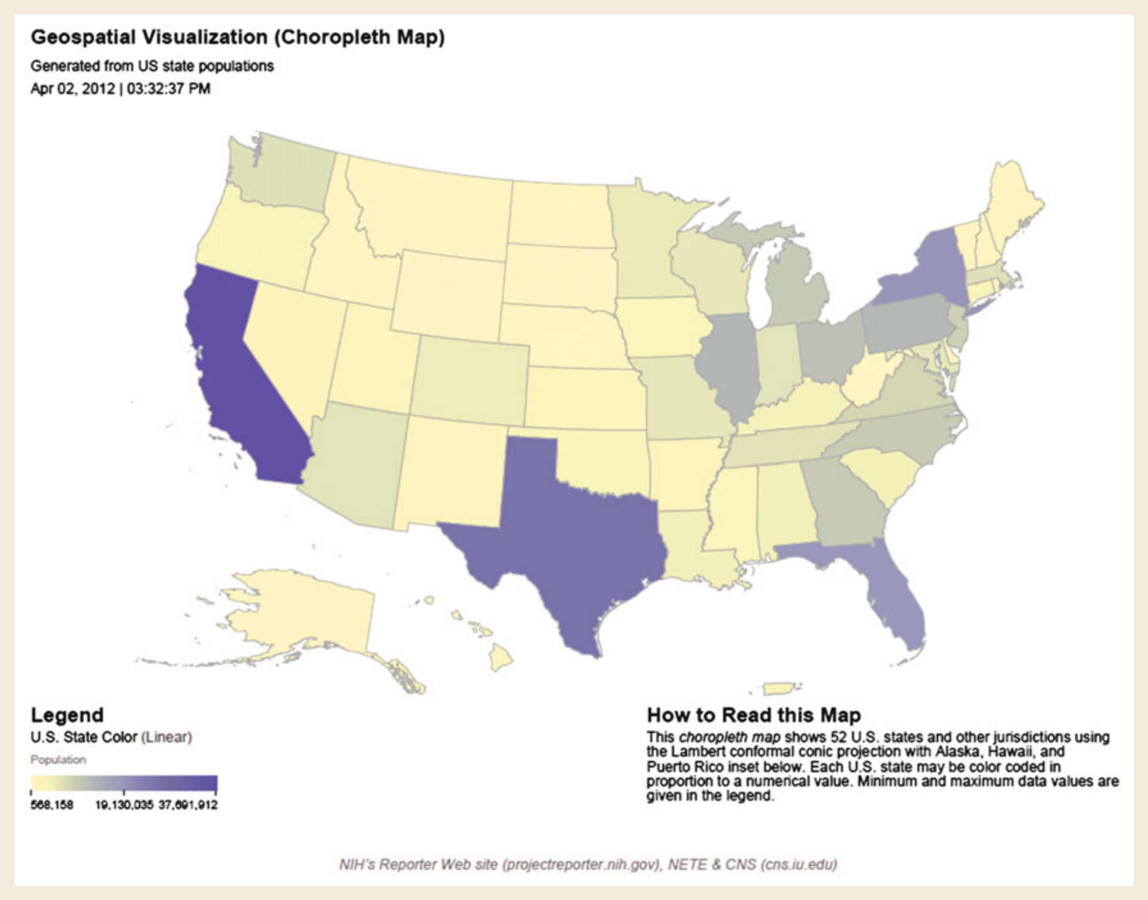

Fig. 7.11 Sci^2 Tool: geospatial visualization [7.40]

13. Stem cells [7.48]
14. Safety science [7.112]
15. Primary care databases [7.113]
16. Green development models [7.114].

As can be observed, it is a software with a large number of studies published. Thus, it is one of the best options for performing a science mapping analysis.

Data Processing

VOSviewer [7.41] can extract bibliographic networks (co-authorship, co-occurrence, and citation-based ones) from bibliographic data. This data is added from files downloaded from WoS, Scopus, PubMed, and in RIS format. Furthermore, it is able to import and export network data from GML (Graph Modeling Language) and Pajek formats.

Analysis Options

VOSviewer incorporates advanced layout and clustering techniques which can be set up using several parameters. According to the literature [7.41], VOSviewer constructs the map based on a co-occurrence matrix in three steps:

1. *Similarity matrix*. In order to apply the VOS mapping technique [7.115], a similarity matrix is needed as input. VOSviewer uses a similarity measure known as the association strength [7.116]. This measure is sometimes referred as to the proximity index [7.61, 117] or probabilistic affinity index [7.118].
2. *VOS mapping technique*. A two-dimensional map is constructed in which the items are located in such a way that the distance between items reflects the similarity measure approximately, using the VOS mapping technique [7.115]. Therefore, if two items have a higher similarity they should appear closer.
3. *Translation, rotation, and reflection*. In order to correct the optimization problem described in the literature [7.119], the map is submitted to different solutions: translation, rotation and reflection. These transformations are enough to ensure the results consistence.

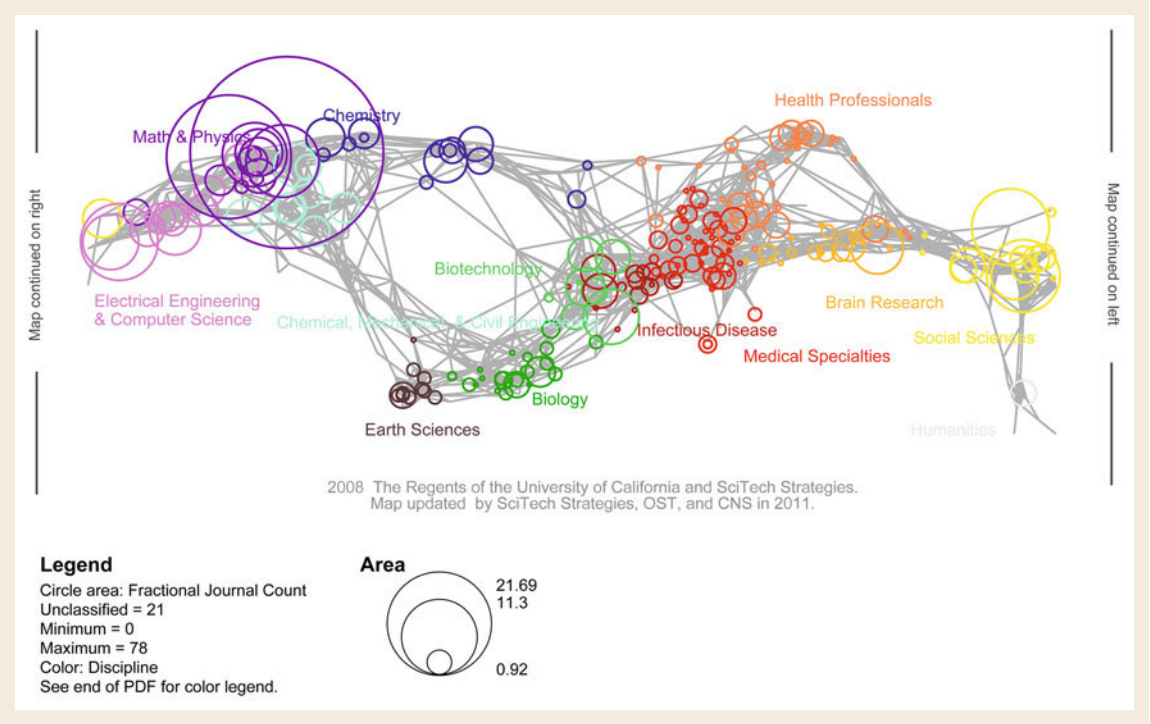

Fig. 7.12 Sci^2 Tool: topical visualization [7.101]

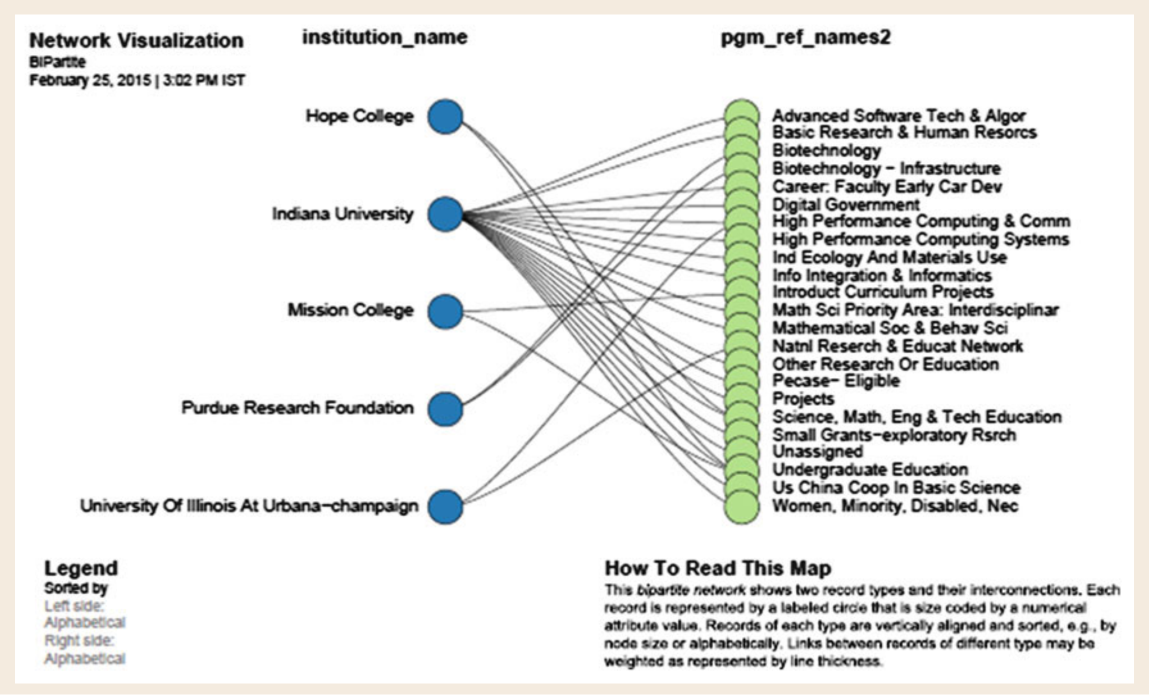

Fig. 7.13 Sci^2 Tool: network visualization [7.40]

Visualization

Distance-based maps were chosen to build the bibliometric maps [7.38]. In these kinds of maps, the distance between two items represents the strength of the relation between them. If an item is close to another, it indicates a stronger relation. Among these types of mapping techniques, there are several options, such as multidimensional scaling [7.119], VxOrd [7.120, 121], and one proposed by *Kopcsa* and *Schiebel* [7.122]. VOSviewer can be employed to view multidimensional scaling maps using statistical software such as SAS (Statistical Analysis System), SPSS, and R. Moreover, the VOS mapping technique [7.115] has been fully integrated, allowing the visualization and construction of this type of map without using other computer program.

In relation to visualization capabilities, this software provides three visualization options:

1. Network
2. Overlay
3. Density.

In what follows, the characteristics of these types of visualizations are described [7.123]:

1. In the *network view* (Fig. 7.14), items are shown by a circle with a label. The volume of the circle and the size of the label depend on the item's importance. Thus, if an item is more important, its label and circle are bigger. The color of the circle is related to the cluster assigned to a group of items. The color is useful for representing some network characteristics such as topic, work group, etc.
2. In the *overlay view* (Fig. 7.15), the network is represented as in the network view, but the items are colored differently. At the bottom part of the main panel, a gradient color bar based on the scores given to the items is shown. These scores can be obtained from the score column in a map file, or the user can specify the items' colors. If any information is given, the overlay view is not available.
3. In the *density view* (Fig. 7.16), there are two different visualization options, which can be selected in the options panel:

   - Item density: Each point in a map has a color determined by the items' density at that point. The map is shown with colors from red to blue. Thus, a larger number of items is represented in red, and a smaller number of items is represented in blue.
   - Cluster density: This is used only if items have been assigned to clusters. An item's density is displayed separately for each cluster. The color is determined by the cluster's color and is more or less intense depending on the weighting.

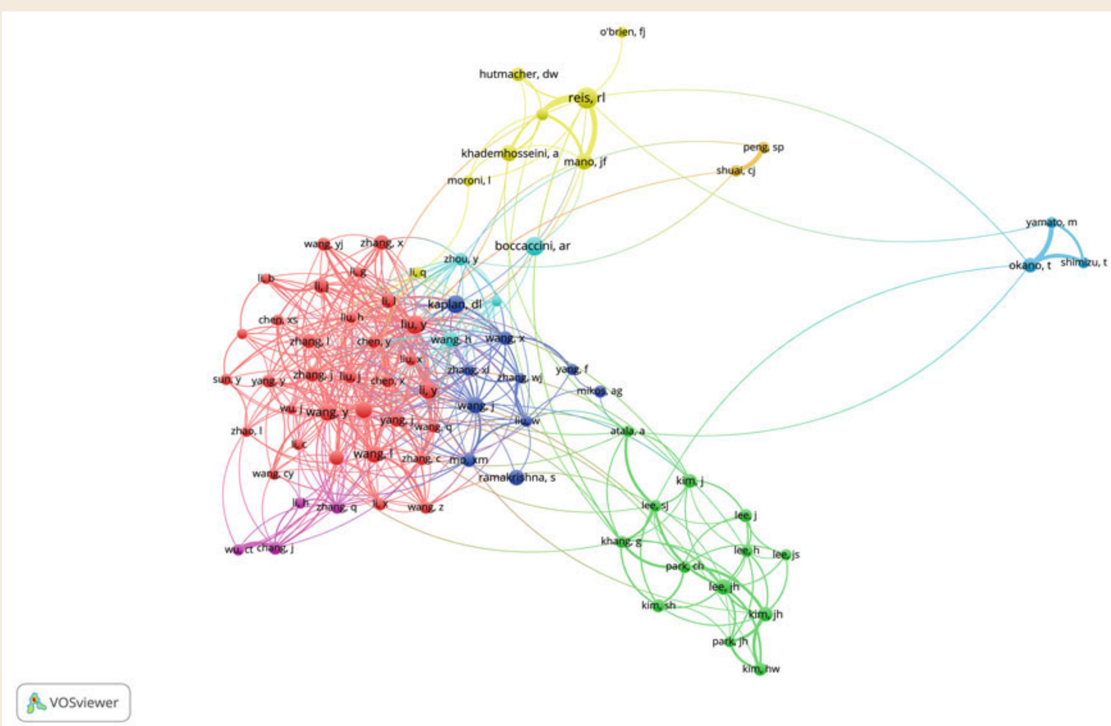

Fig. 7.14 VOSviewer: network view

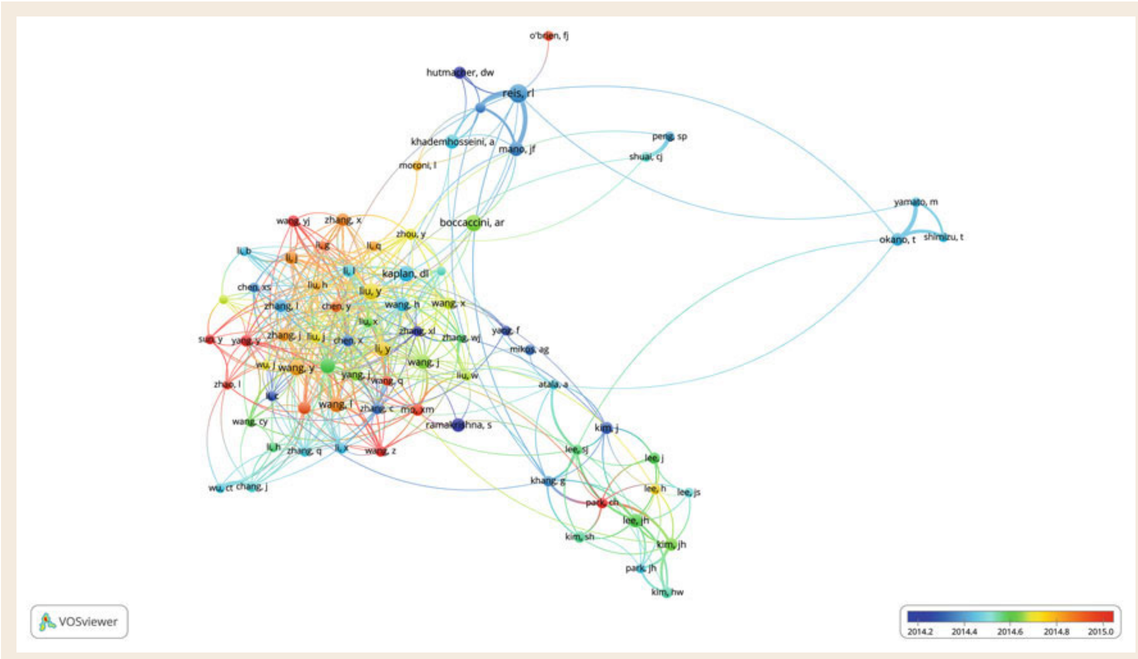

Fig. 7.15 VOSviewer: overlay view

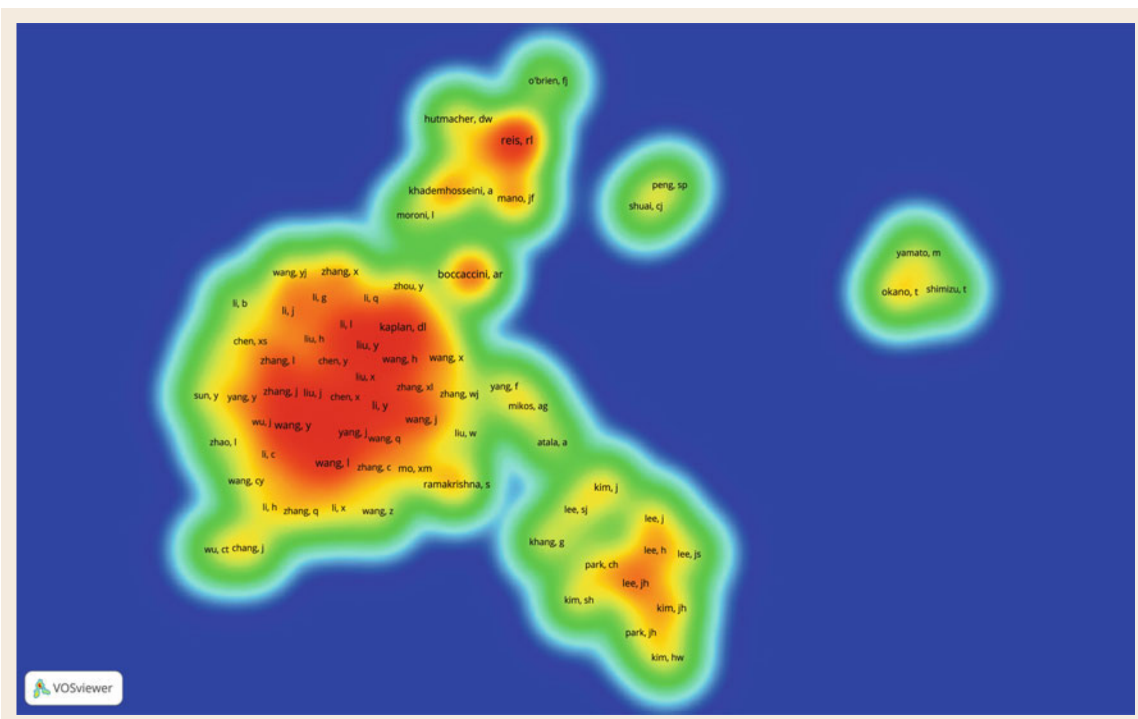

Fig. 7.16 VOSviewer: density view

Moreover, the zoom and scroll functionality and smart labeling algorithm prevent labels from overlapping. VOSviewer incorporates the zoom and scroll option in order to facilitate a detailed examination of the map generated. This functionality used in three ways:

1. Using the mouse
2. Using the navigation buttons (upper right corner)
3. Using the keyboard.

Furthermore, because labels tend to overlap in a large amount of network items, the software incorporates a labeling algorithm to prevent this.

Finally, all of the visualizations generated can be saved in different graphical file formats, such as bitmaps or vectors. This option makes it easy to include the analysis output in any format, digital or printed.

7.4 Software Characteristics: Summary and Comparison

Once the main characteristics of the software have been described, a comparison of tools' features is shown. In the following paragraphs, different features are discussed and evaluated:

1. Operative system
2. Data sources
3. Preprocessing
4. Bibliometric analysis
5. Bibliographic networks
6. Normalization.

According to Table 7.3, all the software run on Windows. Nevertheless, there are only two types of software exclusively for this system, BibExcel and CiteSpace, the rest are multiplatform ones (Windows, OSX, and Linux). On the other hand, they can all use ISIWoS and Scopus as the source. If a user wants to perform an analysis from a different database, a tool that allows to perform the analysis or tries to transform the data file must be selected.

Table 7.3 Operative systems and data source of the science mapping tools

Software tool	Operative system	Data source
BibExcel	Win	ISIWoS, Scopus, proCite, BibExcel format
CiteSpace II	Win	ISIWoS, Scopus, PubMed, arXiv, patents
CitNetExplorer	Win, OSX, Linux	ISIWoS, Scopus
SciMAT	Win, OSX, Linux	ISIWos, Scopus
Sci^2 Tool	Win, OSX, Linux	ISIWoS, Scopus, Google Scholar, Bibtex, EndNote
VOSviewer	Win, OSX, Linux	ISIWoS, Scopus, PubMed

In Table 7.4 some characteristics in relation to the analysis options offered by the different tools are shown. Several preprocessing options are available in the tools analyzed. Data and network reduction is available in all of them, but there are other options, such as time slicing (e.g. CiteSpace II, SciMAT, or Sci^2 Tool) and duplicate detection (e.g. SciMAT and Sci^2 Tool). In relation to bibliographic networks, most of them are able to manage co-citation, coupling, and collaboration networks, only CitNetExplorer is specifically centered on co-citation networks. Finally, it is worth highlighting that there are several possibilities with regard to the normalization process. The two software from the CWTS, CitNetExplorer, and VOSviewer use the association strength as a normalization measure. Salton's cosine and Jaccard's index is available in BibExcel, CiteSpace II, and SciMAT. Furthermore, there are other, less frequent, measures, such as Vladutz and Cook measures in BibExcel, Dice index in CiteSpace II, or the equivalence index in SciMAT.

It is well known that science mapping analysis is characterized by the visualization of the data. From Table 7.5, it can be observed that the visualization output in each software is totally different. Each software uses a kind of visualization in order to represent the information in an adequate manner. There are several options, the most common being network visualization, but other interesting ones are tree rings, geospatial maps, or evolution maps. These visualizations will fit to the type of actor to be analyzed.

Table 7.4 Analysis options of the science mapping tools

Software tool	Preprocessing	Bibliographic network	Normalization
BibExcel	Data and network reduction	Co-citation, coupling, collaboration	Salton's cosine, Jaccard's index, or Vladutz and Cook measures
CiteSpace II	Time slicing and data and networks reduction	Co-citation, coupling, collaboration	Salton's cosine, Dice or Jaccard strength
CitNetExplorer	Data and network reduction	Co-citation	Association strength
SciMAT	Duplicate and misspelled items detection, time slicing, data and network reduction	Co-citation, coupling, collaboration	Association strength, equivalence index, inclusion index, Jaccard index, and Salton's cosine
Sci^2 Tool	Duplication detection, time slicing, and data and networks reduction	Co-citation, coupling, collaboration	User defined
VOSviewer	Data and network reduction	Co-citation, coupling, collaboration	Association strength

Table 7.5 Visualization options of the science mapping tools

Software tool	Visualizations
BibExcel	**External software*
CiteSpace II	Tree ring, geospatial map
CitNetExplorer	Network
SciMAT	Strategic diagram, cluster network, overlapping map, evolution map
Sci^2 Tool	Temporal, geospatial map, topical, network
VOSviewer	Network, overlay, density

Therefore, we can state that the variability in measures and network analyses is high. The user needs to know the main characteristics of the software in order to adapt the expectations to the final output. The tools shown in the present review are powerful and offer several possibilities. Each software allows us to analyze and discover different aspects about the network. Thus, it could be useful to use several types of software in order to obtain complementary outputs.

7.5 Conclusions

Bibliometrics is the application of quantitative analysis to publications. This evaluation is used in almost all science fields to measure growth, maturity, the main actors, and conceptual and intellectual development, discovering the trends of a scientific community. In order to perform this kind of analysis, different bibliometric software are needed.

In the present chapter, six tools have been analyzed:

1. BibExcel [7.36]
2. CiteSpace II [7.37]
3. CitNetExplorer [7.38]
4. SciMAT [7.39]
5. Sci^2 Tool [7.40]
6. VOSviewer [7.41].

All of these offer different possibilities to build science maps. There are several differences among data processes, analysis options, and visualizations. The use of one or the other depends on the preferred output and consequent analysis. Although there are software with a wide number of options, none of them implement all the desirable characteristics. There are software that are more focused on visualization and others on analysis. However, they can be used in combination to obtain complementary outputs.

In relation to the data sources, probably CiteSpace II and Sci^2 Tool are the software with the larger number of possibilities. All of the tools offer the option of reducing data and networks, although some of them are able to perform time slicing, such as CiteSpace II, SciMAT, and Sci^2 Tool, and duplicate detection, such as SciMat and Sci^2 Tool. In relation to bibliographic networks, only CitNetExplorer is centered on co-citation; coupling and collaboration networks are also available in the other software. Finally, the normalization measures are varied, and each software offers those that are considered more suitable.

The visualizations offered by the software could cover the user's necessities depending on the expected output. CiteSpace II or Sci^2 Tool are good options to represent a collaboration network; they offer the geospatial map visualization that facilitates the analysis of the publication relationships. If the desired output is to represent temporal development or evolution, SciMAT, Sci^2 Tool, and VOSviewer can be selected, because they incorporate a specific representation. In general terms, all of the software offer an adequate representation of citation networks.

To sum up, there are several freely available science mapping software with a strong potential. They offer all capacities and features to perform this type of analysis during the whole workflow in a more or less easy way. The choice depends on the type of actor to be analyzed and the output expected.

Acknowledgments. The authors would like to acknowledge FEDER funds under grants TIN2013-40658-P and TIN2016-75850-R and also the financial support from the University of Cádiz, Project PR2016-067.

Jose A. Moral-Munoz

Department of Nursing and Physiotherapy
University of Cádiz
Cádiz, Spain
joseantonio.moral@uca.es

Jose A. Moral-Munoz received a PhD degree from the University of Granada, Spain, in 2016. He is currently working as an Assistant Professor in the Department of Nursing and Physiotherapy at the University of Cádiz, Spain. His research interests include science mapping analysis, bibliometrics, citation analysis, scientometrics, research evaluation, and data visualization.

Antonio G. López-Herrera

Department of Computer Science and Artificial Intelligence
University of Granada
Granada, Spain
lopez-herrera@decsai.ugr.es

Antonio G. López-Herrera is an Associate Professor in Computer Science and Artificial Intelligence at the University of Granada, and Vice-Dean for Academic Organization and Quality at the Faculty of Library and Communication Studies. His research interests include fuzzy information retrieval systems, fuzzy recommender systems, social media, and bibliometrics.

Enrique Herrera-Viedma

Department of Computer Science and
Artificial Intelligence
University of Granada
Granada, Spain
viedma@decsai.ugr.es

Enrique Herrera-Viedma is a Professor in Computer Science and AI at the University of Granada, and Vice-President for Research. His research interests include fuzzy decision making, bibliometrics, recommender systems, and social media. His h-index is 53 (>12500 cites WoS) and he is a Highly Cited Researcher according to Clarivate Analytics in the categories of Engineering and Computer Science from 2014.

Manuel J. Cobo

Department of Computer Science and
Engineering
University of Cádiz
Algeciras, Spain
manueljesus.cobo@uca.es

Manuel J. Cobo received his MSc and PhD degrees in Computer Sciences from the University of Granada, Spain, in 2008 and 2011, respectively. He is currently an Associate Professor with the Department of Computer Science and Engineering, University of Cádiz, Spain. His research interests include science mapping analysis, bibliometrics, scientometrics, text mining, graph mining, data visualization, quality evaluation, decision making, and recommender systems.

8. Creation and Analysis of Large-Scale Bibliometric Networks

Kevin W. Boyack, Richard Klavans

In the more than a decade since the last *Handbook of Quantitative Science and Technology Research* [8.1] was published, a sea change has occurred in the creation and analysis of bibliometric networks that describe the Science & Technology (S&T) landscape. Previously, networks were typically restricted in size to hundreds or thousands of objects (papers, journals, authors, etc.) due to lack of data access and computing capacity. However, recent years have seen the increased availability of full databases, increased computing capacity, and development of partitioning and community detection algorithms that can work effectively at large scale. As a result, much larger networks–comprised of millions or tens of millions of objects–are being created and analyzed. These large-scale networks have enabled analyses that were simply not possible in the past, analyses that require the context of complete networks to give accurate results.

In this chapter, we focus on large-scale, global bibliometric networks, and on the types of analysis that are enabled by these networks. We start by providing a historical perspective that sets the stage for recent advances that have culminated in the ability to create and analyze large-scale bibliographic networks. We then discuss data sources and the methods that are commonly used to create large-scale networks. We review many of these networks, along with the types of unique analyses that they enable, and ways that their results can be effectively communicated. After reviewing the state of the art, we discuss our most recent large-scale topic-level model of science in detail as an example of a global bibliometric model and show how it can be used for various applications.

8.1 Fundamentals and Scope

Science is a complex system that is comprised of researchers that create scientific and technical knowledge. Researchers typically work for institutions (universities, companies, etc.) and author articles that are published in journals or conference proceedings. Various metadata such as titles, abstracts, keywords, etc. associated with these articles are indexed in databases. Networks intended to elucidate the structure of science have been created from all of these features. For example, the network of articles can be used to partition science into topics and specialties. Journal networks are often used to identify fields and disciplines. Author networks are used to identify communities, and terms (i. e., keywords or words and phrases extracted from titles and abstracts) are used to create networks of concepts. Each network provides a representation of the structure of science. Often, networks created from different metadata give similar views of science, while at other times different networks reveal different or complementary features.

Scientific networks can be global or local. A local network is one that provides a representation of a particular discipline, specialty, or closely linked set of topics. In contrast, we define a global network as one that provides a representation of all of science or technology. Thus, global networks can only be based

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_8

on comprehensive data sources. Studies of local networks far outnumber studies of global networks for the simple reason that creation of a global network requires electronic access to an entire database that covers all of science, such as the Web of Science (WoS) or Scopus, or to some other very large database such as PubMed. Few researchers have this type of access. However, many researchers have institutional access to these same databases through the Internet, and can download and analyze small (local) portions of these global data. Local networks are very useful for providing some types of information, such as the dominant topic structure within a specialty, or the top researchers and institutions within a specialty. However, local networks cannot answer questions that require a larger context. For instance, a local network simply cannot identify science outside the specialty that could prove disruptive to the science within the specialty, nor can it identify which science within the specialty is–to use current buzzwords–the most interdisciplinary, translational, or transformative. Local networks cannot identify the most emergent topics across all of science. These are all boundary conditions, and without including information from outside the specialty, one cannot say where the boundaries really are. Global data are required for these types of problems.

Many studies that create and analyze local or global scientific networks use clustering or partitioning approaches. There are myriad approaches; many different similarity types and clustering algorithms are used. The full scientific network is robust at high levels of granularity [8.2, 3]–for example, physics is always closely linked to chemistry. Detailed networks are less robust. We acknowledge the fact that different methods give results that differ in detail [8.4], and that the results from any single model are a subset of many possible results. Understanding the breadth of possible results and why they occur is a very important question that has not yet been answered in the literature, and thus will not be addressed here. Despite the breadth of possible results, our experience is that the different network representations that result from different methods provide perspectives that are interpretable in their details, and that can be useful to decision makers.

In this chapter, we do not consider analyses of small-scale or local networks, but instead focus on large-scale, global bibliometric networks, and on the types of analysis that are enabled by these networks. We start by providing a historical perspective that sets the stage for recent advances that have culminated in the ability to create and analyze large-scale bibliographic networks. We review many of these networks, along with the types of unique analyses that they enable, and ways that their results can be effectively communicated. After reviewing the state of the art, we discuss our most recent large-scale topic-level model of science in detail as an example of a global bibliometric model and show how it can be used for various applications.

8.2 Background

In this section, we provide a historical perspective that suggests why one should consider using global bibliometric data to model the structure and dynamics of science. In addition, we discuss data sources, methods, and algorithms that are commonly used to create and partition global networks from these data.

8.2.1 Historical Perspective

The nature, structure and evolution of scientific networks has been a topic of interest for many decades, particularly from the perspective of citation networks. Early theory was stimulated by the desire to identify emerging topics and was centered around the notion of a 'research community'. The importance of these two concepts–identification of hot or emerging topics and delineation of research communities–to the development of methods to create and explore bibliometric networks cannot be overstated. Not only were these two of the original goals of citation analysis, but they have also formed the motivational basis for much of the work done in scientometrics over the past 60 years.

Eugene Garfield's article that introduced citation indexes [8.5] provides a clear description of the first issue–identification of emerging topics. Garfield found that subject indexes (i. e., keywords) were poor sources for identifying an emerging scientific topic as it was emerging, even if many of the key studies in that topic were published within a single journal. He found, however, that citations had the potential to track the emerging topic, and as a result he introduced the first citation index. As the citation index grew, he was able to use citation data to understand the history of key scientific breakthroughs, such as the development of DNA [8.6]. Several years later *Henry Small* introduced cocitation clustering as a way to study the specialty structure of science [8.7]. Given the computing resources available in the early 1970s, the technique was limited in practice to clustering of only the most highly cited articles [8.8]. When applied to a full database such as the Science Citation Index, cocitation clustering using only the most highly cited articles–for instance, the top 1% highly cited–produces clusters that are analogous to hot topics. This specific methodology–cocitation clustering of the most highly cited papers–has remained relatively unchanged since that time. In fact, the Research Fronts reports published annually by *Clarivate Analytics* [8.9] have used this methodology since their inception. Numerous studies using both small and large document sets have been performed specifically to identify emerging topics; see the literature review in [8.10] for a more detailed treatment. Today, identification of hot or emerging topics remains a primary concern of funders and research institutions [8.10, 11].

The notion of a research community and the desire to delineate such communities also goes back some 60 years. *Thomas Kuhn*'s [8.12] conception of a research community was of a group of about 100 researchers working on a common (empirical) problem, defined within the context of detecting scientific revolutions (or identifying emerging topics!) as they were occurring. *Nicholas Mullins*' [8.13] study of the research communities in sociology revealed a few research communities of approximately this size, along with a host of much smaller communities. Subsequent work by *Diana Crane* [8.14] also suggested that there would be roughly 100 people per research community. Both Mullins and Crane viewed the evolutionary paths of these communities in a similar fashion as follows. One starts with a large number of very small research communities that are weakly organized. A major discovery in a community–a relatively infrequent event–results in a thickening of the network relationships in that community. With additional discoveries, the research community attracts new members and grows larger until it is comprised of around 100 researchers. As the community ages, the rate of discovery drops and the community size stabilizes. As the rate of scientific or technical advance decreases further, the size of the community declines as researchers migrate to other communities and research problems.

A model of the scientific literature that is based on global bibliometric data fits very well with this conceptualization of research communities and also with the notion of topics. If one defines a topic as a collection of documents with a common intellectual interest, or as a particular problem or closely related set of problems in science, one can also define a research community as the group of researchers working in that topic, and the two ideas can be roughly equated. Topics/communities can be new or old, large or small, and growing or declining in terms of their membership. Each topic has a story, and it is that story that is of interest to the various stakeholders in the science system, whether they be funders, administrators, or researchers. We seek methods that allow us to accurately identify topics and their dynamics that will enable us to tell the stories associated with topics. Global data is critical to this endeavor. While some topics identified using small (i. e., local) datasets, such as those created from journal sets or keyword searches, are complete and relatively accurate, other topics based on local data can be incomplete or even misleading in terms of the stories they tell [8.15, 16].

Of course, our understanding of topics can also be incomplete if we do not understand the larger context within which scientific and technical work takes place. Scientometrics has historically focused its attention on the analysis of scientific papers, one of the key outputs of the science system. Although this is understandable from the standpoint that literature data is relatively available, it is time that the scientometrics community starts to investigate, incorporate, and link other data sources into their thinking and analyses.

As an example of the types of data that could be considered for bibliometric analysis, and more particularly for large-scale analysis of bibliometric networks, we refer to Latour's model of the research laboratory in his book *Science in Action* [8.17]. This is a much more complex view of the science system than is indicated by publications alone (Fig. 8.1). Latour proposed a positive feedback loop in which one starts with new discoveries that are published (*argued*) in the scientific and technical literature. These discoveries give rise to *innovations*, which are rewarded by more funding (*money*) that can be spent on salary (*workforce*) and *instrumentation* that are used to do more research and create laboratory *objects* or artifacts. The cycle then continues, with researchers presenting their newer findings in the scientific and technical literature, etc. The model represents a positive feedback loop where growth occurs as long as current findings are considered to be significant contributions. Although Latour's model was based on observations of how research laboratories grow, we view it more generally–it is intuitive to think of it as a conceptual model of the evolution of topics or research communities. We note that Latour's model only shows movement from smaller to larger circles. In contrast, we note that the activity in some topics can and does decline over time, and thus expand upon the model in that way.

The balance of this chapter will build on the perspectives developed above. We suggest that large-scale bibliographic networks are needed to accurately identify topics in the scientific (and technical) literature. What is large scale? For the purposes of this chapter, we define a large-scale data source as one that is relatively comprehensive in terms of coverage and thus provides

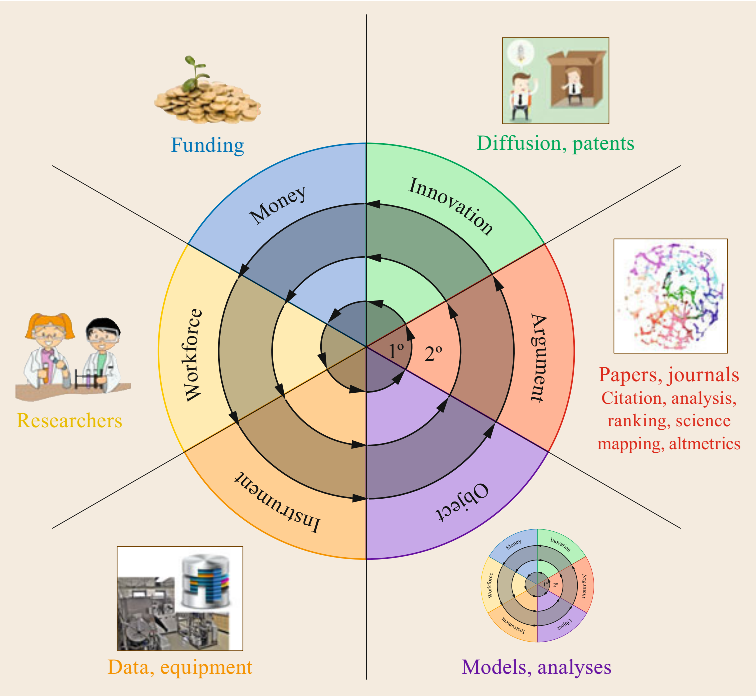

Fig. 8.1 Latour's model of the process of science, overlaid with examples of features we associate with each portion of the process. Many of these features, alone or in combination, are amenable to network analysis (after [8.17, p. 160])

Table 8.1 Large-scale bibliometric data sources

Source type	Source	# Records	Availability
Scientific literature	Scopus (1980–2016)	50 M	Subscription
	WoS (1980–2016)	47 M	Subscription

a reasonable representation of either all of science or technology or a deep representation of a high-level field (such as physics, computer science, or medicine). Further, to be a large-scale network, we suggest that the network created from the data must be granular and detailed. The bibliometric networks that we will consider here will, for the most part, be comprised of at least 1 000 000 documents and will have thousands or tens of

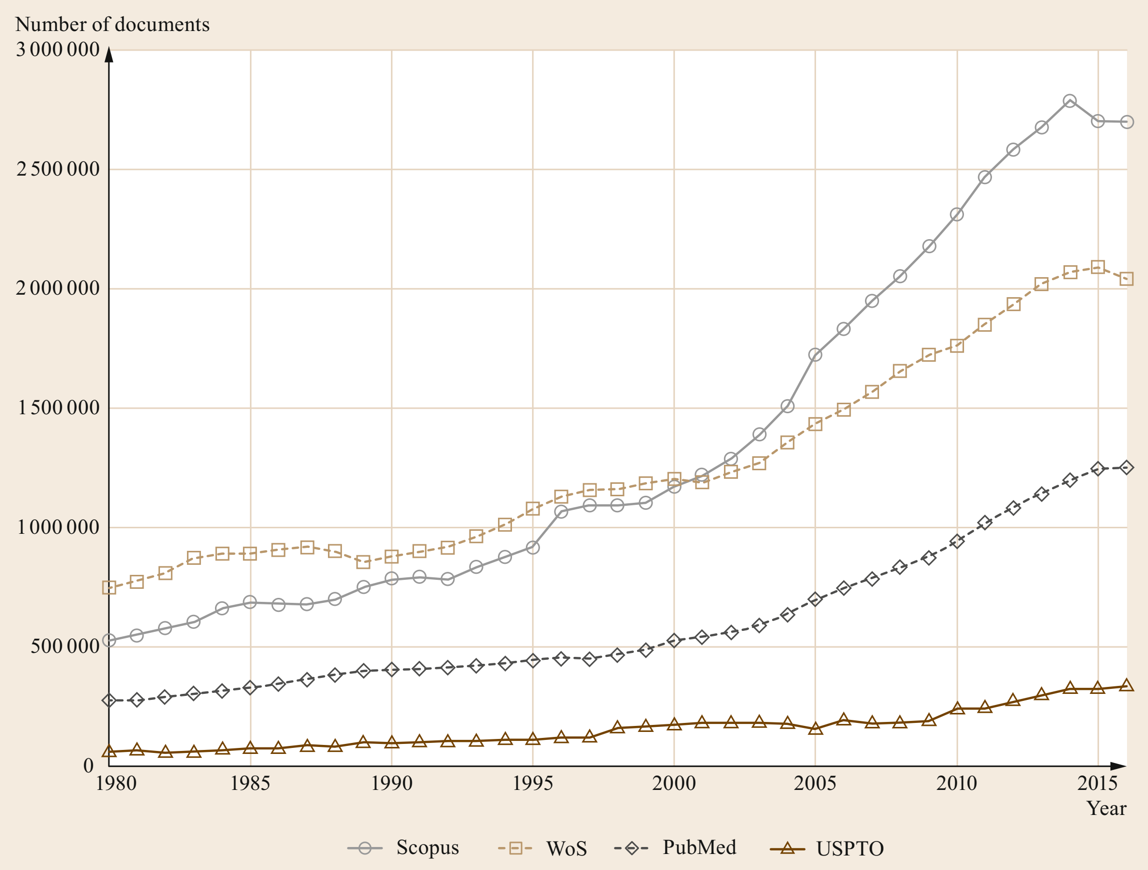

Fig. 8.2 Numbers of records by year for four prominent databases

thousands of clusters. We further suggest that we should expand the types of data (and thus networks) that we analyze to include funding, researchers, equipment, and laboratory artifacts. We realize that these data have historically been less available than publication and patent data, but this does not mean that we should simply dismiss the possibility that these data will help us better elucidate the stories associated with the science system to the benefit of all stakeholders. Rather, we suggest that we should attempt to procure more of these data for analysis so that we can better understand the science system.

8.2.2 Data Sources

There are many data sources that can be used to create large-scale bibliometric networks. Table 8.1 lists a number of these, along with approximate numbers of records and the availability of each source. This list is certainly not complete, but does cover the majority of large-scale sources that have been used for bibliometric studies. Each source will be described briefly here.

Scientific Literature

The two primary scientific literature databases used for most scientometric and bibliometric studies are Scopus (Elsevier) and the Web of Science (WoS, Clarivate Analytics). These are the dominant databases because they are the only two that cover (more or less) all scientific fields and include cited references, thus enabling citation analysis and the construction of citation-based networks. WoS is descended from Garfield's original Science Citation Indexes and was the only citation database available until 2004 when Scopus was introduced. Among the two databases, Scopus has broader recent coverage (since 2001; Fig. 8.2) while WoS has far more historical coverage. Both databases require a subscription, and access to either full database in electronic form typically requires a specific license.

PubMed and Medline are literature databases that are maintained by the US National Library of Medicine (NLM). Medline primarily indexes publications from the life and medical sciences, while PubMed includes all of Medline along with select publications (although not entire journals) from outside those fields. PubMed does not include cited references, but does include MeSH (Medical Subject Headings) terms, chemicals, accession numbers, and other data types that link to other databases maintained by NLM. Data from these fields, along with the standard textual fields (title and abstract), can be used to create co-occurrence networks between PubMed records. The majority of PubMed records are also available in Scopus and WoS, with Scopus claiming 100% PubMed coverage. PubMed has the advantage of being an open database that can be downloaded freely for scientometric analysis.

Microsoft Academic Graph is another large-scale resource that has recently become available. As suggested by the word *graph* in its name, it includes cited references that enable creation of a large-scale bibliometric network. Although it contains around 130 million records, only 35–50 million of those records are linked by citation [8.18, 19]. Nevertheless, it is free for research purposes (but not for commercial use), which makes it a very valuable resource for the creation and exploration of large-scale networks. CrossRef, in addition to being a Digital Object Identifier (DOI) registration agency, maintains metadata associated with DOIs that can be downloaded for analysis. We do not list Google Scholar in Table 8.1 because, although it is perhaps the largest bibliometric resource in the world (estimated at 160 million records), it has not been made available in bulk for scientometric analysis.

The other three scientific literature databases listed in Table 8.1 each focus primarily on a single large field–Chemical Abstracts on chemistry, JSTOR on the social sciences, and CAB Abstracts on agriculture. Each is subscription-based, and none has been used extensively for scientometric analysis, but could conceivably be used to create and analyze a large-scale network of topics in those fields. Many other literature databases exist, but they are typically much smaller than those listed and are either subject-specific or region-specific, and will not be covered here.

Full-Text Literature

In addition to those databases containing literature metadata, several vendors and services now maintain databases with large numbers of full-text documents. None of these yet has the type of broad and deep coverage offered by either Scopus or WoS. Nevertheless, we can expect access to full-text documents to increase in the future, and as such, they have the potential to become significant sources for large-scale bibliometric networks and analysis. Table 8.1 lists ScienceDirect (Elsevier) and IEEE Xplore, each of which houses millions of full-text documents. ScienceDirect is broad, covering most fields of science, while IEEE covers mainly electrical engineering and computer science. Although not listed in Table 8.1, Springer, Wiley, and other publishers are also making full text available to their subscribers, and many of these publishers (including Elsevier, Springer, and Wiley) allow downloading of their documents in XML format. Full-text data from CiteseerX, arXiv, and PubMed Central are all freely available through their APIs (application programming interfaces), and can be mined for references, citation contexts, and other features that can be used to create networks.

Patents

Patents are another type of output from science and technology. We list patent sources in Table 8.1 for completeness, but will not elaborate much on patent networks in this chapter since they will be covered in detail in other chapters. Nevertheless, there are multiple vendors (Espacenet, PatStat, Derwent, and LexisNexis) that collect and unify patent data from jurisdictions around the world. It is difficult to determine large differences in these sources without detailed examination of each, so we have listed them as equivalent in terms of coverage in Table 8.1. Although there are undoubtedly differences between vendors, the bulk numbers of worldwide patents covered by each is likely to be roughly similar. Patent data contain references to prior art, including prior patents, patent applications, and scientific papers. Links to scientific papers, known as nonpatent references (NPR) are typically very dirty data, and require cleaning and linking to literature databases to be used properly. We are unaware of any public source of cleaned patent-to-paper linkage data, but are aware of institutions that have done this work and maintain these links for their own use [8.20, 21].

Patents are also assigned to categories in one or more classification systems. Both feature types (links and categories) can be used to link patents into large networks. Among free sources, we list data from the US Patent & Trademark Office (USPTO) and PatentsView, a source for cleaned and unified USPTO data that has been funded by the US National Science Foundation (NSF) for many years to process these data and make them more widely available.

Project-Level Funding

Data on the funding of science are perhaps the hardest data to obtain for many reasons. Although aggregate data are available in reports from, for example, the Organisation for Economic Co-operation and Development (OECD) and US National Science Board, project-level data are needed to really understand the effects of funding on science and technology at the topic level. Private funding by companies or foundations is, of course, proprietary to the funding institutions. Few public institutions, such as government agencies, have made their project-level data publicly available. Perhaps the largest repository of funding data currently available is UberResearch, a relatively young company that gathers project-level funding data from sources around the world and makes analysis based on those data available to subscribers.

Among open data sources, the largest dataset, in terms of numbers of projects and funding amounts, has been made available for bulk download by the US StarMetrics consortium. These data contain project-level metadata including annual funding amounts since 2008 for many US agencies including the National Institutes of Health (NIH), NSF, and the National Aeronautics and Space Administration (NASA). Abstracts are available for most projects, and the data also include links from PubMed articles to NIH projects mined from PubMed publications and internal NIH source materials. Links are not yet available for projects from other agencies, but will hopefully be added in the future. Project-level data (including links) for NIH for years prior to 2008 are available through the NIH RePORTER and ExPORTER websites, while earlier data for NSF are available through an API.

Data that link specific projects and scientific articles are also available from WoS, Scopus, and PubMed. WoS began indexing acknowledgments in 2008, and has indexed nearly 11.7 million specific grant-to-article links through 2016. Scopus also indexes acknowledgments; however, they started later, and the number of annual links indexed by Scopus is only about one third of those indexed by WoS. PubMed also lists grant numbers; however, they do not keep all information, but limit their listings to NIH grants and select grants from a few other funders such as CDC and the Wellcome Trust. In general, the grant-to-article data from PubMed are largely redundant with those available from NIH ExPORTER.

We note that there are a couple of other smaller sources of project-level funding data that are publicly available. Cordis makes available files with data from 40 000 grants from the FP6, FP7, and Horizon 2020 EU funding cycles. The UK Gateway to Research (GtR) lists perhaps 70 000 grants with metadata and articles reported to have acknowledged those grants. We have linked the GtR data to Scopus articles, and have posted the link file for download at http://www.mapofscience.com/wp-content/uploads/2016/05/links_pub_gtr.xlsx.

All of the data sources listed above are suitable for creating large-scale bibliometric networks. Perhaps more interestingly, we look forward to the day when data of multiple types–papers, patents, funding, and perhaps other things like equipment–will be linked together to form more detailed and accurate pictures of science, technology, and innovation.

8.2.3 Methods

The process that is used to create a bibliometric network, whether small or large, is relatively simple conceptually, and consists of the following general steps:

1. Data extraction
2. Similarity calculation
3. Clustering
4. Layout and visualization.

In some cases, there can be multiple iterations of the similarity calculation and clustering steps. Despite this difference in detail, the four steps listed here are the major building blocks of any network creation and/or visualization. Each will be discussed further here. An alternate, and more general, explanation of these steps that is applicable to both small and large networks can be found in [8.22].

Data Extraction

Bibliometric networks, like all other networks, consist of objects and the links between those objects. When speaking of a network, we often refer to these as nodes (objects) and edges (links). The first steps in creating a bibliometric network are to decide which data to use, what the nodes will be, and what feature or features will be used to create the edges. For networks based on large-scale bibliographic data, either a full database or a substantial fraction of that database is typically used. For instance, one can use the full Scopus database (tens of millions of articles) as the data source, or one can use a one-year slice of the database (2–3 million articles) as the basis for the network.

The choice of what to use as the network nodes depends on the question that is being asked and the type of network that can be used to answer that question. If the question is about how authors link together, then a collaboration network based on coauthorship is good choice. If the question is about the relationship between concepts, then a network based on the relationship between terms or keywords is a good choice. If the question is about topics and their dynamics, then a network of topics, which we have previously defined as collections (or clusters) of documents with common intellectual interest, is a good choice. The balance of this chapter addresses questions that are best answered from a topic perspective, and we will thus move forward with this example.

For a topic network, we ultimately define nodes as topics or clusters of documents, and edges as either citation or textual links between topics. However, since topics are not available in any database, we must create topics from documents. Topics result from clustering a large-scale bibliometric network of documents. For our example network, we thus define articles as nodes, and we will define the edges as citation-based relationships between the nodes. Note that we could define the edges based on any type of valid relationship between documents. Examples include co-occurrence of textual features in the titles and abstracts of documents or co-occurrence of authors across documents. We choose to use citation relationships because they are typically intentionally chosen by authors, and in our experience are less interchangeable than words.

Having chosen to use documents as nodes and citations to create the edges of our network, we make sure that our data extractions include these pieces of information. In this case, a list of the edges (pairs of citing and cited document IDs) is our starting point, because the list of edges necessarily contains all of the nodes.

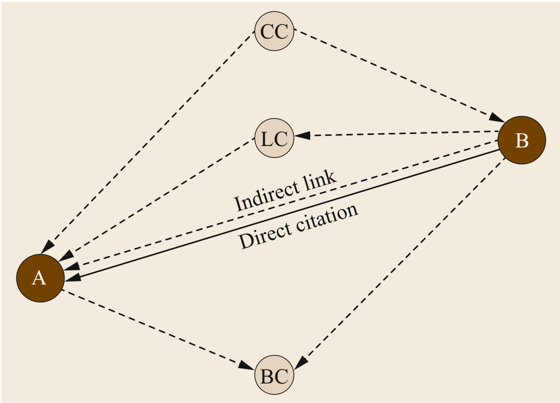

Fig. 8.3 Citation links can be used to create several different types of edges that can be used to create bibliometric networks (after [8.23]). Indirect link types include CC (cocitation), BC (bibliographic coupling), and LC (longitudinal coupling)

Similarity Calculation

The next step in creating a bibliometric network is to calculate the similarity between pairs of nodes in the network. This is not as trivial as it may seem. Of course, for our example network comprised of documents and the citation relationships between documents, one could take the simplest approach and simply designate each citing-cited document pair as an edge, and weight each edge equally. This is the simplest approach, known as direct citation, and it can work quite well. However, citation data enable more sophisticated similarity measures as well. While direct citation is a first-order link between two documents, indirect links can also be created and used as the basis for similarity between documents. Figure 8.3 shows three such linkage types–cocitation (CC), which occurs when a document cites documents A and B; bibliographic coupling (BC), which occurs when documents A and B both cite the same document; and longitudinal coupling (LC), which occurs when A cites a document that cites B. Each of these similarity types can be generated from the same set of initial edges, forming a new derivative set of edges that is typically much larger than the original set of edges. The different edge types can also be combined as was demonstrated by *Small* [8.23].

Figure 8.3 exemplifies edges that are based on simple counts of links. While direct citation links between pairs of documents are singular (except in rare cases), indirect links between the same pair of documents can occur many times. For example, a pair of documents that are cocited together in many subsequent papers will have a large number of such indirect links, and can thus be said to have a large cocitation score. These raw scores can be used to weight the edges in a large network. However, experience and experimentation have shown that in most cases, normalizing the raw count scores leads to a more accurate clustering of the network. Thus, edges with normalized weights are typically used to create bibliometric networks.

Many common normalization methods are available; different normalizations are used for different types of similarities. For edges based on direct relationships, such as direct citation edges, normalization is typically based on the number of edges for each node. One method assigns each edge a weight of $1/n$ where n is the number of edges leaving the node [8.24], for example, for scientific documents n would be the number of cited references in the document. Another method assigns edge weights based on edges entering and leaving the node [8.25].

For edges based on co-occurrence relationships, including cocitation and bibliographic coupling, coterm analysis and coauthor analysis, most normalization approaches are based on the numbers of edges related to both nodes. The cosine, Jaccard, and inclusion indexes, and the association strength, are all commonly used and their relative strengths and weaknesses were recently compared [8.26]. Historically, the choice of which of these measures to use seems to have been personal rather than driven by any particular evidence. Regardless of which choice is made, for this step a list of edges with weights is calculated from the list of edges generated from the data extraction step, and this list of weighted edges is then used as input to the clustering step. At this point, for completeness, we note that although we typically use citations to estimate the relatedness between document pairs, others prefer to use textual characteristics. There is relatively little difference between the accuracies of the best text-based and citation-based relatedness measures when it comes to clustering documents [8.24, 27]. However, computation requirements for citation-based relatedness measures are typically far less than for text-based measures.

To continue our example, in this step we choose to use direct citation as the basis for our edges, and will normalize the edges by the number of references per citing document. Our edge file thus contains all pairs of citing and cited document IDs along with edge weights that are present in our dataset.

Clustering

Now that we have an edge file that represents a very large network of documents, it is time to partition the overall network into groups of documents that represent topics using a clustering algorithm. We do not undertake a history of clustering algorithms here, but mention only those that are currently capable of clustering tens of millions of objects and that are somewhat familiar to bibliometric researchers. A detailed review of clustering or community detection techniques can be found in [8.28].

There are several classes of algorithms that can cluster a very large network (at least one million nodes and ten million edges), including modularity, label propagation, spectral analysis, and map equation algorithms. It is difficult to compare the results from different clustering algorithms because a valid comparison is best made when the cluster size distributions are very similar. A recent study comparing clustering results using algorithms from each of the classes listed here on data sets of 1.2 million and 11 million nodes was inconclusive because the cluster size distributions from the different classes were quite different [8.29]. However, the authors did conclude that map equation algorithms performed best when comparing results on smaller datasets focused on bibliometrics and information science. They thus advocate that map equation algorithms should receive more attention than they currently do. These recommendations could not be extended to larger networks.

Each class of algorithm has its advocates. For instance, map equation algorithms, such as InfoMap [8.30], are used on very large networks by Jevin West and associates at the University of Washington [8.31], while modularity-based algorithms include the well-known Louvain algorithm [8.32] and the smart local moving (SLM) algorithm [8.33] developed at Leiden University. We personally favor the SLM algorithm, and its VOS predecessor [8.25], because they are highly versatile and can be tuned to generate networks with different numbers of clusters. When partitioning large networks into large numbers of clusters, our experience is that the cluster size distributions are relatively flat, spanning only two orders of magnitude in size.

To summarize this step in our process, although details differ, most clustering algorithms accept lists of weighted edges in some form as input, and return a list of the cluster to which each node is assigned as an output. To continue our example, using a list of direct citation weighted edges as input, and using the SLM algorithm for clustering, our output would be the cluster assignments for each document. If we set the input parameters such that the documents were partitioned into roughly 100 000 different clusters, each cluster would represent a single topic in science.

Layout and Visualization

The final step in our general process is to create a visual map of the resulting network. In some cases, this step is not needed. If the research question does not require visualization, the cluster solution resulting from the first three steps is sufficient, particularly if the cluster contents and their metadata are maintained in a database that can be queried to answer questions. However, we find that visualization is helpful in many regards to disseminate results, and is thus applicable to most network analyses.

Visual maps of networks can be created with many different tools. Several of these tools combine the similarity calculation, clustering, and visualization steps, leaving only the data extraction to the user. For example, CiteSpace [8.34, 35] inputs a set of records downloaded from WoS or other data sources, and creates a number of different visualizations based on cocitation clustering. VOSviewer [8.36] is widely used to create useful visualizations of documents, journals, terms, or authors from records downloaded from either WoS or Scopus, and clusters the data as well as providing a visual rendering. Several other such tools exist [8.37, 38]. However, they are all designed to work with document-level records–with data directly obtained from WoS, Scopus, or another database–and are not well equipped to work with cluster-level data that has already been created using the process mentioned above. These tools are also limited in the size of the dataset they can process and visualize.

Layout (i. e., assigning coordinates to each node) and visualization of a network of clusters are best accomplished using other tools. Network layout algorithms require nodes and edges as input. Thus, to visualize cluster-level data, an additional step must be taken here–similarity between pairs of clusters must be calculated. Cluster-to-cluster similarity can be calculated in a variety of ways as mentioned above in Sect. 8.2.3, *Similarity Calculation*. It can be based on aggregated citation relationships between clusters, or it can be based on another feature such as the text associated with the documents in each cluster. Once the cluster-level similarity has been calculated, an edge list is created where the edges consist of cluster IDs and the edge weights (or cluster-cluster similarity values). At this point one can either cluster the data again using the *clustering* step mentioned above to create higher-level clusters, or one can create a layout of the cluster-level network using a graph drawing or network layout algorithm such as Kamada-Kawai [8.39], Fruchterman-Reingold [8.40], or DrL/OpenOrd [8.41]. Fortunately, this step is not as difficult as it might sound because these algorithms are implemented in other user-friendly network analysis tools such as Pajek [8.42] and Gephi [8.43]. Statistical packages, such as R, are also capable of sophisticated network analysis and graph drawing.

Tools like Pajek and Gephi can be used to do the layout and visualization of a cluster-level network, or they can be used to simply visualize a network whose layout is calculated elsewhere, such as with a standalone version of DrL, which can handle networks of several million nodes. This is the process that we use. To continue our example, once we have created topics, or clusters of documents using direct citation edges, we assemble the text for each cluster and calculate a cluster-to-cluster similarity using the BM25 text relatedness measure [8.44, 45]. We then use DrL to create a layout of the clusters, and use Pajek to visualize the resulting network [8.46]. Figure 8.4 shows an example of the visual map resulting from the example that we have used to illustrate the process steps given here. Each topic, represented by a dot, is a cluster of papers that are linked by citations. Topics that use very similar text are near to each other in the map. Each topic in the map has been designated as belonging primarily to one of twelve high-level fields, and is correspondingly colored in Fig. 8.4. These designations were made by assigning papers to fields using the University of California San Diego (UCSD) journal-to-field assignments [8.47].

8.3 Studies of Large-Scale Bibliometric Networks

Now that the general process for creating a large-scale bibliometric network has been explained, we turn to a review of recent studies of these types of networks. In addition to the work to cluster large-scale bibliometric networks, we will also review other studies that create large-scale networks but that do not necessarily cluster them.

8.3.1 Networks of Scientific Topics

The general methodology mentioned in the previous section can be used to cluster and visualize networks of all different sizes. It is not specific to large-scale networks, and in fact has been used much more often on small- and medium-sized networks (those with fewer than 100 000 documents, for instance) than on large-scale networks. There are far fewer studies that present and analyze large-scale networks, largely because few institutions have access to complete bibliographic databases in electronic form. Nevertheless, since this chapter is specifically about large-scale networks, we ignore the large body of work on smaller networks, and focus here on work based on sets of roughly one million documents or more. We also ignore journal networks here because, although some journal network studies have been based on millions of documents, the networks have ultimately been composed of either thousands of journals or hundreds of journal categories, and thus do not meet our criteria for being a large-scale bibliometric network. This section will also include studies of large-scale data seeking to establish the relative accuracy of different similarity methods because the results of such studies naturally reflect on the accuracy of the application space associated with large-scale bibliometric networks.

Clustering of documents in bibliometric studies was limited to document sets of far less than one million documents from the early 1970s until the late 2000s. Here we review those studies of one million documents or more in roughly chronological order, as shown in Table 8.2. *Boyack* [8.48] was the first to publish a study (in 2009) where a million documents were clustered into topic-level categories. Using a set of one million documents from the 2003 WoS file year and seven million bibliographic coupling links between documents, he used VxOrd (the predecessor to DrL) to create a document layout. Although the layout did not assign documents to clusters, it did concentrate them in cluster-like structures. Single-link clustering using edges and distances was then used to create clusters from the layout results, with the one million documents being assigned to 117 435 clusters, each of which represented a scientific topic. This classification was then used to identify specific potential collaborations because one can reasonably expect that authors in the same topic that have not previously coauthored together could become collaborators in the future. Using specific sets of topics in physics, these potential collaborations were aggregated at the institution level to identify those institutions that had a high potential overlap, and thus a high potential for fruitful collaboration, such as Sandia National Laboratories. This is an illustration of but one practical application of clustering documents into a large number of topics. The results would have been much less specific, and potentially much less actionable, if the documents had been clustered into fewer clusters. Specificity increases with granularity, and this specificity is crucial to many applications, such as the identification of potential collaboration.

A related process was used shortly thereafter by *Klavans* and *Boyack*, but using Scopus data, cocitation links rather than bibliographic coupling links, and the DrL layout algorithm to cluster 2.08 million reference papers that were cited in 2007 [8.49]. The cluster formation step was somewhat different in this case. DrL employs edge cutting, and is a stochastic algorithm in that changing the starting seed value changes the order in which edges are considered, and thus changes the edges that will be cut. Results from two DrL calculations on the same input file with different seeds will have highly overlapping, but not identical, sets of uncut edges. In this study, DrL was run with ten different seeds, and an edge was considered robust only if it remained uncut in six of the ten runs. Clustering was done using the uncut edges using a standard average-link clustering algorithm. Once the 84 000 clusters were obtained, 5.68 million papers from a five-year (2003–2007) subset of Scopus were fractionally assigned to the clusters using citation links. These 84 000 clusters were then combined in an idiosyncratic way by institution (i. e., universities, countries), and the results were analyzed to identify the topic-level strengths of those institutions and countries. Portfolio analysis is thus another application that benefits from a highly detailed clustering of the scientific literature.

It was at about this time that SciTech Strategies (STS) received a Small Business Innovation Research (SBIR) grant from NIH to compare the accuracies of citation-based and text-based similarity measures. A team consisting of researchers from several institutions was assembled to do this work. A dataset of 2.15 million documents that were available in both Scopus and PubMed was created, and 13 different similarity measures–three citation-based, nine text-based, and one

Table 8.2 Analyses of large-scale bibliometric networks and associated characteristics. Numbers of nodes and edges apply to the single largest clustering calculations performed in each study, and do not necessarily represent final totals

hybrid (citation and text)–were calculated. The same clustering method, using the commonalities in ten DrL runs, was used for all 13 similarity measures. Clustering results were compared using the concentration of grant-to-article linkages [8.24, 27]. The working assumption behind this metric was that articles acknowledging a single grant would be topically similar, should thus be concentrated in the cluster solution. Cluster accuracy should therefore correlate positively with grant concentration. These studies showed that of the three citation-based similarities, bibliographic coupling was the most accurate, followed closely by cocitation (CC). Among text-based similarities, the PubMed related articles similarity gave the best results, followed closely by the BM25 measure. The best citation-based and text-based approaches gave roughly similar results, and the hybrid measure, which included a textual component with bibliographic coupling, did slightly better than either. Although this study did not address a specific topic-level application such as portfolio analysis, it did establish that text-based and citation-based topics could be created using millions of documents. It also showed that, while bibliographic coupling gave better results than cocitation analysis, the gap between the two was not large, and that there was not a compelling reason to give up cocitation analysis (which STS had been using for years) as the basis for creating models of science.

STS continued to use its cocitation analysis process to create detailed models of science and expanded from using single-year models, each based on more than two million reference papers, to linking together models from adjacent years into thread-like structures [8.16]. Improvements in the early 2010s included the creation of a hybrid CC-BC approach that increased cluster accuracy [8.46]. The intent behind linking annual sets of clusters was to produce a dynamic, rather than a static, view of science that would enable identification of emerging topics. A cluster from one year was linked to a cluster in the following year if the fraction of papers in common was above a certain threshold. These cosine thresholds were lower than one might expect (around 0.25), and reflect the inherent instability of cocitation sets from one year to the next. The most advanced model linked together cluster sets from 16 years, and the resulting threads or topics–those that lasted two years or more–were used to identify discipline-like structures based on documents rather than journals. These topics based on linked cocitation clusters were also used for a couple of practical topic-level applications. The first of these was to distinguish topics along the basic-to-applied spectrum using research levels [8.57]. The second was to characterize the detailed structure and dynamics of sets of topics related to emerging areas in science using research on graphene and dye-sensitized solar cells (DSSC) as two examples [8.58]. This topic-level analysis suggested that research on graphene and DSSC could not be characterized as single topics, but that each area consisted of multiple detailed topics with different dynamics, some of which were focused on fundamental (material) properties and others that were clearly application oriented. Interviews with program officers using cluster contents (on different areas than graphene and DSSC) showed that experts could easily distinguish between these detailed topics, and in many cases knew the specific stories that accompanied each topic.

Each of the studies reviewed so far, while large in scale, were also limited in that DrL has a practical limit of about three million nodes and 30 million edges on a typical computer, and thus cannot be used to cluster the entire contents of a database such as WoS or Scopus in a single operation. This barrier was overcome in 2012 and 2013 by the introduction of new modularity-based clustering algorithms by Ludo Waltman and Nees Jan van Eck at Leiden University that are capable of clustering tens of millions of documents. The first algorithm was an extension of the clustering code used in VOSviewer (VOS in Table 8.2), was written in the C language, and was first used to cluster more than ten million WoS documents connected by 98 million direct citation edges [8.25]. The VOS code is capable of clustering at multiple resolutions, and doing so in a hierarchical manner. In this first demonstration, clustering was done at three different resolutions such that solutions with 20, 672, and 22 412 clusters were created. Characterizations were done at each level of clustering, including a ranking of the hottest topics based on average publication year at the second level. This study established that a very large, multiyear set of scientific publications could be clustered in a single operation, and that at the most granular level the resulting clusters had varying dynamics and a detailed topical focus.

A second modularity-based algorithm, written in Java, and now known as the smart local moving (SLM) algorithm, was also introduced by *Waltman* and *van Eck* [8.33]. SLM was compared to the well-known Louvain algorithm and to a multilevel refinement of the Louvain algorithm. While the results of all three algorithms were very similar for a single iteration, SLM results improve with each additional iteration. Although running multiple iterations does increase the time needed to cluster, the increased modularity (which should correspond with increased accuracy) can be worth the expense. The SLM algorithm was also run on a set of nearly 40 million web pages with 783 million links, thus establishing that it is capable of clustering the complete contents of either WoS or Scopus from a size perspective.

SLM was later used for a practical application by *Ruiz-Castillo* and *Waltman*, who clustered a ten-year set of WoS documents at 12 different levels of granularity, ranging from 390 to 73 205 clusters [8.50]. The purpose of this study was to determine an optimum number of clusters to use as the basis for normalization of indicators used in research evaluation. It was determined that a solution with less than a thousand clusters merged fields that should be distinct from each other, while a solution with tens of thousands of clusters contained many clusters that were too small to be used for research evaluation. Solutions with a few thousand clusters were deemed most acceptable for the purpose of research evaluation. Accordingly, SLM has been used to create the roughly 4000 document clusters used in the Leiden Ranking for the past few years.

In 2012, we (Klavans and Boyack) were very aware of the size limitations of DrL, and had begun looking for ways to cluster larger datasets. We became aware of the VOS algorithm and results in a prepublication version of [8.25] and were excited about the possibilities. We obtained a copy of the code (which was made openly available), and quickly set about replicating the study and performing calculations to compare to our cocitation models. We found that the accuracy of the direct citation VOS cluster solution was comparable to that of our previous cocitation and bibliographic coupling calculations, which suggested that the direct citation results in our previous study on accuracy [8.24] had been adversely affected by the short time window associated with that dataset. Upon detailed examination of numbers of clusters, we became convinced that these direct citation clusters were very good representations of historical views of topics, but that they were also quite different in character from the topics produced by linked annual cocitation models. Where topics based on cocitation were only partially stable from year to year, topics based on direct citation were much more stable in that key papers continued to be built on year after year within the same topic. Few cocitation topics lasted for more than a few years, while a large fraction of direct citation topics lasted for ten years or more.

Given that we were very interested in the identification of emerging topics, we thus sought to combine the inherent stability of direct citation topics with the inherent instability of cocitation topics. We reasoned that if the same papers appeared in the first year or two of topics created using both methods, this would constitute two votes that these papers were part of an emerging topic. Using 15-year cocitation and direct citation models created from the same set of papers, we identified the top 25 emerging topics each year for four years, characterized those topics, and showed that these topics (and their key researchers) were associated with awards and honors at a much higher than expected rate [8.10]. Although this did not prove that these were the most emergent topics, it did suggest that the methodology was sound and identified a very reasonable set of emerging topics.

One thing that was not clear from this study was whether both models (direct citation and cocitation) were needed to identify emerging topics, or if direct citation alone would have worked just as well. It was clear that cocitation would not have worked on its own because the majority of new cocitation topics did not last for more than a year or two. The fact that nearly all of the top 25 emerging topics nominated by the combined approach were in the top 50 using only direct citation suggests that using a direct citation model alone would be a sufficiently accurate way of identifying emerging topics. We ultimately decided to start using direct citation with VOS/SLM clustering rather than using cocitation because:

1. The clusters were sufficiently accurate
2. The entire database could be clustered in a single calculation rather than linking annual models
3. It nominated a very defensible set of emerging topics; and
4. It requires far less computing time than using cocitation because there are far fewer links.

One known disadvantage of direct citation with respect to other document relatedness approaches is that it has tended to provide somewhat lower coverage. The major reason for this is that, in most calculations, the direct citation links used for clustering have been limited to those within a document set. This is particularly problematic for older documents. If, for instance, a ten-year dataset from 2001 to 2010 is used for clustering, some of the documents published in 2001 have no references within the dataset, and of these, documents not cited later are not linked and are thus not included in the clustering. Having made the decision to use direct citation clustering, and knowing of this disadvantage, we decided to investigate the effect of using what we call extended direct citation (EDC), which includes cited documents that are not in the dataset (i. e., nonsource documents) in the clustering. Using a 16-year dataset from Scopus, we compared a clustering using only source documents with one that included nonsource documents [8.51]. Inclusion of nonsource documents in the clustering significantly increased the coverage of source documents, from 85.6 to 96.4%. In addition to the 21.4 million source documents in the larger calculation, 22.0 million nonsource documents were also included in the clusters. While these nonsource documents have not been used for research evaluation, they can be used for other purposes. For instance, one can easily see the effect of books on topics in science, and one can also see how well the citation databases cover different subjects. In this study, it was shown that while source items comprise 88% of the documents in medical fields (in the 16-year source period), they only comprise 53% of documents in the social sciences. The social sciences could thus benefit much more than medicine from the additional coverage provided by nonsource documents.

Figure 8.5 graphically illustrates the difference between the direct citation (DC) and EDC approaches. EDC includes nonsource documents along with the links from source documents to nonsource documents, and enriches the clustering as a result. For instance, document N in Fig. 8.5 cannot be clustered using DC, but is included in a cluster using EDC. EDC not only increases coverage, but also improves the clustering of source documents because it uses more signal–it nearly doubles the number of edges included in the calculation, all of which provide additional information for clustering of the source documents. For instance, Fig. 8.5 shows document C being clustered with documents D and O using direct citation. However, when using the extended methodology, document C is no longer clustered with documents D and O because its links to nonsource documents pull it into another cluster. Recently, *Waltman* et al. [8.59] have shown experimentally that EDC can create more accurate clusters than DC, CC, or BC using a dataset of 273 000 documents in condensed-matter physics.

The accuracy of this EDC approach was also recently demonstrated in a study of a very large dataset. Although it was not compared with DC, EDC clearly outperformed BC and CC at multiple levels of granularity [8.52]. The most detailed EDC model in this study was created from 48.4 million documents with 582 million edges, resulting in a solution with 91 726 topics. This model will be described in more detail later along with several applications of the model that have policy implications.

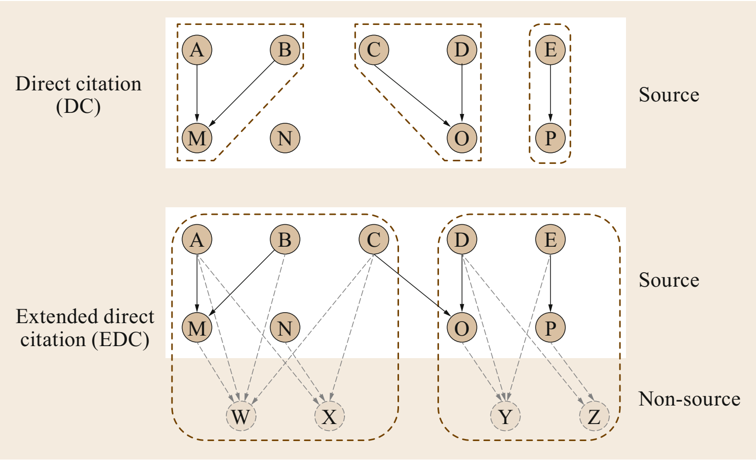

Fig. 8.5 Conceptual comparison of direct citation (DC) and extended direct citation (EDC) approaches. *Dashed boxes* indicate clusters

To this point, we have discussed only those studies of large-scale bibliometric networks published by SciTech Strategies and Centre for Science and Technology Studies at Leiden University (CWTS), being the two laboratories that have historically worked with such networks. Other laboratories with access to full databases have also started doing analysis of large-scale networks, although they have not created topic-level structures. Foster, Evans, and colleagues have been working with millions of records from Medline. Rather than clustering documents to create topics, they have been clustering chemicals [8.53] or authors and MeSH terms (chemicals, diseases, and methods) [8.54] for the purpose of characterizing the novelty of the linkages between these clusters. Although the numbers of clusters have not been large, these studies are noteworthy in that they are among the first studies using large-scale bibliometric data to explore edges rather than nodes. In addition, these studies have shown that the new or novel links that are formed each year are between objects that are already neighbors. Reference [8.54] in particular shows that most new connections come through things of a different type. For example, new connections between methods may come through diseases, and vice versa. Studies such as these are rich in that they are starting to explore and cross-link the Latourian feature space shown in Fig. 8.1.

As mentioned above, Microsoft Academic Graph (MAG) is a bibliographic database that has recently become available for research. These data were specifically used for the Web Search & Data Mining (WSDM) Cup 2016 where the challenge goal was to provide the best ranking of search results (i. e., other papers) using publications as queries. Teams from many countries participated in the challenge. Although they did not cluster the data into *topics*, the three teams with the highest cup scores all used network information to create their rankings. In other words, they all created document-to-document similarities using the network graph. These similarities could have easily been used to cluster the data, although this step was not taken because it was not part of the challenge. The methods to create similarities that were used included combined information from citations, authors and venues [8.60], an eigenfactor ranking method based on direct citation [8.55], and a modified relative citation ratio method based on cocitation clustering [8.19]. The direct citation eigenfactor solution is notable in that it has been expanded into a larger-scale recommendation engine combining inputs from MAG and several other databases [8.56], and has been converted into a web-based service that is publicly available.

The types of methods and applications described here for large-scale networks of scientific literature could be also applied to patents. However, we are unaware of any published work that clusters an entire patent database into patent topics. Thus, we present here a map of 2.8 million US patents from 1991 to 2011 to show the feasibility of such an approach. Patent citations were used as the direct citation links with the VOS code, resulting in a set of 27 118 clusters. A visual map of the clusters was created using cluster-cluster similarity calculated using the BM25 text relatedness measure, and is shown in Fig. 8.6. Labels were added to the map manually by looking at cluster contents in local areas of the map. Clusters were colored using the same colors used in our science maps (e. g., Fig. 8.4). This was done by assigning a color to each IPC4 code using the patent-to-paper links from author-inventors [8.61], and then determining the dominant color for each cluster based on its IPC4 codes.

As shown in Fig. 8.6, many patent clusters link to science, particularly computer science and electrical engineering (pink), other engineering (cyan), chemistry

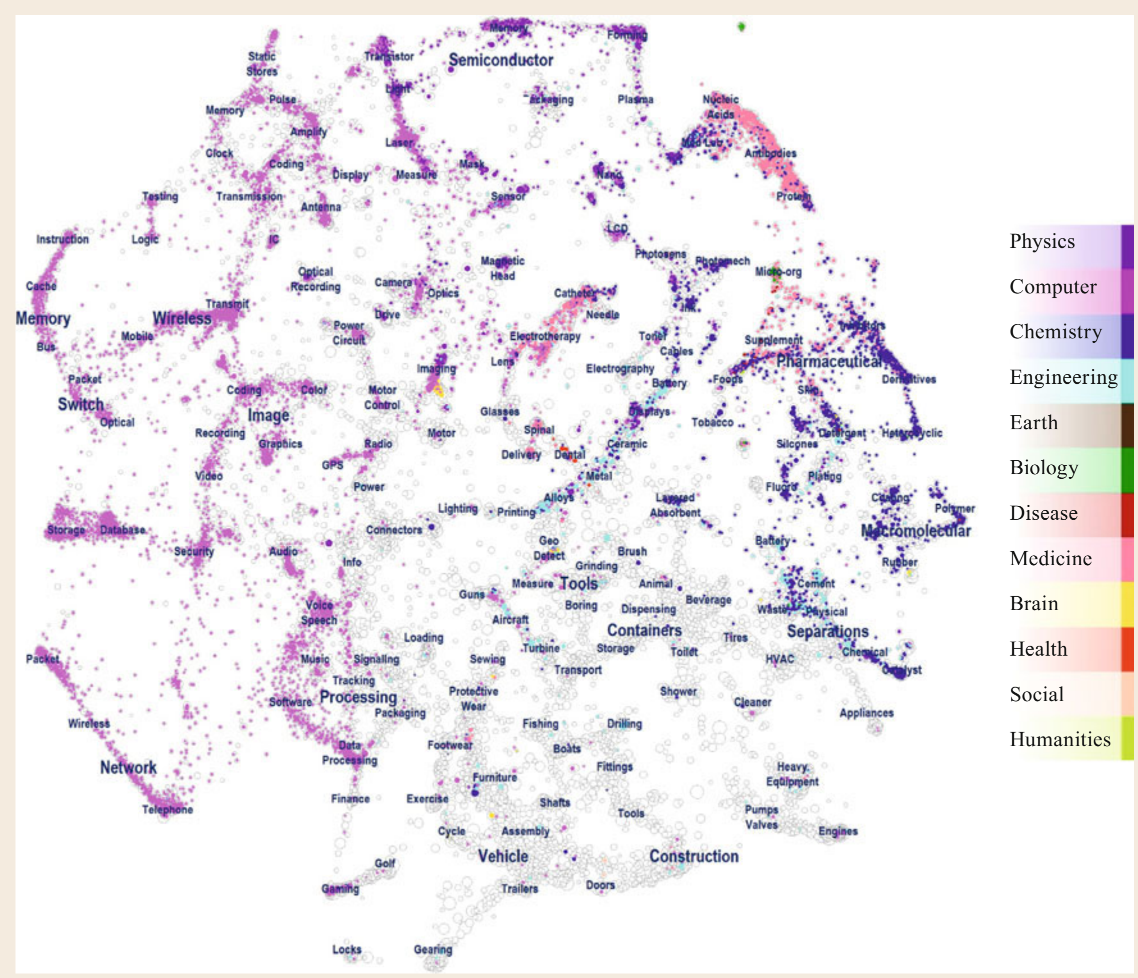

Fig. 8.6 Visual map of clusters of patents based on direct citation where each *dot* represents a cluster

(blue), and medicine (salmon). However, many patent clusters do not have strong links to science. These have been colored gray in the map, and most such clusters are focused on consumer goods. As with the topic-level clusterings of the scientific literature mentioned above, patent clusters can be used for many applications, such as portfolio analysis and the identification of emerging clusters.

8.3.2 Networks from the FUSE Program

In 2011, the US Intelligence Advanced Research Projects Activity (IARPA) funded the Foresight and Understanding from Scientific Exposition (FUSE) program with the intent of developing automated methods to identify technical emergence from literature sources. Four research teams were chosen to participate in this effort. As with many programs funded by US intelligence agencies, relatively little information about FUSE and its outcomes is publicly available. It can be deduced from published outputs, however, that very large networks were created and used in the task. For instance, a short program review in Nature mentions that FUSE mined "millions of papers and patents in both English and Chinese" [8.62]. The article also mentions that FUSE "has identified several hundred indicators, such as new collaborations or expressions of excitement in text, that highlight emerging areas." Work from the team headed by researchers at Columbia University makes it clear that network properties from 48 million WoS articles based on direct citation links and coauthorship links were among those indicators [8.63]. The combined cocitation and direct citation network analysis to identify emerging topics mentioned above [8.10] also came from the FUSE program; large-scale network analysis was routinely used in the FUSE program, although very few published outputs mention this fact. Finally, FUSE technology is also being commercialized by Meta, who licensed the technology developed in the FUSE program by SRI International to mine very large literature databases. Meta has recently joined the Chan Zuckerberg initiative with the intention of making their technology available to people worldwide to help them understand the state of scientific knowledge (https://meta.com). Although detailed information about FUSE outputs is sparse, we mention it here to illustrate that large-scale network analyses are perhaps more advanced than those in the academic world may realize.

8.3.3 Author Disambiguation

Author disambiguation is another application of large-scale bibliometric networks. Although most author disambiguation studies have been done with small datasets from a single field of science, there have been several studies that have developed methods to disambiguate author names over full large-scale databases. Common among the five studies listed in Table 8.3 are that they were each done using a full large-scale database, and each clustered author-paper pairs to identify unique authors. The first of these efforts, the Author-ity model created by *Torvik* and *Smalheiser* [8.64], used 15.3 million papers from Medline. It used multiple features including title words, coauthors, MeSH terms, affiliations, and email addresses to estimate the probability that two papers sharing the same author name (last name with first initial) were actually written by the same person. Each author-paper pair was assigned to one of 6.7 million individuals. The Author-ity model was later adapted for use on the US patent database by *Li* et al. [8.65], who included secondary data sources such as geospatial country files and geographic name unification files as inputs to their clustering. Improved author and inventor assignments enable more accurate characterization of these people and their mobility.

Liu et al. revisited the disambiguation of biomedical authors by working with 22 million records from PubMed [8.66]. They attributed their improvement over the Author-ity methodology to their "machine-learning method driven by a large-scale training set and the clustering algorithm regulated by a name compatibility scheme preferring precision." Their disambiguation results have been used by PubMed since May 2012 to provide better search results in those 36% of queries that contain author names. *Schulz* et al. designed a disambiguation method that is fundamentally different that those already listed in that it is based primarily on shared references and citations [8.67]. The assumption behind this approach is that two papers written by the same author are much more likely to be connected by a citation link (i. e., a self-citation) than two papers written by two different authors sharing the same name. This approach was applied to the entire WoS database (47 million articles) with good results. *Caron* and *van Eck* [8.68] applied a similar approach to the full WoS database, using author and article-based features along with citation characteristics. Author disambiguation is an extremely important application of large-scale bibliometric networks because lumping together of multiple authors has a relatively large (unwanted and negative) effect on network measures [8.69], and can lead to incorrect analysis.

8.3.4 Other Relevant Analyses

Sections 8.3.1–8.3.3 have mentioned those studies that have created and analyzed large-scale bibliometric networks where the network has been partitioned into clusters or has been considered as a whole. In this section, we consider several studies of two other types: a) those that analyze individual links in large-scale data, but that do not consider the entire network; and b) studies that are too small to be considered large-scale (using our criteria), but that use the data sources from Sect. 8.2.2 in important ways that could be scaled to larger-scale analysis.

Studies of Individual Links

Citation analysis has been used for many years to try to predict which papers will end up being the most highly cited. Recent studies using millions of articles from WoS and Scopus have characterized individual cocitation links by their novelty, and have correlated the presence of novel or interdisciplinary cocitation links with scientific impact. *Uzzi* et al. used cocited journal-

Table 8.3 Large-scale author disambiguation studies based on the clustering of author–paper pairs to identify unique authors

Study	Data	Unit	Sim	#Nodes
Torvik and *Smalheiser* [8.64]	Medline	Authors	Co-occur	6.7 M
Li et al. [8.65]	USPTO	Authors	Co-occur	2.67 M
Liu et al. [8.66]	PubMed	Authors	Co-occur	10.2 M
Schulz et al. [8.67]	WoS	Authors	Co-occur	6.5 M, h>1
Caron and *van Eck* [8.68]	WoS	Authors	Co-occur	All WoS

journal relationships to determine whether any pair of cited references is typical or atypical, and found that the highest impact articles are likely to have a combination of typical and atypical cocited journal pairs [8.70]. *Boyack* and *Klavans* reproduced their study and showed that the disciplinary effects were far more prevalent than claimed by Uzzi et al. [8.71]. Multidisciplinary journals like Science, Nature, and PNAS were disproportionately involved in atypical combinations. Regardless of the details, both studies confirmed that highly cited articles are, in general, enriched in atypical (or novel) combinations of cocited references. A similar study by *Larivière* et al. [8.72] used cocited journal categories rather than cocited journals, and showed that interdisciplinary research, as measured by cocited journal categories, leads to higher-impact research.

Additional Studies of Key Data Sources

In Sections 8.2.1 and 8.2.2 we made the point that the types of data sources that we analyze should be expanded well beyond just the scientific literature to gain a better understanding of the science system. We thus review here a few studies that are not large-scale network studies to show the state of the art regarding some of these additional data sources. Although we showed a large-scale patent map in Sect. 8.3.1, most patent studies have dealt with smaller sets and have not clustered individual patents. For example, *Kay* et al. [8.73] created an overlay patent map of 400 International Patent Classification (IPC) categories from a set of 760 000 European patents using cocategory analysis. The map is useful for showing portfolio overlays, but lacks the topic-level details.

Two recent studies have created models from grant data using a latent Dirichlet allocation (LDA) topic modeling approach. *Talley* et al. used topic modeling to calculate grant-grant similarities on a set of 80 000 NIH grants, and then generated a visual map of the grants using DrL [8.74]. Nichols used topic modeling to assign 170 000 NSF grants to topics, and then characterized each grant in terms of its interdisciplinarity (i. e., its profile over multiple topics). We wish to make clear that topic modeling is not network analysis. It is a statistical technique based on text that probabilistically assigns documents to topics. However, topic modeling can be used to create topic structures than can then be subjected to network analysis. These two studies, while not large-scale network analyses, are the largest such efforts using grant data of which we are aware, and thus are worthy of consideration. It is our hope that as more grant data become available, along with more data linking grants to their outputs, large-scale analysis of these data will become more common. Along those lines, a recent poster presentation by *Freyman* et al. [8.20] reports on work that has been done to create linkage data between scientific articles, patents, grants, and technology licensing agreements by matching records across multiple databases. They have identified more than 400 000 links from articles to NSF grants, more than five million links from US patents to articles, and more than 10 000 links from agreements to patents. This type of linking has obvious policy implications, and we suggest that much more of this type of work needs to be done in the future.

Finally, as mentioned above, the full text of scientific articles is becoming more available with time. The FUSE program was very involved with mining full-text articles for features such as named entities, citation sentiment, and the rhetorical status of sentences [8.63]. Simpler features, such as the number and location of in-text references, have the potential to impact large-scale bibliometric networks. First steps have recently been taken to understand the distributions of references in full text [8.75, 76]. Reference counts, ages, and positions follow certain patterns, with some field dependency. These data have the potential to increase the accuracy of similarity measures, which would lead to more accurate identification of topics, and perhaps even to better measures of impact. Work to explore these possibilities is planned.

8.4 The STS Global Model of Science

Having reviewed relevant literature on the creation and analysis of large-scale bibliometric networks, we now present the current SciTech Strategies (STS) model of science in detail, and show how it can be used for various applications. As mentioned above, this model was recently shown to create topics that were very consistent with the referencing patterns of experts (those writing papers with at least 100 references) [8.52], and we thus use it as an example of a reasonably accurate model of the structure and dynamics of science. We do not suggest that this is the best model possible, but rather that it is reasonably comprehensive and accurate, and that it has been found to be useful for several different types of analysis by clients. Other topic-level models of science that are equally (or perhaps even more) accurate and useful can certainly be created.

The original STS model of science consists of 48 398 815 documents from Scopus. Of these, 24 615 844 documents are indexed source documents from Scopus 1996–2012, while the remaining 23 782 971 are nonsource documents that were each cited at least twice by the set of source documents. Including nonsource documents extends the coverage of the model to include important science not indexed by Scopus, including many books. In particular, the social sciences are heavily augmented when nonsource documents are included [8.51]. The set of 48.4 million documents are connected by 582 million direct citation links, which were used to create the model. Clustering was done using the SLM approach from CWTS at Leiden University [8.33] that has recently been shown to be among the most accurate clustering algorithms available [8.77]. The similarity value (a_{ij}) between each pair of papers i and j was set to $1/k$ where k is the number of edges (both citing and cited) for paper j [8.25]. Note that symmetry is not assumed; a_{ij} and a_{ji} are typically different since the numbers of edges for papers i and j are rarely the same. The CWTS methodology allows a desired minimum cluster size and resolution value to be specified–these can be tuned to produce a desired number of clusters. We desired a solution with approximately 100 000 clusters. Our experience is that at the 100k cluster level: a) experts can easily differentiate between clusters [8.58]; and b) funding data can be assigned to topics and is highly correlated with topic-level metrics [8.78]. Using a minimum cluster size of 50 papers and a resolution of 3×10^{-5}, a cluster solution was obtained with 91 726 clusters above the minimum size. Each cluster represents a topic, and is comprised of the papers on that topic and the community of researchers working on that topic. A total of 134 066 (0.28%) of the documents ended up in clusters with fewer than 50 documents. These clusters are small and disconnected from the rest of the graph, and thus are not considered further. Creation of a model such as this obviously entails many choices in terms of relatedness measures, clustering algorithms, thresholds, etc. The choices we have made along with the reasoning for those choices is available in [8.78] and is not reproduced here.

Figure 8.4 shows a map of the 91 726 topics created to provide a visual depiction of the structure of science. It was created using the following process:

1. The Similarity between pairs of topics was calculated from the titles and abstracts of the documents in each topic using the BM25 similarity measure.
2. The resulting similarity list was filtered to keep only the top-n (between 5 and 15) similarities per topic.
3. A layout of the topics was created using the DrL algorithm [8.41], which gives each topic an x,y position based on the similarity graph.

One might wonder why an additional direct citation step is not used to create the visual map. This could certainly be done, but we have found that using text creates a more accurate and visually appealing map than using a citation-based measure for this step [8.46]. Each of the 91 726 topics in the map has been designated as belonging primarily to one of twelve high-level fields, and is correspondingly colored in Fig. 8.4. These designations were made by assigning papers to fields using the UCSD journal-to-field assignments [8.47].

At a high level, the field structure shown in Fig. 8.4 is very similar to that of many other global science maps, including the consensus map of science [8.2]. Physics, chemistry, and engineering are highly related, and are adjacent to each other. The medical areas (disease, medicine, health sciences, brain sciences) are also adjacent to each other. Biology is adjacent to chemistry and medicine, earth sciences is primarily adjacent to engineering, and social sciences are adjacent to health sciences, while computer science lies between physics (which includes mathematics) and the social sciences.

This model has a number of features that attest to its robustness and that make it useful for a variety of applications. In terms of robustness, nearly 90% of the source documents in the map are found in their dominant cluster. For example, for the nearly four million documents published in 2009 and 2010, 89.2% of them are in the cluster to which they have the greatest number of links (combined citing and cited), and on average 58% of their links are to that dominant cluster. There is also a relatively high correlation between text and links in the model. Although created using direct citation, the topics are very well differentiated from each other textually. Of papers with a sufficiently large abstract, 75% can be accurately assigned to the cluster in which they reside using the BM25 similarity measure based on title and abstract [8.78]. This high level of topic differentiation, both in terms of citation and text, enables relatively accurate linking of documents of other types to individual topics.

The model also exhibits size distributions that are consistent with what we would expect given other complex networks. Figure 8.7 shows distributions for topic sizes (numbers of documents) along with the numbers of unique authors per topic for 2010. These are compared to the distribution of US city sizes. All curves are roughly linear on a log–log scale at the upper end of the distribution, and then each tails off at the lower end. The slope for topics is lower for all years combined than for a single year; combining years smooths the distribution. In addition, the fact that some topics are very large, and that others are very small, correlates with *Derek de Solla Price*'s notions of Big Science and Little Science [8.79]. Big Science refers to ma-

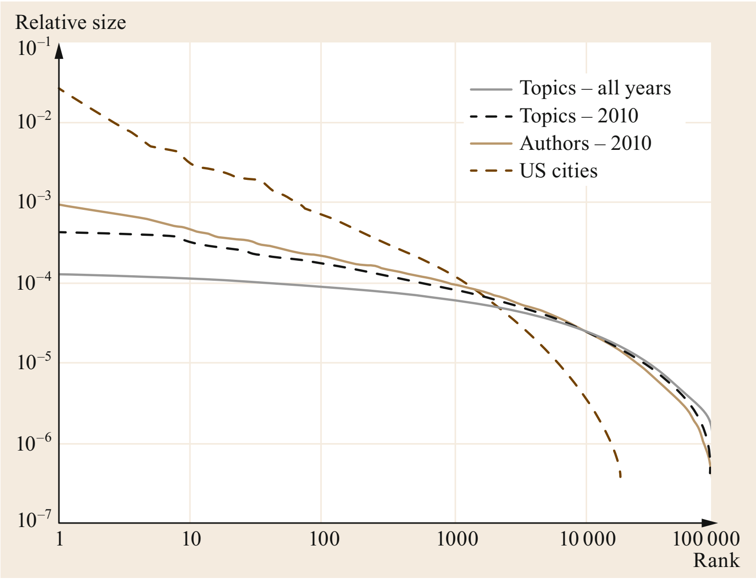

Fig. 8.7 Size distributions for topics and authors from the STS model of science and US city populations

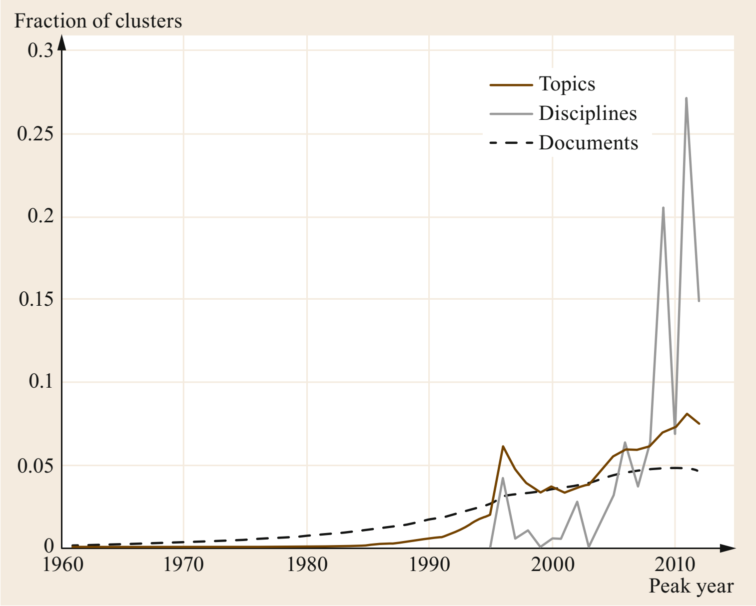

Fig. 8.8 Distributions of peak years for different partitioning strategies. *Spikes* in 1996 are due to boundary effects in the Scopus database–references were only available for papers starting in 1996

jor investments in infrastructure and the corresponding creation of research communities involving potentially hundreds of researchers. Big Science communities are especially common in biomedical research and high-energy physics, and are occasionally found in other fields as well. Significant funding for infrastructure is a necessary prerequisite for Big Science. Little Science can survive on the existing infrastructure and requires much less external funding.

The evolution of scientific areas, and more particularly the identification of emerging areas, is a topic that is of interest to most people involved in the science system. Identification of emerging areas is highly dependent upon the granularity of a model. Figure 8.8 shows the fractions of clusters that peak by year for our topic-level model, and also for an aggregation of topics to 188 discipline-level clusters. These distributions are both compared to a curve showing the fraction of documents by year in the model; one might expect the distribution of peak years to be similar to the overall distribution of documents given that topics in science ebb and flow with the changing priorities of agencies, researchers, etc. Well over half (69%) of disciplines peak in one of the most recent four years. To a large degree,

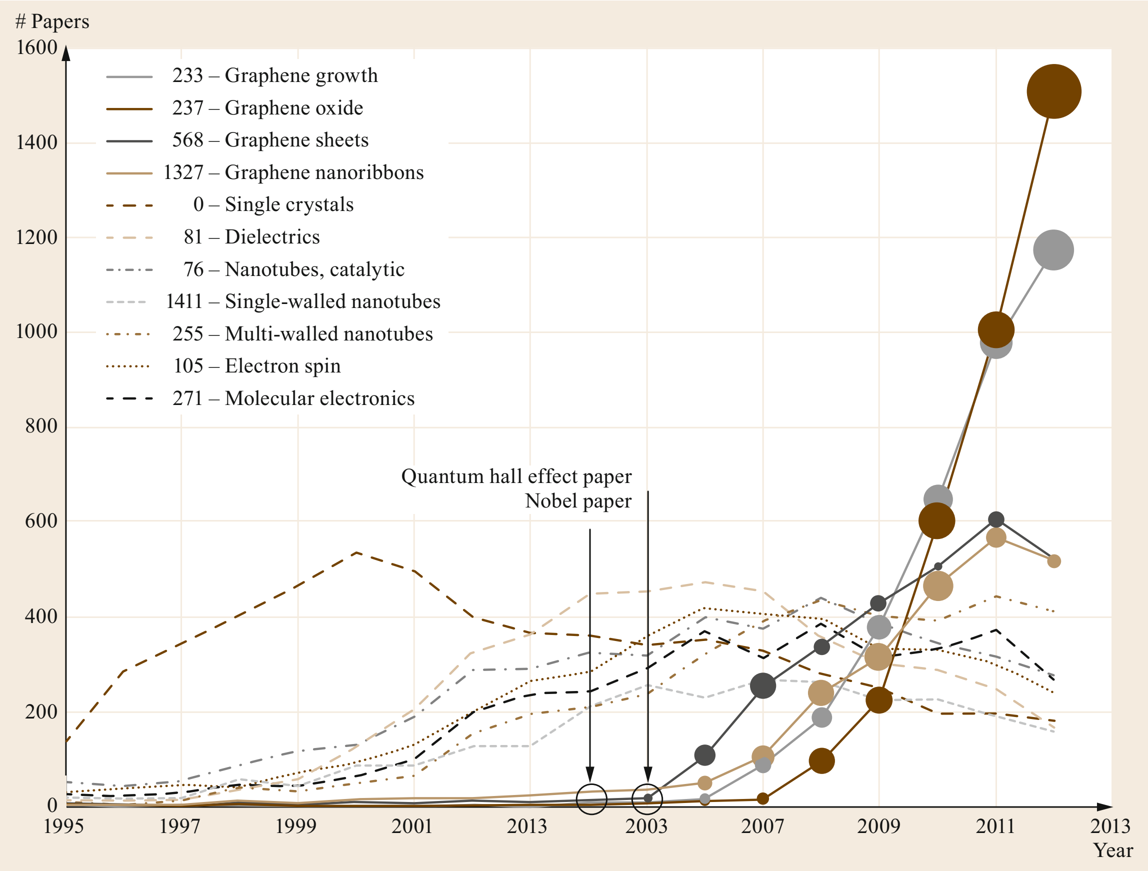

Fig. 8.9 Detailed histories for emerging graphene-related topics and other topics from which graphene researchers migrated. *Dots* represent the numbers of hot papers (top 1%) in the four graphene topics by year

disciplines grow monotonically, mirroring the growth of the entire model, and thus very few disciplines are currently in decline. In contrast, topics have peak years that are more evenly distributed. Topic peak years are far more similar to the temporal document distribution than are discipline peak years. This distinction is important for the identification of emerging topics because, at the discipline level, most scientific areas look like they are emerging or have recently emerged. Topic-level clusters provide a much more differentiated view of evolution and of scientific areas, and are far better than discipline-level clusters at identifying emerging areas.

Topic-level clusters also enable detailed analysis of emerging topics and their relationships with existing and/or declining topics. Graphene is an example of a scientific subject with multiple emerging topics [8.10]. Figure 8.9 shows four distinct graphene-related topics that emerged in the mid-to-late 2000s, all of which experienced extremely rapid growth at that time. None of these four topics sprang out of thin air; each had a low level of activity in the late 1990s and early 2000s, and all four topics at that time were focused on graphite (another carbon structure) research until the (Nobel Prize-winning) breakthrough of graphene paper was published in 2004. Once the breakthrough was made, and over the next several years, large numbers of researchers shifted their research to graphene-related topics, migrating from existing topics, many of which started to decline as research on graphene emerged and grew. We note that the topics that supplied the largest numbers of graphene researchers were inherently related to graphene, and included research on carbon nanotubes, single crystals, and electronic properties. It was thus natural for researchers in these topics to migrate to more attractive (emergent) research topics.

Another feature of our topic-level model is that it shows that science is inherently multidisciplinary in many areas. Figure 8.10 shows a zoomed-in region of the map from Fig. 8.4. Although there are some areas of the map where only a single color (see the Fig. 8.4 legend) is found, there are also many regions of the map where topics with four, five, or six different colors–indicating research from several different

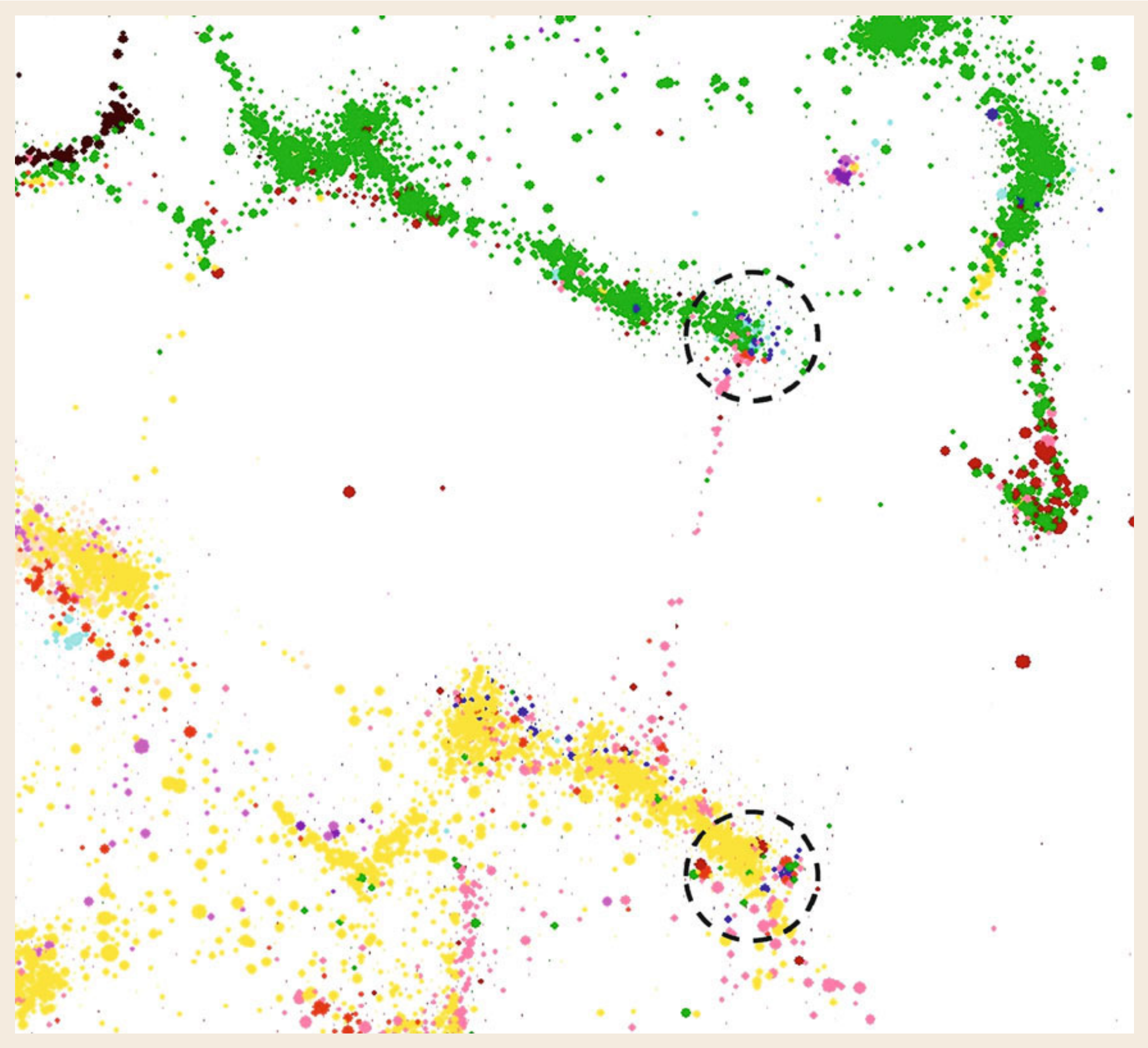

Fig. 8.10 Detail from the map of Fig. 8.4. Local scientific areas with adjacent topics of multiple colors are inherently multidisciplinary

fields–are adjacent to one another. For example, the circled region near the top of the map contains clusters of six colors–this region contains topics from biology, medicine, health sciences, engineering, chemistry, and computer science all in close proximity. The circled region near the bottom of the map contains adjacent topics from brain sciences, medicine, biology, chemistry, and computer science. Of course, there are also areas of the map dominated by a single field (color). Recall that this map was created using a sequentially hybrid process. Clusters (or topics) are groups of papers related through direct citation, while the positions of the clusters are based on textual similarity between clusters. Thus, neighboring clusters of different colors are an indication that very similar language is used in multiple disciplines, and thus that an area of science with many colors is multidisciplinary. Current science contains a mix of disciplinary and multidisciplinary work. However, given that there are many areas in science receiving contributions from several different broad fields, it raises the question in our minds as to what *multidisciplinarity* really means today.

The STS model of science has also been used in several other studies with practical applications. For example, it has been used as a template to create a visual map of PLoS thesaurus terms that can then be used as an overlay map in its own right [8.80]. Its topics have been aggregated into higher-level groupings that have then been used to characterize the research focuses of different nations [8.81].

Perhaps most importantly from the perspective of topics, StarMetrics funding data have been linked to individual topics. Given that papers can be assigned to topics with 75% accuracy, and since project abstracts are similar in content to abstracts in scientific papers, it is reasonable to assume that projects can be accurately assigned to topics with similar accuracy. Each project with sufficient text has thus been individually linked to those topics to which it is most similar, which enables topics to be differentiated by the amount of funding they receive. We find that the most highly prominent topics–those that are most visible–receive about \$90 000 annually per US author from StarMetrics funding sources. Topics that are the least prominent receive only about \$2000 per US author annually from those same funding sources. Furthermore, we find that these data enable prediction of those topics that will receive increased funding in the future, which is very important information for a number of stakeholders in the science system [8.78]. Although this analysis only accounts for a small amount of the worldwide funding, it is nevertheless a substantial amount ($\approx$ \$160 billion) and thus shows the potential for topic-level metrics based on funding.

8.5 Summary and Implications

The analyses presented in Sect. 8.4 suggests that a robust and accurate topic-level model of science can be created using comprehensive citation data and network techniques, and that models such as this can be usefully applied to pertinent questions about the science system. Although we use direct citation links, the CWTS clustering algorithms to create our models, and prefer models with around 100 000 topics, it is clear that very useful models can also be created using other citation or text-based approaches with other algorithms, and at different levels of granularity. Although we prefer to use full databases, and have evidence that topics in a global model are more accurate than topics in a local model, we also acknowledge that topics created from smaller datasets can be extremely useful to answer practical questions, provided that the data are well matched to the question. The methods presented in this chapter are not specific to large-scale models using full databases, but can be used with datasets of any size.

Regarding the future, we suggest that Latour's model represents an opportunity. Network research related to research communities and the science system has traditionally been done where data has been most readily available–i. e., using papers, journals, authors, and patents. Much less work has been done using data on funding, equipment, and the types of laboratory artifacts that are often the building blocks of scientific work (e. g., chemicals, models, etc.). Still less work has been done with bipartite or multipartite networks comprised of many of these features. Modeling of single features (e. g., papers) has helped us to gain a rudimentary understanding of the science system. However, given that science is comprised of so many features with their myriad connections, it is likely that a clearer understanding of the science system can only be gained through analysis of networks comprised of multiple features.

Several directions for future work seem particularly promising to us. One could focus on the nature and fate of transient authors. What do they do? Are they more likely to be members of corporations? If their jobs are at risk, we can hypothesize that transient authors that publish when there is a spike are more likely to change employment over the next few years. Transient authors that publish during normal times (a much lower percentage of transient authors) are less likely to change employment over the next few years. Overall, a better understanding of transient authors is needed. We simply don't know much about the very large author population.

From a pragmatic perspective, any indicator that can predict when a topic becomes 'unattractive' is extremely useful. The current emphasis is on indicators of attractiveness (hot papers, high vitality, and citation impact). There is corresponding emphasis on (positive) turning points (a sudden shift to becoming attractive). There is far less effort on developing indicators that a topic is switching from being attractive to being unattractive. These indicators would be especially useful if they can predict negative changes in funding.

From a science policy perspective, the role of instrumentation is an underresearched, but extremely important, area to focus on. Kuhn, Price and Latour have all emphasized the importance of instrumentation, and the role of instrumentation has played a central role in the development of the model presented in this paper. But it has been our experience, and it is our strong suspicion, that future developments in instrumentation are far more likely to come from software instead of hardware. For example, in 1985 we needed to rent a mainframe computer and create our own algorithms to cluster 100 000 documents at a cost that exceeded \$10 000 / year [8.82]. Computing power today is ubiquitous. If we do not own computers capable of large calculations, cloud computing is widely available at low cost. Open-source algorithms such as SLM that cluster 50 million documents are also available. Highly accurate and low-cost experimentation using bibliometric data is possible today. We do not think this is an isolated event. Computing capability continues to increase. Advances in software, particularly open-source software, are being made perhaps even more rapidly. If this trend continues, the infrastructure requirements of large topics may lessen, and the long-term shift towards Big Science may be reversed. Eventually, we will realize that instrumentation is fundamentally changing because of the information revolution, and take this into account in science policy studies.

Finally, from a theoretical perspective, we find that it is extremely short-sighted to exclude the motives of the circle of actors in Latour's model from our analysis. Price placed great emphasis on the motives of the pure scientist–the 'search for knowledge' that should be protected from the practical requirement of solving social problems. Latour emphasized the need to find common motives (e. g., the search for a cure of a disease by funders is aligned with the potential discoveries from doing genetic research) and referenced some of the broad motives normally associated with R&D investment (e. g., health, national security, and economic welfare). Instead of arguing which motives take priority, we strongly suspect that common motives can be found by looking at the full set of altruistic motives that are expressed by people [8.83]. This is a line of investigation that is almost completely unexplored. We strongly suspect that by understanding the motives of stakeholders, we will gain a much more thorough understanding of the science system, and would love to see others join us in pursuing research along these lines.

kboyack@mapofscience.com

Kevin W. Boyack has been President of SciTech Strategies, Inc. since 2007. He received a PhD in Chemical Engineering in 1990. Since joining SciTech his work has centered on developing more accurate global maps of science. He has published over 50 articles dealing with science mapping and related metrics. His current interests include understanding the structure and dynamics of science, technology, and the missions and motives that drive them.

Richard Klavans

SciTech Strategies, Inc.
Wayne, PA, USA
rklavans@mapofscience.com

Dick Klavans is the founder of SciTech Strategies, Inc. He received an Engineering degree from Tufts, a Master's degree from Sloan/MIT, and a PhD from Wharton/U Penn. He has published extensively on the art and science of science mapping (visual representations of the structure and dynamics of research). These maps are primarily for research planning in industry (e.g., Abbott Labs, Astra Zeneca) and for government agencies (e.g., DOE, NSF).

9. Science Mapping and the Identification of Topics: Theoretical and Methodological Considerations

Bart Thijs

This chapter focusses on the drivers for the advancement of mapping of science and the detection of topics as often applied in scientometrics. The chapter identifies three different drivers for this advancement: technological innovation resulting in increased computational power, the improved community detection approaches available today, and advancements in scientometrics itself with respect to the actual linking of documents through citations or lexical approaches. We will show that the main drivers are the first two, with the last one somewhat lagging behind. Next, severe methodological issues have been identified in network science related to the application of these techniques for community detection. The resolution limit and the degeneracy problem are described. The last section shows how different approaches are taken to enable scientometricians to create global maps of science and how they come to comparable results at higher levels of granularity but that the validity of more fine-grained clusters and topics suffers strongly in the discussed problems, which raises serious questions with respect to the applicability of these global techniques with a strong local focus.

9.1 General Drivers for Advancement of Science Mapping

This chapter focusses on the different techniques and methodologies used in bibliometrics to map the cognitive structure of science and the use of clustering techniques for the detection of topics and topical emergence. Traditionally, these mapping exercises are carried out with citation links or textual approaches as the basis for such analysis. But methodologically speaking, it builds strongly on the developments in network science. This chapter will focus on both fields. The first field is of course our own field of bibliometrics, which already has a rich tradition in science mapping, where many studies have been done to suggest new and improved approaches or to compare the different approaches. The focus in these comparative studies is on the type of relations between documents, be it citation-link-based or lexical approaches, but also combinations of both—hybrid networks—have been proposed. Additional work has been done on the labeling of clusters and measurements for the accuracy of the obtained results.

The other field is network science with its roots in both graph theory in mathematics and physics and in social network analysis as part of sociology. The focus of research related to partitioning or community detection is mainly on the development of faster and more accurate algorithms. Finding the best clustering among all

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_9

possible partitions is considered to be NP-hard ([9.1] or [9.2]), which makes it nearly impossible to find an exact partitioning for large-scale graphs. The approach taken by many researchers is to introduce heuristics which exploit some of the properties of the network and that point the algorithm into a particular direction in its search for the optimal solution. Other papers in this field discuss the shortcomings of different approaches or present improvements to existing algorithms to overcome these shortcomings which include the resolution limit [9.3] or the degeneracy problem [9.4]. There is a link between bibliometrics and network science as studies in the latter often use data sets extracted from bibliographic databases.

A third strong driver is the technological advancement in computational resources available to the bibliometrician. In line with Moore's law [9.5], CPU capacity has grown continuously and still is. In addition, the growth in hard disk capacities and the recent introduction of solid state drives combined with the available memory has resulted in a reasonably priced desktop computer capable of the processing of large-scale networks [9.6]. A further advancement has been the development of distributed online cloud computing facilities with enormous computational and storage capacities. Such facilities are publicly available through a renting service, charged by the hour at the fraction of the cost required for the acquisition of such computational power.

Figure 9.1 presents the interplay between these three drivers and their influence on the development of science mapping. The technological development not only enables the analysis of larger document sets but also drives the development of new and improved algorithms. These algorithms are adapted by science mappers but also give a boost to novel research on approaches for the construction of networks amongst scientific papers. The *arrows* in Fig. 9.1 indicate the input of a driver for the advancement of science mapping and its size is relative to its effect. Technological development is the strongest driver, mainly because of the speed of its growth. Next comes the network science input. Newly proposed techniques such as Louvain clustering [9.8], Smart Local Moving [9.2], or the Map Equation [9.7] are rapidly incorporated into the knowledge space of our field.

Much slower, however, is the advancement in scientometrics with respect to the construction of the underlying data sets [9.9]. Citation links were introduced by pioneers like *Garfield* [9.10], *Small* and *Griffith* [9.11] or *Kessler* [9.12]. But after this early emergence of citation links, its development did not assume a fast-growing pace. Studies about the appropriate thresholds can be found along with some applications of second-order similarities. Lexical similarities and hybrid approaches were only added to science mapping in the last decade of the twentieth century. It is only recently that techniques from computational linguistics using natural language processing have been deployed for the creation of document networks.

The slow pace of development in scientometrics as a driver of evolution in science mapping has not prevented this application from quickly adopting to and absorbing the latest advancements in the two other

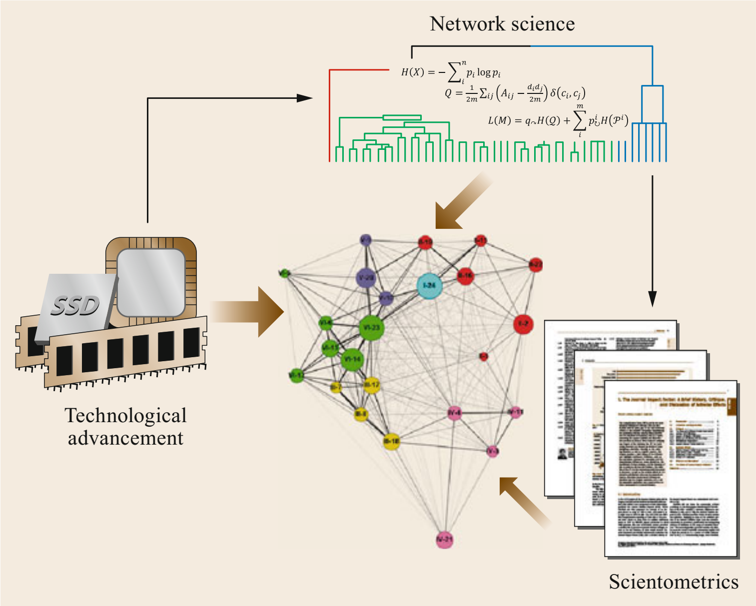

Fig. 9.1 Interaction between and role of the three drivers for advancement in Science Mapping; formulas taken from [9.7]

drivers. The dynamics in the domain of science mapping has been very well described by *Klavans* and *Boyack* [9.13] in their study on the most accurate taxonomy of scientific knowledge.

The objective of this chapter is to provide the reader with a summary overview of the current state of the art of science mapping and topic detection while integrating both the developments in network science and bibliometrics. The main question that will be answered in this chapter is thus:

> How can science mapping benefit from advancements in these two fields while balancing between complexity and accurateness and without losing sight of the requirements set by the different applications?

In other words: how can a scientometrician with a focus on local phenomena whether at individual, institutional or regional level benefit from the latest developments with respect to topic detection?

Another approach to the identification of topics or delineation of subfields is provided by an application that is commonly known as topic modeling which uses hierarchical probabilistic models like latent Dirichlet allocation [9.14], which are based on the assumption that documents can cover more than one but a limited set of topics and that documents use only a limited set of words that are associated to these topics. Such approaches take a term-by-document matrix and result in a term-by-topic model or structure.

In the remainder of the chapter, I will first discuss the development and state of the art of bibliometrics related to the creation of document networks using link-based, lexical and hybrid similarities. Next, community detection techniques commonly used in science mapping are touched upon. After this, methodological constraints related to community detection are discussed together with their implication to the partitioning of document networks. The last section integrates the prior sections in a discussion of local versus global clustering.

The publication data used in this chapter was extracted from the 25 annual volumes of Clarivate Analytics Web of Science (WoS) Core Collection ranging from 1991 up to 2015. Only citable documents are retained and citation links are processed through the custom reference identifiers supplied by Clarivate Analytics. These identifiers can be assigned both to indexed and nonindexed publications.

9.2 Creation of Document Networks

This section starts with a formal definition of a network and then discusses the different approaches taken in the scientometric literature for the construction of document networks.

A graph or network can formally be defined as $G=(N,E)$, being a pair of two distinct sets of information [9.15]. The first set contains all the nodes, whilst the second set holds all the edges. Depending on the topology of the network, edges can be restricted to unordered pairs of elements from set N for undirected unweighted networks, ordered pairs for directed versions or triplets having two elements from N and the third element being a numeric value indicating the strength of the link between the two nodes.

Bibliographic databases allow the creation of networks using different types of nodes. Collaboration studies have been using countries, regions, institutes and individual researchers as nodes. Especially author collaboration networks can hint towards some topical structure in a field. But, as more senior researchers often cannot be pinned to a single topic or even single domain, the reliability of such collaboration networks for topic detection is rather low. At the beginning of this Chapter, alternative methods focussing on aggregation or grouping of the terms are mentioned. Author Cocitation Analysis [9.16] links authors that are cocited to reveal the cognitive structure of a domain. But this chapter will focus on the creation and use of document networks. Attributing documents to clusters allows later a straight forward assignment at higher levels of aggregation. Authors, institutes or journals can then be profiled by the share of their papers among the different clusters. Such a fractionated profile pays tribute to the multitopical multidisciplinary activities of the actor. Hard clustering of entities at these higher levels of aggregation will always hamper the creation of such multifaceted profiles.

9.2.1 Citation-Based Links

Three different types of citation-based links are commonly used in the scientometric literature for science mapping.

Direct Citations

The most straightforward method of linking publications is the use of the actual references found in the citing publication. These references are indeed directed edges from one particular node to another. But the links can be converted into undirected edges which results in an unweighted, undirected network. Such networks have been used by *Ludo Waltman* and *Nees Jan Van Eck* [9.2, 17, 18] who clustered about 10 million papers and by *Kevin Boyack* and *Richard Klavans* [9.13, 19] who were able to produce a map of 43 million documents. Both networks have degrees (number of edges associated with a node) that range around 10. This degree highly depends on the selected publication window and selected publication source. Table 9.1 gives some statistics for publication sets extracted from the Web of Science over different publication windows. The top row shows that 2015 contains 1.6 million documents and less than 1 million links. Taking into account that the link in an undirected network is counted for both nodes for the degree calculation we observe an average degree of 1.13. This degree increases with the extension of the publication window, but the growth has a slow decay. The density of the network given by this formula $2l/(n(n-1))$, with l the number of links and n the number of publications, is extremely low but rather stable, and the least sparse network can be found in a 15-year window.

The low degree indicates the low appropriateness of direct citation (DC) link models for the clustering of short publication windows.

An important conceptual remark has to be made related to the citation behavior of researchers which might have an influence on the applicability of direct citations. Authors referring to prior literature have to be selective as they cannot cite all relevant literature on the studied topic. This means of course that the direct citation link among two documents is created intentionally by the citing authors. The probability of false-positive citation links can thus be discarded. However, the choice of cited literature is subject to affinity to a particular community or even a school of thought which clearly results in false-negatives.

Cocitation

Small and *Griffith* [9.11] introduced a new document analysis approach based on cocitation which was defined as the frequency at which two documents are cited together. They used this model for the creation of network models with the objective of studying the structure of science. The patterns they observed using cocitations were highly similar to those obtained using direct citations and differed significantly from the bibliographic coupling (BC) patterns. Small and Griffith decided to use cocitation because that allowed them to restrict their analysis to publications within a single year without the requirement to include all cited documents [9.13].

Cocitation analysis has been regularly used for the detection of research fronts due to the dynamic component that is inherently connected to this model. The relation between documents can change over time if the source time window is shifted.

Boyack and *Klavans* [9.19] put forward four main features of cocitations in the modeling of science which they collected from prior literature:

1. They could show that the clusters generated using cocitations are sufficiently accurate [9.20].
2. Because of the weighted nature of cocitation links, papers can be fractionally assigned to clusters. And clusters can be linked through paper overlap [9.21].
3. Cocitation analysis tends to produce unstable solutions which is regarded as being very useful for the detection of emerging topics [9.22].
4. The study of the dynamics of science benefits from the longitudinal structures that characterize the cocitation clusters [9.23].

Bibliographic Coupling

Two papers are bibliographically coupled when they share at least one reference, see for example [9.12, 24]. When we consider references as an indication of use of a particular set or item of knowledge we can infer that papers that share a reference also have some common use of prior knowledge and share a partial topical similarity. The problem of the possible false-negatives in citation links also affects the bibliographic coupling links between documents, especially if community- or

Table 9.1 Number of publications and links, both expressed in millions (m) and average degree and density networks over different publication windows

Publication window	Number of publications (in millions)	Number of links (in millions)	Average degree	Density
2015–2015	1.6	0.9	1.13	7.08×10^{-7}
2013–2015	4.6	13.1	5.65	1.22×10^{-6}
2011–2015	7.4	38.9	1.47	1.41×10^{-6}
2006–2015	13.3	140	20.99	1.57×10^{-6}
2001–2015	18.0	256	28.44	1.58×10^{-6}
1996–2015	22.2	362	32.54	1.46×10^{-6}
1991–2015	26.0	448	34.50	1.33×10^{-6}

Data sourced from Clarivate Analytics Web of Science Core Collection

field-specific motivations drive the selection of cited papers.

Comparisons between cocitation and bibliographic coupling can be traced back to as early as the *Small* and *Griffith* paper [9.11], which proved the distinct nature of this latter approach as opposed to the other citation-based links. In 1996, Glänzel and Czerwon pointed out that almost all relevant papers in a document set have references and that these references are present at the time of publication which means that bibliographic coupling links can be created as soon as a paper is published. Cocitation links only appear after a paper gets its first citation.

The large amount of data that can be used as the source for the creation of bibliographic coupling networks is illustrated by Table 9.2. For an increasing publication window from one up to ten years, a set of statistics are provided. In the full ten-year window from 2006 up to 2015, more than 60 million different cited documents can be identified in the Web of Science (not all of them are indexed by the WoS). About 48% of these documents are mentioned in more than one indexed publication and can thus be used to link these publications. On average, each reference is cited 12.8 times in the ten-year window. But as citation distributions are very skewed, the most frequently cited reference has received 45 147 citations in the database that was used. This is the paper by *Sheldrick* [9.25] about a software package called *SHELX*, which is commonly used in crystallography.

Dealing with such a high number of citing papers requires a performant processing environment. In the past, several researchers have surpassed this problem by the application of certain thresholds. References were removed from the set if they were cited more than a fixed number of times. Recently, I presented a more sophisticated methodology which allows the choice of selection criteria and threshold at the level of the reference itself. This proved to improve the scalability of the creation of bibliographic coupling networks and showed that removing the most cited references from the set results in the absence of many small BC-links between documents while the removal of the large set of references that are only cited a few times hampers the detection of strong links between documents [9.26].

9.2.2 Lexical Similarities

Textual analysis became part of the bibliometricians science mapping toolbox much later. It was *Callon* et al. [9.27] who was the first to demonstrate the usability of coword analysis. An important reason for this lagging behind the link-based approach is the late digital availability of large text corpora data and the extensive computational requirements. In Leiden, *Tijssen* and *Van Raan* [9.28] used co-occurrence of keywords in patents and publications for the detection of links between science and technology. In Leuven, *Glenisson* et al. [9.29, 30] started experimenting with full text retrieved from scientific papers instead of terms extracted from keywords, titles or abstracts. They concluded that the preference for full text over title and abstract approaches is not as yet clear and still open to discussion.

The creation of a document network using lexical similarities requires a much more elaborated approach than the citation link counterpart. There are no direct, author-chosen textual links between documents. This implies that any lexical link or similarity between two documents has to be deduced from the actual content of both documents. The science mapper has to use different techniques to extract textual information, match documents with each other and calculate lexical similarities. Many of these techniques were developed in the field of information retrieval and in (computational)

Table 9.2 Descriptive statistics of references used as the source for bibliographic coupling counts expressed in millions

Publication window	Unique reference count (in millions)	Linking references (in millions)	Share of linking references (%)	Average number of documents linked	Occurrence of most-frequent references
2006	11.5	4.69	40.8	3.80	3826
2006–2007	17.5	7.95	45.4	5.33	7711

Data sourced from Clarivate Analytics Web of Science Core Collection

linguistics and have been adapted for application in the specific context generated by scientific literature. Before a text-based document network can be built the process has to pass through four major steps:

1. Source selection
2. Preprocessing
3. Mathematical representation
4. Document linking.

Choices made during each of these steps have consequences for the final result of the clustering of documents and scientometricians should be well aware of the impact of their choices on the complexity of the analysis and the accuracy of the identified topics in the document sets.

Source Selection

The augmented complexity of the lexical similarity already starts with the selection of the source data to be used for the creation of the document network. Of course, first and completely in line with the citation-link approach, the relevant document set has to be delineated. But after that, an abundance of possible choices is present to the science mapper. The lexical similarity can be based on the title [9.10] keywords (given by the author or editor) [9.31], on extended versions of keywords like Keyword Plus provided by Web of Science, on specialized headings [9.32] or terminology like the Medical Subject Headings (MeSH). More comprehensive are lexical similarities based on the combination of title and abstract or on full texts of papers [9.29]. The problem with the last option is the lack of availability of large sets of digital full text documents covering a complete topic. Often, only a limited selection of papers within a domain are freely available.

Both Scopus and Web of Science provide the title and abstract of nearly all papers indexed together with the different versions of keywords. Several authors have published a small, local mapping exercise using full text for which they downloaded all relevant full papers from the journals websites or from online repositories. Nowadays, authors tend to make use of the possibility offered by several publishers to self-archive draft or prefinal versions of their own papers. These papers can then be automatically retrieved and used to enrich the bibliographic database. Dealing with the extraction of relevant text from files in different formats like PDF, XML or HTML is not straight forward. The availability of several (well-priced) commercial products proves the complexity of automating this task.

Preprocessing

After the source is selected and the data is retrieved, the preprocessing phase can start. The different tasks in this step are common to most text processing projects. Text indexing software packages like Lucene (https://lucene.apache.org/core/) include tools for tasks such as segmentation and tokenization, filtering, stemming and analyzing.

The preprocessing starts with the extraction of relevant terms from the digital document files or database records. In the case of keywords and subject headings like MeSH terms, only a little further preprocessing is required, i.e., conversion to lower case, removal of specific tags or codes [9.33].

For title and abstracts, a more complex procedure should be followed. The text must be tokenized using white space and punctuation. Numbers or words containing digits may be removed.

Stop words are words that are very common and bear no specific meaning or semantic value and should be removed during preprocessing. Many software packages provide their default stop word lists which can be extended when needed.

Stemming is a process that reduces the term to its root form. Because of inflection, which expresses differences in e. g., number, gender, person or tense, terms appear in different forms across texts. Lexical similarity between documents will be underestimated if no stemming is applied. The best-known stemmer is the Porter stemmer [9.34], using a simple rule-based scheme.

Both stemming and stop word removal have the additional advantage that they reduce the dimensionality of the vector space.

After all this preprocessing, *Glenisson* et al. [9.29] still encountered some disadvantages for single-term approaches and he added a set of 500 bigrams selected by using the Dunning Likelihood ratio test [9.35]. These bigrams were among the most frequent occurring combinations of two terms. However, this bigram-based solution only increased the computational complexity without clear added benefits.

Leopold et al. [9.36] mentioned the possible advantages of the application of Natural Language Processing (NLP), which incorporates structural properties of the text over a bag-of-words approach where all words are treated equally and independently from each other. At that time, 2004, they thought it was impossible to implement such an NLP-framework for a large amount of texts with the techniques and computational resources available then ([9.36, p. 202]) and they suggest Shallow Parsing as a more pragmatic alternative [9.37]. One decade later, *Thijs* et al. [9.38] started using Natural Language Processing for the extraction of noun phrases (NPs) from title and abstracts. The main rationale behind this approach is that when using text mining for science mapping the textual information should be restricted to those parts that actually reflect topics and concepts. Syntactic parsing enables the extraction of noun phrases while neglecting verbs and adpositional phrases. In this paper Thijs et al. [9.38] used the Stanford Core NLP package. Figure 9.2 gives the output from parsing the following sentence obtained from a sample publication in the document set:

> Results of the study show that information systems downsizing may produce benefits such as improved information systems, improved organizational structure, higher productivity, and lower cost. [9.39]

Only those elements that are tagged by NP are retained for the analysis and after tokenization, stemming and removal of stop words, term shingles were created which contain at least two distinct terms.

Retaining all noun phrases that contain only a single term would be nothing more than a further extension of the bigram approach taken by *Glenisson* et al. [9.29] and would not significantly contribute to the improved accuracy and applicability of the lexical component in document clustering.

The NLP approach also proved very successful while analyzing large document sets. The technique was used for the detection of topics in the astronomy dataset holding more than 110 K documents within reasonable time and space constraints [9.40].

Mathematical Representation

The most common approach to create a mathematical representation of a document set is to adopt a vector space model to encode each document using a k-dimensional vector with k equal to the total number of terms or phrases present in the total set of documents. Such a model results in a sparse document-by-term matrix as most documents will only contain a limited set of the terms present in the complete set. The cells in the matrix can contain binary values indicating the presence/absence of a particular term in the document but the value can also be an integer indicating the number of occurrences of the term in the document or even a real value with a weighted or normalized term frequency.

The standard Term Frequency-inverse Document Frequency (TFiDF) as proposed by *Salton* and *Buckley* [9.41] is given by the formula

$$w_{t,d} = \mathrm{tf} - \mathrm{idf}_{t,d} = \mathrm{tf}_{t,d} \times \mathrm{idf}_t \,,$$

which gives a weight to term t in document d. High TFiDF values are obtained for terms occurring several times in a document but only a limited number of times across different documents.

TFiDF is a typical bag-of-words approach as each term is processed independently from the other terms in the document or independently from its morphological function in the sentence. Ordering of the words in the

Fig. 9.2 Syntactic tree as a result of parsing the example sentence

sentence or in the document is completely lost. The approach for the extraction of noun phrases from titles and abstracts developed by *Thijs* et al. [9.42] moves away from this bag-of-words framework as terms and phrases are selected based on their function in the sentence and the order of the terms is retained to some extent through the use of shingles.

Special care has to be taken for those terms or phrases that occur in only one document. They can be excluded from the vector space. Table 9.3 gives some statistics about the number of noun phrases in the Web of Science publication set from 2006 up to 2015. About 13% of the noun phrases extracted from the publications using the above-described methodology are shared among at least two documents. This share is much lower than the 48% found in Table 9.2 for cited references. The average document frequency for the shared NPs ranges from 7.45 up to 12.02. These are still reasonable values. However, when looking at the most common noun phrase (`long term`) we see very high values. This noun phrase occurred in more than 340 000 documents.

Other very common (stemmed) noun phrases include: `follow up`, `signific differ`, `electron microscopi`, `signific higher`, `significant increase`, `important role`, `cross section`, `risk factor`, `ray diffract`, `year old`, `statist signific`, `first time`, `confid interval`, `real time`, `gene express`, `scan electron`, `three dimension`, `control group`, `cell line`, `present paper`.

The presence of such common words is completely in line with Zipf's law and indicates the importance of the weighting factor, the inverse document frequency [9.43]. There are several approaches for the calculation of the iDF. An implementation grounded in information theory is given by this formula

$$\log\left(\frac{N}{\|\{d \in D : t \in d\}\|}\right)$$

which is the log of the inverse of the probability that a randomly picked document d contains the term t and thus related to Shannon's entropy or the average information contained in the fact that term t can be found in document d. The compliance of the frequency distribution to Zipf's law results in the sparse data problem [9.36]. Documents, and especially the combination of title and abstract, contain only a very limited set of terms identified in the complete data set. Consequently, the vectors containing the mathematical representation of the document will contain mainly empty or null-valued cells.

A common solution applied in data mining is to reduce the hyperdimensionality of the vector space model with nearly 70 million different noun phrases through the application of dimensionality reduction techniques like PCA (principal component analysis), which is based on the covariance matrix, or SVD (singular value decomposition) and LSA (latent semantic analysis) which take the source matrix. These techniques do not take the skewed frequency distribution into account and might result in less accurate results. A method that is more suited to text mining is probabilistic latent semantic analysis [9.44]. Other techniques like Random Project, which are less computationally demanding, are applied to larger data sets [9.45].

Document Linking

The last step in the creation of the document network is linking documents to each other.

Salton proposed a *cosine similarity* score for document retrieval defined as the dot product between the two vectors in the VSM (vector space model) associated with a document and a particular query. This can easily be adapted to a score between two documents in a document space

$$\operatorname{sim}\left(d_i, d_j\right) = \frac{\sum_{t=1}^{N} w_{t,i} w_{t,j}}{\sqrt{\sum_{t=1}^{N} w_{t,i}^2}\sqrt{\sum_{t=1}^{N} w_{t,j}^2}} .$$

Another function taken from information retrieval is the *Okapi BM25* ranking function (or short BM25, where BM stands for Best Match) as proposed *Spärck-Jones* et al. [9.46] and applied in science mapping by *Boyack* et al. [9.33]. This is a probabilistic model that is sensitive to the size of a document and thus suited for larger documents while keeping the complexity rather low [9.47]. The formula for the calculation of the BM25 similarity is given by

$$\begin{aligned}&\operatorname{sim}\left(d_i, q\right)\\&\quad = \sum_{t=1}^{n} \mathrm{IDF}(q_t)\frac{f_{t,i}\left(k_1+1\right)}{f_{t,i}+k_1\left(1-b+b\frac{\|d_i\|N}{\sum_{j=1}^{N} d_j}\right)}\end{aligned}$$

with typical vales for k_1 and b set to 2.0 and 0.75.

Although the calculation of both cosine as BM25 are straightforward for any given pair of vectors, the task becomes very time consuming with a growing network. In fact, the calculation requires the matching of all possible document pairs available in the network. This number grows quadratically as the number of possible links in a network with n nodes is equal to

$$\frac{n(n-1)}{2}$$

Table 9.3 Descriptive statistics of noun phrases (NP) used as the source for lexical similarities

Publication window	NP count (in millions)	Linking NPs (in millions)	Share of linking NPs (%)	Average number of documents linked	Occurrence of most frequent NP
2006	49.4	6.23	12.6	7.45	25 287
2006–2007	92.1	12.0	13.1	8.53	50 999
2006–2008	140	18.6	13.3	9.29	83 409
2006–2009	188	25.2	13.4	9.86	117 125
2006–2010	236	31.7	13.5	10.31	149 911
2006–2011	286	38.6	13.5	10.71	184 717
2006–2012	340	46.0	13.5	11.09	222 159
2006–2013	395	53.5	13.5	11.42	260 273
2006–2014	456	61.6	13.5	11.73	300 048
2006–2015	519	69.8	13.5	12.02	340 607

Data sourced from Clarivate Analytics Web of Science Core Collection

Tests with a small publication set about 'Information Systems Research' in the social sciences revealed a network with extremely high density of 96% [9.42]. Almost all of the possible links in this network of 6144 documents were present. Similar high density scores are obtained with other text-based networks as most document pairs share at least one or a few very common terms. The application of noun phrase detection as described above solved this issue with the density of the networks dropping drastically.

Next, storing such a lexical network is challenging. In the above example with publication data from 2006 up to 2015, the noun phrase `long term` appeared in 360 607 documents. This term alone creates 6.5×10^{10} document pairs. Assuming that each document is identified by a code of 4 bytes and that the similarity between the documents requires an additional 4 bytes, storing the network of documents connected by the noun phrase `long term` alone would require 78 gigabytes of disk space. The use of a weighting or normalization of the term frequencies by an inverse document frequency does not lower the required storage as only the weight decreases but the link does not disappear. Applying a certain threshold for the weight of the document link might help as it will allow us to remove a large portion of very small lexical links.

However, the proposed methodology would still require a long computation time as the links between documents must first be calculated before they are rejected due to being below a threshold. Recent approaches including the use of Locality Sensitive Hashing [9.48] for lexical approaches or Drakkar for bibliographic coupling [9.26] solve this problem as they use randomization and hashing functions to reduce the number of pairwise comparisons. The reduction is relative to the probability that two documents share terms or references. The higher the probability that two documents share terms or references, the higher the probability that they are assigned the same value by the hashing function in LSH (locality-sensitive hashing).

The complexity involved in the creation of document networks using lexical similarities is indeed a serious burden for the applicability of this approach. *Van Eck* and *Waltman* [9.18] deservedly state that homonyms (similar words with different meaning across topics or fields) or very common or general terms (like `long term`) can distort the analysis.

9.2.3 Hybrid Approaches

It was *Bichteler* and *Eaton* [9.49] who were the first to suggest the combined use of different document similarities (bibliographic coupling and cocitation), although it was in the context of document retrieval. About a decade later, *Braam* et al. [9.50, 51] and *Zitt* and *Bassecoulard* [9.31] proposed the combination of text- and link-based similarities for science mapping. They added coword analysis to improve the efficiency of the cocitation approach.

One of the reasons for the improved performance of the combined approach is that link-based networks tend to be extremely sparse and underestimate the actual links among documents.

Janssens et al. [9.52] combined the distances based on bibliometric features with a lexical weighted link using this formula

$$D^{\mathrm{INTEGR}} = \lambda D^{\mathrm{TEXT}} + (1-\lambda) D^{\mathrm{BIBL}}$$

But the different distributional characteristics of both underlying similarities posed an immediate threat to the applicability of this procedure. *Thijs* et al. [9.38] plotted both distributions for a selected set of papers from information systems research. Figure 9.3 is taken from this paper and shows a clear distinction between the distribution of the weighted degree

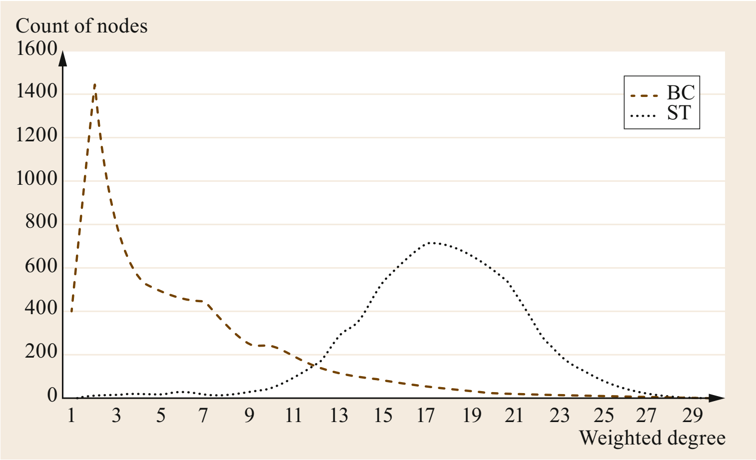

Fig. 9.3 Distribution of weighted degree of single term (ST) and bibliographic coupling (BC) networks

in a bibliographic coupling network and one based on lexical similarities using single terms (ST) for the calculation of Salton's cosine. The latter approximates a normal distribution while the first displays much more scale-free properties commonly found in real world networks [9.53].

A probabilistic method was later proposed by *Janssens* et al. [9.54] where they re-scaled each similarity into the corresponding p-value based on a cumulative distribution function of the similarities in a completely randomized dataset. This method solved the issue of different distributions drastically but it introduced a calculation scheme that was hardly applicable for large networks.

In 2012, we proposed another approach [9.55] where we used the fact that both measures are cosines expressing the similarity or angle between two vectors in a vector space model. In particular, the hybrid similarity measure r is defined as the cosine of the linear combination of the underlying angles between the vectors representing the corresponding documents in the vector space model, i. e.,

$$r = \cos\left(\lambda \cdot \arccos(\eta) + (1-\lambda) \cdot \arccos(\xi)\right) ,\quad \lambda \in [0, 1] ,$$

where η is the similarity defined on bibliographic coupling and ξ the textual similarity, $\arccos(\eta)$ and $\arccos(\xi)$, respectively, denote the two underlying angles. The λ parameter defines the convex combination which allows us to put more weight on one or the other component.

In the first applications of this approach, the λ parameter ranged between 0.75 and 0.875 and was used to improve the clustering results obtained from the bibliographic coupling. It seemed that the hybrid approach with a small portion attributed to the lexical, bag-of-words component was capable of generating more focussed maps than relying solely on the bibliographic coupling. Extensive testing showed, however, that shifting the balance more towards the lexical component would blur the map completely [9.56]. The improvement of the lexical component through the application of NLP changed the interplay between both components drastically. The distributions of the weighted degree of both similarities is now more in line with each other and the risk of distorting the partitioning through the choice of an inappropriate parameter is drastically reduced. Changing the λ parameter is now more analogous to changing the viewpoint on a document set while keeping the focus of your map [9.42].

9.3 Techniques for Community Detection

9.3.1 Linkage and Goodness of Clustering

The absence of a clear definition of communities or clusters supported by scholars across disciplines implies the inability to come up with a set of universal principles to judge the quality of the partitioning. The validity of a given definition for clusters, communities or partitions not only depends on the formal correctness but also on the relevance of the concepts for the actual application in which the community detection is applied. In most general terms one could state that:

> A clustering of nodes in a document network for the identification of topics is successful if papers that deal with the same topic are grouped together and those papers which don't deal with a particular topic are excluded from that cluster.

The success of an approach not only depends on its ability to group papers but also on its discriminative power [9.57]. The solutions should be fine grained enough without generating trivial high-level general clusters like *life sciences* versus *natural sciences*. Such a general statement when formulated more formally by researchers is then used as the basis for the development and implementation of clustering algorithms. *Newman* and *Girvan* [9.1] focussed on the number of links inside a cluster in contrast to the links between clusters. A good clustering partitions the network in such a way that most edges are found inside and not between clusters. To measure the difference between both they introduced the concept of *Modularity*. A completely different approach was proposed by *Rosvall* and *Bergstrom* [9.7] who used concepts from information theory and combined this with the notion of random walks in networks. They introduced the *Map Equation* function which assumes that the optimal clustering of a network allows the shortest coding of any path a random walker takes across the network.

Having a formal definition of a good clustering with an associated formula and implementation does not provide us yet with an algorithm that enables us to obtain this best clustering. Having to calculate the Modularity or Map Equation function for all possible partitions of a network would be nearly impossible, especially for larger graphs. *Newman* and *Girvan* considered this problem to be NP-hard (see also [9.2]). Many different approaches have been developed using heuristics that guide the algorithm towards the optimal solution. This is related to the linkage criteria in more traditional clustering. Most research has been devoted to finding the best heuristics to solve this problem. In what follows, I will provide a more detailed description of both the Modularity and the Map Equation function and then focus on the most common techniques developed for their maximization.

9.3.2 Modularity

Newman and *Girvan* [9.1] defined their measure for the quality of the partitioning of a network (called Modularity) as the difference between the fraction of edges within the clusters and the expected fraction given a complete random distribution of edges in the network. The idea for looking at the difference between strength of the links in subgroups as opposed to those between subgroups dates to *Bock* and *Husain* [9.58] who proposed looking at the ratio of the number of links inside versus the number of links between clusters both normalized by the number of possible links based on the size of the network and the cluster [9.15].

Instead of using a ratio, Newman and Girvan proposed subtracting the expected share of links inside a cluster from the actual observed share. The expected share of links is based both on the links within but also on the links to other clusters. The original formal definition in their 2004 paper is

$$Q = \sum_i \left(e_{ii} - a_i^2\right)$$

Here e_{ii} refers to the fraction of edges that interconnect nodes within a community over the total set of all edges in the network and a_i^2 expresses the expected fraction of inside links. a_i is based on the row-total for all vertices in a cluster in the adjacency matrix. The formula can be rewritten to incorporate this adjacency matrix A.

$$Q = \frac{1}{2m} \sum_{ij} \left(A_{ij} - \frac{d_i d_j}{2m}\right) \delta\left(c_i, c_j\right) \qquad (9.1)$$

Here m is the total number of edges in the network, d_i is the number of edges for node i (its degree) and $\delta\left(c_i, c_j\right)$ is the *Kronecker delta* being 1 if i and j belong to the same cluster.

Theoretically, the modularity score ranges from -1 up to $+1$ but these are asymptotical values. However, these values are not reached in real world situations and even not in small, perfectly partitioned networks as is demonstrated in Table 9.4. Suppose a network with 5 perfect modules, having only links inside the cluster and none from one cluster to another. The highest possible modularity score only reaches 0.768, far below the theoretical maximum of 1. This value of 1 is only reached with an infinite number of clusters where the expected share is infinitesimally small compared to the observed share.

Table 9.4 Demonstration of the maximum score in a perfectly partitioned network

Cluster	1	2	3	4	5
Number of links	75	100	45	35	45
e_{ii}	0.25	0.33	0.15	0.116	0.15
a_i^2	0.06	0.11	0.02	0.013	0.02
$\left(e_{ii} - a_i^2\right)$	0.19	0.22	0.13	0.103	0.13
Modularity score					0.768

One of the consequences of this practical limit to the maximum modularity score is the incomparableness of scores among different solutions with a different number of clusters.

Newman and *Girvan* [9.1] and later *Newman* [9.57] proposed a divisive approach starting from one large cluster and iteratively splitting clusters up to the point a certain stopping criterion is met. In the first paper, cuts or splits are executed after the calculation of edge betweenness using random walkers. In the second paper, Newman reformulates the modularity function in terms of the spectral properties which reduces the maximization problem to an eigenvalue problem.

A commonly used heuristic for modularity optimization is that of the local mover. The idea is that nodes can only be merged with other nodes or clusters along the edges that connect them. Nodes are thus potentially moved following their edges and after each possible move the change in modularity is calculated. The move with the highest increase in modularity is retained. This procedure is successfully implemented by *Blondel* et al. [9.8] in their *Louvain* method.

Blondel and colleagues proposed a bottom-up linkage procedure where each node starts in its own cluster. Next, changes in modularity are calculated if nodes are merged into neighboring clusters by moving them along the path that connects the node with its direct neighbors. The move that results in the highest increase will be retained. This process is repeated until no further increase can be obtained. The process will now aggregate all nodes within one cluster and creates a new network based on the aggregated nodes or clusters and the intercluster links. The procedure then starts again and moves clusters along their links to neighboring clusters. It is important to realize that the nodes are moved in a sequential order where the sequence in which nodes are considered has an undeniable effect on the result of the clustering. Often, this is dealt with by the implementation of multiple runs of the same algorithm but with a different, randomly organized sequencing of the nodes. Several researchers have since built on the work of Blondel et al. to improve their approach. *Rotta* and *Noack* [9.59] introduced a more effective approach which uses multilevel refinement and *Waltman* and *Van Eck* [9.2] extended the approach by an additional application of the local moving heuristic inside each community during the procedure.

9.3.3 Map Equation

Rosvall and *Bergstrom* [9.7] take a completely different approach when defining criteria for a good clustering. Their key idea is rooted in the seminal work of *Shannon* and *Weaver* [9.60] in information theory which states that a stream of information can be coded in such a way that it capitalizes on the structure or regularities of the underlying system. Rosvall and Bergstrom propose the use of the concept of a random walker across the network for the description of the information flow. The objective is then to find the most optimal coding scheme to describe the path through a network where optimal is considered as being as short as possible. The map equation framework further builds on these assumptions:

- Nodes that are more frequently visited by the random walker get a shorter code
- Codes can be reused among different partitions or modules in the network
- Modules themselves are also coded
- A specific code indicates the exit of a module by the random walker
- In order to avoid death locks of the random walker, a small teleportation probability similar to the one applied in Google's PageRank [9.61] is added.

The direct advantage of the use of a random walker for the description of information flow is that it intrinsically allows the use of both edge directions and edge weights.

In fact, the objective is not to implement a real random walker and find the actual coding of its path but to calculate the expected code length given the underlying network structure, the proposed partitioning and the above-mentioned constraints. Here, Shannon's entropy for a random variable can be used as a lower bound for the average code length.

$$H(X) = -\sum_{i}^{n} p_i \log p_i$$

with X being a discrete random variable having possible values in $\{x_1, x_2, \ldots, x_n\}$ and associated with a probability mass function $P(X)$.

Finally, *Rosvall* and *Bergstrom* [9.7] use a weighted combination of the entropies for the flow of information across the modules and the flow inside each of the distinct partitions.

$$L(M) = q_{\curvearrowright} H(\mathfrak{Q}) + \sum_{i}^{m} p_{\circlearrowright}^{i} H\left(\mathfrak{P}^{i}\right)$$

This formula describes thus the lower bound for the expected code length for a random walker in a network with a partitioning M of m different modules.

As mentioned above, a clustering or community detection algorithm must also implement a linkage scheme. For this, *Rosvall* and *Bergstrom* [9.7] find their inspiration in the local moving heuristics used already by *Blondel* and others [9.8]. For a detailed description of the map equation procedure and application of the framework I refer the reader to the tutorial by *Bohlin* et al. [9.62].

The random walker approach taken in the map equation framework has opened the door for many very interesting but quite natural extensions of this community detection approach:

- Dynamics: Changes in network structures are detected using a two-stage approach. First, clustering is performed for each time slice or publication window and next an alluvial diagram is used to highlight the structural changes [9.63].
- Bipartite networks. Often, clustering approaches to bipartite networks will first try to project the bipartite structure of the network into a unipartite counterpart. Because the map equation is built on a random walker being a Markov process at discrete time, a continuous time generalization was possible [9.64] and an implementation for bipartite networks was developed by *Kheirkhahzadeh* et al. [9.65] without the need for a unipartite projection.
- Overlapping modular organization: Sometimes, nodes are located at the boundaries of clusters or communities and the minimum average code length calculated in the map equation framework benefits from assigning nodes to overlapping clusters where random walkers passing through this node and remaining in the same cluster in the next step never have to be coded as leaving the cluster. Such nodes get distinct codes in each of the overlapping clusters [9.66].
- Multilayered networks. These networks have multiple types of edges or links between the nodes. In the case of the previously discussed hybrid networks there would no longer be the need to merge bibliographic coupling and lexical networks as both links can exist next to each other in a multilayered network. *De Domenico* et al. [9.67] showed the capabilities of the map equation framework on a scientist network using their joint affiliation and their collaboration.

9.4 Methodological Constraints

9.4.1 Resolution Limit

Fortunato and *Barthélemy* [9.3] identified and described an important drawback of clustering based on the optimization of the modularity function. In fact, the approach holds a particular (*intrinsic* as they call it) scale property which depends on the total number of edges or links present in the network. Because of this limit, small clusters with a size close to or below this scale will be neglected in the most optimal solution and be absorbed by other, larger clusters. In extreme cases, the existence of a single link between a small clique and a larger cluster can be sufficient for the phenomena to occur. *Fortunato* and *Barthélemy* [9.3] coined the term resolution limit to denote this problem and they pointed out that it arises from the fact that the optimization is based on a sum of terms where one has to balance between many lower terms (many modules with lower modularity) and a few terms with higher values. They concluded that modularity-based methods tend to have some a priori set, mathematically defined optimal solution which is possibly not in line with the real structure of the underlying network. The problem is most likely to happen in large networks with diverse cluster sizes.

Finally, Fortunato and Barthélemy make a strong point against the use of quality functions that are based on a global model for setting the expected share of links and they advocate for a local definition of the quality of a good partitioning.

Blondel et al. [9.8] argue that the Louvain community detection approach does not suffer from the resolution limit due to the multilevel nature and due to the local moving heuristic; nodes are moved around but it is very unlikely that all nodes from one cluster are moved towards a neighboring cluster. In a later stage, clusters might indeed be merged together, maybe due to the resolution limit. *Van Eck* and *Waltman* [9.18] use the argumentation from *Traag* et al. [9.68] to claim that their approach does not suffer from the resolution limit as they have replaced the expected share of links from the global random graph model by a general resolution parameter.

Kawamoto and *Rosvall* [9.69] estimate the resolution limit of the map equation framework and show that the problem is much smaller than for modularity-based approaches. However, when the network becomes large enough the detected community structure will suffer from the resolution limit. This is in line with the findings from *Traag* et al. [9.68] who refer to the use of global quality functions as a general cause.

Related to the resolution problem, *Lancichinetti* and *Fortunato* [9.70] discussed another, strongly related, problem. Resolution limit describes the problem of absorbing smaller clusters into larger ones. But at the same time, the opposite problem might occur: modularity maximization approaches split clusters. Lancichinetti and Fortunato could prove that it is impossible to avoid both problems at the same time and that it is related to the optimization of a global quality function analogous to the conclusions that *Traag* et al. [9.68] reached at nearly the same moment. Even a multilevel approach or the introduction of a resolution parameter does not resolve the issue and is insufficient to make the community detection approach insensitive to one or both problems.

9.4.2 The Degeneracy Problem

Beside the widely studied problem of the resolution limit, *Good* et al. [9.4] describe two additional issues which modularity maximization suffers from. These are related to the general acceptance of several assumptions underlying the practical application of such methods.

Good and his colleagues [9.4, p. 2] listed three of them:

1. It is possible to find the optimal partitioning for real networks with a clear community structure.
2. Other partitioning's with high scores on the modularity function will have similar community structure as the optimal clustering.
3. The obtained modularity score can be compared across networks.

But, actually, none of these assumptions hold in real world networks. First, they could prove that a large number of possible alternative solutions have modularity scores that approach the highest value (the optimum) while providing clearly deviating partitions. A plot of modularity scores is not topped by a single peak but rather an irregular shaped plateau, often called *glassy* in physics literature. Any algorithm could easily get caught in one of the many small spikes that constitute this typical form. Moving away from this spike will result in a decrease of the total modularity score and brings the algorithm to a halt. This issue is called the *degeneracy problem* in community detection and places a serious burden on the validity of any single partitioning result. This same problem is also recognized by *Lancichinetti* and *Fortunato* [9.70] where they point out that it can be quite easy to find a partition with a modularity score that is quite close to the optimal value but that at the same time it is impossible to find this optimal solution.

Next, they noted that the maximized modularity score for a particular network cannot be compared with other scores as the obtained value does not solely depend on the quality of the partitions but also on the size of the network and on the number of modules.

They close their paper with a strong caution warning users that community detection using global optimization techniques are sensitive to problems that are caused by incorrect merging and splitting of clusters. They see these global techniques only performing well with networks consisting of clusters of similar size while this is especially not the case in large-scale networks [9.70].

A common approach to overcome these issues is the application of multiple runs of the same algorithm with different initialization parameters. Better, however, is to run multiple algorithms on the same network or to choose a technique that performs a local level optimization.

9.5 Local Versus Global Applications

After the presentation of the different approaches for both the creation of networks and for the most commonly used recent algorithms for community detection together with possible methodological problems, I want to tackle the problems that are introduced by the density of the underlying networks and the problems imposed on the validity of the application of these techniques in the framework of global topic detection and science mapping.

The validity of a combination of techniques does not solely depend on the accuracy of the results of the analysis. This accuracy can be measured by looking at the structure of the partition (e.g., silhouette values, [9.71]) or at consistency among different partitions (adjusted Rand-index; [9.72]). Accuracy could also be measured using additional data like lexical information or funding and grant information. But partitions (and also any other result of an analysis) can be very accurate but not relevant to the underlying question. In an earlier edition of the *Handbook of Quantitative Science and Technology Research* [9.9] *Noyons* states correctly that in science mapping exercises within a science policy context: "the actual question to be answered should be explicit". It is in the light of the actual question that the choices regarding data source, type of document link and clustering algorithm have to be made.

One issue that was only lightly touched upon in the previous sections is that of the density of the network. Density refers to the share of actual links compared to the number of possible links. With a focus on growing networks to be analyzed we are confronted with a quadratic increase of the number of possible links. Network approaches with a higher density will thus follow this quadratic growth of the number of edges when networks are extended. The analysis of such larger networks will not scale up linearly with the increase of the number of nodes but at least linearly to the number of edges.

However, none of the presented community detection algorithms discusses the scalability of the procedure with respect to the density of the network. *Waltman* and *van Eck* [9.2] for example, state that their smart local moving algorithm is capable of processing tens of millions of nodes and hundreds of millions of edges. Comparing these amounts with each other results in networks with 10 million nodes and a density of 2.0×10^{-6}. This contrasts strongly with the density of a global bibliographic coupling network. The BC-network form all citable documents in the 2013 volume of the Web of Science Core collection has a density of 0.05, which is more than 250 times higher and reaches nearly half a billion edges. Despite the enormous progress in computational capabilities and the performance of many clustering procedures, such numbers still make it very difficult to run the analysis on larger and less sparse networks.

There are different approaches to this density-imposed problem:

- Increase computational power
- Creation of large but extremely sparse networks
- Impose thresholds in weighted networks
- Improve feature extraction
- Shift the analysis to a higher level of aggregation.

One obvious solution would indeed be to *increase the computational power* one has at one's disposal. As mentioned in the introduction, services like EC2 from Amazon Web Services, Microsoft Azure and Google Cloud Platform provide very powerful data processing and analytic services at a marginal cost compared to the acquisition of similar power. But available hardware is not enough. These cloud-based services are all offering a distributed environment built on Hadoop or analytical frameworks like Spark [9.73] and not all algorithms are adapted to this Bulk Synchronous Parallel [9.74] paradigm for distributed computing. Luckily, a few volunteers have provided adapted versions of both the Louvain method (https://github.com/Sotera/spark-distributed-louvain-modularity) and the Map Equation framework (https://github.com/uwescience/GossipMap).

The next solution that has already been used in several papers [9.17, 19] is to lower the density of the network drastically by choosing the directed citation link as the connector between publications in the document network. As shown before, this will result in *extremely sparse networks*.

Waltman and *van Eck* [9.17] presented a three-level solution where the third level consists of 22 412 research areas with large differences in publications ranging from 4710 down to only 50 publications. However, this size of 50 was set in advance as a selection criterion for the inclusion of obtained clusters. The shape of the size distribution with only a few clusters with many documents and then a steep decline, followed by a long tail of small to very small clusters resembles that of cluster solutions that are very sensitive to the degeneracy problem where nearly random variations of the community structure result in similar maximization scores close to the optimal [9.70]. In contrast to the lowest level the communities from the second-level analysis (672 clusters) are plotted labeled with six major fields: mathematics and computer science; physical sciences; earth, environmental and agricultural sciences; biomedical sciences; cognitive sciences and lastly social and health sciences. This plot seems very convincing.

Klavans and *Boyack* [9.13] compared, among other classifications or taxonomies, direct citations and bibliographic coupling. Given the publication window constraints for the applicability of direct citations they used a publication window of 1996 up to 2012 while the bibliographic coupling network was restricted to 2010. Using highly cited papers as the reference for the measurement of accuracy they found that the DC approach had a slightly higher score than BC. This improved accuracy but comes with the necessary extension of the publication window.

Using a *threshold* at the level of calculated similarity or at the level of source data is also a proven strategy. As early as 1974, Small and Griffith had already applied a threshold in their cocitation-based global map of science. Their starting point was the identification of a set of highly cited papers and to calculate cocitation links among them. *Klavans* and *Boyack* [9.13] removed those references which were cited more than 100 times for the creation of their bibliographic coupling. And the Drakkar technique I developed [9.26] analyses the amount of information associated to the cited references based on the number of citations. The very large number of references with low citation rate provide a large amount of information responsible for the detection of the strong links among documents while the highly cited references are capable of connection to many papers with only low similarity.

Also for the application of lexical similarity is the application of a certain threshold on similarities a valu-

Table 9.5 Rank, label and number of journals of the top and lowest ranked clustering in a journal crosscitation network as reported by *Rosvall* and *Bergstrom* [9.63]

Rank	Label	Journals	Rank	Label	Journals
1	Molecular & cell biology	512	79	Creativity research	2
2	Medicine	765	80	Travel sociology	3
3	Physics	502	81	Medical informatics	3
4	Neuroscience	224	82	Leprosy	2
5	Ecology & evolution	349	83	Sociology (Russian)	3
6	Economics	159	84	Cryobiology	2
7	Geosciences	223	85	Death studies	2
8	Psychology	210	86	Rehabilitation counseling	2
9	Chemistry	145	87	Steel	2
10	Psychiatry	178	88	Futurist	1

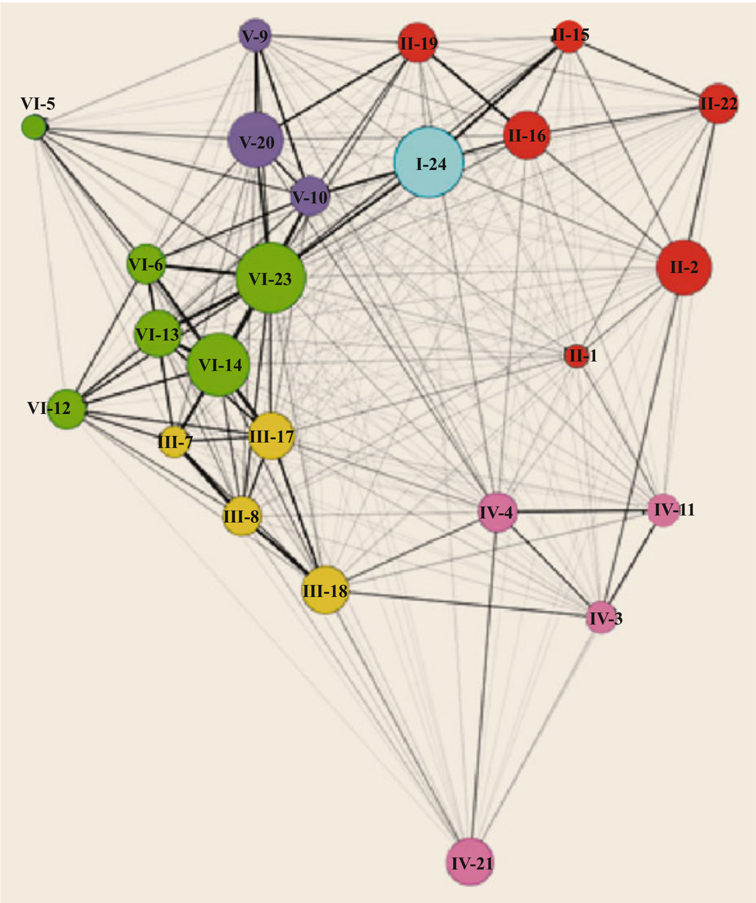

Fig. 9.4 Global map of science using 24 clusters of journals using a second-order bibliographic coupling network. Data sourced from Clarivate Analytics Web of Science Core Collection, figure reprinted from [9.75]

able approach. The threshold could be imposed in analogy to *Klavans* and *Boyack* [9.13] or *Thijs* [9.26], where the most frequently used terms or noun phrases are removed from the term list.

Using a threshold for the removal of cited references or used terms can be seen as a simple strategy for feature selection. But more advanced approaches for improved *feature extraction* or selection are available. The extraction of noun phrases [9.38] proved to be a successful strategy to reduce the density of the lexical network. But a lot of improvement can still be expected from this approach. Citation context [9.76] can be used for an adapted version of bibliographic coupling where only references cited in the same section or paragraph are considered to be linked.

Table 9.6 Codes and labels for global clustering of a journal network based on bibliographic coupling

Level I – code	Level III – code	Level III – Main subfields
I	24	Chemistry; material sciences
II	1	Statistics & probability
	2	Computer science; applied mathematics
	15	Physics; astronomy & astrophysics
	16	Engineering; classical physics
	19	Geosciences; geography
	22	Pure mathematics
III	7	Neuroscience; neurology
	8	Psychology; psychiatry
	17	Public health; nursing
	18	Social psychology; therapy; counseling
IV	3	Management; marketing; innovation
	4	Sociology; social & political sciences; law
	11	Economics; accounting
	21	Arts & humanities
V	9	Agriculture; plant science
	10	Microbiology; biotechnology; food sciences
	20	Biology
VI	5	Veterinary sciences; animal sciences
	6	Immunology; respiratory medicine
	12	Noninternal medicine
	13	Haematology; oncology; surgery; radiology
	14	Internal medicine; cardiovascular medicine
	23	Biosciences; biomedical research

Data sourced from Clarivate Analytics Web of Science Core Collection, table sourced from [9.75]

The last possible solution that is presented in this chapter to create a global map of science is to shift to a higher level of aggregation. The most natural next level of aggregation is then to cluster the scientific journals. Because of the fact that the number of nodes in the network is strongly reduced, many researchers have already produced such maps and taken different approaches. Very relevant to this chapter is the analysis by *Rosvall* and *Bergstrom* [9.7] in their paper which introduces the map equation framework. They used their flow-based approach on a journal crosscitation network with 6128 nodes and more than 6 million directed links between the journals. This resulted in 88 modules or clusters of large heterogeneity in size which they plotted in a U-shaped map with engineering and social sciences at both ends and physics, chemistry, (molecular biology) and medicine the connecting path between these ends. A short cut between both ends is provided by probability and statistics. This organization of the areas is also in line with the plot of the second-level clustering and six labels presented by *Waltman* and *van Eck* [9.17]. Table 9.5 provides the labels and the shares of the ten largest and ten smallest clusters.

While the top-ranked clusters in the left half of the table are convincing the tail with many very small clusters with only a few journals is rather peculiar. It is hard to understand that a topic like Russian sociology or Death Studies should be placed at the same level as Medicine in a global map of science. It would have been better if the final solution was limited to a set of clusters with a size above some threshold. The reported list of modules suffers from the degeneracy problem as described by *Good* et al. [9.4].

An approach that combines bibliographic coupling at the journal level with second-order similarities was taken by *Thijs* et al. [9.75]. Second-order similarities build on the concept of Friend-Of-A-Friend from social network analysis [9.77]. BC-links are calculated in a journal-by-journal matrix and, next, pairwise cosine similarities are obtained from journal vectors holding the BC-similarity to all other journals. The traditional hierarchical clustering with Ward agglomeration [9.78] was used to create clusters at three different levels. Figure 9.4 presents the structure of the network with the coloring and labeling according to the first and third level. This figure also presents a U-shaped map from engineering to social sciences with the described path between both fields and even the statistics & probability-shortcut is present.

Table 9.6 gives the codes and labels at each level. This approach resulted in 24 clusters at the third level. However, because of the very dense structure also visible in the figure (the network is almost complete) any analysis at a deeper level trying to identify smaller topics or clusters will fail due to both the resolution limit and the degeneracy problem. The high density will result in a nearly random local moving and merging from journals to clusters and will lead to arbitrary results. Also *Klavans* and *Boyack* [9.13] found similar results when comparing journal-based versus paper-based clustering at higher levels of granularity.

9.6 Conclusions

In this chapter, an overview was given of two drivers of the advancements in science mapping and topic detection, i. e., the developments in scientometrics itself and that in network science. Although the application shows an enormous constant growth in the size of the underlying networks, it becomes clear that the driver for this growth was not the advancement in scientometrics itself but rather a consequence of the opportunities offered by the increased computational resources and the advancement in scalability of community detection techniques. This chapter points the scientometrician and users of science maps to this discrepancy in growing pace of those three motors.

An important second track of research in network science relevant to topic detection is the investigation of the anomalies and artifacts created by community detection techniques based on either modularity or on the map equation (to a lesser extent). This literature clearly shows that problems like resolution limit or the degeneracy problem will always be present in any clustering approach and can place a serious burden on the validity of the obtained results. As shown in the literature, these problems start to emerge at a too fine grained level. When running the different maximization algorithms at low levels of granularity and many clusters, the formula becomes a summation of a long list of small terms. The nearly random shift or movement of nodes to another cluster results in marginal changes (increase or decrease) of these small terms. The different studies presented above all agree on a kind of U-shaped global map of science with a central role for biology and bioscience and medicine and social sciences and engineering at both ends. Any deeper clustering comes with much lower accuracy and solutions start to diverge.

This brings us to the issue of validity. As mentioned in the last section, scientometrics has always been strongly rooted in science policy and management at different levels of aggregation. In line with this applied nature of the field, the validity of the techniques suggested and used in quantitative science studies must be directly related to the research question that has to be answered. And the analysis should be performed at the most suited level or scale without a one-map-fits-all-needs approach. Science maps should not only be accurate and complete but they should in the first place be helpful to their users or readers for the cognitive structuring of their surrounding scientific reality.

Bart Thijs is a Senior Researcher in Bibliometrics at KU Leuven – ECOOM. His research focusses on the identification of global and local network structures within scientific communication and on the development and application of citation-based indicators. He combines a background from Mathematical Psychology (Master's degree from KU Leuven) and Social Sciences (PhD from Leiden University) with professional experience as a statistical consultant in his work.

Part B Advancement

Part B Advancement of Methodology for Research Assessment

10. Measuring Science: Basic Principles and Application of Advanced Bibliometrics

Anthony van Raan

We begin with a short history of measuring science and discuss how the Science Citation Index has revolutionized the quantitative study of science and created a strong application potential. After reviewing the rationale of bibliometric analysis, we present the basic principle of the bibliometric methodology, with complex citation networks as a starting point. We show that the two main pillars of advanced bibliometric methods, citation-based analysis and science mapping, are both reducible to one and the same principle. From this basic principle we deduce a set of main indicators, particularly for the assessment of research output and international impact. Important elements include new approaches for identifying fields and research themes on the basis of a publication-level rather than a journal-level network; publication and citation counting; normalization of citation measures; the use of indicators based on averages versus those based on citation distributions; and weighting procedures and statistical reliability. In this account of the state of the art of advanced bibliometrics, we highlight in particular the developments in our Leiden institute, given its long-standing, extensive, and broad experience.

The next part of this chapter deals with practical applications of indicators, particularly real-life examples of evaluation studies. We further discuss several crucial issues such as the use of journal impact factors and h-index; the relation between peer review judgment and bibliometric findings; definition and delimitation of fields; assignment of publications; the influence of open access; webometrics and altmetrics; ranking of universities; and general objections to bibliometric analysis.

The second main pillar of the advanced bibliometric methodology is the development of science maps. We discuss the basic elements and the construction of both citation-relation and word-relation science maps. Further, we present a method to combine the two main pillars: the integration of citation analysis in science maps. This combined citation analysis and science mapping can be used to explore research related to socioeconomic problems. Recently developed bibliometric instruments enable tunable mapping, which opens up new analytical opportunities in monitoring scientific research. Finally, we contend that bibliometric indicators and maps are not just evaluation tools for science policymakers, research managers, and individual researchers, but also powerful instruments in the study of science.

10.1 A Short History of Scientometrics

The quantitative study of science, generally referred to as *scientometrics*, is aimed at advancing our knowledge on the development of science and its communication structure, as well as in relation to social, technological, and socioeconomic aspects. This field is both problem-oriented and basic in nature. There are important interdisciplinary links with the philosophy, history and sociology of science, with policy and management studies, mathematics and physics, with innovation studies, and particularly with information science. Within scientometrics, the research on scientific communication, in particular with data from publications, citations, and journals, is called *bibliometrics*. For more compact reviews we refer to earlier papers of the author [10.1–3] on which this handbook chapter is partly based and from which pieces of text that can be regarded as basic descriptions are taken. An impressively comprehensive overview of the early developments in the quantitative study of science was given in 1976 by *Francis Narin* in his seminal report, *Evaluative Bibliometrics* [10.4].

10.1.1 The Quantitative Study of Science Before the Science Citation Index

Perhaps the first scientometric study was the work in 1873 by *Alphonse de Candolle* [10.5], in which he described the changes in the scientific strength of nations by membership of scientific societies. He tried to find *environmental factors* of all kinds, but particularly religion (Protestant versus Roman Catholic, including the role of the celibate), for the scientific success of a nation. In 1926, *Alfred Lotka*—famous for his Lotka–Volterra equations in population dynamics—published a remarkable study on the productivity of chemistry researchers [10.6]. It is the first scientometric finding that can be expressed in a simple mathematical way: the productivity of scientists follows an inverse square law. In other words, the number of scientists producing N papers is proportional to N^{-2}. This *law of scientific productivity* holds that within a given period of time, the majority of researchers produce only one or two papers, and just a few authors produce ten or more papers. It is the first evidence, later followed by much more, that science is characterized by skewed distributions. Another early (1940s) discovery of skewed distribution in science was that the literature on a given subject was heavily concentrated in just a small core set of journals [10.7]. This phenomenon, known as *Bradford's law* provided a convenient way to estimate the number of journals that must be checked to obtain a specific degree of coverage of the literature on the subject.

Between 1940 and 1950, we see increasing interest on the part of librarians in determining how papers in specific journals are cited by papers in other journals. The idea emerged that analyzing these journal-to-journal citations could be used to assess the usefulness of journals for university libraries. This works as follows [10.4]: Given a set of journals already present in a library, one may analyze which journals outside the set are frequently cited by the journals within the set. These journals can then be considered important enough to add to the library collection. The beginning of the 1950s witnessed the appearance of the first *science maps* based on journal-to-journal citations. *Robert Daniel* and *Chauncey Louttit* constructed such a map for the field of psychology in order to show its development based on structures hidden in the literature [10.8]. By composing a journal-to-journal-citation matrix, they calculated similarity measures and applied cluster analysis. In this way they created a science map (given in [10.4]) and discovered a general and an applied core of the psychology literature. All this had to be done by hand, with a huge amount of printed journal volumes, a hell of a job without computers and automated databases …

Initially, citation analysis was restricted to journals as a whole. Citation analysis of individual publications, grouped into fields, countries, universities, departments, research groups, or individual scientists, was not possible due to the lack of relevant data sources. All such studies had to wait for the creation of the *Science Citation Index* in 1955.

10.1.2 The Science Citation Index Revolutionized the Study of Science

The creation of the *Science Citation Index* (SCI) by *Eugene Garfield* [10.9] was undeniably a major breakthrough [10.10], which completely revolutionized the field. The systematic collection and registration of all references in all publications in a large number of scientific journals opened the way to statistical analyses of the scientific literature on a very large scale. It marks the rise of bibliometrics as an application-driven empirical field within the studies of science. Garfield founded a company, the *Institute for Scientific Information* (ISI), to develop the SCI and related databases. The SCI is the predecessor of the *Web of Science* (WoS). As most publications are connected to other publications by citations, the science communication system represented by publications is in fact a gigantic network to which currently around two million publications per year are added. It is therefore no surprise that in bibliometric research today, advanced network analysis methods from mathematics and physics are used.

Eminent US scientists such as *Derek de Solla Price* [10.11, 12] and *Robert Merton* [10.13] immediately recognized the enormous potential of Garfield's creation: Price, from the perspective of contemporaneous history of science, and Merton from the perspective of normative sociology. Price is the pioneer of a *physical approach* to science, wherein he tried to find laws to predict further developments, inspired by the ideas of Newtonian and statistical mechanics. In this approach, quantitative measures of science, *indicators*, are guides to finding and, as a crucial next step, understanding basic features of the scientific communication system. He made a number of important bibliometric discoveries based on SCI data: *Price's law* on the distribution of publications over authors, stating that 25% of all authors are responsible for 75% of all published papers (this is in fact a more accurate revival of the Lotka study); the exponential growth of scientific literature that started at the beginning of the 18th century; the exponential decay of citations received by publications as a function of time, which defines a *half-life* of publications; and the *power law* distribution of citations over publications. This last finding is the most important example of skewed distributions in science: the vast majority of publications receive only a few citations (or none), and only a few publications receive many citations [10.11, 12, 14]. *Price* also proposed the idea of *cumulative advantage* [10.15], which means that publications which are already frequently cited have a higher probability of receiving even more citations. In complex network theory, this concept is now better known as *preferential attachment*.

The creation of the SCI opened the way for the analysis of citations at the level of individual publications. In the early 1960s, *Michael Kessler* at MIT developed the method of *bibliographic coupling* (BC): two publications are bibliographically coupled if they have references in common; the more common references they have, the stronger their relation [10.16]. Ten years later, Henry Small at ISI developed the mirror of bibliographic coupling, which he named *co-citation analysis* (CC). With this method, publications are defined as related if they are cited together by other papers: the more papers cite a specific pair of papers (references), the stronger the co-citation strength of these cited papers. The strength of the relations between publications provides similarity measures, and hence the possibility to cluster in such a way that both BC and CC can be used for mapping [10.17]. In Sect. 10.2 we will discuss these bibliometric methods in detail.

The SCI also made it possible to use citation analysis to assess the impact of publications: the more they are cited, the higher the impact. From the beginning it was recognized that the process of citation is complex, and certainly does not provide an ideal monitor of scientific performance. This is particularly the case at a statistically low aggregation level, such as an individual publication. But the application of citation analysis to the work of a group of researchers as a whole over a longer period of time does yield (particularly in the natural sciences and the medical fields) a reliable indicator of scientific performance, as will be discussed in this chapter. The sociologists Jonathan Cole and Stephen Cole were the first to use citation analysis to determine scientific impact. They found high positive correlations between receiving citations, winning awards, membership in scientific academies, being widely known among colleagues, and working in prestigious institutes. They also concluded that it seemed as though only a small number of scientists contribute to scientific progress [10.18, 19].

The 1970s saw a rapid increase in research on quantitative aspects of science. Due to the increasing availability of data, the quantitative appraisal of science gained influence in national and international organizations as well. It was the beginning of the development of *science indicators* based on publication and citation data. Stimulated by the success achieved by economists in developing quantitative measures of political significance (e. g., unemployment, gross national product), the National Science Foundation, UNESCO, the OECD, and the European Commission (EC) began systematically collecting data to measure and analyze the development of science and technology. A landmark publication was the first report of a biennial series of *Science Indicators* published by the US National Science Board in 1973 [10.20]. We note that the first OECD report on *The Measurement of Scientific and Technological Activities*, the famous Frascati manual, had appeared already 10 years earlier, in 1963 [10.21].

Meanwhile, the creator of the SCI, *Garfield*, introduced the concept of a *journal impact factor*, in which he used citation analysis as a tool for journal evaluation [10.22, 23]. Here, Garfield recognized another potential application of citation analysis: journals can be ranked by citation frequency for science policy purposes. The policymaking implications of bibliometric analyses were discussed even more explicitly in the pioneering work by *Narin* on evaluative bibliometrics mentioned earlier [10.4]. Narin was the first scientist-entrepreneur who used SCI data for a commercial enterprise, in a company called Computer Horizons, Inc. With a research contract from the National Science Foundation, Narin extensively described the use of publication and citation analysis in the evaluation of scientific activities. The focus was on creating performance indicators based on the data of thousands of journals. He also developed a new journal impact indicator utilizing a recursive method, the *journal influence weight* [10.24]. In recursive indicators, citations receive a higher weight the more their citing sources themselves are cited. *Narin* also wisely realized that patent analysis was necessary to explore the links between science and technology, and that a combination of citation and patent databases would be crucial [10.25]. An analysis on the basis of millions of individual publications was at that time still a bridge too far. However, in addition to the availability of more and more data through the SCI, computer power and memory capacity were rapidly increasing (by the end of the 1990s, computing power and memory storage capacity was about 10 000 times what it was in the early 1980s; nowadays it is about 10 000 000 times). It took only a few more years to bring about large-scale citation analysis of (sets of) individual publications.

10.1.3 Europeanization and Further Development of Bibliometrics

Until that time, there was not been much activity in bibliometrics outside the United States, but this changed around 1975. During a 4-month working visit at the National Science Foundation, Cees le Pair, the then director of research at FOM (*Fundamenteel Onderzoek der Materie*, the physics research council, part of the Netherlands Organization for Scientific Research), became interested in *measuring science* and got to know Derek de Solla Price and Eugene Garfield. He conducted the first citation analysis studies of two fields of physics: magnetic resonance and electron microscopy [10.26, 27]. These studies showed that citation analysis made it possible to identify the most important basic research contributions to these fields. In the field of magnetic resonance, high correlations were found between the results of citation analysis and peer assessments. However, in the case of applied and technological research—particularly in the field of electron microscopy—citation analysis did not work that well. Patent analysis appeared to be necessary to adequately describe the developments. Clearly, the limits of the bibliometric methodology were already understood in these early studies.

Around the same time, the Hungarian chemist Tibor Braun established a flourishing bibliometric research unit at the Hungarian Academy of Sciences in Budapest. At first, the results of bibliometric research were published mainly in sociology or general journals, even top journals such as *Science*. An important sign of the emancipation of the field of bibliometrics was the creation of its first journal, *Scientometrics*, by Braun in 1978. *Scientometrics* is still one of the core journals of the field. In the same year, 1978, another milestone was reached: the publication of *Toward a Metric of Science: The Advent of Science Indicators* [10.28]. Many issues discussed in this remarkable book are still relevant today. In the 1970s, important issues in bibliometric research included the use of co-citation analysis to structure fields of science, automatic indexing of search terms in databases, journal interrelationships, scientific collaboration, the role of science in innovation, the growth of science, mobility and scientific careers [10.29–32].

In 1979 the Leiden University executive board introduced a new institutional policy: the funds allocation model used to divide the block financing from the Ministry among faculties should no longer be primarily dependent on student numbers, but should also have a research quality-dependent factor. The crux was to find a reliable method for assessing research quality. In 1980, the first experiments were performed: a citation analysis of all chemistry departments, followed by a second citation analysis study of the entire Faculty of Sciences and the Faculty of Medicine, combined with expert interviews [10.33]. Never before had a bibliometric study been performed on so many (about 140) departments within a research-intensive university. But certainly, shortly before and around the same time, there were other important bibliometric studies, of which the work on radio astronomy by *Martin* and *Irvine* in 1983 [10.34] can be considered groundbreaking.

The publishing company Elsevier became particularly interested in creating new performance indicators for and mapping of scientific journals. In the early 1980s, there was a rapid rise in the number of co-citation analysis studies including author co-citation [10.35–37]; an increasing emphasis on important themes such as advanced statistical analyses of bibliometric parameters [10.38, 39]; citation analysis in evaluation studies [10.33, 34]; application of bibliometric methods in the social sciences [10.40], comparison of peer opinions and bibliometric indicators [10.41], the development of indicators of interdisciplinary research [10.42], scientific collaboration [10.43], the normalization of citation impact [10.33], online searching [10.44], and patent indicators [10.25, 45, 46]. A new development was *co-word analysis* [10.47, 48]. Mathematically, this is similar to co-citation analysis, but instead of using the references mentioned in publications, it is based on the use of the concepts mentioned in publications. To put it simply, next to the list of references in publications, we can also characterize publications by a list of concepts used in them. After a slow start, co-word analysis skyrocketed, becoming one of the primary methods for creating science maps. But it took a long time, almost two decades, before sufficient computer power was available to create maps in a relatively short length of time so that it became possible to analyze the effects of changing the map parameters such as a threshold for the similarity strength.

The first international conference on bibliometrics and the theoretical aspects of information retrieval (the predecessor of the International Society for Scientometrics and Informetrics (ISSI) conferences) was organized in 1987 by Leo Egghe in Hasselt (Belgium), again an important step in the emancipation of the field. In 1988, the first *Handbook of Quantitative Studies of Science and Technology* was published [10.49], and the Centre for Science and Technology Studies (CWTS) organized the first International Conference on Science and Technology Indicators, in Leiden (the Netherlands). The field of bibliometric research became increasingly dynamic—and even heated. As could be expected, opponents of the use of citation analysis started to agitate the field, for instance by pointing to the many different motives authors may have to cite or not to cite, thus questioning the validity of using citations as a performance measure. Although such debates can be quite irritating, they are part of a healthy development of the field. At the same time, more and more large-scale empirical work was done. For instance, the Budapest researchers *Braun* et al. published an extensive study on the normalization of citation impact and the publication output and field-specific citation impact of scientific work in about 100 countries [10.50, 51]. Important work in the second half of the 1980s focused on areas such as research performance in the humanities and social sciences, further development of multidimensional scaling analysis for science mapping based on co-citation and co-word analysis, improvement of journal-based field classification, citer motivations and citation behavior, and interdisciplinary research.

The 1990s witnessed an increase in contract work on the use of bibliometric indicators in research evaluation, commissioned by organizations and institutions worldwide, but especially in the European Union (ministries, national research councils, charities, universities). These practical applications of bibliometric methods were extremely important: they led directly to the improvement of bibliometric indicators and maps, but also to a strong intensification of basic research. We mention work on the combination of co-citation and word analysis, the skewness of science, journal impact measures and their appropriateness in evaluation studies, the correlation between peer judgments and outcomes of citation analysis, international collaboration of the upcoming Asian powers, technology mapping based on patent analysis, and the interface of science and technology. Also, quite exotic issues such as the fractal structure of science became the subject of investigation. Furthermore, the first webometrics studies appeared [10.52–59].

In 1992, Garfield decided to sell his Institute for Scientific Information. After a few years of different owners, ISI became part of the information giant *Thomson Reuters*. Things began to change gradually, with research becoming increasingly determined by business interests. As Tibor Braun once noted, this was the end of the romantic period for the bibliometric world. In the second half of the 1990s in particular, bibliometric methods for assessing and monitoring research performance were applied on a large scale in the Netherlands. Two major programs stand out: first, the *Netherlands Observatory of Science and Technology* (NOWT), with the aim of compiling the biannual Science and Technology Indicators Report for the Ministry of Education, Culture and Sciences; and second, the VSNU (*Vereniging van Samenwerkende Nederlandse Universiteiten*, Association of Universities in the Netherlands), with detailed national research assessment procedures for disciplines such as biology, chemistry, physics, and psychology, in which extensive bibliometric analyses were performed for all research groups of these disciplines in the Netherlands. Parallel to these applications we see that bibliometric researchers strongly warn about the danger of *easy bibliometrics*, particularly the inappropriateness of journal impact factors for research evaluation [10.60–62].

10.1.4 Bibliometrics in the Internet Age

At the beginning of the new century, several significant events took place. First, not surprisingly, the Internet had changed scientific communication. In addition to the publication and citation data provided by the WoS database, a vast amount of other publication data included in institutional and personal websites became available. Thus, next to citation analysis, the use of data provided via the Internet, *webometrics*, was (and still is) considered to offer interesting opportunities to complement citation-based analysis in evaluation and mapping approaches. We discuss these developments in Sect. 10.3. An important second event was the emergence of university rankings. Probably the first ranking of European universities was the EC-commissioned study on scientific excellence within the framework of the European Research Area [10.63]. In a global context, the Academic Ranking of World Universities (ARWU, ShanghaiRanking) [10.64] was the first in 2003. The Times Higher Education (THE) launched its ranking in 2004 [10.65], and in 2007 the first Leiden Ranking [10.66, 67] was published, followed by the QS ranking (2009) [10.68], the Scimago ranking (2009) [10.69], and U-Multirank (2011) [10.70]. Despite the many problems inherent in the ranking of universities [10.71], this new phenomenon evoked a rapidly increasing public and political interest in the performance of universities. In fact, it drove the application of research assessment, particularly with bibliometric methods.

The third important event was Elsevier's development and 2004 launch of *Scopus*, the first competitor of Thomson Reuters' WoS. After a run-up of a few years, the commercial launch of Scopus as the new citation index marked the end of a very long period of strict monopoly of the WoS. A fourth remarkable event was the introduction in 2005 by *Jorge Hirsch* of the h-index [10.72]. This new indicator attracted enormous attention. A simple method for individual scientists to find their h-index is to rank their publications, for instance in the WoS, according to the number of times the publications are cited (starting with the highest-cited). Somewhere in this ranking there will be a publication with a number of citations that is the same as its rank number; that number is the h-index. A real torrent of publications describing numerous variants of the h-index followed, as we shall encounter in Sect. 10.3.

The Internet became more and more important, also for citation counting, particularly by the launch of Google Scholar in 2004 with a citation index including publications from sources in addition to journals, such as books and conferences [10.73, 74]. In the beginning of the first decade of the new century, important research issues included the triple helix model of government–industry–academy interaction [10.75]; h-index and variants; the influence of language on the citation impact of particularly German and French research groups; webometrics; university rankings, their influence and limitations; patent citation analysis and the identification of industrially relevant science; the rapidly advancing scientific performance of China; improvements in text mining; the identification of scientific excellence; and sleeping beauties (a sleeping beauty in science is a publication that goes unnoticed (i. e., is not cited, *sleeps*) for a long time and then, almost overnight, attracts a great deal of attention (*is awakened by a prince*), as measured by citations.

The years 2006–2010 can be characterized as a period of strong growth in business-based bibliometrics: commercial database producers began introducing their own bibliometric products: Elsevier's Scopus with SciVal and Thomson Reuters with InCites. In research we see a strong focus on webometrics, a further discussion of the properties of the h-index, new methods for identifying emerging topics, improvements in the visualization of science maps such as the VOSviewer, applications of Google's PageRank algorithm, source-normalized citation impact, and measures of journal interdisciplinarity. In the current decade, the number of publications on webometrics and altmetrics issues increases substantially, and the bibliometric community enters into fierce debates on new *crown indicators*, university rankings, fractional or full counting, and publication-level versus journal-level field classifications. A growing number of advanced network analytical methods are applied to bibliometric data and used to improve science maps. In Sect. 10.3 we will discuss these developments in greater detail, along with reference to relevant literature.

And so we arrive at the present-day developments in bibliometrics, and we conclude our historical overview. In the following survey of the state of the art of advanced bibliometrics, we highlight in particular the developments in our Leiden institute, given its long-standing, extensive, and broad experience. The remainder of the chapter is structured as follows. In Sect. 10.2 we discuss the rationale of and the practical needs for advanced bibliometrics. The majority of Sect. 10.2 is devoted to a discussion of the basic elements of advanced bibliometrics. Section 10.3 addresses major issues in the practical application of bibliometric performance indicators and provides a real-life example of a bibliometric evaluation study. In Sect. 10.4 we focus on the basic elements, construction, and application of science maps. We conclude the chapter in Sect. 10.5 with a few thoughts about the measurability of science.

10.2 Bibliometric Analysis: Rationale, Practical Needs, Basics

10.2.1 Why Bibliometric Analysis?

Science is an abstract concept. How can we approximate its characteristics quantitatively? In other words, how can we measure science; what is the metric? Measuring basically means counting of standard units. Measurement in physics is a well-understood process in which observed quantities are related to well-defined standard units. But in the non-physics world there are no perfect standard units, such as one hydrogen atom, one kilogram, or one meter. There are only units with a reasonable similarity, e. g., inhabitants of a city, students at a university, and publications in a field of science.

The daily practice of scientific research shows that inspired scientists, particularly in the natural sciences and medical research fields, go for publication in international journals. Certainly, journal articles are not in all fields the main carrier of scientific knowledge. And they differ widely in importance. But work of at least some importance provokes reactions from colleagues. They are the *invisible college* by which research results are discussed, and they play their role as members of this invisible college by referring in their own work to earlier work of other scientists. Scientific performance relates to the quality of the contribution in terms of *increasing our knowledge* (scientific progress) as perceived by other knowledgeable researchers (peer review), quantified and archived by citations. This process of citation is undoubtedly a complex one, and it does not provide an ideal monitor of scientific performance. This is particularly the case at a statistically low aggregation level, such as the individual researcher. But the application of citation analysis to the work of a group of researchers as a whole over a longer period of time does yield, in many situations, a strong indicator of scientific performance [10.1]. In this context, citations are seen as providing a measure of international impact, which in turn is considered a good proxy for scientific quality, also in terms of relevance and visibility. For many years, the Science Citation Index, now the Web of Science (WoS, produced by Thomson Reuters, now owned by Clarivate Analytics) was the only large multidisciplinary citation data source worldwide. In the last 10 years or so, Scopus, produced by Elsevier, has provided a second comprehensive citation database. We note that, since the early 1990s, the SLAC National Accelerator Laboratory (formerly Stanford Linear Accelerator Center) has maintained a website with a freely accessible high-energy physics database, SPIRES, including citations.

The motives for giving (or not giving) a reference to a particular article may vary considerably [10.76–82]. There is, however, no empirical evidence that these motives are so disparate or so randomly given that the phenomenon of citation would lose its role as a reliable measure of impact [10.81]. Nevertheless, contentious discussion around how authors choose their references regularly flares up, often in relation to processes of cumulative advantage such as the Matthew effect [10.13], for instance, in which authors tend to cite papers that are already highly cited [10.82]. In general, this Matthew effect is taken for granted. However, studies on PhD graduations with honors question the predominant role of the Matthew effect in acquiring citations [10.83, 84].

Why bibliometric analysis of research performance? Peer review is and must remain the principal procedure of quality judgment. But peer review is not sacrosanct. It may have serious shortcomings and disadvantages; it might even suppress innovation [10.85]. Subjectivity, i. e., dependence of the outcomes on the choice of individual committee members, is one of the major problems. This dependence may result in conflicts of interest, unawareness of quality, or negative bias against younger people or newcomers (nepotism) to the field and women (sexism) [10.86–88]. To make peer review more objective and transparent, it should be supported by advanced bibliometric methods. Of course, this does not provide an ideal instrument, working perfectly in all fields under all circumstances. But it works very well in the large majority of the natural, medical, applied, and behavioral sciences. These fields of science are the most cost-intensive and the ones with the strongest socioeconomic impact. For a comprehensive discussion on the validity and reliability of evaluation of scholarly performance, we refer to [10.89].

A first and good indication of whether bibliometric analysis is applicable to a specific field is given by the publication characteristics of the field, in particular the role of international refereed journals. If international journals are a major means of communication in a field, then in most cases bibliometric analysis is applicable. This is generally the case for the natural and medical sciences but less so for engineering, social sciences, and particularly the humanities [10.40, 90–96]. Therefore it is important to study the publication practices of a research group, department, or institute, in order to determine whether bibliometric analysis can be applied reliably. A practical measure to this end is the share of publications covered by WoS or by Scopus in the total research output. For publications not covered by the WoS or Scopus, a restricted type of analysis is possible, insofar as these publications are cited by articles in journals covered by the WoS or Scopus. This *non-source* approach is particularly important for bibliometric analysis in the social sciences and humanities [10.93, 95].

A frequently posed question concerns the delay problem: does citation analysis suffer from a substantial, *inherent delay* in the measurement of research performance [10.97]? This supposed inherent delay implies that colleague-scientists (peers) in some field of science are already familiar with a specific piece of research work, but it takes some time before they begin citing the work. In other words, a time delay between *peer awareness* and *bibliometric notification* (i. e., by citing the work). An answer to this question needs further refinement: delay compared to what? To the average processing time of a publication? To the average running time of a project? Or to peer review time cycles? The average duration of a major research project is about 4 years, and the same is true for most peer review time cycles. Also, during the publication process, the awareness of scientific community evolves (e. g., average time between field-specific conferences). Nevertheless, it is not unusual for important papers to be cited already in the year of publication. Apparently bibliometric notification does not necessarily take more time than peer awareness. But it is not that easy; circular reasoning lies in wait. How do *you* know that researchers in some field of science already know specific work? Often bibliometric notification is taken as a sign of this peer awareness—for instance, in the study of *delayed recognition*: in relatively rare cases, it takes a long time for peer awareness, reflected by the absence of citations over a longer period of years [10.98, 99]. The publications suffering from delayed recognition are called *sleeping beauties*; we come back to this phenomenon in Sect. 10.3. Perhaps altmetric methods will enable us to ascertain whether there is a time lapse between peer awareness and bibliometric notification.

As we discussed in our historical overview, the Internet has changed scientific communication. Researchers use the web for both information-seeking and presenting. In addition to the publications not covered by the WoS or by Scopus, there is a large number of other publications and data included in institutional and personal websites. As we will discuss in Sect. 10.2, data provided via the Internet, *webometrics*, offer interesting additional opportunities to aid citation-based analysis in evaluation and mapping studies.

10.2.2 Advanced Bibliometrics and Practical Needs

We define *advanced bibliometrics* as the state-of-the-art design and application of mathematically sound quantitative methods based on publication, citation, and textual data for research impact assessment and for mapping of scientific fields. Also, these methods can be applied more generally in the study of a wide range of properties of science and of its communication system, such as growth and differentiation of scientific research, diffusion of knowledge, mobility of researchers, scientific collaboration, and the identification of breakthroughs. In this chapter we focus on research impact assessment and mapping. Advanced bibliometrics is built on three cornerstones:

1. *Reliable statistics*, e. g., corrections for differences in publication and citation practices between scientific disciplines; robustness with respect to outliers
2. *Highest possible accuracy of data*, e. g., carefully cleaned institutional addresses and author names
3. *Sets of consistent*, sufficiently divers, and transparently designed and calculated quantitative measures, called *indicators*.

Above all, the most fundamental bibliometric operation, the identification and storage of *citing-cited pairs* (links between a citing and a cited paper), must be completely transparent. There can be no advanced bibliometrics if somehow and somewhere in whatever data manipulation black boxes are present. Advanced bibliometrics enables universities and research councils to support their decisions on the key questions they are facing. These are summarized in Scheme 10.1.

Scheme 10.1 Key questions of advanced bibliometrics

- What is our output and international impact, and what are the trends?
- Do we see notable changes?
- Can we identify breakthrough work?
- Where is our research located on the map of science?
- Where does our impact come from (specific institutions, fields)?
- With which universities and research institutes do our scientists cooperate, and how intensively?
- How do we distinguish ourselves to attract excellent staff and students?
- How should we organize and monitor our research given new and often interdisciplinary developments?
- How should we divide funds?
- What is the societal impact of our research?
- How do we rate output and quality compared to input and composition of a research unit?
- Can we apply bibliometric indicators in engineering, social sciences, and humanities?
- To what extent is our research related to new, emerging research themes?
- How can we identify experts and panel members for peer review and advice?

In order to achieve the best possible level of utilization, advanced bibliometrics must enable users to perform analyses at different aggregation levels (university, institutes, departments, groups, programs) within time periods as desired, and to create their own reports with visualizations (tables, figures, maps) of the outcomes of the analyses. In this way the users are provided with a *bibliometric monitor*. Such a monitor enables comparisons between departments and research groups within an institute, but also inter-institutional comparisons in order to identify strengths and collaboration opportunities. Of course, nothing in nature is ideal, and advanced bibliometrics also has its limitations. In the following sections we will discuss the basic elements and applications of advanced bibliometrics. We will see that there are many challenges in the application of bibliometrics in evaluation practice, that there is still a need for further improvement, and that there are things we have to live with. Making quantitative measures of anything thinkable fascinates many of people, but it horrifies others as being nonsense and taking us back to a magic number world. Because scientific quality is so precious and often regarded as immeasurable in all its aspects, it is no wonder that the application of advanced bibliometrics may evoke strong emotional reactions, as we will see in this chapter.

10.2.3 The Fundament of Bibliometric Methods: The Publication-Attribute Network

The fundament of bibliometric analysis is the publication-attribute network (PAN). The two main methods—citation analysis and science mapping—can both be derived from the same network principle. In this approach, publications have specific *attributes*, and these relations can be represented by unidirectional linkages in the PAN, which can be regarded as the primary network. These attributes can be *cited papers*, i. e., the references of a paper, or *concepts* (keywords), as well as authors and institutions. In Fig. 10.1 we give a simple example of a PAN. We have four publications $p_1, \ldots, p_4$ and five attributes $a_1, \ldots, a_5$. Publication p_1 has all five attributes; p_4 has none. From the PAN, two secondary networks can be derived: the attribute network (AN) and the publication network (PN). The connecting lines indicate the strength of the relation between attributes or between publications. For instance, in the AN, a_1 and a_4 are connected with linkage strength 3, because these attributes have three publications in common, namely p_1, p_2, and p_3. In the PN, p_1 and p_3 are connected with linkage strength 2, because these publications have two attributes in common, namely a_1 and a_4. In Scheme 10.2, we give a simple mathematical explanation of the relation between the primary and the two secondary networks.

If the attributes are *cited papers* (references), the PAN represents *direct citation* (DC) of the cited papers (as attributes) by the citing papers. The AN represents the co-citation (CC) network and the PN represents the bibliographic coupling (BC) network. In Scheme 10.2 we explain how attributes (for instance, cited papers) and publications are linked together with a strength that can be calculated.

These strengths provide similarity measures (the stronger the linkage between attributes or publications, the more similar these attributes or publications are). This enables us to make maps in which distances between attributes or publications are inversely proportional to their linkage strengths. Linkage strengths also enable us to analyze clustering of groups of attributes or publications. With the BC network, we can create maps on the basis of publications in their *citing* modality; in the CC method, the maps are constructed on the basis of their *cited* modality. As the citing modality can no longer be changed (the references in publications are fixed and thus remain forever the same), the BC maps are static, whereas the CC maps are dynamic (publications can be cited later on, again and again). For pioneering research on co-citation mapping, we refer to the work of *Small* [10.17, 100–103], and on the thematic identification of co-citation clusters to [10.52, 53].

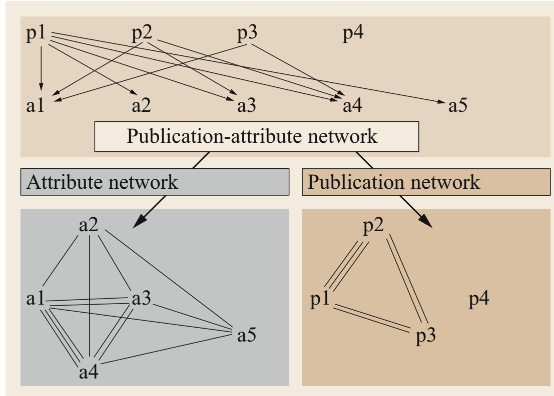

Fig. 10.1 The primary (PAN) and secondary networks (AN and PN)

Scheme 10.2 Simple mathematical explanation of the relation between the primary and the two secondary networks

In Fig. 10.1 we showed a simple PAN in which we have four publications p_1, p_2, p_3, and p_4, and five attributes a_1, a_2, a_3, a_4, and a_5. We see that p_1 contains all attributes a_1 through a_5; p_2 contains a_1, a_3, and a_4; p_3 has only a_1 and a_4; and p_4 has none of the five attributes. Mathematically, the publications can be written as vectors in the attributes space, e. g., $p_1 = (1, 1, 1, 1, 1)$. The PAN can thus be written as matrix $\mathbf{N}$ in which the rows represent the publications and the columns the attributes,

$$\begin{array}{cccccc} & a_1 & a_2 & a_3 & a_4 & a_5 \\ p_1 & 1 & 1 & 1 & 1 & 1 \\ p_2 & 1 & 0 & 1 & 1 & 0 \\ p_3 & 1 & 0 & 0 & 1 & 0 \\ p_4 & 0 & 0 & 0 & 0 & 0 \end{array} .$$

Formally written as

$$\begin{pmatrix} 1 & 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} = \mathbf{N} \tag{10.1}$$

Pre-multiplication of matrix $\mathbf{N}$ with its transpose $\mathbf{N}^{\mathrm{T}}$ yields the (symmetrical) attribute-correlation matrix

$$\begin{aligned} \mathbf{N}^{\mathrm{T}} \cdot \mathbf{N} &= \begin{pmatrix} 1 & 1 & 1 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 1 & 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{3} & 1 & 2 & 3 & 1 \\ 1 & \mathbf{1} & 1 & 1 & 1 \\ 2 & 1 & \mathbf{2} & 2 & 1 \\ \mathbf{3} & 1 & 2 & \mathbf{3} & 1 \\ 1 & 1 & 1 & 1 & \mathbf{1} \end{pmatrix} = \mathbf{A} \end{aligned} \tag{10.2}$$

In this way, we have transferred the PAN (represented by matrix $\mathbf{N}$) into the AN (represented by matrix $\mathbf{A}$). The *diagonal* values (in boldface) of this matrix $\mathbf{A}$, $a(i,i)$, indicate the number of publications with attribute a_i. For a_1 this is $a(1,1) = 3$, for a_2 we find $a(2,2) = 1$, and so on. Thus, the matrix diagonal represents the *occurrence* of each attribute. The *off-diagonal* values, $a(i,j)$, give the *co-occurrences*; for instance, a_1 and a_4 (value in red) are both present in $a(1,4) = 3$ publications (namely in p_1, p_2, and p_3, as can be seen in Fig. 10.1). Thus, $\mathbf{A}$ provides the *strengths* of the links between each possible attribute pair based on the number of publications in which an attributes pair occurs. In the case the attributes are cited papers, the diagonal values are the number of times a specific paper is cited within the given set of publications; the off-diagonal values give the (not-normalized) co-citation strengths.

If we now take the mirrored matrix multiplication of (10.1), i. e., post-multiplication of the original matrix with its transpose, we get the (symmetrical) publication-correlation matrix

$$\begin{aligned} \mathbf{N} \cdot \mathbf{N}^{\mathrm{T}} &= \begin{pmatrix} 1 & 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{pmatrix} \cdot \begin{pmatrix} 1 & 1 & 1 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{5} & 3 & 2 & 0 \\ 3 & \mathbf{3} & 2 & 0 \\ \mathbf{2} & 2 & \mathbf{2} & 0 \\ 0 & 0 & 0 & \mathbf{0} \end{pmatrix} = \mathbf{P} \end{aligned} \tag{10.3}$$

Now we have transferred the PAN (represented by matrix $\mathbf{N}$) into the PN (represented by matrix $\mathbf{P}$). The *diagonal* values (again in boldface) of this matrix $\mathbf{P}$, $p(i,i)$ indicate the number of attributes in each publication. For p_1 this is $p(1,1) = 5$, for p_2 we find $p(2,2) = 3$, and so on. The *off-diagonal* values give the number of attributes shared by any two publications; for instance, p_1 and p_3 (value in red) share $p(1,3) = 2$ attributes (namely a_1 and a_4, see Fig. 10.1). Thus, $\mathbf{P}$ provides the *strengths* of the links between each possible publication pair on the basis of how many attributes a publication pair has in common. In the case the attributes are cited papers, the off-diagonal values give the (not-normalized) bibliographic coupling strengths.

To keep our explanation simple, we do not go on with further mathematical elaboration, for instance the calculation of similarities by size-normalization of the strengths and other methods of normalization of co-occurrence matrices. The discussion on the best normalization procedure is endless and goes on for over 35 years; we refer to the relevant literature, for instance [10.104, 105].

If the attributes are concepts—for instance, keywords given by the author(s) and/or by the database, or terms and noun phrases identified by grammatical parsing of a publication's title and abstract—the AN represents a co-word map. We will discuss this type of mapping in detail in Sect. 10.4. For early pioneering work on the construction of co-word maps using combined multidimensional scaling and clustering, we refer to [10.106, 107].

In this section we continue with *cited papers as attributes*, and with that we focus on the basics of citation analysis. Citation analysis can be defined as the collection of all thinkable measures enabled by the PAN in which the attributes are cited papers. It covers the broad spectrum from what is often seen as simple counting to sophisticated citation-based mapping. As one might have guessed, the assumed simple counting is not that simple. It can be done in many ways: for example, the number of citations for a single publication or for an author, group, program, institute, university, country, field; in a specific period of time; from specific fields and institutions; the total distribution of citations over publications in a field. The idea (not infrequently of clients of bibliometric work) that citation analysis is just simple counting is unfortunate; it is one of the main sources of bad practice in the application of bibliometric methods for research performance assessment.

Citation-based mapping is currently in a phase of rapid development, with new application opportunities, particularly the building of a publication-level classification system of science. Analysis of the PAN—which represents direct citation (DC)—applied to the entire WoS database in the period from 2000 to the present has recently been used to construct a large-scale clustering of publications [10.108–111], representing nearly 20 million publications with around 300 million citation relations in the period 2000–2015. About 8% of the publications are excluded due to insufficient citation links. With new, advanced mathematical techniques [10.108, 109], three levels of clustering have been identified:

1. *Macro*-level clusters representing 27 broad disciplines.
2. *Meso*-level with 817 major fields.
3. *Micro*-level with 4113 fields. The micro-level fields are used for citation-impact normalization in, for instance, the Leiden Ranking [10.66, 67].

Each cluster at the micro level can be interpreted as a research field in the scientific literature. Publications are uniquely assigned to one field. The 4113 fields cover all scientific disciplines, including the social sciences. Some topics are highly interdisciplinary and encompass publications from many different research disciplines. Each of the clusters is labeled in an algorithmic way by extracting the five most relevant terms from the titles and abstracts of the publications belonging to a cluster. In this way a fine-structured citation-based taxonomy of science is created. Given its fine granularity, DC-based publication-level clustering is well suited for identifying emerging research themes by searching for new clusters and monitoring their evolution over a period of a few years after their appearance. With proper data collection and calculation algorithms, this large-scale publication-level clustering can be automated. Thus, new bibliometric tools can be constructed, for instance the *CitNetExplorer* for analyzing and visualizing citation networks [10.110, 112] and the *VOSviewer* for creating science maps based on citation or concept relations [10.113, 114]. We will come back to these bibliometric tools and other applications of publication-level clustering for science mapping in Sect. 10.4.

In Fig. 10.2, an example is shown of a small part of the entire science network at the lowest clustering level: field 175, scientometrics/bibliometrics [10.108, 109]. It covers 12 717 publications; in the figure, the 5910 publications with more than 10 citation relations are represented. The titles of these publications are given (first 30 characters), with the size of the letters proportional to the number of citations. The network is created with the VOSviewer. Each cluster within this field is indicated by a different color; the creation of clusters and their colors follows automatically from the citation relations in the network. We clearly see that the clusters within the field represent different re-

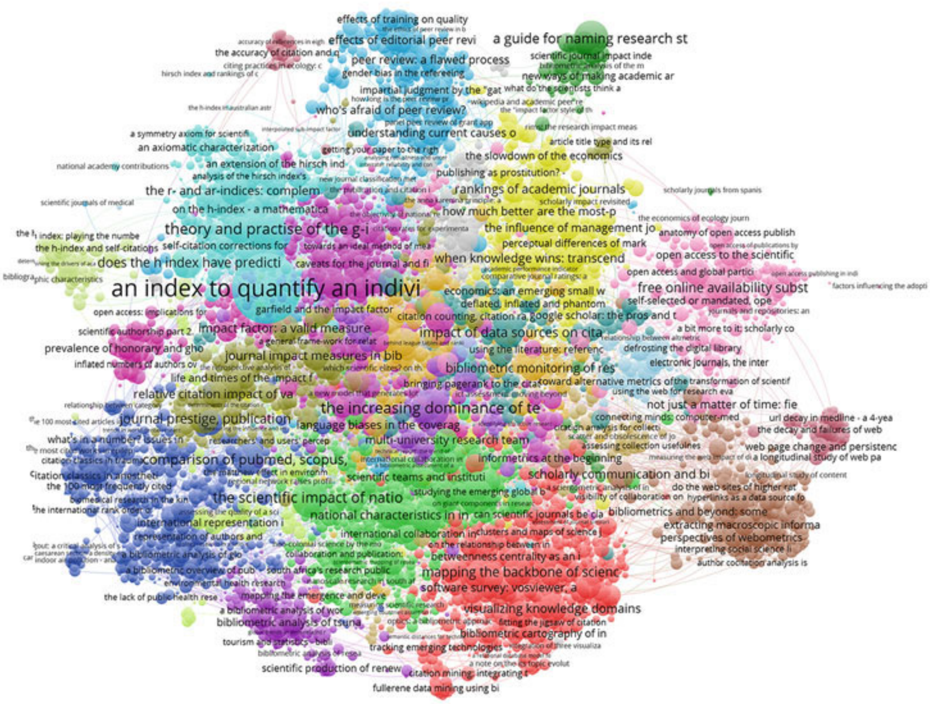

Fig. 10.2 Map of the publication-level network showing the field of scientometrics/bibliometrics

search themes within scientometrics/bibliometrics. For instance, the red cluster in the lowest part of the figure relates to bibliometric mapping; the blue cluster in the upper part relates to peer review; the light purple cluster on the right side relates to open access; the light blue cluster on the left side relates to the h-index. We see two prominent papers: *An index to quantify an individual's scientific research output*, the paper in which *Jorge Hirsch* launched his h-index [10.72] (cited 3474 times in the WoS Core Collection through December 1, 2018); and *Theory and practise of the g-index* of *Leo Egghe* [10.115] (cited 770 times in the WoS Core Collection through December 1, 2018). We stress that this publication-level clustering is *journal-independent*: all relevant scientometrics/bibliometrics publications are covered, including those in journals other than the typical scientometric journals. The above-mentioned highly cited Hirsch paper, published in the *Proceedings of the National Academy of Sciences of the United States of America*, is a striking example.

On the basis of a comparison of the three standard citation-based analyses (DC, CC, or BC) it was shown that DC provides a more accurate taxonomic representation of science than either BC or AC [10.116]. This does not imply, however, that the accuracy of DC-based publication-level classification cannot be enhanced by additional BC-based local clustering. Comparisons of different methods for mapping scientific publications on the basis of citation relations focus specifically on clustering methods, community detection, and hierarchical map-equation methods [10.117–119].

10.2.4 Indicators of Research Output and Impact

The Construction of Indicators

The central task in bibliometric research is the development of methods and techniques for the design, construction, and application of quantitative indicators on important aspects of science. What is the difference between *data* and *indicators*? How do we convert data into indicators? An indicator is the result of a specific mathematical operation (often straightforward arithmetic) with data. For the very basic indicators, there is hardly any difference from data, for instance the mere number of publications or citations of a research group. Clearly, the difference between data and indicators becomes more pronounced if citation counts of all publications of a research group in a particular field are normalized to citation counts of all publications worldwide in the same field. An indicator is a measure that explicitly addresses some assumptions. In our example, the assumption is that this is the way to calculate the international scientific influence of a research group. This raises an interesting question: what features of science can be given a numerical expression? Thus, indicators cannot exist without a specific goal in mind. They must be problem-driven; otherwise they are useless [10.1]. They have to address specific questions such as those presented in Sect. 10.2. In this way, indicators enable us to gauge important driving forces in science—for example, how scientific progress is related to specific cognitive (e. g., open questions in science) as well as socioeconomic aspects (e. g., opportunities to apply research results). Indicators have to describe the recent past in such a way that they can inform us about the near future.

The above suggests a fundamental role of indicators: their ability to test aspects of theories and models of scientific development and its interaction with society. In this sense, indicators are not only performance assessment and mapping tools for science policymakers and research managers, but also instruments in the study of science. *Price* [10.120] strikingly described the mission of the indicator-maker: find the simplest pattern in the data at hand, and then look for the more complex patterns that modify the first. What should be constructed from the data is not a number but a pattern, a cluster of points on a map, a peak on a graph, a correlation of significant elements on a matrix, a qualitative similarity between two histograms. If these patterns are found, the next step is to suggest models that produce such patterns and to test these models with further data. A numerical indicator or an indicative pattern, standing alone, has little significance. The indicators must give perspective: the change in an indicator with time, different rates of change in two different indicators, and numerical quantities replaced by geometrical or topological objects or relations [10.121]. In principle, bibliometric indicators can be seen as vectors in a three-dimensional space. The first dimension relates to performers: individuals, research groups, universities, countries, or combinations of these such as all universities in the EU countries. The second dimension relates to aspects: output, impact, collaboration, or combinations of these such as output and impact in international collaboration. The third dimension relates to subjects: research themes, journals, fields, broader disciplines, the whole of science. This performer-aspect-subject space is helpful in understanding relations between bibliometric indicators. And of course, as in the real world, the fourth dimension relates to time.

We start simply but will be confronted soon with the complications associated with creating indicators. The basic indicators, number of publications and citations, are illustrated by Fig. 10.3. At first sight it might appear to be just counting numbers. But the

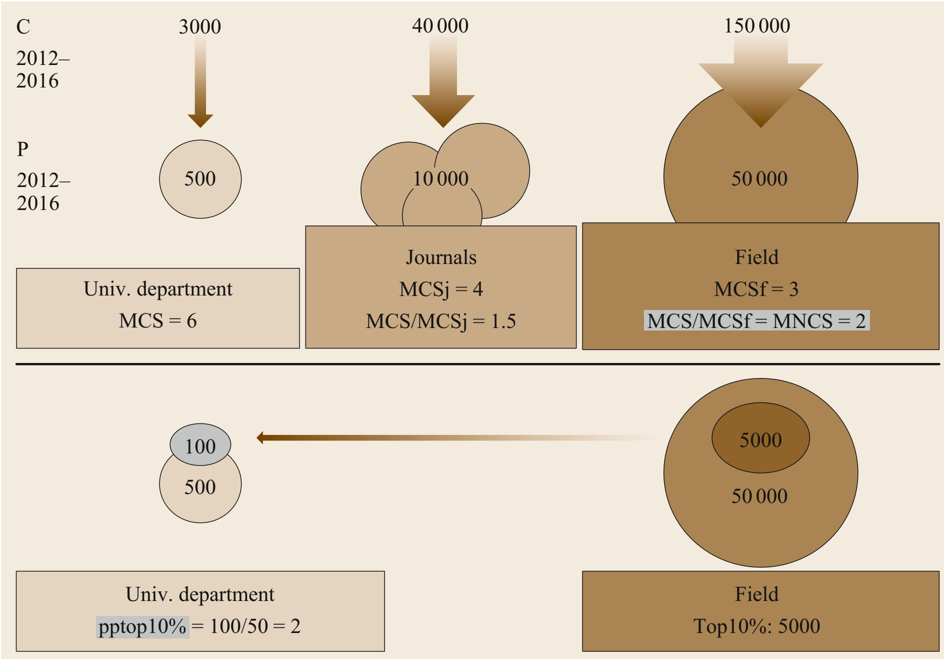

Fig. 10.3 Basic and normalized bibliometric indicators. The *upper part* of the figure shows the indicators based on averages, the *lower part* indicators based on the citation distribution function. See Schemes 10.3 and 10.4 for further explanation

reliable determination of even these two most basic indicators is far from trivial. Verification is crucial in order to remove errors and to detect incompleteness of addresses of universities, departments, and groups, and to ensure correct assignment of publications to research groups and completeness of publication sets. *Standardized procedures* for carrying out the analysis as conscientiously as possible are absolutely crucial. These procedures must be thoroughly discussed beforehand with the institutes concerned. This approach has been a long-standing common practice at CWTS [10.1, 122, 123]. For its data analysis and the calculation of bibliometric indicators, CWTS uses a dedicated bibliometric database which is an improved and enriched SQL-based version of the WoS database (*SQL*, Structured Query Language, is a standardized language used in programming and designed for managing data stored in a relational database management system). It is important to stress that a bibliometric database must have an open, highly interoperable structure [10.124].

Most readers, I am sure, are familiar with the two types of indicators that can be distinguished: indicators based on *averages* and indicators based on the *citation distribution* within fields. The latter approach is important, because the distribution of citations over publications is skewed [10.54, 125]. The indicators are explained in more detail with an example in Schemes 10.3 and 10.4. The normalization procedure is particularly crucial [10.126]. Moreover, research groups publish in more than one journal, and they are active in more than one field. Therefore, weighted average values have to be calculated, the weights being determined by the total number of publications published by the institute or department in each journal or field.

Scheme 10.3 Indicators Based on Averages

We showed in Fig. 10.3 a university department (or institute, research program, university) that has 500 publications in the recent 5-year period 2012–2016 ($P = 500$). This is the research output defined as the number of articles of the department in the given period as far as coverage by the WoS (or Scopus). We consider as articles the following publication types: normal articles (including proceedings papers published in journals), letters, notes, and reviews (but not meeting abstracts, obituaries, corrections, editorials, etc.). Within the same period, these 500 publications are cited 3000 times ($C = 3000$). This is the total impact defined as the number of publications that cite in the given period the research output of the department.

The average number of citations per publication MCS (mean citation score) $= 6$. This is the size-normalized citation impact of the department. It is important to be clear as to how publications and citations are counted: the counting procedure is directly related to the definition of the *citation window*. We discuss the counting procedure in Schemes 10.5. For field-specific normalization purposes, the citation impact of a department is compared with similar measures for:

1. *All journals used for publication by the department* (in the example in Fig. 10.3, these journals cover in total 10 000 publications that are cited 40 000 times): the journal impact MCSj (mean citation score of the journals based on a weighted average, measured over the same 5-year period and taking article type into account) in this example MCSj = 4.
2. *All journals in all fields in which the department is active* (in total 50 000 publications that are cited 150 000 times): the field average MCSf (mean citation score of all journals in all fields based on a weighted average, again measured over the same 5-year period and taking article type into account). In this example, MCSf = 3.

We observe the following. The department performs better than both the journal and the field average, MCS/MCSj = 1.5 and MCS/MCSf = 2.0, respectively. The latter indicator, the average number of citations of the publications normalized for field differences and publication year, is for the sake of brevity written as MNCS. We also see that the journals chosen by the department for publications are the journals with an above-average impact in the fields: MCSj/MCSf = 1.3. We call this indicator the mean normalized journal score, for the sake of brevity written as MNJS.

The above indicators are a simple representation of the normalization procedure. In reality, this normalization procedure is somewhat more complicated [10.127–129]. We confine ourselves to remarking that normalization of the number of citations is in principle a comparison of the *real number* of citations with an *expected number* of citations based on, for instance, the average number of citation of all publications published in the same journal or field, in the same year, and with the same document type.

For many years, the MNCS and its predecessor [10.127–129] have commonly been regarded as the *crown indicator*, because this indicator directly measures the extent to which a research group, department, institute, research program, or university performs significantly above the international level of their own field(s). From long-standing experience, we know that at the department level, an MNCS value above 2.0 indicates a very strong department, and above 3.0 the department can be generally considered to be excellent and comparable to the top departments in the same field at the best US universities. Thus, if the threshold value for the MNCS indicator is set at 3.0, excellent groups can be identified with high probability. Because the above indicators, and particularly the MNCS, are based on averages, they are sensitive to outliers. This less attractive property may lead to the *Göttingen effect* discussed in Sect. 10.3.

Scheme 10.4 Indicators Based on the Citation Distribution within Fields

Again we look at Fig. 10.3, *lower part*. The indicator ppttop10% is the proportion of the publications of a department (or institute, program, university) that, compared with other publications in the same field and in the same year, belong to the top 10% most frequently cited. In the example, the field has 50 000 publications in the given time period (2012–2016), of which by definition 5000 belong to the top 10% of the citation distribution. Say 100 of these 5000 are publications of the department which has a total of 500 publications. Thus, the statistical *expectation value* for the number of top-10% publications is 50, but the department has twice that number, so the pptop10% for this department is 2.

Given the earlier-mentioned skewed distribution of citations over publications, we regard the pptop10% indicator as the most appropriate bibliometric impact measure. Generally, the correlation between the average-based MNCS and the distribution-based pptop10% is high, particularly at higher aggregation levels such as larger research institutes and universities [10.66, Fig.2]. This distribution-based indicator is insensitive to outliers (we again refer to the discussion of the Göttingen effect). With a statistical technique known as bootstrapping, 95%-stability intervals can be calculated. A stability interval indicates a range of values of an indicator that are likely to be observed when the underlying set of publications changes to a specific extent. For an example of the stability intervals of the pptop10% indicator, we refer to the methodology section of the Leiden Ranking [10.67]. Of course, the top 10% is a rather arbitrary choice. But, at least at the level of universities, pptop5% or pptop20% give very similar results as pptop10%. Thus the top threshold is not that important in this range; for empirical results we refer to [10.66].

Scientific fields differ substantially in citation practices: differences in average number of references, in average percentage of references to recent publications and of references to other fields, in the coverage of publications by a database such as WoS or Scopus, and in the growth rate of a field. These differences can be very large. For instance, the average number of references (i. e., citations given) in biochemistry & molecular biology is about an order of magnitude larger than that in mathematics. In other words, there are large differences in citation density between fields. But even *within* fields, citation density may vary considerably [10.130], as we will see in Sect. 10.4. Therefore, inevitably, in normalization procedures for citation-based indicators, such differences have to be taken into account for meaningful comparisons of citation impact between fields and within a field. In our example, we discussed how the MNCS indicator and the pptop10% indicator correct for differences in citation practices between scientific fields based on the WoS field journal-based classification system. As illustrated in Fig. 10.3, each publication belongs to one or more fields, and the citation impact of a publication is calculated relative to the other publications in the same field(s). The accuracy of journal-based classification of fields is an issue of continuous discussion [10.131], particularly the extent to which the classification system allows for overlap of categories. We note that indicators such as MNCS and pptop% will have different values for different field definitions (for instance, the journal-based WoS categories versus the publication-based micro-level fields), because the calculated normalization depends on the field definition.

Because the pptop10% indicator is not sensitive to outliers, it is more stable than the MNCS indicator. In that sense, the pptop10% indicator has taken over the role of crown indicator. With an advanced bibliometric data system and proper algorithms, it is no problem to identify for instance the top-1% publications. Often the idea is that these very highly cited papers mark new developments, scientific breakthroughs. But be careful. A top-1% publication is not necessarily a breakthrough or highly innovative paper. Also, in science, there are hypes and trends, and a very highly cited paper could be a paper that fits well in a specific trend which may be short-lasting. Furthermore, papers in which extended reviews or important research methods and algorithms are presented can be very highly cited. Such papers, notwithstanding their importance, are more mainstream and not necessarily innovative.

In another, recently developed approach called *source normalization* (SNIP: source normalized impact per paper, also called *citing side normalization*), the normalization procedure is applied by analyzing the referencing behavior of citing publications. Thus a specific publication, or set of publications, is, as it were, compared with its own environment, namely the references of all papers citing the specific publications, instead of comparison with the publications across the entire field. In this way, SNIP corrects for differences in citation practices between scientific fields [10.132–134]. An extensive discussion of the SNIP approach and its variants is given in [10.135].

A recent review of the literature on citation-impact indicators is given in [10.136]. The above-discussed impact indicators have been regularly criticized, particularly in terms of the relation between these indicators and input, i. e., resources such as number of staff, experience of staff, or available funding. The opposition to the MNCS indicator, particularly its size-independent character, recently took the form of a crusade [10.137, 138], and this provoked many counterreactions [10.139–146]. In main lines, the outcome of this debate is that input normalization is very tricky, because the assessment of, for instance, time spent on research cannot be measured accurately and is easy to manipulate. Furthermore, in practice, the MNCS works quite well; its calculation is relatively simple, transparent and straightforward. This is an important user value, and in this respect there are really no better alternatives. Moreover, in any research evaluation procedure, not just one but a set of indicators must be used (including the pptop10%, see our real-life example in Sect. 10.3). This provides a broader view of the performance of a research group or institute under evaluation [10.140]. Curiously, this debate ignores the extensive work regarding the effects of size-independent indicators on size-dependent indicators [10.147, 148].

Counting and Weighting Procedures

We already remarked that nothing seems to be simpler than counting. But the precise way in which publications and citations are counted is a crucial part of the construction of bibliometric indicators. In Scheme 10.5, we present a practical approach to publication and citation counting, taking citation window length and evaluation period length into account.

Scheme 10.5 Example of a practical approach to publication and citation counting taking citation window length and evaluation period length into account

There is ample empirical evidence that in the natural and life sciences, the peak in the number of citations occurs on average in the third or fourth year after publication. A 4-year period is therefore appropriate as a *citation window* for impact assessment. If longer-term impact is expected to be important—which is often the case for engineering, social sciences, and humanities—the time period of the citation window and the time blocks used in the trend analysis need to be broadened. Note that the length of the citation window is not the same as the length of a total evaluation period (which can be short or long).

How can the length of the citation window be combined with the total length of the evaluation period while including the most recent citation year?

For a trend analysis, the *roof-tile approach* is often used: rolling and partially overlapping 4-year periods (blocks) in order to smooth out insignificant annual fluctuations. For instance, for the 10-year evaluation period 2007–2016, 2007–2010 is the first 4-year block (roof tile), followed by 2008–2011, and the last block is 2013–2016. The counting procedure is as follows. We start with the first block 2007–2010. For the 2007 papers, citations are counted during 2007–2010, for 2008 papers citations during 2008–2010, for 2009 papers citations during 2009–2010, and for 2010 papers the citations only in 2010. Then, in the next block everything shifts 1 year, so now for the 2010 papers citations will be counted in 2010 and 2011. Finally, in the last block 2013–2016, citations to the 2013 papers will be counted during 2013–2016, for the 2014 papers during 2014–2016, for the 2015 papers during 2015–2016, and for the 2016 papers during 2016.

We also note that the importance of a publication does not necessarily appear immediately, even to peers, and that specification of quality may take considerable time. Therefore, it is important to make assessments with shorter as well as longer time windows. Extreme and relatively rare cases of delayed recognition are sleeping beauties, mentioned earlier (see also Sect. 10.3).

As we discussed above, a clearly described publication- and citation-counting procedure is a crucial and absolutely necessary technical element in bibliometric analysis. Is this the end of our counting story? Certainly not. We are now faced with the more fundamental question of whether publications and citations should be counted with integer 1. This is the problem of *full* versus *fractional* counting, which is in fact a form of weighting. Indicators can be calculated using either a full counting method or a fractional counting method. The full counting method gives equal weight (with value 1) to all publications of a specific entity such as a group, department, institute, or university, regardless of collaboration. The same goes for the citations received by these publications. The fractional counting method, however, gives less weight to collaborative publications than to non-collaborative ones, simply because the publications (and their citations) are divided over the collaborating institutes. The counting modality influences normalization; for discussions on the relation between fractional counting and field normalization, we refer to [10.133, 149, 150]. The fractional counting method leads to a more proper field normalization of impact indicators [10.151, 152]. We emphasize that in an advanced bibliometric system equipped with the proper algorithms, it is not a problem to calculate indicators with both full and factional counting. Because of the better normalization properties, fractional counting is regarded as the preferred method in the Leiden Ranking, but both modalities are available in this ranking [10.66]. The advantage in having both is that it provides a good idea of the robustness of the outcomes. At higher aggregation levels such as universities, the correlation between the ranking based on full counting and that based on fractional counting is high [10.66].

Indicators of Research Collaboration

It is normal bibliometric practice to calculate a set of indicators of *scientific collaboration* [10.66, 67]. The most general one is P(collab) and pp(collab), the number and proportion, respectively, of inter-institutional collaborative publications—for example, the proportion of the publications of a university that have been co-authored with one or more other organizations. But collaboration has many aspects. For instance, we can distinguish collaboration at a national or international level, between universities and the business sector, and collaboration at smaller or larger distance. Therefore, next to the above general indicator, we can extend the set of collaboration indicators with a number of specific collaboration indicators. First, international collaboration: P(intcollab) and pp(intcollab) are the number and proportion of international collaborative publications—for example, the proportion of the publications of a university that have been co-authored by two or more countries. Second, collaboration with the business sector: P(UIcollab) and pp(UIcollab) give the number and proportion of collaborative publications with industry, such as the proportion of the publications of a university or within a research program that have been co-authored with one or more industrial partners.

Although it has been demonstrated many times that international collaborations generally produce more highly cited science than national collaborations, the physical distance between collaborating research groups remains an interesting variable. Recent work showed that physical proximity of collaborators positively influences the scientific impact of their publications [10.153, 154]. As a first step in taking collaboration distance into account in performance studies, distance indicators can be calculated based on the largest geographical distance between two addresses mentioned in each of the publications—for instance, P(<100 km) and pp(<100 km), the number and proportion of relatively short-distance collaborative publications; and P(>5000 km) and pp(>5000 km), the number and proportion of long-distance collaborative publications. Using the Leiden Ranking menu [10.66], one immediately sees that much of the Australian international collaboration involves long distances. Collaboration indicators are always calculated using the full counting method [10.67]. There is a vast amount of literature on the many aspects of scientific collaboration. An overview is given in [10.155]; for recent work on university-industry collaboration, we refer to [10.156].

Indicators of the Growth of Science

We conclude Sect. 10.2 with a small excursion outside the world of research performance. Measuring science also entails the *measurement of properties of science as a whole* or of its main fields. Examples are scientific development in terms of growth, aging of literature, statistical properties of important distribution functions, size distribution of clustered publications or journals, and so on. Section 10.4 of this chapter discusses the mapping of science and therefore deals with several such macro issues. Here we confine ourselves to the first two topics mentioned: growth of science and aging of literature. Researchers prefer to cite the more recent work. Thus, analyzing the number of references as a function of their age, i. e., as a function of the publication year of the cited publication, enables us to measure the aging of scientific literature and the differences in aging between the disciplines. However, in earlier times, there were much fewer documents published than in recent times. Thus, the time-dependent distribution of references will always be a specific combination of aging and growth of the scientific literature. How to disentangle these two independent phenomena? Empirical work shows that a typical aging process is particularly active in an exponential fashion for a period of up to about 10 years back from the publication year of the citing publications. For earlier years, it appears that this aging process is much less strong, so that either aging is still present but with a much slower exponent, or, in a first approximation, there is no longer any aging. In the latter case, the number of references will be approximately proportional to the number of papers available at that time, and provides a measure for the growth of the science [10.157].

10.3 Practical Application of Research Performance Indicators

It is also not unreasonable to expect that in citation-based performance analysis, pitfalls and sources of error will always be with us. In the *Leiden Manifesto* [10.158], principles to guide the use of research metrics, in particular bibliometrics, are formulated. Most of the guidelines were already discussed some 20 years ago [10.159, 160], but the recent increase in a rather uncontrolled use of bibliometric indicators forced the bibliometric community to formulate, loud and clear, the principles of proper use of bibliometric methods. I think we have to see whether this will work. Very recently, an experienced member of EU evaluation panels remarked

> You cannot imagine the extent of less good practices, which, however, seem to have become very popular everywhere (such as the use of h-index or impact factors in connection with individual researchers).

10.3.1 Methodological and Technical Issues in Evaluation Studies

Methodological and technical issues must first be recognized, after which, where possible, an adequate solution to the problem must be found. Here we present a list of ten important issues that must be taken into account in every bibliometric analysis:

1. *Applicability of bibliometric methods* in the different scientific disciplines, particularly in engineering, social sciences, and humanities. This applicability is directly related to the coverage of publications by the WoS or Scopus database (coverage in relation to the list of publications provided, for instance, in annual research reports). If this coverage is too low—for example, less than 50%—bibliometric analysis based on citations will only give a partial picture of the research performance [10.91–96]. Another increasingly important problem is the need to correct the bibliometric data for *retracted papers* [10.161–163].
2. *Influence of language*, particularly German and French, on the assessment of research performance and on the ranking of universities [10.164, 165]. Non-English publications count as output if they are covered by WoS or Scopus, but their impact is usually very low. This causes considerable dilution of the average impact. In order to avoid this problem, one has to conduct the analysis with English publications only. See also the discussion on core publications in [10.67].
3. *Length of citation windows*: important publications may be cited after many years. This is the phenomenon of delayed recognition [10.98, 99] or, in extreme cases, *sleeping beauties* [10.166–177]. Generally, evaluation periods are restricted to rel-

atively short periods in order to assess research performance as recent as possible, for instance the last 5 years. Although the probability is not high, it is possible that scientific work finds recognition long after publication, for instance after 8 years or more. Therefore, where possible, one should also use longer citation windows.

4. *Statistical properties* of bibliometric indicators, for example, their skewness and scaling behavior [10.147, 148, 178]. We already discussed the importance of taking into account the skewed distribution of citations over publications for the construction of indicators. The scientific productivity of researchers will also often show a skewed distribution in larger institutions. This is relevant when using input indicators based on averages.
5. *Concerns about the journal impact factor* [10.60–62, 179] *and h-index* [10.72, 180–182] for accurate research performance assessment. These easily available, low-cost indicators are often used to perform a quick, simple, and cheap bibliometric research evaluation. They may give first impressions of performance, but cannot replace advanced bibliometric methods.
6. *Relation between peer review* judgment and bibliometric findings [10.41, 147, 180, 183–186]. This is an important issue in research performance assessment. Neither peer review nor bibliometric analysis is free from shortcomings. Furthermore, bibliometric findings and outcomes of peer review are not independent variables in the quality judgment space: peers use bibliometric elements in their judgment; for instance, they generally attach great value to publications in top journals.
7. *Open access*, *webometrics* and *altmetrics* [10.187–205]. The ever-increasing accessibility and availability of data on research activities has created new forms of research metrics, which quickly become important for the analysis of different aspects of research performance. But this type of metrics is also not problem-free.
8. *Definition and delimitation* of fields as well as *assignment of publications* to these fields or to other specific entities such as research groups, institutes, or universities. The problem of accurate assignment of publications is often underestimated. It is, for instance, far from trivial to correctly collect the publications of a university [10.67].
9. *Large differences in citation density between and even within major fields* demand the use of advanced normalization procedures [10.130]. We again stress the crucial importance of proper normalization in the construction of indicators, as we did in the preceding section [10.126]. It is important to realize that field definitions determine the outcomes of the normalization procedure and, with that, the values of indicators.
10. *Rankings of universities*, though controversial, enjoy a great popularity. They are probably influential in guiding the choice of young scientists and research students [10.63–71]. For interpretation of ranking results, it is crucial to know all relevant properties and, particularly, the methodological and technical questions of these ranking properties.

In the next sections we discuss the following issues in greater detail: concerns about journal impact factors and h-index for research performance assessment; assignment of publications to research groups, institutes, and universities; relation between peer review judgment and bibliometric findings; role of open access, webometrics, and altmetrics; and ranking of universities. We conclude this section with a discussion on arguments against bibliometric analysis in general.

Journal Impact Factor

The definition of the *journal impact factor* (JIF) can be described as follows. We take as an example the year 2016. The JIF of 2016 for a specific journal is the total number of citations (given by articles in all possible journals covered in the WoS) received in 2016 by the publications of 2014 and 2015 in the journal, divided by the total number of these publications of 2014 and 2015.

Simplistic or *easy-to-go* approaches in the use of bibliometric data are popular in many research evaluation practices, particularly the use of the abovementioned JIF. In this *poor man's citation analysis*, publications of a research group are weighted with the impact factors of the journals in which the publications have appeared. In this way, a total score is calculated and thus a ranking of groups can be established. This ranking can then be used as a basis for financing. Bibliometric researchers have for more than 20 years explicitly warned against the use of journal impact factors for research evaluation purposes [10.60–62]. Weighting publications with impact factors is usually a poor estimate of the actual impact of (a group of) publications, because of (1) the *skewed distribution of citations* over individual publications in a journal, and (2) the fact that impact factors are strongly influenced by *review papers*, which are often more highly cited than normal publications. This latter point is also a general issue: in normalization procedures, article type has to be taken into account. The use of journal impact factors has an equalizing effect: two groups A and B publishing in the same journals have the same impact, as their publications are weighted with the same impact factors, although the publications of group A are much more frequently cited than those of group B. Moreover, journal impact factors can be heavily affected and even manipulated by journal self-citation [10.206].

We note that the skewed distribution of citations over individual publications also applies not only in journals, but for any set of publications—for instance, in research groups. This is the reason that citation-distribution-based impact indicators such as the pp-top10% are to be preferred over the citation-average-based indicators such as the MNCS. On the other hand, already at a quite low aggregation level, such as a research group, the correlation between the average citation score of the publications of the group (actual impact) and the average citation score of all articles in all journals used by the research group (journal-based proxy of impact) is high [10.147]. The concerns about the JIF are related to the use of this indicator as a measure of the impact of individual publications within a journal. In spite of the availability of reliable bibliometric methods, journal impact factors are still commonly used in research evaluation practices. Fortunately, researchers and journal editors are becoming increasingly aware of this problem, as evidenced in the *San Francisco Declaration on Research Assessment* (DORA) [10.207]. The bibliometric community made their position forcefully clear in the earlier-mentioned *Leiden Manifesto* [10.158].

Journal impact indicators are certainly not useless. They should be used for the goal for which they were developed: a measure of journal prestige. Nevertheless, recent research [10.208] takes a provocative stance and shows that the use of the JIF for assessing individual articles need not necessarily be wrong. Other indicators of journal performance have been developed, including the *cited-side-normalized* indicator MNJS discussed in Sect. 10.2. This journal indicator also correlates significantly at a higher level—e. g., all publications of a research group—with the actual impact, i. e., the average citation score of the publications of the group (see [10.147]; here, in fact, the predecessor of the MNJS indicator was used). Furthermore, as discussed earlier, *citing-side-normalized* indicators have been developed, such as the SNIP indicator and the audience indicator [10.209, 210]. Recently, CWTS developed a free-access SNIP journal indicator application tool based on Scopus data for about 20 000 journals [10.211]. Scimago developed its Scopus-based journal indicator [10.212, 213], and Elsevier launched the Scopus-based Elsevier CiteScore, which is quite similar to the JIF, but it takes all document types into account in a more consistent manner [10.214]. Data quality determines the quality of the indicators. Recently, authors have discussed a typology of errors and inaccuracies in the Scopus database [10.215, 216].

Shortly after the launch of the JIF [10.22], a recursive journal performance indicator, the influence weight indicator, was introduced [10.24]. Twenty years later, this idea returned in the form of the PageRank algorithm for the Google search engine [10.217]. This inspired the construction of new recursive indicators such as the Eigenfactor [10.218]. For a comparison of these indicators, we refer to [10.210].

The h-index

A remarkable event in the history of bibliometrics is the introduction of the *Hirsch-* or *h-index* named after its creator *Jorge Hirsch* [10.72]. This new indicator attracted enormous attention, particularly for its charmingly simple structure: an author has an h-index with value n if n of his/her papers have at least n citations each and the other papers have at most n citations each. A torrent of publications describing numerous variants of the h-index followed [10.115, 181]. The attractiveness of this measure lies in the ease with which it can be determined: by simply ranking in the WoS or Scopus the publications of a researcher by the number of citations received, one will find a publication with ranking number equal to the number of citations it received. For instance, for the author of this chapter, his publication with ranking number 42 in the WoS has 44 citations, whereas the publication with ranking number 43 has 42 citations, thus fewer citations than the ranking number. It follows that the h-index of the author is 42 (December 1, 2018).

Although the h-index gives a first impression of a researcher's impact, we advise against its use as a basis for comparison of researchers, for the following reasons. First, the h-index is a typical *lifetime indicator*, strongly dependent on the total number of a researcher's publications. This means that the h-index will most probably put younger researchers at a disadvantage. Second, as we already noted, there are large differences in citation density between and even within research fields. In medical fields, the clinical subfields often have significantly lower citation density than the basic science subfields [10.130]. Let us give a practical example. For a new chair in neurology, a university must choose between two candidates. One is more clinically oriented, the other more basic. If the choice is based on the h-index, the more clinically oriented candidate will be at a disadvantage, because his/her h-index will most likely be lower than the h-index of the other candidate, given the large difference in citation density between the clinical and basic fields of neurology. Third, *Waltman* and *van Eck* have shown that the h-index is mathematically inconsistent, and illustrate this with a simple example [10.182]. Fourth, a simple determination of the h-index as described above will include self-citations and is therefore open to manipulation. For a comparison of the h-index with bibliometric indicators as discussed in Sect. 10.2 in the performance assessment of a large set of research groups, we refer to [10.180]. An interesting experiment is the development of agent-based models to describe the process of generating publications and citations including a prediction of the h-index [10.219].

Assignment of Publications

In evaluation and monitoring procedures, it is crucially important to know which results—for instance, publications—have to be assigned to a specific research entity (group, institute, university, program, etc.). This is not always that easy. The problem is largely related to a proper definition and delimitation of the research entity. We take universities as an example. Even at this high aggregation level, the assignment of publications is not a straightforward task. A university may be referred to using many different (often non-English) name variants and abbreviations. In addition, the definition and delimitation of universities as separate entities is not always obvious. International differences in the organization of academic systems also poses difficulties in terms of identifying the proper unit of analysis. In the following, we draw our discussion largely from the text in the methodology section of the *Leiden Ranking 2016* [10.67].

Instead of applying formal criteria (if possible at all), it is more effective to follow common practice based on the way the institutions are perceived locally. For instance, the University of Cambridge is to be considered as one entity, but in the case of the University of London, one must distinguish between the constituent colleges. For the United States, university systems (e. g., University of California) have been split into separate autonomous universities. The higher education sector in France, as in many other countries, has gone through many reorganizations in recent years. Many French institutions of higher learning have been grouped together. However, for comparison of university performance, one must distinguish between the different constituent institutions, except in the case of full mergers. Furthermore, universities may be split into various entities, for instance the Austrian universities where medical faculties became separate universities in 2004; or the reverse, such as the University of Lisbon merged in 2013 with the Technical University of Lisbon.

A major problem relates to affiliated institutions, i. e., research institutes and, in particular, hospitals associated with universities. Among academic systems, wide variation exists in the types of relations maintained by universities with these affiliated institutions. Typically, these relationships are shaped by local regulations and practices, and affect the comparability of universities on a global scale. As there is no easy solution to this issue, it is important that a transparent methodology is used in the treatment of affiliated institutions. Particularly in the case of university hospitals, the correct or incorrect assignment of publications to a university may have significant consequences, given the often large output of medical research. Specific name-based assignment algorithms are necessary, because researchers employed by a university but working at affiliated institutions may not always mention their university in publications. Universities have become increasingly aware of this problem, which affects their visibility in research publications, and they actively exert pressure on researchers to mention their affiliation with the university in publications. CWTS developed a practical approach in which three different types of affiliated institutions are distinguished; we refer to [10.67] for details.

Peer Review and Bibliometric Findings

One of the first questions that comes to mind when speaking about research evaluation is, how do bibliometric findings relate to peer review judgments? On the basis of ample experience [10.185], we find that there is generally a significant correlation between the opinions of peers and the results of indicators [10.122]. This is even the case for young scientists: studies on PhD graduations show that *cum laude* graduates have a significantly higher citation impact than graduates without the honor degree [10.83, 84]. A study on peer review and bibliometrics in the field of condensed-matter physics [10.183] showed that the number of publications correlates only weakly with peer review judgments, whereas the field-normalized citation indicator shows a considerably stronger correlation. This would indicate, at least for the field studied, the absence of a *publish-or-perish* mentality. The often-heard presumption that both bibliometric analysis and peer review would undervalue interdisciplinary research finds no empirical support, at least not in physics [10.184].

Correlations are statistical measures based on large numbers. It is very well possible that peer review judgment and indicators may disagree substantially in specific cases. Based on long-standing experience, we estimate that, in the case of research groups, this happens in about 25–30% of cases. In half of these, peers have a positive judgment and the indicators show low performance, and in the other half the opposite is true. These are of course interesting cases to determine what is going on. Did the bibliometric analysis not grasp the essence of a group's performance? Are the peers well informed? Both bibliometric analysis and peer review have their shortcomings. Some authors even state that peer review suppresses scientific innovation [10.85]. Other authors have claimed that peer review reinforces nepotism and sexism, and that it puts women at a disadvantage [10.86]. Further research, however, does not support these assertions [10.87, 88]. For a study on the selection of excellent research through peer review committees and a comparison with bibliometric indicators, we refer to [10.186]. A specific problem in the comparison of peer judgments and bibliometric results is that there is scarcely any information about the dissensus within a peer committee. Thus, the statistical uncertainty of the peer judgment is largely uncharted territory.

In our opinion, the combination of peer review and bibliometric analysis is the best strategy for evaluation and monitoring procedures, at least in those research fields where bibliometric analysis can be applied. Peer review must play the central role; bibliometric analysis provides supporting instruments such as a consistent set of indicators and maps. This combination enables a reliable, objective, and transparent assessment of research performance [10.123]. Bibliometric analysis should not be used as a standalone tool. This is a decades-old statement, currently revitalized as "the humility dimension in responsible metrics" in the apologetic jargon of bibliometric circles. Nevertheless, advanced bibliometric analysis is important, because the indicators and maps provide detailed information—of which peers may not always be aware—on crucial aspects of research performance and scientific communication such as international impact, collaboration patterns, and position on the map of science. There is another good reason for using bibliometric analysis: it also stimulates hard questions that might be avoided by peers. After a pilot exercise in 2009, the Higher Education Funding Council for England (HEFCE) concluded that "citation information was insufficiently robust to be used formulaically or as a primary indicator of quality" [10.220]. No serious practitioner in advanced bibliometric analysis, however, would ever assert that this use of citation data could be the case.

The costs of an advanced bibliometric analysis are generally less that the costs of peer review procedures. Finding an appropriate team of experts in terms of reputation, experience, and size is time-consuming, and costs vary depending on the number of experts involved. Automation of data collection and data analysis reduces the costs for bibliometric analysis considerably, particularly in the case of follow-up monitoring and evaluation. Once an extensive analysis of a research group, institute, or program has been carried out, the basic data can be stored in an evaluation data system, and updating can be realized at relatively low costs. In a next phase of the evaluation procedure, the bibliometric findings and the peer judgments have to be compared, and a discussion is necessary on the differences in findings between the two approaches. In most cases, research group publications have multiple authorship. Therefore, another point of discussion, which cannot be solved bibliometrically, is the role of the individual researchers. Again, the message remains: never use bibliometric analysis, regardless of how advanced it may be, as a standalone tool for research evaluation.

Open Access, Webometrics, Altmetrics

Open access means unrestricted online access to peer-reviewed (not always), published research, primarily for journal articles, but also for a growing number of theses, book chapters, and monographs. Open access can be provided by authors by self-archiving their journal articles (not necessarily an open-access journal) in an open-access repository or in other open-access websites, for instance of their own university (*green* open access), or by publishing in an open-access journal (*gold* open access) which provides direct open access, in most cases on the publisher's website. A renowned open-access repository for physics and related fields is the preprint database *arXiv*. An example of an influential open-access journal is *PLoS ONE*. In the case of non-open-access journals, the production costs associated with publishing accepted articles lie entirely with the subscribers; in the case of open-access journals, with the authors. Open access makes scientific results more accessible, while maintaining the intellectual rights of the authors. Steven Harnad is one of the most active promoters of open access. His website offers international, up-to-date information on all possible aspects of open access [10.187]. Citation data for the Web of Science and Scopus are not free: they are provided commercially by Clarivate Analytics (until 2016 by Thomson Reuters) and Elsevier, respectively. Therefore, in a sense, the free provision of citation data by Google Scholar can also be considered a form of open access. Google Scholar offers an opportunity to use this freely accessible web search engine for the evaluation of research, particularly in the social sciences and the humanities, because it covers significantly more literature sources than simply journal articles [10.73]. Meanwhile, the WoS and Scopus have increased the coverage of books. A new methodology for comparing Google Scholar and Scopus is discussed in [10.221]. Recently, the Dimensions database was launched. This freely accessible search tool links publications to citations, grants, funding agencies, and patents [10.188, 222].

An important issue is the extent to which open access influences bibliometric properties of research publications, particularly whether open access increases the number of citations to publications [10.189]. Generally, open access is considered as a means to effective early warning, a possibility to speed up citations to publications. It is not clear yet, however, whether open access has a longer-lasting effect on citations. There are also doubts whether open access is really good for science over the longer term [10.190]. Other authors argue that open access can provide new measures of research performance based on public availability of articles, their archival location, licenses, access costs, and supporting information [10.223].

Almost two decades ago, a new way of assessing research performance emerged: *webometrics* [10.191–193]. This method (also called cybermetrics) is based on an analysis of the many connections available via the Internet, for instance the number of web connections to a university from other institutions. With a similar analysis, the Cybermetrics Lab of the Spanish National Research Council (CSIC) developed a global webometrics ranking of universities [10.194, 224]. Obviously, research institutions can exert a strong influence on the number of connections to their websites. It remains to be seen to what extent webometrics provides a reliable assessment of research performance and how it influences bibliometric measures. Related to webometrics and open access are new developments in altmetrics, short for *alternative metrics* [10.195, 196]. Altmetrics focuses on the collection and analysis of data available through the Internet [10.197], primarily data on the use of publications [10.198], views of HTML versions, and downloading of PDFs [10.199], but also mentions of publications and other forms of visibility in social media [10.200] such as scholarly blogs [10.201], Twitter [10.202], and ResearchGate [10.225].

There is fast-growing interest in altmetrics. Publishers are increasingly providing altmetrics data on papers; for example, the open-access journal group *PLoS* is active in developing standardized methods for the collection, analysis, and use of altmetrics data [10.226]. Oxford University Press provides access to the number of online views for each article, the number of citations to the article, and the Altmetric score for each article [10.227]. With Mendeley, a reader-counts database, Elsevier is strongly involved in the development of altmetrics. This reflects the commercial interest in developing alternative measurements of scientific productivity and impact. We refer to the Elsevier quarterly magazine *Research Trends* [10.203] for an overview of the major trends in altmetrics written by leading researchers in this field. Also, the websites of additional players in the field, such as Altmetrics.org [10.228] and ImpactStory [10.229], are important for keeping up with the new developments. Recent research focuses in particular on the relation between altmetrics data and citation counts [10.204]. Of course, not all of these developments are quite so harmless. Inevitably, since data from social media are also used in altmetrics, scientific and public interest are mixed. It is critical to distinguish between these two aspects, because they concern different dimensions of research [10.205]. Furthermore, it is plausible that social-media-based altmetrics is sensitive to manipulation. Like citation data, altmetrics data—and particularly the reader counts data of Mendeley—have to be normalized because of differences between fields of science [10.230, 231].

In an effort to achieve greater structure and standardization in altmetrics research, the NISO (*National Information Standards Organization*, Baltimore, USA) initiated the Alternative Assessment Metrics Project in 2013. Important issues include the development of specific definitions for altmetrics, proper usage of the term *altmetrics*, identification of best practices for aggregating multiple data sources, and the development of a statement on the role of altmetrics in research evaluation. The latest initiatives can be found on the NISO website [10.232]. Data submitted by applicants for proposals, evaluation data, data on panel members, and data on grantees can also be considered as sources of altmetrics. These data enable the combination of advanced bibliometric indicators with proposal- and grant-related data. Data extracted from the proposals could also be of importance for the realization of an effective research information system. Grantees of a research council can provide further data, for instance, acknowledgments, career development (institutional mobility, interdisciplinary mobility, leadership, training capacities), and the use of their research in socioeconomic and technological areas. In this way, a broad data system for the assessment of research can be developed with which interesting patterns in funding, mobility, and career development could be identified.

Finally we note that altmetrics-like issues have long played a role in peer-review evaluation of research groups, such as in the use of annual research or self-evaluation reports. In such reports, many forms of scientific performance are mentioned: grants from research councils and charities, contract research, lectures in international meetings, lectures for a broader public, other forms of science popularization such as radio, TV and newspaper presentations, membership of professional and social organizations and committees, and editorial work, among others.

Ranking of Universities

Scientific research has always been an international enterprise. The growth of worldwide R&D activities and of the higher education sector in developed and developing countries over the past few decades has reinforced established academic institutions and created many new ones. At the same time, the number and intensity of student and researcher exchange programs, international collaborations, and working stays outside the own country has rapidly increased, propelled by the ever-growing global mobility. An important parallel development, also stimulated by the growth in the higher education sector, is the strong demand for accountability, evidence of quality, and *value for money*. These developments have led to increased competition for funding and for the best students and researchers among universities within nations and worldwide. Universities strive to achieve top position in their country, or even the world. This implies the existence of some kind of a league (national or international) to which one can be admitted only on the basis of performance. The higher the performance, the better chances a university has to become a member of an elite league and to reach a high-ranking position in this league, which reinforces the university's appeal for the talented people.

Several organizations produce annual rankings of universities on the basis of survey data, bibliometric data, or both. We already mentioned in Sect. 10.1 the Academic Ranking of World Universities (ARWU, Shanghai Ranking) [10.64], the Times Higher Education (THE) ranking [10.65], the Leiden Ranking [10.66, 67], the QS ranking (2010) [10.68], the Scimago ranking [10.69], and the U-Multirank [10.70]. University rankings, though controversial, enjoy great popularity. They have become unavoidable: whether we like it or not, they are now part of academic life and of science policy. They create a reality that cannot be ignored. They are likely quite influential in guiding educational choices among young scientists and research students, and also in research collaboration strategies among universities. As soon as the first results of whatever university ranking cast their shadow, the media are happy to pounce on it. Universities use the outcomes of rankings in their rivalry with other institutions, no matter the lack of transparency of the ranking method and the significant methodological issues involved in calculating reliable ranking indicators [10.66, 71]. And when a university has fallen, say, five places, which is statistically insignificant, the university board is in trouble. It would be no exaggeration to say that the academic world, the public, and the media nowadays are obsessed by rankings.

We briefly summarize a few important issues with university rankings. Some rankings, for instance THE and QS, combine their scores for teaching and research performance into one final score. We think that this is not desirable, because teaching and research are different tasks of universities. A combined score may not take into account the university's specific mission (focus on teaching, or on research). The ARWU/Shanghai and Leiden rankings focus specifically on research only. In the ARWU/Shanghai ranking, size-dependent (e. g., number of papers in *Nature*) and size-independent measures (particularly the use of size-dependent indicators per staff member) are combined. This deserves no methodological beauty prize. If indicators are not clearly field-normalized, universities with a focus on engineering or on social sciences and humanities will be disadvantaged. The comparison of ranking scores in a time series can be seriously affected if, meanwhile, the number of universities covered by the ranking is increased substantially. Any indicator, including a ranking score, is subject to statical uncertainty. Only the Leiden Ranking uses a well-defined uncertainty measure, the stability interval.

Most rankings use citation indicators based on averages. As we discussed in Sect. 10.2, average-based indicators are sensitive to outliers. There is generally a strong correlation between average-based indicators such as the MNCS and distribution-based indicators such as the pptop10%. But there are remarkable exceptions. A famous case is the earlier-mentioned *Göttingen effect*. In 2008, a paper published by a researcher of the University of Göttingen became extremely highly cited, many thousands of times a year, within a very short time (G.M. Sheldrick, A short history of SHELX, Acta Crystallographica A 64, 112–122, 2008; cited 67 693 times (WoS Core Collection), December 1, 2018). As a result, for several years after this publication, Göttingen achieved a very high position in the rankings. But with a distribution-based indicator, the ranking position of this university was much lower. For instance, in the Leiden Ranking 2011, Göttingen ranked second based on the MNCS indicator, while it was ranked 238th based on the pptop10% indicator. Without this single extremely highly cited paper, the average-based citation impact of Göttingen would have been only half of the value, and the rank would have been 219 instead of 2—so a difference of about 200 ranking positions because of just one publication. Of course, this is an exceptional case. But there are similar less dramatic cases, and the point we make is that with exactly the same data, the difference in normalization may affect the ranking of universities with tens of positions. For a detailed discussion of the Göttingen case, we refer to [10.66].

As mentioned earlier, *retraction of papers* is an increasingly important issue, particularly in the construction of rankings. Papers are retracted for scientific misconduct such as fraud, data fabrication, plagiarism [10.162], serious errors, and sloppiness. Intentional misconduct is the main reason for retraction in about 60% of cases [10.163]. This means that bibliometric databases used for research evaluation must be continuously cleaned in order to remove retracted papers as well as all citations received by the retracted papers. This is the case for the CWTS bibliometric database, used for the Leiden Ranking. Updates on new retractions and discussions on issues related to retractions are provided, for instance, by Retraction Watch (non-undisputed, see [10.161]) and by The Scientist [10.233]. The number of retracted papers is very small: of all papers published in 2009–2013 and covered by the WoS, about 0.05% were retracted. Retractions are observed more commonly in fields with strong international competition and rapid publication processes [10.163].

For a recent comparison of five ranking systems—ARWU, Leiden, THE, QS, and U-Multirank—we refer to [10.234]. New approaches to rankings and other methods for comparison of universities from a national and international perspective, along with factors that affect the reliability of rankings, are discussed in [10.235–237].

Objections to Bibliometric Analysis

Without doubt, the application of even the most advanced bibliometric method has its limitations, and this handbook chapter discusses many of these limitations in detail. But the headaches that bibliometric analysis has caused are far from over. Next to methodological and technical problems there is also a considerable undercurrent of opinions, fears, and prejudices against bibliometric analysis. Critics maintain that the mere use of bibliometric indicators in research evaluation will lead to perverse publication behavior among authors, particularly *gaming*. Gaming is not a clear concept. It may relate to the manipulation of the data on which bibliometric indicators are based (particularly number of publications and citations) to deliberately give an inaccurate impression of research quality (negative or harmful gaming). But it also relates to seeking strategies to improve the visibility of published work, with the possible consequence of increasing the measured impact (positive or beneficial gaming). Examples of the first kind are citing your own work more frequently, arranging citation cartels, and *salami slicing*. With respect to self-citations, in advanced bibliometric methods, author self-citations are excluded in the citation counts. As a result, increased author self-citation has no effect on the value of citation impact. Arranging a citation cartel? Active researchers, and certainly research groups, receive citations from hundreds of different authors and institutions. The distribution of citations among citing authors is very skewed, and the tail of the distribution is relatively large and contributes considerably to the total number of received citations. As one might have guessed, one would need citation cartel arrangements with many institutions in order to a create a substantial increase in citation impact. Practicing salami slicing, which is dividing your work into *the smallest publishable units*? Most likely this strategy will result in a lower value of the normalized citation impact. Nevertheless, harmful gaming exists, particularly journal impact factor manipulation, for instance, by excessive journal self-citation; for a recent overview we refer to [10.206] and to the website of the Committee for Publication Ethics (COPE) [10.238]. Bibliometric researchers recently demonstrated the vulnerability of Google Scholar's citation metric to gaming by placing fake papers with many citations to their own work on a webpage of their university [10.239].

An example of the second kind of gaming is trying to publish your work in higher-impact journals. Although journal impact correlates quite significantly with the actual citation impact at the level of a research group, a study of 150 chemistry research groups [10.147] showed that top-performing groups (both based on peer judgments and as measured with the crown indicator) were on average more successful in citation impact over the entire range of journal impact. In other words, they performed better in both the lower-impact and higher-impact journals. Quality is the decisive factor, not journal impact.

Perhaps not surprisingly, other objections to bibliometric analysis, based on little more than anecdotal evidence, relate to certain persisting opinions. For example, some say that the use of bibliometric indicators in research evaluation would favor researchers who work on fashionable topics and who avoid innovative and *risky research*. I do not know of any decent empirical evidence for this assertion. And there are also *negative citations*, i. e., a publication can be criticized, for instance, because of errors and consequently be well cited. Most probably, however, erroneous publications will not be cited but rather ignored, and in the case of serious errors, the paper will be retracted. Another belief is that bibliometric indicators would encourage the writing of reviews instead of original papers, because reviews are generally more frequently cited. In advanced bibliometrics, however, the article type is taken into account in the normalization of the citation impact calculations. Yet another argument is that bibliometric analysis would encourage cannibalization of old papers by refurbishing and republishing them. Perhaps this will happen every now and then, but it is very unlikely that a research group would have a high impact over a longer period of time just by cannibalizing its older work. Nevertheless, the use of bibliometric indicators in evaluation procedures may influence the publication strategy of researchers [10.240, 241], but certainly not always in a negative sense [10.242].

A more politically and socially sensitive objection against bibliometric indicators is that they would discriminate against young researchers, women, and minorities. Indicators such as the h-index undoubtedly favor, practically by definition, the older and experienced researchers, but advanced indicators such as the normalized citation impact do not have this disadvantage. However, the supposed discrimination problem is not in the construction of the indicators as such; it lies deeper—for instance, the work of women would receive fewer citations, in cases of equal quality, compared to the work of men [10.243].

A great deal of the skepticism about bibliometric methods, for instance in the Research Excellence Framework (REF) 2014 [10.244], relates to the application of bibliometric analysis to individual papers. This is because the REF 2014 was an article-based assessment, and not an assessment of research groups or departments. Also, the Italian VQR evaluation (Valutazione della Qualità della Ricerca—Evaluation of Research Quality) [10.245] was an article-based assessment. Approximately 1000 (REF) and 10 000 (VQR) experts had to judge the quality of around 100 000–200 000 papers. The mere size of such an amount of review work per expert may raise questions about the reliability of these qualitative assessments. We think that the application of advanced bibliometric methods is optimal when applied to groups, department, or institutes, and not at the level of individual papers. The main reason is that individual papers are mostly part of a coherent research oeuvre, and thus the assessment should be applied to the oeuvre as a whole and not to isolated papers. Also, if evaluation is applied to groups, peers will most probably take important contextual information into account, such as the viability of a group and the relevance of its research [10.122]. This information is completely absent in an article-based assessment. Furthermore, if longer timescales are used, the evaluation of the entire groups' oeuvres also significantly reduces the effects of any possible gaming.

Bibliometrics is not all sorrow and misery, but in some cases critics preach hellfire and damnation in quite hysteric words, predicting that bibliometric analysis may become the ultimate tombstone of science. Even worse, bibliometric researchers should be sent to "the darkest omnivoric black hole that is known in the entire universe, in order to liberate academia forever from this pestilence" [10.246, 247]. That at least one important publication is written on a tombstone may give some comfort to the cursed bibliometricians (Fig. 10.4).

10.3.2 Real-Life Example of Evaluation Studies

Hoping that we will get over our distress, we pursue in this section the most interesting side of bibliometric indicators: their application in a real-life research evaluation. As an example, we take the bibliometric portion of the extensive evaluation of the Institute of Veterinary Research of Utrecht University (IVR-UU), which also included peer review by an international committee. Reports on both the peer review findings and the bibliometric analysis can be found in [10.249]. As we mentioned earlier, CWTS already has for decades used fully standardized procedures discussed beforehand with client institutes in order to carry out bibliometric analysis as conscientiously as possible. In this sense, advanced bibliometric analysis is practically identical to what has recently been called *contextualized scientometric analysis*.

We show in Table 10.1 the main bibliometric indicators for the entire evaluation period (2001–2011) as well as a trend analysis. There is ample empirical evidence that in the natural and life sciences, basic as well as applied, the peak number of citations occurs on average in the third or fourth year after publication. Therefore, a 4-year period is appropriate for impact assessment. The indicators *P*, MCS, MNCS, MNJS, and pptop10% and the details of the trend analysis were discussed in Sect. 10.2.

It is possible that publications are not cited within a period of 4 years, but will be cited after a longer time, i. e., the earlier-discussed phenomenon of delayed recognition or, in extreme cases, sleeping beauties [10.98, 99, 166–177]. Contrary to popular belief, sleeping beauties do not concern mostly whimsical research; about half of them are related to applied research and may be sleeping technological inventions [10.169, 171]. Delayed recognition may dilute the impact measured in a 4-year period (because they are published but not cited in the given period). This effect, however, is generally not large at the level of research groups [10.250–252]. Nevertheless, it is important to assess research performance for a longer citation window as well, and that is why the indicators are also calculated for the entire evaluation period, as can be seen in Table 10.1 and subsequent tables. Note that all indicators are corrected for self-citations. With coverage, we indicate the fraction of publications presented by the institute in its evaluation protocol that are covered by the WoS and thus also in this bibliometric analysis. We observe that the coverage of IVR-UU is about 85%, so that one can be confident not to miss a substantial part of the institute's oeuvre in the analysis.

We see that IVR-UU performs very well above the international level (MNCS = 1.58 and pptop10% = 0.18 in the last period). With an MNCS value above 1.5, such as in our example, the institute can be considered scientifically strong. The proportion of highly cited (pptop10%) papers increases from 14% to 18%. The indicator MNJS shows that the impact of the journals used by IVR-UU for their publications is significantly higher than the average of the fields to which the journals belong. In other words, IVR-UU publishes in the higher-impact journals. We also observe the lower number of publications in the last period. This is because, at the time of the analysis, papers published in 2011 did not have a full year to be cited and were excluded in this analysis. This shows that a clear explanation of the bibliometric results is necessary; otherwise the user would think that there was a significant decrease in the number of publications.

Researchers of an institute publish in journals of different fields, often in many more fields than one would tend to think. Therefore, a next step in the analysis is to construct a research profile: the *breakdown* of the institute's output into research fields. For this breakdown we use the fields as defined in the WoS (*subject areas*), but other field definitions, such as publication-level-based, are possible. The advantage of using the WoS subject areas is that many researchers are familiar with these field definitions and that they make comparison of the profiles of different groups easier. We show the research profile of IVR-UU in Fig. 10.5. Fields are ranked by their number of publications; the first 20 are shown.

The bars represent the fields, and the length of the bar is determined by the number of publications in a field. Clearly, for IVR-UU, the field of veterinary science is by far the largest. But it is also clear that IVR-UU researchers are active in many other fields, including immunology and microbiology. Furthermore, the *impact* of IVR-UU research in each of the fields is given by the MNCS values, and we see a high MNCS value for most of the fields, as is to be expected given the high MNCS of the total output. There are fields in which IVR-UU researchers have a particularly high impact, such as microbiology and food science & technology. We see also fields with a lower MNCS, for instance, immunology and endocrinology & metabolism. This is important information for the institute and its researchers in order to understand why the

Table 10.1 Bibliometric indicators for IVR-UU for the total evaluation period 2001–2011 and trend analysis in 4-year periods. This table is taken from [10.249]

IVR-UU	Coverage	P	MCS	MNCS	MNJS	pptop10%
2001–2011	*0.86*	*3891*	*13.69*	*1.46*	*1.33*	*0.17*
2001–2004	0.84	1492	6.68	1.31	1.26	0.14
2002–2005	0.85	1567	6.96	1.34	1.28	0.15
2003–2006	0.86	1542	7.30	1.38	1.30	0.16
2004–2007	0.87	1556	7.57	1.39	1.31	0.17
2005–2008	0.87	1530	7.94	1.47	1.34	0.17
2006–2009	0.88	1544	7.32	1.46	1.38	0.17
2007–2010	0.88	1626	5.84	1.56	1.42	0.18
2008–2011	0.88	1250	5.11	1.58	1.44	0.18

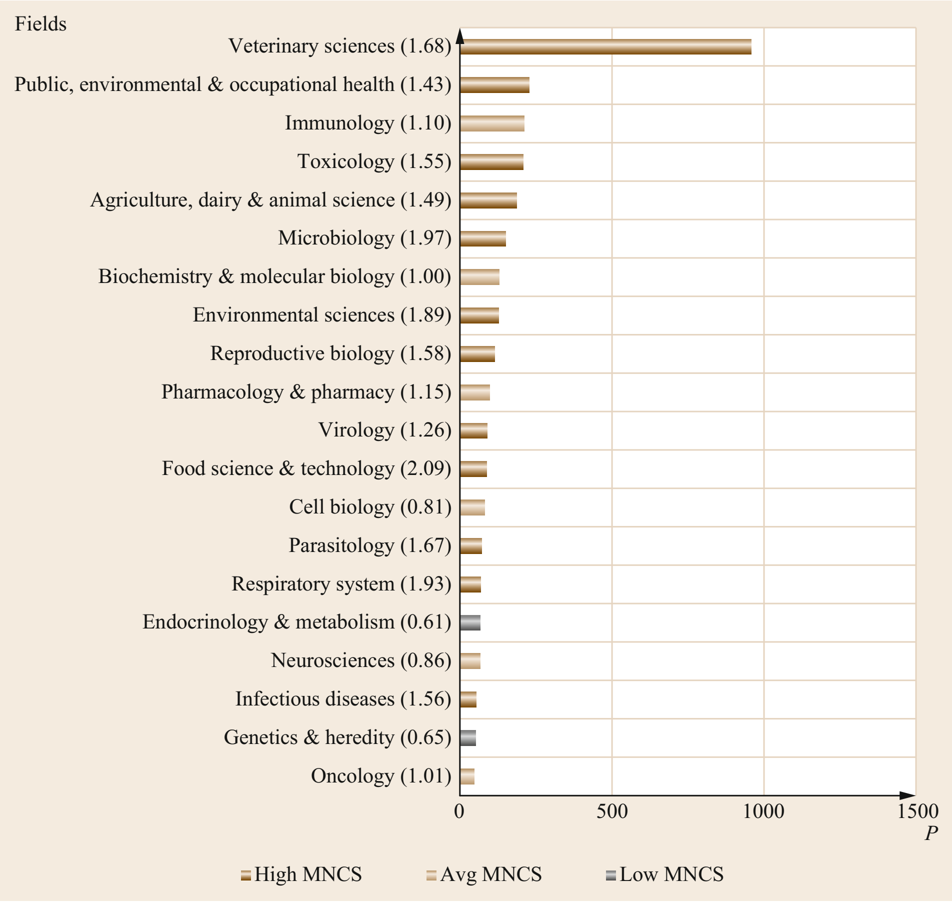

Fig. 10.5 Research profile of IVR-UU: output and impact per field, 2001–2011. A *dark brown bar* indicates a high MNCS (> 1.20), *light brown* indicates an average MNCS (between 0.80 and 1.20), and *gray bars* indicate a low (i. e., below the international average of the field) MNCS (< 0.80). MNCS values are given after the name of the field. This figure is taken from [10.249]

impact in these fields is relatively low. Similar profiles can be made for the papers *citing the work of an institute*, see for instance [10.253].

In Sect. 10.2, we have discussed indicators of collaboration. In most evaluation studies, a somewhat simpler approach is sufficient: publication with no collaboration, publications with national collaboration, and publications with international collaboration. We present the collaboration profile of IVR-UU in Fig. 10.6. In all types of collaboration, the MNCS value is significantly above world average. The findings show a quite general picture: publications in international collaboration are the largest group and have the highest impact; publications with no collaboration are the smallest group and their impact is lower (but still significantly above the worldwide average).

At the time of the evaluation, the research within IVR-UU was organized in six programs: Biology of Reproductive Cells (BRC), Tissue Repair (TR), Emotion and Cognition (EC), Risk Assessment of Toxic and Immuno-modulatory Agents (RATIA), Strategic Infection Biology (SIB), and Advances in Veterinary Medicine (AVM). As an example of bibliometric analysis at a lower aggregation level, we present results for the BRC and the TR programs. For additional results, we refer to the complete IVR-UU report [10.249]. First, we present in Table 10.2 the bibliometric indicators for both programs for the total evaluation period 2001-2011 and trend analysis in 4-year periods, similar to Table 10.1 (but without indication of coverage). The TR program started in 2006, so for this program we have data from 2006 onward.

For both programs we see high MNCS and pp-top10% values over the entire evaluation period, which confirms the high impact of the Utrecht veterinary research. In the TR program in particular, journals of high impact are used for publication (high MNJS values). The peer review judgment of the quality was "very good" for both programs [10.249]. In Fig. 10.7 we show the collaboration profiles of the BRC and TR programs. We see that in the BRC program, the publications in international collaboration receive the highest impact ratings. In the TR program, the publications in national collaboration have the highest impact, whereas

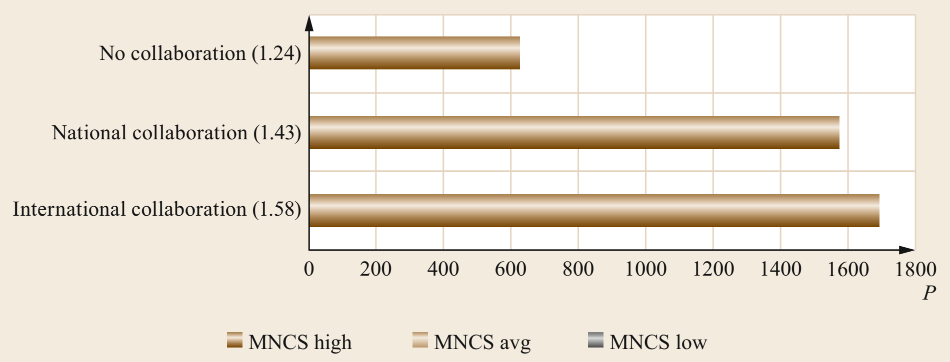

Fig. 10.6 Collaboration profile of IVR-UU: output and impact per type of collaboration, 2001–2011. A *dark brown bar* indicates a high MNCS (> 1.20), *light brown* indicates an average MNCS (between 0.80 and 1.20), and *gray bars* indicate a low (i. e., below the international average of the field) MNCS (< 0.80). MNCS values are given for each type of collaboration. This figure is taken from [10.249]

Table 10.2 Bibliometric indicators for IVR-UU programs Biology of Reproductive Cells (BRC) (*upper part*) and Tissue Repair (TR) (*lower part*) for the total evaluation period 2001–2011 and trend analysis in 4-year periods. This table is taken from [10.249]

IVR-UU/BRC	P	MCS	MNCS	MNJS	pptop10%
2001–2011	*274*	*14.39*	*1.38*	*1.14*	*0.16*
2001–2004	119	6.71	1.22	1.17	0.14
2002–2005	126	7.20	1.45	1.21	0.18
2003–2006	124	7.35	1.51	1.22	0.19
2004–2007	120	7.27	1.45	1.17	0.17
2005–2008	110	7.88	1.58	1.15	0.19
2006–2009	101	6.84	1.31	1.15	0.14
2007–2010	101	5.74	1.28	1.16	0.15
2008–2011	73	5.33	1.35	1.17	0.16
IVR-UU/TR	**P**	**MCS**	**MNCS**	**MNJS**	**pptop10%**
2006-2011	*368*	*4.97*	*1.50*	*1.46*	*0.16*
2006–2009	255	4.99	1.40	1.41	0.17
2007–2010	241	4.60	1.60	1.49	0.19
2008–2011	236	3.93	1.74	1.53	0.19

the publications with no collaboration have an average impact.

This example of *bibliometrics in practice* shows the importance of an indicator system in which all relevant indicators are calculated and presented in a coherent way, i. e., based on the same underlying data, such as a specific set of publications and a specific time period, with clear visualization of the results. A next step is automation of such an indicator system, offering the user possibilities to choose, for instance, other time periods and other target groups. This means a menu-driven application instrument for research performance assessment and monitoring of groups, university departments, institutes, and research programs. Novel features can be added, such as geographical maps with indication of research groups worldwide citing and/or collaborating with the institutes or within research programs. In this way, crucial information on the impact and other properties of research can be provided. Such an automated indicator system for monitoring and evaluation based on the methodological principles discussed in this chapter has recently become available in a first version, with new extensions currently in preparation [10.254]. It hardly comes as a surprise that this type of advanced bibliometric analysis offers the user information on research performance of a scope and quality far beyond the level of what we described as easy-to-go bibliometrics.

What can we conclude from all this? Above all, that it is important to have diverse indicators, as discussed in the above example. It may help to understand peculiarities of the assessed groups. This diversity can be extended with several other bibliometric indicators, for instance the percentage of not-cited papers and the number of authors (more authors may affect impact [10.255]), as well as with *non-bibliometric indicators* such as properties of the most highly cited papers of the group (for instance: are these reviews, or original research work?), patents [10.256, 257], acknowledgments, altmetrics data, staff size and staff composition of the research group, and other input measures [10.137]. For an example of a university-wide evaluation in which both bibliometric analysis and peer review are used, we refer to the evaluation study for Uppsala University [10.123].

10.3.3 Summary of Guidelines for the Use of Bibliometric Indicators

Number of publications is database-dependent and language-dependent, and there are large field-specific

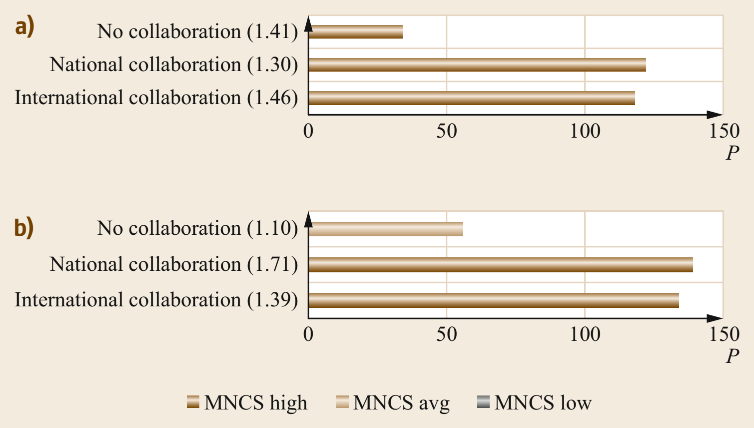

Fig. 10.7 **(a)** Collaboration profile of the IVR-UU program Biology of Reproductive Cells. **(b)** Collaboration profile of the IVR-UU program Tissue Repair. MNCS values are given for each type of collaboration. This figure is taken from [10.249]

differences in publication culture. This is particularly the case for most of the humanities and some of the social sciences as well as the engineering fields. Nevertheless, in the humanities, the social sciences and the engineering fields, journal publications become more important and bibliometric indicators can be applied experimentally. Be aware that not all publications of a research group will be captured—for example, publications written for practitioners. Thus, the productivity of a research group cannot be based on the number of papers covered by the WoS or Scopus alone. Specify the database used, and do not compare different fields in terms of absolute number of publications. Fractional counting has the advantage that averages add up worldwide to 1, but it is often not fair in fields where collaboration is practically inevitable, such as astronomy. Thus, both fractional and whole counting are necessary. The difference between the two counting modalities provides information on the robustness of the whole indicator system: if the difference between the modalities is large, then there is good reason to analyze the data in greater detail to see what is going on. In international comparisons, it is necessary to remove the non-English-language journal papers. This may differ by 20–25% in the impact for French and German research groups and institutes. It is also necessary to remove retracted papers and all citations received by these papers. Attribution of publications to affiliations is a difficult and often underestimated problem. The bibliometric researchers must have the expertise and capacity to clean, unify, and otherwise define possible research affiliations as best as possible. Moreover, research is often teamwork, and the lifetime of a team may be shorter than the period studied. Take into account composition of and changes in teams. Crucially important: always use a set of consistent indicators, such as the set P, MNJS, MNCS, MCS, and pptopx% discussed in this chapter.

Number of citations, i. e., the number of citing publications, is also database-dependent, language-dependent, and directly related to the publication culture; there are large field-specific differences in citation culture. Again, this is particularly the case for most of the humanities and some of the social sciences as well as the engineering fields. The building blocks for citation analysis are pairs of citing and cited publications. We must have very accurate knowledge of the citation data on this level. We can then aggregate to higher levels such as groups, institutes, programs, and universities. Specify precisely the database used; do not compare different fields in terms of absolute numbers of citations. Carefully define citation windows, for instance with the roof-tile procedure. The choice of citation window length and structure of the citation window is critical: the importance of a publication does not necessarily appear immediately, even to peers, and identification of quality may take considerable time. Therefore, it is important to make assessments with shorter as well as longer time windows. The number of citations can be affected by type of collaboration and number of authors.

Number of highly cited publications requires an accurate calculation of the entire citation distribution within a field; this is necessary to determine, for instance, the top-1%, top-5%, and top-10% publications; the distribution function depends on the definition of the field. Again, choice of citation window length and structure of the citation window are essential. Specify precisely how the fields are defined, in which database, and how the citation distribution is calculated. The top-10% category is generally more informative than the top 1% or top 5%. A top-1% publication is not necessarily a breakthrough or highly innovative paper. Papers in which extended reviews or important established research methods and algorithms are presented can be very highly cited. Such papers are important, but they are often mainstream and not necessarily innovative. Also, highly cited papers could be work that fits well in a specific trend, which may be short-lasting.

Number of non-cited publications depends on the choice of citation window length and structure of the citation window; as we already noted, in the case of delayed recognition and sleeping beauties, not being cited is a time-dependent phenomenon. Thus, specify in which period of time the number of non-cited publications is calculated.

Research field classification by journals is problematic because many important journals are too broad to be classified in one field. Therefore, journal-based classification is less accurate than publication-based classification. Nevertheless, a journal classification such as the WoS journal categories is still useful because it is a simple, easy-to-understand, well-established classification known in the academic community worldwide, and it is quite stable. We stress that in evaluation studies, it is preferable to use a publication-based classification next to the journal-based classification. In an advanced bibliometric data system with proper algorithms, this can be done without too much trouble.

Normalized citations are very sensitive to the definition of a field. For instance, the MNCS or pptop10% indicators will have different values if the normalization is based on a publication-level-defined field as compared to normalization based on a WoS field. Choice of citation window length and structure of the citation window is critical. Specify precisely how the fields are defined, in which database, and how the normalization is calculated, for instance on the basis of averages or on the basis of the citation distribution. Calculate stability intervals or other proper measures of statistical significance. Show that the applied normalization is a proper one, given the often large heterogeneity of citation density particularly within fields. Also, journal impact has to be normalized in a similar way as the normalization of citations to the publications of a research group. Combine information on output and impact by field in a research profile as discussed in this chapter.

National and international collaboration measures are database-dependent, and there are large field-specific and country-specific differences in collaboration culture. Also, large differences exist between fields for the fraction of co-authored publications and number of co-authors per publication. We already stressed that definition of (collaborating) affiliations is a cumbersome task. In order to visualize collaboration patterns, apply advanced network/mapping techniques combined with citation-impact analysis as described in this chapter, for instance with help of the VOSviewer. Specify precisely the database used. Differences between fields provide important information on collaboration cultures. Impact calculations for different types (e. g., national, international) of collaboration are necessary. Use carefully designed and transparently calculated collaboration indicators such as those described in this chapter. Impact calculations for different numbers and percentages of co-authorship may provide important information about teamwork.

Number of patents is characterized by large differences between scientific fields in patenting possibilities as well as large differences between technological sectors in patenting culture. There are different classification systems with different fine structures. Classification of technological products within sectors is necessary, and the rules as to how smaller products are considered to be components or parts of a larger product may differ considerably between technological sectors. Specify precisely how the technological sectors are defined, in which database. Patent-to-patent and paper-to-patent citations may reveal important information on the interaction between science—and especially applied research—and technological developments.

Altmetrics indicators tend to measure the social impact of research rather than the scientific impact. There are large differences in the extent to which specific developments in science are trendy for the public. Trendiness changes continuously over time depending on current social, economic, political, and cultural issues. In addition, critical thinking is the fundament of science, often in disagreement with majority thinking as reflected by trends. Field-specific normalization of altmetric indicators is extremely difficult, if not impossible. Regard altmetrics as an experimental approach to capture social relevance.

10.4 What Is a Bibliometric Science Map?

After having reveled long enough in the Wild West of bibliometric indicators, it is now time to explore the other side of the bibliometric world, science mapping. It is a challenge to identify hidden patterns in the enormous amount of published scientific knowledge, given that all these publications (and patents) are connected by common references and concepts. Co-citation and co-word techniques are important examples of approaches for unraveling this gigantic network of interrelated pieces of scientific knowledge. These are important steps toward *imaging cognitive processes*. Maps of science, with the locations of the major actors, are specific representations of scientific activities. They have practical values (e. g., strategic overviews) as well as cognitive values (e. g., what type of scientific activities are represented on the map, and how they develop over time).

10.4.1 Basics and the Construction of Science Maps

We begin by recalling that the bibliometric network PAN forms the basis for the construction of bibliometric indicators as well as for science mapping. If the publication attributes are cited papers, the bibliometric tool *CitNetExplorer* can be applied to map the citation relations between the target paper and its cited papers (references) [10.110], including a timescale. This citation-links mapping enables us to find the *scientific roots* of the target paper, and possibly an older but important breakthrough paper. With the CitNetExplorer, the target paper can also be mapped with its citing publications, as we will see further on. For a more detailed analysis and mapping of the publications citing a target paper, a second bibliometric tool, the *VOSviewer*, can be applied [10.113]. As explained in Sect. 10.2, BC networks and CC networks can be constructed. In the BC network, *the citing publications* are mapped on the basis of the co-occurrences of their references. With advanced clustering techniques, a BC network transforms into a map which visualizes a structured landscape of all publications citing a specific target paper. It thus provides us with information on the research building on the target paper.

In the CC network, *the references of the citing papers* are mapped. Again, with advanced clustering techniques (related to modularity-based clustering), a CC network transforms into a map which visualizes a structured landscape of the references of the citing publications. The target paper is the reference of all citing papers. So it will take a central position in the CC map. This provides us with information as to which publications are often cited together with the target paper, and therefore publications that are probably just as important as, or even more important than, the target paper. As an example, we take the highly cited paper of this author on rankings [10.71]. We download the WoS record of this paper with its cited papers (the references) as well as its citing papers. In a next step, these data are uploaded into the CitNetExplorer. Fig. 10.8 presents the results of the CitNetExplorer application. The upper part of the figure shows the papers *cited by the target paper*; the lower part represents the papers *citing the target paper*. In both cases we marked the target paper with a square in the figure. Connecting lines indicate citation relations. These lines always go in an upward direction, which is backward in time.

These citing papers do, of course, cite additional papers, including mutual citations within the set of citing papers. These mutual connections (number depends on the citation threshold) are also visible in Fig. 10.8a. With the uploaded set of citing papers, a more comprehensive analysis of all citation links can be performed interactively with the CitNetExplorer by *tuning the citation threshold*. This automation of reference analysis has promising applications, given possibly hidden patterns within references [10.258, 259].

As a next step, we upload the same data of the target paper in the VOSViewer. In Fig. 10.9 we show the CC map of the *papers citing the target paper*. This creates a visualization, including clustering, of the research used (cited) by these citing papers. The target paper is in a central position because, by definition, all of the citing papers have the target papers as one of their references. Co-citation may involve more than just two papers, and thus one can expect clustering of papers that depends on the reference preferences of the citing papers. Given the heterogeneity of the citing papers, different clusters will exist, as can be seen in the figure, where clusters are distinguished by color. Also, the VOSViewer makes it possible to create maps with different thresholds: *tunable co-citation analysis*. At a high threshold, only the strongest co-citation relations will be mapped. Thus, tunable analysis increases the value of interactive mapping, but at the same time we caution for an overload of information.

The above-discussed results are all based on citation links—in other words, on the PAN in which the attributes are cited papers. If the attributes are *concepts*, mapping procedures similar to those for citations can be carried out. To do so, we can apply natural language processing (text mining) to extract the important, publication-specific concepts (terms such as keywords or noun phrases) from the titles and abstracts—or even from the full text—of a set of publications. Alternatively, keywords given by the authors and by the database can be used. Choice and selection of relevant keywords is not a trivial thing, and it is important to experiment with and compare different methods [10.260]. By measuring all co-occurrences of any possible pair of concepts, co-word maps (also called term maps) can be created, in which the conceptual structure of the research represented by the set of publications is visualized. Thus, on the basis of the above considerations, a term map is a two-dimensional representation of a field in which strongly related terms are located close to each other, and less strongly related terms are located further away from each other.

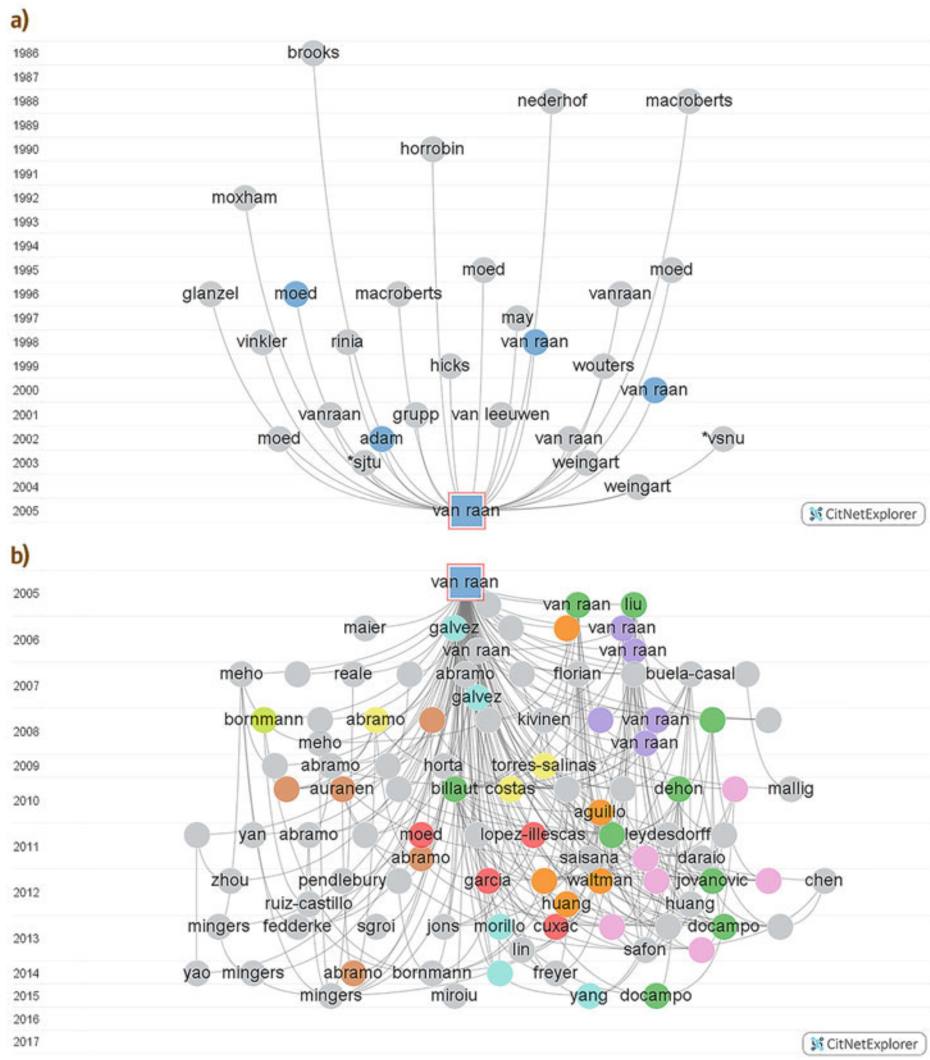

Fig. 10.8a,b Maps of the citation links of the target paper. **(a)** The cited papers (references) of the target paper; **(b)** the citing papers of the target paper. *Connecting lines* indicate citation relations; these go always in an upward direction. *Colors* indicate clusters based on mutual citation relations

A term map provides an overview of the structure of a field. Different areas in a map correspond to different subfields or research areas. A time series of maps enables us to discover emerging and converging research themes.

In Fig. 10.10 we present the term map based on author—as well as database—given keywords of all papers citing our target paper. We clearly observe many concepts directly related to the target paper, particularly *ranking* and *universities*. Colors indicate clusters of concepts, and these clusters can be seen as research themes. For instance, the red cluster is about methods and properties of bibliometric indicators, the purple cluster is about applications of bibliometric indicators, the green cluster is about the position of universities in rankings, and the light green cluster focuses on problems in the ranking methodology. It is important to note that in the interpretation of a term map, only the distances between terms are relevant. A map can be freely rotated, because this does not affect inter-term distances. This also implies that the horizontal and vertical axes have no special meaning.

There is a continuous effort to further improve mapping of science and its visualization. In recent work, multilayer concept networks are studied [10.261], and comparisons are made between bibliometric maps and topic modeling [10.262, 263]. A combination of different types of maps based on journal-to-journal citations, shared author keywords, and co-occurrence of title words and cited reference is discussed in [10.264]. A quite rarely conducted but interesting experiment is *back-to-the-future mapping*, i. e., reconstructing the

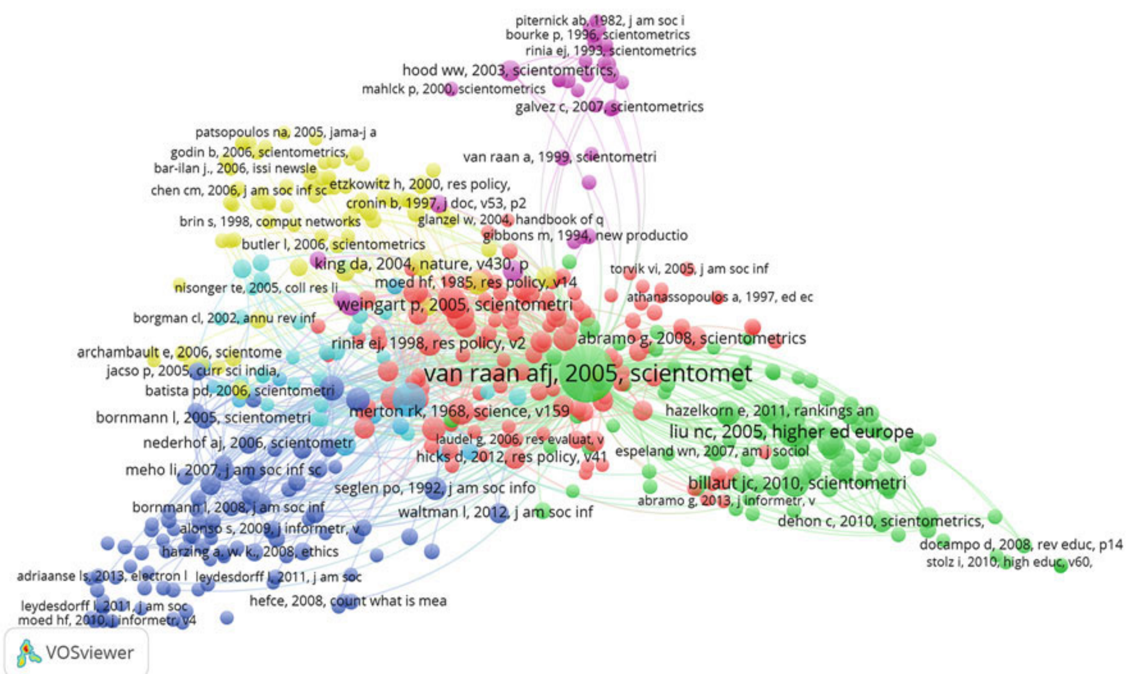

Fig. 10.9 Co-citation map of papers citing the target paper (co-citation threshold = 3). The size of the *circles* is proportional to the number of times a paper is cited in the uploaded set. By definition, the target paper [10.71] is the most cited paper, as all papers in the set cite the target paper

past (maps of research fields, say, 10 years ago) with currently used concepts, and the other way around, the construction of current research with concepts used 10 years ago [10.265].

10.4.2 Combining Citation Analysis and Science Mapping

A next step is the combination of the two main bibliometric methods, citation analysis and mapping. We present in Fig. 10.11 as an example (from [10.266]) the medical field of clinical neurology defined by its journal category in the WoS (for further work on science mapping based on WoS categories we refer to [10.267, 268]). The map is based on all publications classified as *article* or *review* and published between 2006 and 2010 (105 405 in total). For each publication, citations are counted through the end of 2011. Each circle represents a term. In this case, terms have been extracted by text mining from the titles and abstracts of the publications in a main field. For some terms, only a circle is displayed, not the term itself. This is done in order to prevent terms from overlapping each other. The size of a term (circle) reflects the number of publications in which the term occurs. Larger terms occur in a greater number of publications. As discussed above, the distance between two terms reflects their relatedness. In general, the closer the distance between two terms, the stronger their relatedness, as measured by the number of publications in which these terms occur together.

The relative citation impact of each term is determined and indicated by a color. In order to correct for the age of a publication, for each publication the number of citations is divided by the average number of citations of all publications that appeared in the same year. This yields a time-consistent normalized citation score for a publication. A score of 1 means that the number of citations of a publication equals the average of all publications that appeared in the same field and in the same year. Next, for each of the 2000 terms, the normalized citation scores of all publications in which the term occurs (in the title or abstract) are averaged. The color of a term is determined by the resulting average score. Colors range from dark blue (average score of 0) to green (average score of 1) to red (average score of 2 or higher). Hence, a blue term indicates that the publications in which a term occurs have a low average citation impact, while a red term indicates that the underlying publications have a high average citation impact. VOSviewer software is used to visualize the term map resulting from the above steps.

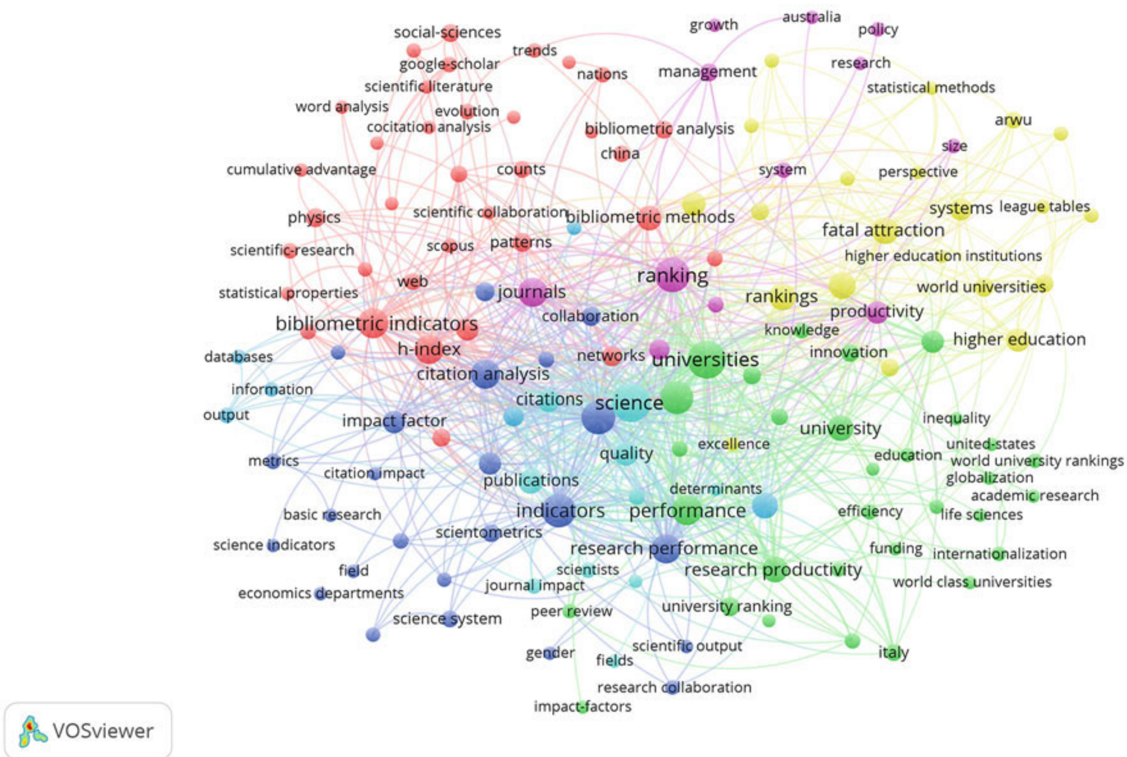

Fig. 10.10 Concept (term) map of the papers citing the target paper (mapping parameter: co-occurrence threshold = 3)

Look at the division of impact over the map: we observe a striking feature which is common to most medical fields. The typical *clinical* (hospital-related) research areas tend to be located mainly in the left part of the maps, and *basic* research areas mainly in the right part. Connections between basic research areas and clinical research areas are also visible. The maps display bridges that potentially represent *translational research*, that is, research aimed at translating basic research results into clinical practice. The color difference between the left and the right part is striking. Thus, the distinction between different research areas is visible in the structure of the maps, but also in the impact-related colors of the terms. In general, clinical research has a below-average impact (blue color), and the research areas that are more focused on basic research have an above-average citation impact (red color). We note that within an area in a map, terms are usually colored in a quite consistent way: terms tend to be surrounded mainly by other terms with a similar color. This is an important indication of the robustness of the maps.

In this section, we discussed how science mapping as an advanced visualization technique based on bibliometric data provides researchers and research institutions with an overview of the structure of a research field. It is important to note that term maps can be constructed with *any set* of chosen publications, and not necessarily with a predefined set such as the WoS or Scopus journal-based fields. For instance, maps can be made on based on the publication-level clusters discussed in the preceding sections. But one can also create sets of publications that are defined by research programs of institutes and organizations, or the publications of a university department, and use these sets to make maps of their research. Mapping of publication-level clusters based on direct citations can be used to discover emerging fields [10.269], particularly by identifying clusters with no publications in the first few years, followed by a rapid increase in citations in the subsequent years. Author co-citation analysis is also applied to detect emerging fields [10.270]. Recent work has discussed the use of heterogeneous bibliographic networks as an efficient tool for identifying emerging topics [10.271].

Another important application is the use of mapping to visualize research related to a specific socioeconomic problem. This approach enables institutes and organizations to assess their societal impact by determining how and where their research is involved in tackling

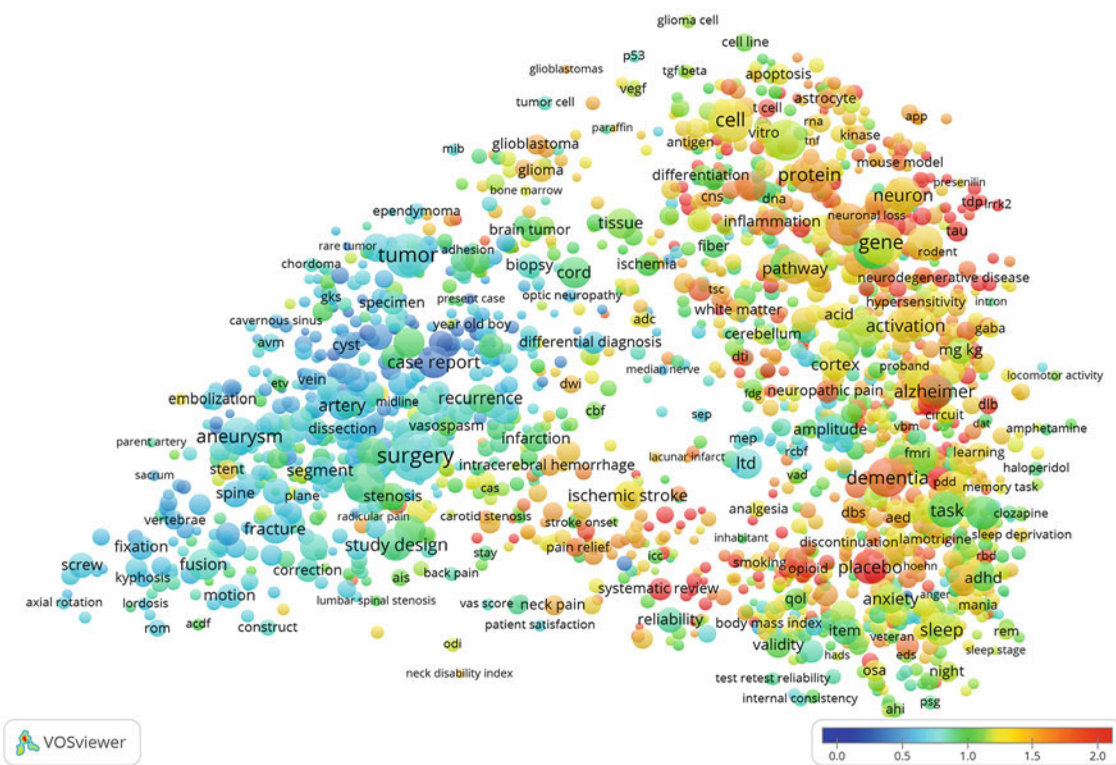

Fig. 10.11 Term map of neurology. *Colors* indicate local citation density. For a detailed discussion of this map we refer to [10.266]

a specific socioeconomic problem. A broader approach could be the following. Most likely there will be quite a strong societal consensus in defining the, say, ten most important socioeconomic problems. Identify all publications related to these problems, for instance, by using relevant concepts. Next, create maps for these problems, which are now defined as research fields based on the identified publications. Finally, use the maps to determine where specific groups, institutes, universities, or countries are active, as well as their impact in each of the socioeconomic fields.

Our discussion of science maps hopefully makes clear that mapping is a fascinating part of the advanced bibliometric methodology. It is constantly in a stage of further development, but as we showed, challenging applications are already within reach.

10.5 Can Science Be Measured?

Forty years ago, *Gerald Holton* [10.272] posed this question. The question is quite topical, and related to theories of scientific development. It is an everlasting endeavor in the social studies of science to find a final theory of science which provides *the* methodology of measurement. With very high probability, such a theory doesn't exist. It is normal practice in empirical science to begin investigations without theoretical clarification, and then later try to establish a model to explain the findings. Certainly, in such measurements, we do have at least implicit basic ideas about *how things work*, and the same is true for the construction and application of the indicators discussed in this chapter. Therefore, it is crucial to make these implicit assumptions clear to the outside world. But we need more empirical work based on the richness of available and future data in order to develop a better quantitative understanding of the processes underlying scientific evolution. Take, for example, science maps: do science maps derived from citation- or concept-similarity data have reality in a strict spatial sense? In other words, do measures of similarity imply the existence of metric space? For instance, it remains fascinating that science can be represented quite well in two-dimensional space. Nevertheless, maps based on exactly the same set of publications but constructed with different types of concepts, particularly text-mined concepts versus author-given concepts, can differ substantially. Changing thresholds for the occurrence as well as the co-occurrence of concepts will increase the diversity of maps even more, still based on exactly the same set of publications. So we need further research to determine what the best achievable *cartographic representation* of scientific research is, and why.

In this handbook chapter, we showed that the network of publications, with their attributes such as references (cited papers) and concepts, provides necessary elements to develop an advanced bibliometric methodology for measuring and mapping important aspects of science. We discussed how these measurements demonstrate the international influence of scientific work in a reliable, transparent, and objective way, particularly in the natural science and medical fields. Based on the same network principles, the advanced bibliometric methodology allows us to create science maps and to discover patterns in the structure and evolution of fields. Bibliometric mapping makes it possible to identify interdisciplinary developments and emerging fields, knowledge flows between fields of science, and research related to important socioeconomic issues.

Our choice was to focus on the above issues; other important applications of advanced methodology were mentioned only briefly, with relevant references. Many of these other applications relate directly to challenging topics that are open to further research: statistical properties of the publication network, its changes over time, improved clustering, and community detection; aging and durability of scientific literature and delayed recognition; growth and fragmentation of science; collaboration, mobility, and scientific migration flows; the interface between science and technology, particularly the role of new devices, machines, instruments; the combination of bibliometric and non-bibliometric data, particularly patent data; mapping with full-text analysis; the role of women in science; the role of cities in knowledge production and innovation.

The above shows that bibliometric indicators and maps are not just evaluation tools for science policymakers, research managers, and individual researchers, but also powerful measurement instruments in the study of science. Any instrument inevitably gives partial and distorted *images of reality*, caused by the characteristics of the instrument. Therefore, it is critically important in advanced bibliometric research, as in all empirical fields of science, to know the characteristics of instruments. This chapter is an attempt to increase this knowledge and to encourage further exploration of the quantitative properties of science.

Acknowledgments. The author thanks Nees-Jan van Eck for the construction of the publication-level citation-based network map and the citation density neurology map. The text parts on the methodology of the Leiden Ranking, the CitNetExplorer, and the VOSviewer are largely based on the descriptions in the relevant CWTS webpages by Ludo Waltman and Nees-Jan van Eck.

Dr. Anthony (Ton) F.J. van Raan is Professor emeritus of Quantitative Studies of Science at Leiden University. He holds a PhD in physics (Utrecht, 1973). His main interests involve the application of bibliometric indicators in research evaluation, mapping of science, statistical properties of indicators, and the scaling behavior of universities and cities. He has published (as author and co-author) around 30 articles in physics and 200 in science and technology studies.

11. Field Normalization of Scientometric Indicators

Ludo Waltman, Nees Jan van Eck

When scientometric indicators are used to compare research units active in different scientific fields, there is often a need to make corrections for differences between fields, for instance, differences in publication, collaboration, and citation practices. Field-normalized indicators aim to make such corrections. The design of these indicators is a significant challenge. We discuss the main issues in the design of field-normalized indicators and present an overview of the different approaches that have been developed for dealing with the problem of field normalization. We also discuss how field-normalized indicators can be evaluated and consider the sensitivity of scientometric analyses to the choice of a field-normalization approach.

11.1 Background

Many scientometric analyses are restricted to a single field of science, but scientometric analyses also commonly stretch out over multiple scientific fields, and they often even aim to cover the entire scientific universe. University rankings, for instance, rely on scientometric indicators that are supposed to provide meaningful information about the performance of universities across many different fields of science. Likewise, many universities regularly carry out scientometric analyses in which they compare their performance in different scientific fields.

Scientific fields, of course, differ from each other in many ways, and some of these differences have important implications for scientometric analyses. For instance, in some fields, researchers tend to produce many more outputs than in other fields. In some fields, researchers focus on publishing journal articles, while in other fields they are more interested in writing books. In some fields, researchers work together in large collaborative teams, often resulting in publications with many co-authors, while in other fields researchers prefer to work individually or in small teams. In some fields, researchers cite a lot, while in other fields they cite much more sparingly, and in some fields they mainly cite recent work, while in other fields they prefer to cite older literature.

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_11

Given these differences between scientific fields, it is clear that the interpretation of a scientometric analysis that covers multiple fields is far from straightforward. Suppose that a biologist has produced 25 publications during the past 5 years, while an economist has produced 10 publications during the same time period. Can it be concluded that the biologist has been more productive than the economist? This depends on our understanding of the concept of productivity. If productivity is understood simply as the number of publications produced during a certain time period, the biologist has obviously been more productive than the economist. However, in many cases, we are probably interested in a more sophisticated concept of productivity. We may have in mind a concept of productivity that accounts for differences between fields in the rate at which researchers tend to produce publications. Based on such a more refined notion of productivity, the answer to our question is much less obvious. It may actually turn out that from this perspective, the economist should be considered more productive than the biologist.

To capture the more sophisticated concept of productivity suggested above, we need a scientometric indicator that in some way corrects for differences between scientific fields in the typical number of publications produced by a researcher. Such an indicator is referred to as a field-normalized indicator. Field-normalized indicators can be constructed not only for the concept of productivity, but also for other scientometric concepts. In the literature, field-normalized indicators of scientific impact, calculated based on citation counts, have received the most attention, and they will also play a prominent role in this chapter.

The design of field-normalized indicators is a significant challenge. In this chapter, we discuss the main issues in the design of these indicators. We present an overview of the different approaches that have been developed for dealing with the problem of field normalization. We also discuss how field-normalized indicators can be evaluated and consider the sensitivity of scientometric analyses to the choice of a field-normalization approach.

This chapter partly builds on a recent review of the literature on citation impact indicators published by one of the authors [11.1].

11.2 What Is Field Normalization?

It is notoriously difficult to define in a precise way what is meant by field normalization. A precise definition of the idea of field normalization requires a definition of the notion of field. It also requires a clear perspective on the way in which scientometric indicators are affected by differences between fields. As we will explain below, these requirements are challenging, and, therefore, the idea of field normalization will almost inevitably remain somewhat ill defined.

Defining the notion of a field is far from straightforward. There is a lack of standardized terminology. No agreement exists on the differences between the term *field* and terms such as *area*, *discipline*, *domain*, *specialty*, and *topic*. In fact, these terms often seem to be used more or less interchangeably. More fundamentally, the idea of a field can be conceptualized in different ways. A useful overview of different conceptualizations is provided by *Sugimoto* and *Weingart* [11.2]. They distinguish between cognitive, social, communicative, and institutional perspectives as well as perspectives based on separatedness and tradition. Each of these perspectives provides a different understanding of the idea of a field.

Defining the notion of a field is made even more difficult by the fact that science is structured in a hierarchical way, allowing fields to be identified at different hierarchical levels [11.3]. For instance, depending on the hierarchical level that one prefers, citation analysis, bibliometrics, information science, and social sciences could all be seen as fields. Moreover, even when one focuses as much as possible on a single hierarchical level, fields typically will not be neatly separated from each other. For instance, bibliometrics, scientometrics, and research evaluation could perhaps be regarded as fields at more or less the same hierarchical level. However, it is clear that these fields are strongly interrelated and have a considerable overlap.

Field normalization of scientometric indicators is motivated by the idea that differences between fields lead to distortions in scientometric indicators. One could think of this in terms of signal and noise. Scientometric indicators provide a signal of concepts such as productivity or scientific impact, but they are also affected by noise. This noise may partly be due to differences between fields, for instance, differences in publication, collaboration, and citation practices. Field normalization aims to remove this noise while maintaining the signal.

However, the distinction between signal and noise is much less clear than it may seem at first sight. To illustrate this, let us consider citation-based indicators of scientific impact. Publications in information science on average are cited much less frequently than publications in, for instance, the life sciences. A citation-based indicator that does not account for this may be considered very noisy. The indicator may be seen as strongly biased against information science research. Suppose, therefore, that we use an indicator that corrects for differences in *citation density* between information science and other fields. Let us now zoom in on information science. Within information science, publications in scientometrics on average receive significantly more citations than publications in, for instance, library science. Again, we may feel that our indicator is too noisy and that we need to get rid of the noise. Consequently, suppose that we use an indicator that corrects for differences in citation density not only between information science and other fields, but also between scientometrics and other subfields within information science. We now zoom in on scientometrics. Within scientometrics, publications on citation analysis tend to receive more citations than publications on a topic such as co-authorship analysis. This may also be seen as noise that we need to get rid of. The next step then may be to use an indicator that corrects for differences in citation density even between different topics within scientometrics. However, we could, of course, argue that even this indicator is noisy. Suppose that empirical publications on citation analysis are cited more frequently than theoretical publications. This could then be claimed to show that the empirical publications have a higher impact than the theoretical publications. On the other hand, we could also argue that empirical and theoretical research on citation analysis represent two different subtopics and that we need to get rid of noise due to differences in citation density between these subtopics. However, if we keep following such a reasoning, at some point everything is considered noise, and there is no signal left, meaning that indicators become completely non-informative.

The above example illustrates that there is no objective way of distinguishing between signal and noise. We may say that scientometric indicators are distorted by noise that is due to differences between fields. However, fields can reasonably be defined at different hierarchical levels, leading to different perspectives on what should count as a signal and what should be seen as noise. When working with field-normalized indicators, choosing a certain hierarchical level for defining fields, and consequently making a certain distinction between signal and noise, is a normative decision. There is no objective way in which this choice can be made. Probably there is agreement that fields should not be defined in a very broad or very narrow way, but this still leaves open many intermediate ways in which fields can be defined. A single optimal way of defining fields does not exist [11.3]. Ideally, the hierarchical level at which fields are defined is chosen in such a way that it aligns well with the purpose of a specific scientometric analysis. In some analyses, it may be desirable to work with relatively narrow fields, while in other analyses broader fields may be appropriate.

11.3 Field Classification Systems

Most field-normalized indicators require an operationalization of scientific fields. We refer to such an operationalization as a field classification system. Different types of field classification systems can be distinguished. We make a distinction between classification systems of journals, publications, and researchers. Many different classification systems exist. We do not aim to provide a comprehensive overview of these systems. Instead, we focus specifically on classification systems that have been used for field-normalization purposes, either in the scientometric literature or in applied scientometric work. Each of the classification systems discussed below deals in a different way with the challenges in operationalizing scientific fields.

11.3.1 Field Classification Systems of Journals

The field classification systems used most frequently by field-normalized indicators are journal-based systems. In these systems, each journal is assigned to one or more fields. Some journal-based classification systems do not allow fields to overlap. A journal can be assigned to only one field in such systems. However, in most journal-based classification systems, overlap of fields is allowed, in which case a journal may belong to multiple fields. Some journal-based classification systems have a hierarchical structure and consist of multiple levels. Each field at a lower level is then considered to be part of a field at a higher level.

The Web of Science (WoS) database offers a classification system in which each journal indexed in the database is assigned to one or more fields. These fields are referred to as categories. There are about 250 fields in the WoS classification system.

A somewhat similar classification system is made available in the Scopus database. This system is referred to as the All Science Journal Classification (ASJC). The system has a hierarchical structure consisting of two levels. There are over 300 fields at the bottom level.

These fields have been aggregated into 27 fields at the top level. Each journal indexed in Scopus belongs to one or more fields. A comparison of the accuracy of the WoS and Scopus classification systems is reported in a study by *Wang* and *Waltman* [11.4]. According to this study, the WoS classification system is significantly more accurate than the Scopus classification system.

In the Essential Science Indicators, a tool that is based on the WoS database, a classification system of 22 broad fields is made available. In this system, it is not possible for a journal to belong to multiple fields. Each journal is assigned exclusively to a single field.

Other journal-based classification systems include the classification system of the US National Science Foundation, the classification system developed by Science-Metrix, and the classification system of *Glänzel* and *Schubert* [11.5]. The classification system of the National Science Foundation covers 125 fields, which have been aggregated into 13 broad fields. A journal can belong to only one field in this system. The system has been used in the Science and Engineering Indicators reports prepared by the National Science Foundation for a long time. Science-Metrix is a company specialized in research evaluation that has developed its own classification system. This system has been made freely available. It includes 176 fields, aggregated into 22 broad fields, with each journal being assigned to only one field. We refer to *Archambault* et al. [11.6] for more details on the approach that was taken to construct the Science-Metrix classification system. The classification system of *Glänzel* and *Schubert* [11.5] consists of two levels. The 67 fields at the bottom level have been aggregated into 15 fields at the top level. Journals may be assigned to more than one field in this system.

Multidisciplinary journals with a broad scope represent a significant challenge for journal-based classification systems. *Nature*, *Proceedings of the National Academy of Sciences*, and *Science* are well-known examples of such journals. Other examples are open access *mega journals* such as *PLOS ONE* and *Scientific Reports*. In a journal-based classification system, these multidisciplinary journals are typically assigned to a special category. In the WoS categories classification system, this category is, for instance, called *Multidisciplinary Sciences*. In the Scopus ASJC classification system, it is referred to as *multidisciplinary*. The use of a special category for multidisciplinary journals is problematic because such a category clearly does not represent a scientific field. In practice, this problem is often addressed by creating a publication-based classification system for publications in multidisciplinary journals and by complementing a journal-based classification system with such a publication-based classification system. This approach, introduced by *Glänzel* et al. [11.7]; see also [11.5], has been widely adopted. Of course, there is always some arbitrariness in deciding which journals should be considered multidisciplinary. It is clear that journals such as the ones mentioned above are of a multidisciplinary nature. However, it may be argued that journals such as *The Lancet*, *New England Journal of Medicine*, and *Physical Review Letters* should also be considered multidisciplinary and that it would be preferable to create a publication-based classification system for publications in these journals.

11.3.2 Field Classification Systems of Publications

Instead of journal-based field classification systems, it is also possible to use publication-based field classification systems. Publication-based classification systems potentially offer a more accurate and more fine-grained representation of scientific fields than their journal-based counterparts. Most publication-based classification systems are restricted to a single scientific discipline. Algorithmically constructed classification systems are an exception and may cover all scientific fields.

There are various scientific disciplines that have their own publication-based classification system. These systems often have a hierarchical structure, and they usually allow publications to be assigned to multiple fields. The use of these systems in field-normalized indicators was studied by *Bornmann* et al. [11.8], *Neuhaus* and *Daniel* [11.9], *Radicchi* and *Castellano* [11.10], and *van Leeuwen* and *Calero Medina* [11.11]. These authors focused on, respectively, the Medical Subject Headings, the Chemical Abstracts sections, the Physics and Astronomy Classification Scheme, and the EconLit classification system. Like in the case of the journal-based classification systems discussed in Sect. 11.3.1, it is important to be aware that publication-based classification systems such as the ones mentioned above were not designed specifically for field-normalization purposes.

Publication-based classification systems that are constructed algorithmically may cover all scientific fields rather than only fields within a single discipline. An approach for the algorithmic construction of publication-based classification systems was proposed by *Waltman* and *van Eck* [11.12]. In this approach, a classification system is constructed by clustering publications based on direct citation relations. Each publication is assigned to only one field. The use of algorithmically constructed publication-based classification systems in field-normalized indicators was studied by *Ruiz-Castillo* and *Waltman* [11.13] and *Perianes-Rodriguez* and *Ruiz-Castillo* [11.14]. A practical application can be found in the CWTS Leiden Ranking, a bibliometric ranking of major universities worldwide that is available at http://www.leidenranking.com. In this ranking, citation-based indicators of scientific impact are normalized using an algorithmically constructed publication-based classification system in which about 4000 scientific fields are distinguished.

An algorithmic approach to the construction of a publication-based classification system is also taken in Microsoft Academic, a recently introduced bibliometric data source somewhat similar to Google Scholar. *Hug* et al. [11.15] found that fields in the classification system of Microsoft Academic are too specific and not coherent, leading them to conclude that the classification system of Microsoft Academic is not suitable for field-normalization purposes.

11.3.3 Field Classification Systems of Researchers

Field classification systems of researchers represent a quite different approach to operationalize scientific fields. The use of researcher-based classification systems in field-normalized indicators is much less common than the use of journal-based and publication-based classification systems. Below we discuss two researcher-based classification systems that have been used in the scientometric literature.

Giovanni Abramo and *Ciriaco Andrea D'Angelo* have published a large number of papers in which they use the official classification system of Italian researchers [11.16]. This is a hierarchical system consisting of two levels. At the top level, 14 fields are distinguished. These fields are referred to as university disciplinary areas. At the bottom level, there are 370 fields, referred to as specific disciplinary sectors, with each specific disciplinary sector being part of a single university disciplinary area. In Italy, each researcher at a university must belong to exactly one specific disciplinary sector. We will return to the Italian classification system of researchers in Sect. 11.5.

Another example of a classification system of researchers is the classification system of the Mendeley reference management tool. This system was used by *Bornmann* and *Haunschild* [11.17] in a proposal for a field-normalized indicator of scientific impact based on Mendeley reader counts. In the Mendeley classification system, a distinction between 28 fields is made. Each Mendeley user is able to assign him- or herself to one of these 28 fields.

11.4 Overview of Field-Normalized Indicators

In this section, we provide an overview of field-normalized indicators that have been proposed in the scientometric literature. The literature on field-normalized indicators is extensive. We, therefore, do not discuss each individual proposal presented in the literature. Instead, our focus is on what we consider to be the more significant contributions that have been made. Other contributions may not be covered or may be mentioned only very briefly. We also do not aim to give a historical overview of the literature. We discuss important ideas presented in the literature but we do not necessarily trace the historical development of these ideas.

In principle, field-normalized variants can be developed for any type of scientometric indicator. In practice, however, scientometricians have put most effort into the development of field-normalized indicators of the impact of scientific publications, where impact is typically operationalized using citations. Our focus in this section is, therefore, mostly on field-normalized indicators of impact, although we also discuss field-normalized indicators of productivity. Most of the indicators that we consider in this section rely on field classification systems such as the ones introduced in the previous section, but we also discuss indicators that do not require a field classification system.

Field-normalized indicators typically normalize not only for the field of a publication but also for the age of a publication. This is important in the case of indicators based on citations, since older publications have had more time to receive citations than younger publications. Indicators may also normalize for other characteristics of a publication. For instance, they sometimes normalize for publication type, where a distinction can be made between categories such as research article, review article, and letter.

11.4.1 Indicators of Impact: Indicators Based on Normalized Citation Scores

The normalized citation score of a publication can be defined in different ways. The most straightforward approach is to define it as the ratio of the actual and the expected number of citations of a publication, where the expected number of citations of a publication equals the average number of citations of all publications in the same field and in the same publication year (and often also in the same publication type category). Whether publications are in the same field is determined based on a field classification system, such as one of the systems discussed in Sect. 11.3.

In order to obtain indicators at the level of, for instance, a research group, a research institution, or a journal, the normalized citation scores of individual publications need to be aggregated. This is typically done either by averaging or by summing the normalized citation scores. Averaging the scores yields a so-called size-independent indicator of impact, while summing the scores gives a size-dependent impact indicator. These indicators are known under various different names. The size-independent indicator is, for instance, known as the mean normalized citation score [11.18], the item-oriented field normalized citation score average [11.19], the category normalized citation impact (in the commercial InCites tool), and the field weighted citation impact (in the commercial Scopus and SciVal tools). The size-dependent indicator is sometimes referred to as the total normalized citation score [11.18].

A recent development is the application of the above approach for calculating field-normalized impact indicators to bookmarks in Mendeley instead of citations. Studies of field-normalized indicators based on Mendeley bookmarks, often interpreted in terms of readership, have been reported by *Fairclough* and *Thelwall* [11.20] and *Haunschild* and *Bornmann* [11.21].

A number of alternative approaches have been explored for defining the normalized citation score of a publication. One alternative is to leave out noncited publications from the calculation of the expected number of citations of a publication [11.22, 23]. Another alternative is to determine the expected number of citations of a publication based on the idea of so-called exchange rates, where the similarity between fields in the shape of citation distributions is used to determine how many citations in one field can be considered equivalent to a given number of citations in another field [11.24, 25]. A third alternative is to apply a logarithmic transformation to the citation counts of publications [11.19, 26–28]. A fourth alternative is to transform citation counts into z-scores [11.29–31]. This approach can be combined with a logarithmic transformation of citation counts [11.19]. A fifth alternative is to transform citation counts using a two-parameter power-law function [11.32]. Finally, a sixth alternative proposed in the literature is to transform citation counts into binary variables based on whether or not publications have been cited [11.28].

There has also been considerable discussion in the literature about the best way to calculate field-normalized impact indicators at aggregate levels, for instance, at the level of research groups or research institutions [11.18, 19, 33–37]. The approach discussed above, in which normalized citation scores of individual publications are averaged or summed, is nowadays the most commonly used approach. An alternative approach is to calculate the average or the sum of the actual citation counts of a set of publications and to divide the outcome by the average of the expected citation counts of the same set of publications [11.38–40]. In this alternative approach, normalization can be considered to take place at the level of an oeuvre of publications rather than at the level of individual publications [11.34]. When an analysis includes publications from multiple fields or multiple years, normalization at the oeuvre level will generally yield results that are different from the outcomes obtained by normalizing at the level of individual publications. We refer to *Larivière* and *Gingras* [11.41], *Waltman* et al. [11.42], and *Herranz* and *Ruiz-Castillo* [11.43] for empirical analyses of the differences between the two approaches.

Another issue in the calculation of field-normalized impact indicators at aggregate levels is the choice of a counting method for handling co-authored publications. Full and fractional counting are the two most commonly used counting methods. In the case of full counting, each publication is fully counted for each co-author. On the other hand, in the case of fractional counting, a publication with n co-authors is counted with a weight of $1/n$ for each co-author. The choice of counting method influences the extent to which an indicator can be considered to provide properly field-normalized statistics [11.44]. We will return to this issue in Sect. 11.5.1.

11.4.2 Indicators of Impact: Indicators Based on Percentiles

Percentile-based impact indicators value publications based on their position in the citation distribution of their field and publication year, where fields are defined using a field classification system, for instance, one of the systems discussed in Sect. 11.3. In the most straightforward case, these indicators make a distinction between lowly and highly cited publications. For instance, all publications that in terms of citations belong to the top 10%, top 5%, or top 1% of their field and publication year may be regarded as highly cited, as suggested by *Tijssen* et al. [11.45] and *van Leeuwen* et al. [11.46]. A generalization of this idea was proposed by *Leydesdorff* et al. [11.47]. In their proposal, a number of classes of publications are distinguished. Each class of publications is defined in terms of percentiles of the citation distribution of a field and publication year. The first class may, for instance, include all publications whose number of citations is below the 50th percentile of the citation distribution of their field and publication year, the second class may include all publications whose number of citations is between the 50th and the 75th percentile, and so on. In the proposed approach, publications are valued based on the class to which they belong. Publications in the lowest class have a value of 1, publications in the second-lowest class have a value of 2, and so on.

A difficulty in the calculation of percentile-based indicators is the issue of ties, that is, multiple publications with the same number of citations. Suppose we want to identify the 10% most frequently cited publications in a certain field and publication year. We then need to find a threshold such that exactly 10% of the publications in this field and publication year have a number of citations that is above the threshold. In practice, it will usually not be possible to find such a threshold. Because of the issue of ties, typically, any threshold will yield either too many or too few publications whose number of citations is above the threshold. This means that fields cannot be made fully comparable, since the distortion caused by the issue of ties will be different in different fields. In the literature, various approaches for dealing with the issue of ties have been explored [11.46–49]. We refer to *Waltman* and *Schreiber* [11.49] for a summary of these approaches and to *Schreiber* [11.50] for an empirical comparison.

Field-normalized impact indicators can also be constructed by combining the idea of percentile-based indicators with the idea of indicators based on normalized citation scores. Such an approach was introduced by *Albarrán* et al. [11.51, 52]. In the proposed approach, indicators are used to characterize the distribution of citations over the highly cited publications in a field. The indicators resemble indicators developed in the field of economics for characterizing income distributions.

Glänzel [11.53] and *Glänzel* et al. [11.54] proposed indicators that, like the above-mentioned indicators proposed by *Leydesdorff* et al. [11.47], distinguish between a number of classes of publications. However, instead of percentiles, these indicators rely on the method of characteristic scores and scales [11.55] to define the classes. Publications belong to the lowest class if they have fewer citations than the average of their field, they belong to the second-lowest class if they do not belong to the lowest class and if they have fewer citations than the average of all publications not belonging to the lowest class, and so on. An alternative approach is to define the classes based on median instead of average citation counts [11.56].

Percentile-based approaches may also be used to normalize altmetric indicators. *Bornmann* and *Haunschild* [11.57] suggested a percentile-based approach for normalizing Twitter counts.

11.4.3 Indicators of Impact: Indicators that Do Not Use a Field Classification System

All field-normalized indicators discussed so far rely on a field classification system that operationalizes scientific fields. As discussed in Sects. 11.2 and 11.3, the operationalization of fields is a difficult problem. Field classification systems offer a simplified representation of fields. By necessity, any field classification system relies partly on arbitrary and contestable choices. In this section, we discuss field-normalized impact indicators with the attractive property that they do not require a field classification system.

An approach that has been explored in the literature is to identify for each publication a set of similar publications, allowing the citation score of the focal publication to be compared with the citation scores of the identified similar publications. Similar publications may be identified based on shared references (i. e., bibliographic coupling relations), as suggested by *Schubert* and *Braun* [11.58, 59]. Alternatively, as demonstrated by *Colliander* [11.60], the identification of similar publications may be done based on a combination of shared references and shared terms. Another possibility is to use co-citation relations to identify similar publications. This idea is used in the relative citation ratio indicator, an indicator introduced by a research team at the US National Institutes of Health [11.61] that has attracted a significant amount of attention. We refer to *Janssens* et al. [11.62] for a critical discussion of the relative citation ratio indicator (for a response by the original authors, see [11.63]). Instead of working at the level of individual publications, it is also possible to work at the journal level. The citation score of a journal can then be compared with the citation scores of other similar journals. The latter journals may be identified based on citations given to the focal journal [11.64].

Another field normalization approach that does not require a field classification system is known as citing-side normalization [11.65], sometimes also referred to as fractional citation weighting [11.65], fractional citation counting [11.66], source normalization [11.67], or a priori normalization [11.68]. Citing-side normalization is based on the idea that differences between fields in citation density are to a large extent caused by the fact that in some fields publications tend to have longer reference lists than in other fields. Citing-side normalization performs a correction for the length of the reference list of citing publications. The basic idea of citing-side normalization can be implemented in different ways. One possibility is to correct for the average reference list length of citing journals [11.65, 69]. Another possibility is to correct for the reference list length of individual citing publications [11.66–68, 70, 71]. A combination of these two options is possible as well, and this is how citing-side normalization is implemented in the current version of the Source Normalized Impact per Paper (SNIP) journal impact indicator [11.72].

Instead of correcting for reference list length on the citing side, an alternative approach is to correct for reference list length on the cited side. In this approach, a correction can be made for either the reference list length of a cited publication [11.73] or the average reference list length of a cited journal [11.74–76]. A third possibility is to correct for the average reference list length of all publications belonging to the same field as a cited publication [11.77]. However, this again requires a field classification system, just like in the case of the indicators discussed in Sects. 11.4.1 and 11.4.2.

Recursive impact indicators, first introduced by *Pinski* and *Narin* [11.78] and often inspired by the well-known PageRank algorithm [11.79], offer another approach that is related to the idea of citing-side normalization. Examples of recursive impact indicators are the eigenfactor and article influence indicators of journal impact [11.80, 81] and the SCImago journal rank (SJR) indicator [11.82, 83]. We refer to *Waltman* and *Yan* [11.84] and *Fragkiadaki* and *Evangelidis* [11.85] for overviews of the literature on recursive impact indicators and to *Waltman* and *van Eck* [11.86] for a discussion of the relation between these indicators and citing-side normalized indicators.

11.4.4 Indicators of Productivity

Although field-normalized indicators of impact have received most attention in the scientometric literature, some attention has also been given to field-normalized indicators of productivity (sometimes also referred to as efficiency). Productivity indicators can, for instance, be calculated for researchers, research groups, and research institutions. A simple productivity indicator is the average number of publications produced per researcher. A more advanced productivity indicator may also take into account the number of citations publications have received. Field-normalized productivity indicators perform a correction for differences between fields in the rate at which publications are produced and citations are received.

Field-normalized productivity indicators play a prominent role in the work of *Giovanni Abramo* and *Ciriaco Andrea D'Angelo*. In particular, *Abramo* and *D'Angelo* make extensive use of an indicator referred to as the fractional scientific strength (FSS). For an individual researcher, FSS essentially equals the sum of the normalized citation scores (Sect. 11.4.1) of the publications of the researcher divided by the salary of the researcher. Likewise, for a group of researchers working in the same field, FSS equals the sum of the normalized citation scores of their publications divided by their total salary. When FSS is calculated for a group of researchers working in different fields, for instance, all researchers affiliated with a particular research institution, a correction needs to be made for differences between fields in the average publication output and the average salary of researchers. One way in which this can be done is by first calculating each researcher's field-normalized FSS, defined as the researcher's FSS divided by the average FSS of all researchers working in the same field and then calculating the average field-normalized FSS of all researchers. We refer to *Abramo* and *D'Angelo* [11.16] for a more detailed discussion of the calculation of the FSS indicator. For a discussion of an alternative productivity indicator, based on highly cited publications instead of normalized citation scores, we refer to *Abramo* and *D'Angelo* [11.87].

In practice, calculating the FSS indicator is highly challenging because it requires data on the publications and the salaries of all researchers working in a field. *Abramo* and *D'Angelo* address this difficulty by taking into account only Italian publications and Italian researchers in the calculation of the FSS indicator. In Italy, unlike in most other countries, the data required for the calculation of the FSS indicator is available. *Abramo* and *D'Angelo* calculate normalized citation scores of publications using the WoS journal-based field classification system (Sect. 11.3.1). However, they also need a second classification system. To calculate researchers' field-normalized FSS, they rely on a classification system of Italian researchers (Sect. 11.3.3).

In most countries, the data needed to calculate field-normalized productivity indicators is not available. Obtaining productivity indicators that allow for meaningful cross-country comparisons is even more challenging, as pointed out by *Aksnes* et al. [11.88]. An interesting proposal for calculating field-normalized productivity indicators, even when only limited data is available, was presented by *Koski* et al. [11.89]. This proposal focuses on the difficulty of researchers that have no publications in a certain time period. These researchers are invisible in databases such as WoS and Scopus, which causes problems when using these databases to calculate productivity indicators. To deal with this issue, a statistical methodology is proposed for estimating the number of researchers without publications.

A number of studies have focused specifically on designing field-normalized indicators of the productivity of individual researchers. In particular, several proposals have been made for variants of the h-index

[11.90] that correct for field differences [11.91–95]. Other interesting proposals for comparing individual researchers active in different fields were presented by *Kaur* et al. [11.96] and *Ruocco* and *Daraio* [11.97].

It is important to be aware of the difference between productivity indicators and size-independent impact indicators. Both types of indicators are independent of size, which is convenient, for instance, when making comparisons between larger and smaller research institutions. However, the two types of indicators are based on fundamentally different notions of size. Productivity indicators take an input perspective on the notion of size, for instance, the number of researchers affiliated with an institution. Size-independent impact indicators take an output perspective on the notion of size, namely the number of publications produced by an institution. From a conceptual point of view, for many purposes the input perspective seems preferable over the output perspective. From a practical point of view, however, taking the input perspective often is not possible because the data required is not available. A more elaborate discussion of the pros and cons of productivity indicators and size-independent impact indicators can be found in a recent special section of *Journal of Informetrics* [11.98]. In this special section, a discussion paper by *Abramo* and *D'Angelo* [11.99] argues in favor of the use of productivity indicators, while other contributions defend the use of size-independent impact indicators. We refer to *Abramo* and *D'Angelo* [11.100] for an institutional-level comparison between productivity indicators and size-independent impact indicators.

11.5 Evaluation of Field-Normalized Indicators

The discussion in the previous section has shown that a large variety of field-normalized indicators have been proposed in the literature. This, of course, raises various questions: Do the indicators discussed in the previous section indeed provide properly field-normalized statistics? What are the advantages and disadvantages of the different ways in which field normalization can be performed? Is it possible to identify one specific approach to field normalization that can be considered superior over other approaches? To provide some partial answers to these questions, we now discuss the scientometric literature on the evaluation of field-normalized indicators. We restrict the discussion to indicators of impact.

To evaluate field-normalized indicators, some scientometricians choose to analyze the theoretical properties of indicators, while other scientometricians prefer to study the empirical characteristics of indicators. Different approaches to evaluate field-normalized indicators sometimes lead to different conclusions. For instance, from a theoretical perspective, an indicator may seem appealing, while from an empirical perspective the same indicator may not seem very attractive. Below, we first discuss the theoretical evaluation of field-normalized indicators. We then turn to empirical evaluation.

11.5.1 Theoretical Evaluation of Indicators

In theoretical approaches to the evaluation of field-normalized indicators, the theoretical properties of indicators are studied. These are properties that do not depend on empirical data based on which indicators are calculated. After the theoretical properties of indicators have been established, the indicators are evaluated by deciding whether or not their properties are considered desirable. Whether a certain property is desirable is a subjective question that may legitimately be answered differently by different people. Theoretical evaluation, therefore, does not offer a universal and definitive answer to the question of whether one indicator is superior over another. Instead, it aims to provide a deep understanding of the key differences between indicators. This may then guide users in choosing the indicator that best serves their needs.

In the calculation of the normalized citation score of a publication, defined as the ratio of the actual and the expected number of citations of a publication (Sect. 11.4.1), theoretical considerations may help to choose between different ways in which the expected number of citations of a publication can be defined. The most common approach is to define a publication's expected citation count as the average citation count of all publications in the same field and in the same publication year. An alternative approach is to consider in this definition only publications that have been cited at least once [11.22, 23]. In the case of the former approach, for each combination of a field and a publication year, the average normalized citation score of all publications in that field and publication year equals exactly 1. This may be regarded as an important property for a field-normalized indicator. The approach in which non-cited publications are left out from the definition of a publication's expected citation count does not have this property, which may be seen as a disadvantage of this approach.

Another issue in the calculation of the normalized citation score of a publication is the way in which publications belonging to multiple fields are handled. Based on the idea that the average normalized citation score of all publications in a field and publication year should equal 1, it can be argued that the expected citation count of a publication belonging to multiple fields should be defined as the harmonic average of the expected citation counts corresponding to the different fields [11.18]. However, a theoretical analysis presented by *Smolinsky* [11.101] showed that there are also other ways in which the expected citation count of a publication belonging to multiple fields can be defined. These alternative approaches lead to additional properties that may be considered attractive, but they have the disadvantage of introducing challenging computational issues.

As discussed in Sect. 11.4.1, there are different ways in which field-normalized indicators can be calculated at the aggregate level of, for instance, a research institution. The oeuvre argument of *Moed* [11.34] is a theoretical argument in favor of one approach, while the consistency argument of *Waltman* et al. [11.18] is a theoretical argument in favor of another approach. According to the oeuvre argument, it should not make a difference whether a citation is given to one publication in the oeuvre of a research unit or to some other publication in the same oeuvre. The basic idea of the consistency argument is that the ranking of two research units relative to each other should not change when both units make the same performance improvement. The oeuvre and consistency arguments can also be used to characterize some of the key differences between two versions of the SNIP journal impact indicator [11.67, 72].

The choice of the counting method used to handle co-authored publications in the calculation of a field-normalized indicator can also be analyzed theoretically. When the full counting method is used, each publication is fully counted for each co-author, as explained in Sect. 11.4.1. On the other hand, when using a fractional counting method, co-authored publications are counted with a lower weight than publications that have not been co-authored. As pointed out by *Waltman* and *van Eck* [11.44], in the case of fractional counting, the mean normalized citation score indicator (Sect. 11.4.1) has the property that the average value of the indicator for all research institutions active in a field equals exactly 1. In the case of full counting, the indicator does not have this property. Using the full counting method, co-authored publications are counted multiple times, once for each of the co-authors. This double counting of co-authored publications, which tend to be publications that have received relatively large numbers of citations, has an inflationary effect. It typically causes the mean normalized citation score indicator to have an average value for all research institutions active in a field that is above 1. Because of this inflanatory effect, which is larger in some fields than in others, the full counting method provides statistics that are only partly field normalized. In order to obtain properly field-normalized statistics, a fractional counting method needs to be used. Alternatively, the use of a so-called multiplicative counting method [11.102] can be considered.

11.5.2 Empirical Evaluation of Indicators

Empirical approaches to the evaluation of field-normalized impact indicators focus on three questions. First, assuming that a certain field classification system offers a satisfactory representation of scientific fields, which field-normalized indicators provide the best normalization? Second, to what extent do different field classification systems offer good representations of scientific fields, in particular for the purpose of field normalization? Third, which field-normalized indicators have the strongest correlation with peer review?

The idea of universality of citation distributions plays a key role in the literature dealing with the first question. Citation distributions are considered to be universal if the distribution of normalized citation scores is essentially identical for all scientific fields. The idea of universality of citation distributions was introduced by *Radicchi* et al. [11.95]; see also [11.10]. They claimed that universality of citation distributions can be achieved using a straightforward normalization approach in which the number of citations of each publication in a field is divided by the average number of citations of all publications in the field (excluding noncited publications). However, in subsequent studies, it has been shown that this straightforward normalization approach yields citation distributions that are only approximately universal [11.29, 103, 104].

Based on the idea of universality of citation distributions, a so-called fairness test for field-normalized indicators was proposed [11.105]. This test has been used in various studies in which field-normalized indicators are compared [11.32, 105, 106]. The objective of having normalized citation distributions that are identical across fields also serves as the foundation of a methodology for quantifying the degree to which field-normalized indicators succeed in correcting for field differences [11.25]. This methodology has been applied in various studies [11.24, 25, 107, 108]. Using the methodology of *Crespo* et al. [11.25], it was found that the normalization approach proposed by *Radicchi* and *Castellano* [11.32], based on a two-parameter power law transformation of citation counts, outperforms a number of other normalization approaches [11.107]. However, the standard approach of dividing the actual number of citations of a publication by the expected number of citations has also been shown to perform well. A study by *Abramo* et al. [11.22] in which a comparison is made of a number of field-normalized indicators is also based on the idea of trying to obtain normalized citation distributions that are identical across fields.

The above-mentioned studies assume that one has a satisfactory field classification system. They do not evaluate whether a certain classification system offers a good representation of scientific fields. This limited perspective on the evaluation of field-normalized indicators was criticized by *Sirtes* [11.109] in a letter commenting on *Radicchi* and *Castellano* [11.105]; for a response, see [11.110]. According to *Sirtes* [11.109]; see also [11.108], it is incorrect to evaluate a field-normalized indicator using the same classification system that is also used in the calculation of the indicator. This brings us to the second question raised in the beginning of this section: How suitable are different field classification systems for the purpose of field normalization?

Evaluations of the use of the WoS journal-based field classification system for the purpose of field normalization have been reported by *van Eck* et al. [11.111] and *Leydesdorff* and *Bornmann* [11.112]. In both studies, the appropriateness of the fields in the WoS classification system for normalization purposes is questioned. For other studies questioning the use of the WoS classification system and proposing the use of alternative classification systems, we refer to *Bornmann* et al. [11.8], *Neuhaus* and *Daniel* [11.9], *van Leeuwen* and *Calero Medina* [11.11], and *Ruiz-Castillo* and *Waltman* [11.13]. A systematic methodology for comparing the suitability of different classification systems for field-normalization purposes was presented by *Li* and *Ruiz-Castillo* [11.113]. We refer to *Perianes-Rodriguez* and *Ruiz-Castillo* [11.14] for an application of this methodology.

Empirical approaches to the evaluation of field-normalized impact indicators also study the extent to which these indicators correlate with peer review. At the level of research programs and research departments in the natural sciences, indicators that use the standard normalization approach of dividing the actual number of citations of a publication by the expected number of citations have been shown to be moderately correlated with peer review assessments made by expert committees [11.114, Chap. 19], [11.115]. The correlation between normalized impact indicators and peer review has also been analyzed based on peer review outcomes from the Research Assessment Exercise (RAE) in the UK [11.116]. The main finding of this analysis is that impact indicators normalized at the level of journals hardly correlate with peer review, while impact indicators normalized at the level of journal-based fields in the WoS database or units of assessment in the RAE correlate significantly with peer review.

At the level of individual publications, the recently introduced relative citation ratio indicator has been claimed to be *well correlated* with expert judgments [11.61, p. 9]. However, in a study by *Bornmann* and *Haunschild* [11.117], the correlation between the relative citation ratio indicator and expert judgments was characterized as *only low to medium* (p. 1064). In addition, it has been shown that, in terms of correlation with peer review, the relative citation ratio indicator has a performance that is similar to other field-normalized impact indicators. The studies by *Hutchins* et al. [11.61] and *Bornmann* and *Haunschild* [11.117] both make use of F1000 post-publication peer review data. Data from F1000 has also been used to analyze, at the level of individual publications, how strongly a number of field-normalized impact indicators correlate with peer review [11.118]. It was found that different field-normalized impact indicators all have a similar correlation with peer review. However, the authors leave open the possibility that F1000 data may not be sufficiently accurate to make fine-grained distinctions between different field-normalized impact indicators.

11.6 How Much Difference Does It Make in Practice?

We have discussed a large number of field-normalized indicators as well as a large number of field classification systems that can be used by these indicators. We now consider the following question: How much difference does the choice of a field-normalized indicator, and possibly also a field classification system, make in practice, for instance, when field-normalized indicators are used in the evaluation of research institutions, research groups, or individual researchers?

Various papers have presented analyses that provide insight into this question, most of them focusing on field-normalized indicators of impact. Before reporting our own analysis, we first briefly mention some of these papers, without going into the details of their findings. At the level of individual publications, the sensitivity of field-normalized indicators to the choice of a field classification system was studied by *Zitt* et al. [11.3]. In the context of quantifying the impact of journals, field-normalized indicators that use a field classification system (Sects. 11.4.1 and 11.4.2) were compared with field-normalized indicators that use citing-side normalization (Sect. 11.4.3) and that do not require a field classification system [11.106, 119]. Similar comparisons have also been made for indicators based on Mendeley bookmarks [11.17]. In the context of quantifying the impact of research institutions and their internal units, a number of studies investigated for specific field-normalized indicators the effect of the choice of a field classification system. The use of the WoS journal-based classification system was compared with the use of other less fine-grained journal-based systems [11.38, 120], but also with the use of more fine-grained publication-based systems [11.13]. In addition to analyzing the effect of the choice of a classification system, studies have also compared different normalization approaches for a given classification system. *Perianes-Rodriguez* and *Ruiz-Castillo* [11.121], for instance, performed a comparison of two different ways in which normalized impact indicators can be obtained at the aggregate-level of research institutions. Finally, as has already been mentioned, field-normalized indicators of productivity have received relatively limited attention in the literature. A comparison of two ways in which the FSS indicator (Sect. 11.4.4) can be calculated at the level of research institutions was reported by *Abramo* and *D'Angelo* [11.122].

11.6.1 Empirical Analysis of the Sensitivity of Field-Normalized Impact Indicators to the Choice of a Field Classification System

Complementary to the studies mentioned above, we now present our own analysis. Our focus is on the sensitivity of field-normalized impact indicators to the choice of a field classification system. We are interested in particular in the sensitivity of the indicators at lower levels of aggregation, that is, at the level of internal units within a research institution. This level is highly relevant in practical applications of field-normalized impact indicators.

The mean normalized citation score (MNCS) [11.18] (Sect. 11.4.1), and the proportion of top 10% publications (PP(top 10%)) [11.49] (Sect. 11.4.2), represent two of the most frequently used size-independent field-normalized impact indicators (taking into account also the use of variants of these indicators in commercial tools such as InCites and SciVal). Given the popularity of these indicators, it is important to understand their sensitivity to the choice of a field classification system. In this section, we, therefore, analyze the sensitivity of these indicators to the choice between, on the one hand, a traditional journal-based classification system, namely the classification system consisting of about 250 fields that is available in the WoS database, and, on the other hand, a publication-based classification system constructed algorithmically using the methodology of *Waltman* and *van Eck* [11.12]. At the level of research institutions, the sensitivity to the choice between these two classification systems has been found to be relatively limited [11.13]. However, this sensitivity has not yet been analyzed in a systematic way for smaller units. Below we present such an analysis for internal units within a large European university.

Our analysis is based on the WoS database. More specifically, we use the Science Citation Index Expanded, the Social Sciences Citation Index, and the Arts & Humanities Citation Index. We use data on the publications of our focal university in the period 2010–2014. Publications are assigned to internal units within the university at three hierarchical levels. We refer to these levels as the faculty level, the department level, and the research group level. We take into only take into account units that have at least 50 publications. Also, only publications classified as research articles or review articles are considered. There are 13 faculties, 36 departments, and 130 research groups with 50 or more publications. Some basic statistics on the numbers of publications of these faculties, departments, and research groups are reported in Table 11.1.

Citations are counted until the end of 2015. Author self-citations are excluded. In the case of the WoS journal-based classification system, publications in journals belonging to the *Multidisciplinary Sciences* category are reassigned to other categories based on their references. In the case of the publication-based classification system, we use a system that includes about 4000 fields. This is in line with the recommendation made by *Ruiz-Castillo* and *Waltman* [11.13]. The calculation of the

Table 11.1 Statistics on the numbers of publications of the faculties, departments, and research groups of the focal university

	Number of units	Number of publications			
		Min.	Max.	Mean	Median
Faculties	13	88	7626	1423.7	945.0
Departments	36	54	2785	560.3	322.5
Research groups	130	50	766	166.4	116.5

MNCS and PP(top 10%) indicators is based on, respectively, *Waltman* et al. [11.18] and *Waltman* and *Schreiber* [11.49]. Normalization is performed for field and publication year, but not for publication type. A full counting approach is taken. Hence, each publication authored by a unit is fully counted for that unit, irrespective of possible co-authorship with other units inside or outside the focal university.

The results of the analysis are presented in Fig. 11.1 for the 13 faculties, in Fig. 11.2 for the 36 departments, and in Fig. 11.3 for the 130 research groups. Each figure shows two scatter plots, one for the MNCS indicator

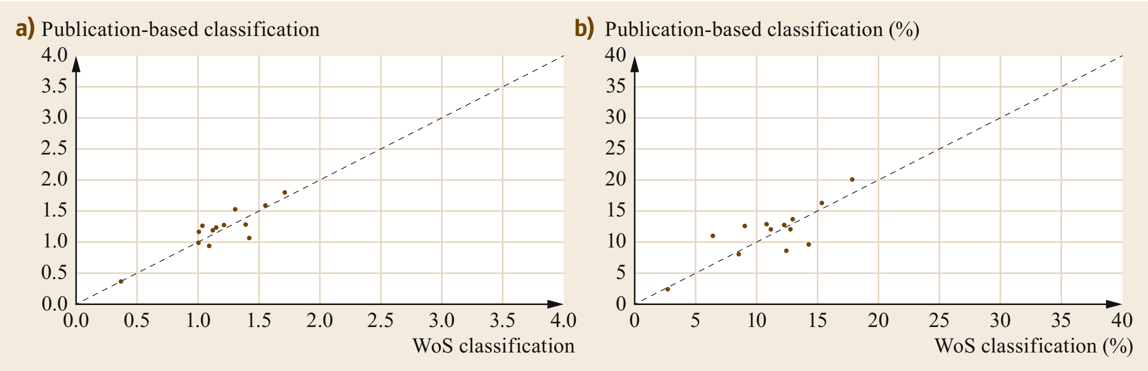

Fig. 11.1a,b Scatter plots of the MNCS **(a)** and PP(top 10%) **(b)** values of the 13 faculties of the focal university, obtained using either the WoS journal-based classification system or a publication-based classification system

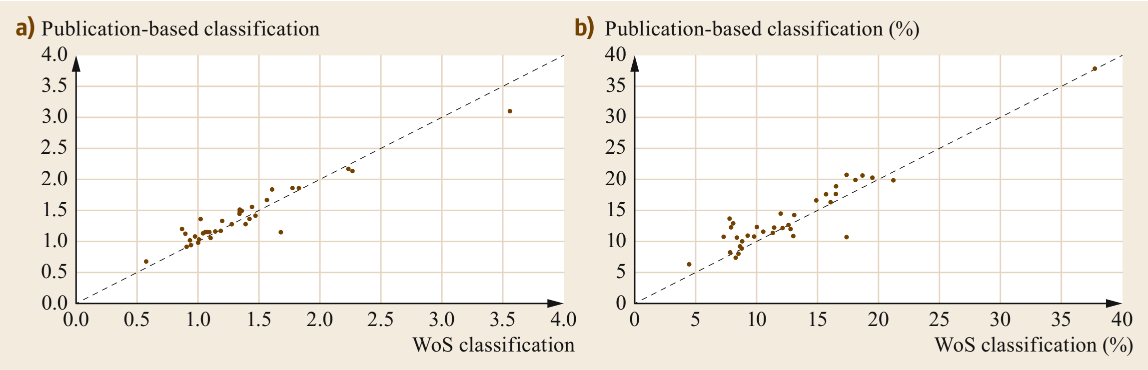

Fig. 11.2a,b Scatter plots of the MNCS **(a)** and PP(top 10%) **(b)** values of the 36 departments of the focal university, obtained using either the WoS journal-based classification system or a publication-based classification system

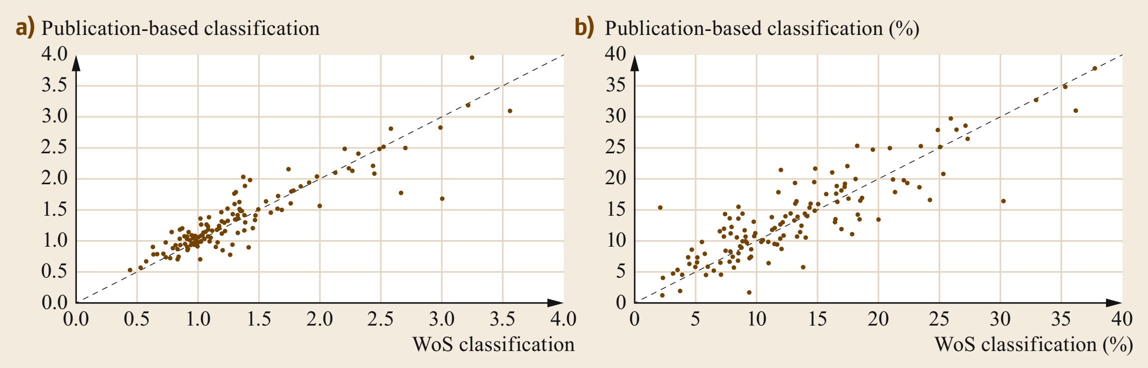

Fig. 11.3a,b Scatter plots of the MNCS **(a)** and PP(top 10%) **(b)** values of the 130 research groups of the focal university, obtained using either the WoS journal-based classification system or a publication-based classification system

Table 11.2 Statistics on the differences between the indicator values obtained using the WoS journal-based classification system and the indicator values obtained using a publication-based classification system

	Pearson correlation		Mean absolute difference		% units with large difference	
	MNCS	PP(top 10%)	MNCS	PP(top 10%)	MNCS	PP(top 10%)
Faculties	0.89	0.80	0.12	2.0%	0.0%	0.0%
Departments	0.95	0.93	0.12	1.8%	2.8%	5.6%
Research groups	0.91	0.87	0.17	2.7%	5.4%	14.6%

and one for the PP(top 10%) indicator. In addition, Table 11.2 reports a number of statistics that summarize the differences between the results obtained using the WoS journal-based classification system and those obtained using the publication-based classification system. For both the MNCS indicator and the PP(top 10%) indicator, the table presents the Pearson correlation between the results obtained using the two classification systems. Moreover, the table also shows the mean absolute difference between the results and the percentage of units for which the difference is considered to be large. A difference in the MNCS value of a unit of more than 0.5 is regarded as large. In the case of the PP(top 10%) indicator, we regard a difference of more than 5 percentage points as large.

The results in Table 11.2 show that the mean absolute differences are larger at the level of the research groups than at the level of the faculties and the departments. Likewise, the percentage of units with large differences is highest at the research group level. These findings may not be surprising. Research groups on average have a much smaller number of publications than faculties and departments (Table 11.1), and, therefore, the MNCS and PP(top 10%) values of research groups can be expected to be more sensitive to the choice of a classification system than the corresponding values of faculties and departments. Based on the results in Table 11.2 and Figs. 11.1–11.3, it can also be concluded that the PP(top 10%) indicator is more sensitive to the choice of classification than the MNCS indicator.

Based on our results, how sensitive are field-normalized impact indicators to the choice of a field classification system? The answer to this question may depend on the expectations that one has. Some readers may consider the differences between the results obtained using the WoS journal-based classification system and the results obtained using the publication-based classification system to be within an acceptable margin. Others may be concerned to see, for instance, that for about one out of seven research groups the PP(top 10%) indicator increases or decreases by more than 5 percentage points when changing the classification system based on which the indicator is calculated (Table 11.2). Our perspective is that the results illustrate the risk of overinterpreting field-normalized indicators, especially at lower levels of aggregation, such as the research group level. There is no perfect way to correct for differences between fields. Different field normalization approaches make different choices in how they correct for field differences. Each approach is informative in its own way. When working with one specific field-normalization approach, it is essential to keep in mind that this approach offers just one perspective on field normalization and that other approaches will give a different perspective, in some cases even a perspective that may be different in a quite fundamental way.

11.7 Conclusion

Some critics question whether field normalization is truly attainable. In the literature, this viewpoint is represented by *Kostoff* [11.123] and *Kostoff* and *Martinez* [11.124], who criticize the idea of field-normalized impact indicators, arguing that citation counts of publications should be compared only if publications are very similar to each other. According to *Kostoff* and *Martinez* [11.124, p. 61]:

> a meaningful 'discipline' citation average may not exist, and the mainstream large-scale mass production semi-automated citation analysis comparisons may provide questionable results.

In principle, critics make a valid point. Taking their position to the extreme, one could argue that every publication is unique in its own way and, consequently, that any comparison of citation counts of publications is problematic. Likewise, it could be argued that every researcher is unique and that any comparison of publication and citation counts of researchers is, therefore, in some sense unfair.

However, one may also take a more pragmatic perspective on the idea of field normalization. In managing and evaluating scientific research, there is often a need to compare different research units (e. g., research institutions, research groups, or individual researchers).

Scientometric indicators, of course, provide an incomplete picture of the units to be compared. Moreover, these indicators are affected by all kinds of distorting factors, for instance, related to the characteristics of the underlying data sources, the peculiarities of the units to be compared, and the nature of the scientific fields in which these units are active. Nevertheless, despite their limitations, scientometric indicators provide useful and relevant information for supporting the management and evaluation of scientific research. In many cases, the usefulness of scientometric indicators can be increased by making corrections for some of the most significant distorting factors, and field differences typically are one such a factor. Field normalization does not correct for all distorting factors, but it corrects at least partly for one of the most important ones. From this point of view, field normalization serves an important practical purpose.

11.7.1 Strengths and Weaknesses of Different Field-Normalization Approaches

We have provided an overview of a large number of approaches to field normalization. Although some field-normalization approaches can be considered superior over others, we do not believe there to be a single optimal approach. Instead, there is a trade-off between the strengths and weaknesses of different approaches. Some field-normalization approaches have a high level of technical sophistication. These approaches may, for instance, use an algorithmically constructed publication-based field classification system or they may not need a classification system at all, and instead of the traditional full counting method, these approaches may use a fractional counting method for dealing with co-authored publications. Other field normalization approaches are much more basic. For instance, they rely on the standard journal-based classification system made available in a database such as WoS or Scopus and they handle co-authored publications using the standard full counting method. In general, the more sophisticated approaches can be expected to better correct for field differences than the more basic approaches. On the other hand, however, the more basic approaches tend to be easier to understand and more transparent. This enables users to carefully reflect on what a field-normalized indicator does and does not tell them, and it allows users to recognize the limitations of the indicator. The more sophisticated approaches tend to be black boxes for many users, forcing users to blindly trust the outcomes provided by these approaches. Due to the low level of transparency, it is difficult for users to understand the limitations of the more sophisticated approaches and to interpret the outcomes obtained using these approaches in the light of these limitations.

As a general rule, in situations in which in-depth reflection on scientometric indicators is desirable or even essential, for instance, when indicators are used to support the evaluation of individual researchers, we recommend the use of simple and transparent field-normalization approaches. Complex non-transparent approaches should not be used in such situations. On the other hand, there are also situations in which the use of more advanced field-normalization approaches, possibly with a relatively low level of transparency, may be preferable. This could be the case in situations in which scientometric indicators are used at a high level of aggregation, for instance, at the level of entire research institutions or countries, where in-depth reflection on the indicators may hardly be possible, or in situations in which scientometric indicators are used in a purely algorithmic way, for instance, when they are embedded in a funding allocation model.

11.7.2 Contextualization as an Alternative Way to Deal with Field Differences

We end this chapter by pointing out that field normalization is not the only way to deal with field differences in scientometric analyses. When detailed assessments need to be made at the level of individual researchers or research groups, an alternative approach is to use straightforward non-normalized indicators and to contextualize these indicators with additional information that enables evaluators to take into account the effect of field differences [11.125]. For instance, to compare the productivity of researchers working in different fields, one could present non-normalized productivity indicators (e. g., total publication or citation counts during a certain time period) for each of the researchers to be compared. One could then contextualize these indicators by selecting for each researcher a number of relevant peers working in the same field and by also presenting the productivity indicators for these peers. In this way, each researcher's productivity can be assessed in the context of the productivity of a number of colleagues who have a reasonably similar scientific profile.

An advantage of the above contextualization approach could be that it may lead to a less mechanistic way of dealing with field differences. In our experience, field-normalized indicators tend to be used quite mechanistically, with little attention being paid to their limitations. This is problematic, especially at lower levels of aggregation, for instance, at the level of individual researchers or research groups, where field-normalized indicators are quite sensitive to methodological choices, such as the choice of a field classification system. In a research evaluation, the contextualization approach outlined above may encourage evaluators to reflect more deeply on the effect of field differences and to perform inter-field comparisons in a more cautious and thoughtful way. It may also invite evaluators to combine scientometric evidence of field differences with their own expert knowledge of publication, collaboration, and citation practices in different fields of science. Hence, peer review and scientometrics may be used together in a more integrated manner, which can be expected to improve the way in which research is evaluated [11.125].

Acknowledgments. The authors would like to thank Lutz Bornmann, Robin Haunschild, Loet Leydesdorff, Javier Ruiz-Castillo, and an anonymous referee for their helpful comments on an earlier version of this chapter. These comments have led to numerous improvements.

Centre for Science and Technology Studies (CWTS)
Leiden University
Leiden, The Netherlands
ecknjpvan@cwts.leidenuniv.nl

Nees Jan van Eck is Senior Researcher at the Centre for Science and Technology Studies (CWTS) at Leiden University in the Netherlands. He is conducting research in the field of bibliometrics and scientometrics. Nees Jan is co-developer of VOSviewer and CitNetExplorer, two well-known software tools for visualizing bibliometric data. His current research interests focus on the study of bibliometric data sources and the analysis of full-text scientific publications.

12. All Along the *h*-Index-Related Literature: A Guided Tour

András Schubert, Gábor Schubert

In this chapter, a survey of the literature related to the *h*-index (referred to as *h*-related literature) between 2005 and 2016 is presented. In the first section, the basic definitions and a brief historical account are given. After providing an overview of the typology of the *h*-related publications and some earlier reviews, the more than 3000 *h*-related publications collected from four databases (Web of Science, Scopus, Google Scholar and Microsoft Academic) are analyzed by bibliometric methods. Document types, publication sources, subject categories, geographical distributions, authors and institutions, citations and references are listed and mapped. Several examples of applications of the *h*-index, within and outside the area of scientometrics, are presented, with particular attention to the possibilities for using the *h*-related indices as a network measure. Among the mathematical models used to explain and interpret the index and its relatives, Hirsch's model, the Lotkaian framework, models based on extreme value theory and on fuzzy integrals, and axiomatic approaches are demonstrated.

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_12

12.1 *h*-Index Basics

In 2005, the seminal paper by *Jorge E. Hirsch* introduced a new approach, the h-index, as a way "to quantify an individual's scientific research output" [12.1]. Since then, the h-index has gained great notoriety, as a flood of papers have appeared in efforts to explain, apply, modify, improve, extend or otherwise exploit the concept. This chapter aims to provide am overview of the h-related literature during the period from 2005 to 2016.

12.1.1 Definitions

To begin, we present a few authoritative or commonly found definitions:

> A scientist has index h if h of his or her N_p papers have at least h citations each, and the other $(N_p - h)$ papers have no more than h citations each. [12.1]

> A scientist has h-index equal to H if the top H of his/her N publications from the ranked list have at least H citations each. [12.2]

> $h = \max_i\{C_i \geq i\} i = 1, 2, \ldots, P \wedge C_i \geq C_i + 1$, where P is the number of papers of an author and C_i is the number of citations of the i-th paper, in decreasing order. [12.3]

> h-index $= \max_i \min(f(i), i)$, where $f(i)$ is the number of citations to the i-th publication ordered by decreasing number of citations. [12.4]

A graphical definition of the h-index from a plot of decreasing citations for numbered papers is shown in Fig. 12.1.

12.1.2 The Prehistory of the Index

In a letter to the journal *Nature* in 2005 [12.5], *Anthony W.F. Edwards*, retired Professor of Biometry at Cambridge, shared a memory of his late colleague, Sir Harold Jeffreys, who used a measure similar to Hirsch's proposed index

> for recording his cycling prowess, n being the highest number of days on which he had cycled n or more miles. I think he told me, some 35 years ago, that his n was 70 and that he first had the idea from his fellow cyclist, the astrophysicist Arthur Eddington.

Attempts to give credit to these pioneers by naming the index after Jeffreys or Eddington did not gain wide popularity. Nevertheless, some instances can be found. For example, a post by Leviathan, *What is your Eddington Number?*, appeared on the road.cc bike forum in 2015 [12.6]. And in an article entitled *Calculate your Eddington Number!* on the swinny.net site [12.7], John Swindells presents statistics on cyclists using the Strava app.

Trivia

The above-mentioned Eddington number is not to be confused with another Eddington number, N_{Edd}, which represents the number of protons in the observable universe. In the 1938 Tarner Lecture at Trinity College, Cambridge, Eddington proclaimed:

> I believe there are 15 747 724 136 275 002 577 605 653 961 181 555 468 044 717 914 527 116 709 366 231 425 076 185 631 031 296 protons in the universe and the same number of electrons.

This large number soon became known as the *Eddington number* [12.8].

12.1.3 The Name of the Index

The letter h of the index is generally regarded as a reference to the initial letter of the family name of its creator.

In an interview with *Gualberto Buela-Casal* [12.9], *Hirsch* offered another explanation:

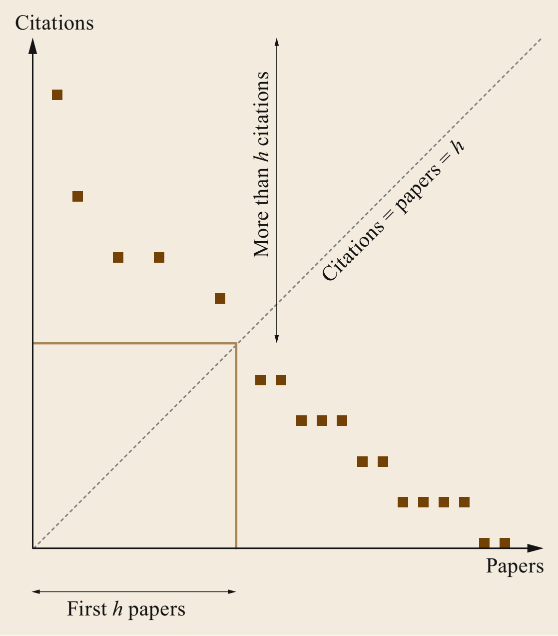

Fig. 12.1 Graphical definition of the h-index (after [12.4])

> I originally thought of calling it 'x index' because it is obtained by determining the intersection between the 'number of citations' (y) versus 'paper number' (x) curve and the $y = x$ line, which leads to an x-shaped graph. Then I thought that 'x' could suggest 'x-rated' so I decided to call it 'h' instead because a high h-index suggests 'highly cited' and 'high achievement'.

Even if it was not his intention, however, Hirsch could not avoid the eponymic association: beginning with *Frangopol*'s paper as early as 2005 [12.10], about 5% of the h-index-related literature refers to the index as the Hirsch index.

A logical choice would be to call the originally conceived formula (h-index for the lifetime achievement of individual researchers) the Hirsch index, and all other indices formed in an analogous manner but with a different premise, Hirsch-type indices or, as shorthand, h-indices. The practice of nomenclature, however, is rarely governed by pure logic.

The attributive *Hirsch-type* appears to have been coined by *Braun*, *Glänzel* and *Schubert* [12.11] to denote indices defined by an algorithm similar to that used by Hirsch in defining the h-index, irrespective of the content of the underlying variables. The term was used in about 2% of the h-index-related literature.

Occasionally, and mainly among journalists and bloggers, the index is also called the h-number or h-factor. It is best to avoid this practice in the scholarly literature, since these terms are widely used in quite different contexts. First, the Hirsch length or Hirsch number of a polycyclic group G is the number of infinite factors in its subnormal series [12.12]. Second, the H-factor is a kinetic model for the rate of delignification in kraft pulping [12.13].

Even the name h-index itself is far from unambiguous. Shannon's diversity index (also referred to as the Shannon–Wiener index) was originally denoted by H', but the name H-index is also frequently used [12.14]. This may be particularly misleading, since it is a statistical indicator of frequency distribution as well. Similarly confusing is the use of H to denote another concentration index: the Herfindahl (also known as Herfindahl–Hirschman) index [12.15]. The term H-index may denote the horizontal (H) component of the index describing geomagnetic disturbance fields [12.16]. It is also typical shorthand for the hemolysis index [12.17], and is used in the acoustic analysis of human speech [12.18].

12.1.4 The Advent of the *h*-Index

Hirsch originally submitted his paper to the Physics and Society section of arXiv on August 3, 2005 [12.19]. The fifth and final version was published September 29, 2005. Hirsch's work gained notoriety after it appeared as the subject of an article by *Philip Ball* published in the journal *Nature* [12.20]. According to the Web of Science, through 2016, Ball's paper was cited in 175 publications, among which more than 90% cited Hirsch's original paper as well.

12.2 A General Overview of the Literature on the *h*-Index

The sudden fame and flame enkindled by Hirsch's paper inspired literally hundreds of scientists and scholars to join the debate. The h-index was celebrated and condemned, specialized and generalized, and improved and deteriorated (although the latter not admittedly) in an ever-growing number of publications. By the end of 2016, more than 3000 publications were connected to Hirsch's paper.

Navigating this literature jungle is facilitated by some excellent reviews.

Alonso et al. [12.21] should be mentioned first, not only because it was the first such review and because of its comprehensiveness and clarity, but also because a somewhat updated version can be found on the authors' *h-Index and Variants* website [12.22], with useful links to the reviewed papers and to several other h-index-related pages.

The work by *Norris* and *Oppenheim* [12.23] appeared almost simultaneously with that of Alonso et al., and in large part addressed the same literature base, although the authors state in the abstract that they "drew on a range of material published in 1990 or so sources published since 2005". Without calling in question the validity of this statement, we find that it is not supported later in the paper.

Two recent books contain extensive literature reviews on the h-index and related topics.

The *Handbook of Bibliometric Indicators* by *Todeschini* and *Baccini* [12.3] is an encyclopedic compilation of all kinds of bibliometric and related indicators. The book contains almost 200 articles (basic indicators or groups of indicators) and more than 1000 keywords in alphabetical order, along with a bibliography of almost 2000 references.

An extensive article on the *h*-index can be found on pp. 162–196, with more than 100 references, commensurate with dedicated review papers.

As the first volume of a new Springer series, *Qualitative and Quantitative Analysis of Scientific and Scholarly Communication*, *Vitanov* published a book with a special focus on bibliometric indicators [12.2]. In Chapter 2 (*Commonly Used Indexes for Assessment of Research Production*), 22 pages (pp. 63–84) and 96 references are devoted to the *h*-index and related indicators. There is also a section in Chapter 5 (*Modeling Production/Citation Process*) where theoretical considerations underlying the *h*-index are treated in detail.

With such excellent review literature available, some of which is quite recent, it seems pointless to reiterate in detail all that has already been said.

Summarizing, and somewhat reconsidering, the above sources, the literature of the *h*-index can be grouped into a few broad categories:

- Introducing the index to specific audiences
  (Fictitious example: *A new index every psychiatrist should know*).
- Application of the index to actual samples
  (Fictitious example: *Top Hungarian oenologists according to their h-index ranking*).
- Comparing/correlating/combining the index with other indicators
  (Fictitious example: *How do the salaries of professors depend on their PageRank and h-index?*).
- Revealing deficiencies (real or imagined) of the index
  (Fictitious example: *The h-index is too complex to reflect real research efforts in soft sciences*).
- Modifying (allegedly, *improving*) the index
  (Fictitious example: *The* $h^{==}$ *index eliminates the effects of social inequalities among researchers*).
- Extending, generalizing the index
  (Fictitious example: *An h-type index in horse betting*).
- Analyzing the theoretical background of the index
  (Fictitious example: *A relativistic quantum h-index for connoisseurs*).

For the majority of papers, of course, categorization is ambiguous or uncertain.

An obvious option, the scientometric analysis of the *h*-index literature, seems to having been somewhat neglected so far. Two papers by *Zhang* et al. [12.24, 25] focus on specific methodological questions rather than providing a general overview.

A substantial part of the *h*-index-related papers argue against the *h*-index. The basis of this criticism is multifarious, and in many respects parallels the objections to the impact factor.

The following provides a typology of objections to the impact factor [12.26, 27]:

(1) Disapproving citation-based or, more generally, all scientometric evaluation
(2) Questioning the suitability of the mean as a characteristic indicator of a sample
(3) Criticizing the choice of publication and citation windows
(4) Condemning the neglect of disciplinary differences
(x) Condemning the neglect of differences between journal types (e.g., review journals)
(5) Condemning the neglect of differences between document types
(6) Condemning the neglect of the role of self-citation
(7) Questioning the use of the impact factor for the evaluation of entities other than journals (individuals, institutions, etc.).

Points (1), (3), (4), (5) and (6) can be transferred to the *h*-index without any change.

Point (x) has relevance only if the *h*-index of journals is considered.

Regarding point (2), the statistical properties of the sample mean are well known, so it is easy to decide whether, in a given case, it is statistically suitable. The *h*-index is much more elusive for standard statistical inquiries. A frequent objection is that it depends on both the sample size (the number of publications) and the distribution of citations. This characteristic is, of course, an inherent property of the *h*-index. The statistical interpretation of this property was therefore an important element of *h*-index research.

Regarding point (7), unlike the case with the impact factor, the use of an index analogous to the *h*-index for objects other than for which it was originally conceived does not seem to present any obstacle. (As we can see, it was even successfully applied to the cyclist community.)

Adding point (8) to the above list, we note that critics often condemn the *h*-index for neglecting the problem of multiauthored papers.

And not mentioned in the above list is point (9): both the impact factor and the *h*-index may be disapproved for the imperfections in the underlying database.

The *disadvantages* of the *h*-index asserted in various sources can largely be classified into one or more of the above categories.

For example, the disadvantages listed in the previously mentioned review by *Alonso* et al. [12.21] (see also the *h-index and Variants* website [12.22]) and in the expedient practical guide to the use of

Table 12.1 Categorization of the reported disadvantages of the h-index

Disadvantage (according to *Alonso* et al. [12.21])	Category
There are inter-field differences in typical h values due to differences among fields in productivity and citation practices, so the h-index should not be used to compare scientists from different disciplines.	(4)
The h-index depends on the duration of each scientist's career, because the pool of publications and citations increases over time.	(3)
Highly cited papers are important for the determination of the h-index, but once they are selected as belonging to the top h papers, the number of citations they receive is unimportant.	(2)
Since the h-index is easy to obtain, we run the risk of indiscriminate use, such as relying only on it for the assessment of scientists. Research performance is a complex, multifaceted endeavor that cannot be adequately assessed by means of a single indicator.	(1)
The use of the h-index could provoke changes in the publishing behavior of scientists, such as an artificial increase in the number of self-citations distributed among the documents on the edge of the h-index.	(1), (6)
There are also technical limitations, such as the difficulty in obtaining the complete output of scientists with very common names, or determining whether self-citations should be removed.	(6), (9)
Disadvantage (according to *Franceschini* and *Maisano* [12.28])	**Category**
h does not take into account multiple co-authorship.	(8)
h does not take into account self-citations.	(6)
h is not useful for cross-disciplinary comparisons because citation rates and scholarly productivity vary considerably among disciplines.	(4)
h does not take into account the age of publications.	(3)
h does not consider the publication type.	(5)
The h-index for a scientist can be easily calculated by using public databases like WoS or GS. Unfortunately, their information can be affected by citation errors—for instance caused by homonymous author names, typographical errors in the source papers, or errors due to some nonstandard reference formats.	(9)

the h-index by *Franceschini* and *Maisano* [12.28] are representative of the categories as indicated in Table 12.1.

Evidently, most of the modifications or improvements proposed in hundreds of papers in the h-index-related literature attempt to circumvent, solve or at least partially remedy these problems.

12.3 Compiling h-Index Bibliographies from Various Bibliographic Databases

Collecting the h-index-related literature is largely facilitated by the fact that a vast majority of papers dutifully cite Hirsch's original paper. Indeed, a citation to Hirsch's paper is an unambiguous sign that the content is somehow related to the h-index. Therefore, works citing Hirsch's paper can be considered a good starting point for a bibliography.

In a bibliometric analysis of the h-index-related literature, *Rousseau* et al. [12.29] compiled a sample of 924 papers counted in the "number of citations received" by Hirsch's original paper in the Web of Science (WoS) between 2005 and 2011 (called H-articles by the authors). Our present analysis is an extension of this effort:

- Extending in time until 2016
- Using a cited reference search to find as many stray citations as possible
- Using and comparing several databases as source
- Complementing citation search with keyword search.

The results of keyword search were carefully cleaned from irrelevant items, where the name Hirsch or the term h-index was used in quite different context.

12.3.1 Web of Science

In the Web of Science (WoS), after careful preliminary studies, the following cited reference search was used:

```
Cited Author: hirsch j* OR hirsh J*
Cited Work: arx* OR ind* OR
an-index* OR p-n* OR pnas OR
natl* OR p*0508025 OR a*0508025
Cited Year: 2005 OR 2006
```

Part B | 12.3

WoS Core Collection (comprising Science Citation Index Expanded (SCI-EXPANDED), Social Sciences Citation Index (SSCI) and Arts & Humanities Citation Index (A&HCI)), Conference Proceedings Citation Index – Science (CPCI-S), Conference Proceedings Citation Index – Social Science & Humanities (CPCI-SSH), Book Citation Index – Science (BKCI-S) and Book Citation Index – Social Sciences & Humanities (BKCI-SSH) have been searched.

Hirsch's paper was found to have been cited in 53 variants (see Appendix 12.A) in a total of 2626 citing papers published between 2005 and 2016.

Two strange "co-authored" versions of Hirsch's paper (in the first and the last row of Appendix 12.A) were the results of errors made by the authors of the citing papers (and in part by the editors of the publishing journals). The authors might confuse the bibliographic data of two consecutive items in the reference list, resulting in a kind of hybrid item. In one case, a correct reference to Hirsch's paper was also present.

In order to find the non-citing *h*-index-related papers, the citation-based list was complemented with the relevant results of an advanced search:

```
TS=(h-index* OR h-indice* OR
((hirsch OR hirsh) SAME (index*
OR indice*))) AND PY=(2005-2016)
```

Irrelevant items were filtered out manually. The citation-based list could thus be complemented with 416 items, resulting in a full WoS bibliographic collection of 3042 papers published between 2005 and 2016.

As we can see, $2626/3042 = 86.3\%$ of the compiled bibliography contained references to Hirsch's original paper. This is an unusually high value, which cannot be explained simply by the originality or the importance of the idea. For instance, in the case of the literature regarding the impact factor (a no less original, important and widely discussed indicator), the original paper by *Garfield* [12.30] collected less than half the number of citations during its full lifetime than did Hirsch's paper, while the total size of the impact factor-related publications was more than four times that of the *h*-index-related literature. The percentage of impact factor-related papers containing reference to Garfield's paper is about 10%, which by and large has remained constant over the last few decades. How strongly a concept is connected to a specific paper is apparently dependent on a multitude of factors that fall outside the realm of bibliometrics.

12.3.2 Scopus

The advanced search

```
REF(hirsch AND j* AND (2005 OR
2006) AND ("index to quantify" OR
0508025))
```

returned 3151 document results published between 2005 and 2016. In addition to 2999 citations in the standard format, 152 stray citations were received by a long list of improper variants. Here we list just a few examples:

Hirsch, J.E., (2005) Arxhiv, 5, pp. 1–5
Hirsch, J.E., (2005) arXiv.org E-Print Archive

A keyword search

```
TITLE-ABS-KEY (h-index OR
hirsch-index OR hirsch-type-ind*)
```

resulted in 458 additional papers after removing duplicates and non-relevant items from the citation search results. The total Scopus bibliography thus contained 3608 items.

The percentage share of documents citing Hirsch's paper in the Scopus bibliography is 87.3%, very similar to the WoS value.

There were 2564 papers included in both the WoS and the Scopus bibliography (84% of the WoS, 71% of the Scopus total). The great majority of the papers were included in both databases. A closer look at the lists reveals some reasons for the differences:

- Scopus covers several non-English (mainly Chinese and Spanish) journals not covered by the WoS.
- There is a difference between the two databases in their handling of the most recent literature: Scopus (understandably) is rather prompt in recording Elsevier journals, but does not contain the reference lists until the paper is in press. These papers are, therefore, irretrievable for citation search.
- There are certain random recording errors in the lists of references, obviously different between the two databases. These are not only stray references, but in our case, the notorious Hirsch reference was sometimes simply missing in one or the other database.

The annual number of documents in the two bibliographies and those contained in each is shown in Fig. 12.2. The dynamic increase in the literature until 2013 seems to have slackened lately, but no real decline has yet been encountered.

12.3.3 Google Scholar

In spite of repeated warnings about its unreliability and manipulability [12.31, 32], even the critics admit that the recent version of Google Scholar (GS) "could become a potentially useful complementary resource" [12.33].

Its much wider coverage is reflected by the fact that it records 6110 documents citing Hirsch's paper between 2005 and 2016 (6278 in total; accessed February 13, 2017). Collection of citing documents was attempted using *Anne-Wil Harzing*'s Publish or Perish software [12.34], but because of the inherent limitations of GS, only the 1000 most highly cited publications could be retrieved. About two-thirds of these were included in the WoS or the Scopus citation-based bibliography. The remaining items were mainly books, documents available only on the internet, and articles in less internationally recognized journals.

In our search for items citing Hirsch's paper, we found nice examples for both the pros and the cons of GS. GS was able to identify papers as citing document even if WoS or Scopus was unable to do so. The paper [12.35] which was found to be the most cited paper ever citing Hirsch's work (6976 citations according to the GS), cited it as "J.E. Hirsch, physics/0508025 (2005)". It was properly assigned to the original paper. In our WoS cited reference search, we were able to include this version in the search profile; thus GS indeed became, in Jacsó's words, a "useful complementary resource". Among the false positives, a striking example is another rather highly cited item: G. Placzek: The scattering of neutrons by systems of heavy nuclei. Physical Review, 86(1) (1952) 377–388, receiving 636 citations according to GS. The source of this obvious error is somewhat—but by no means fully—

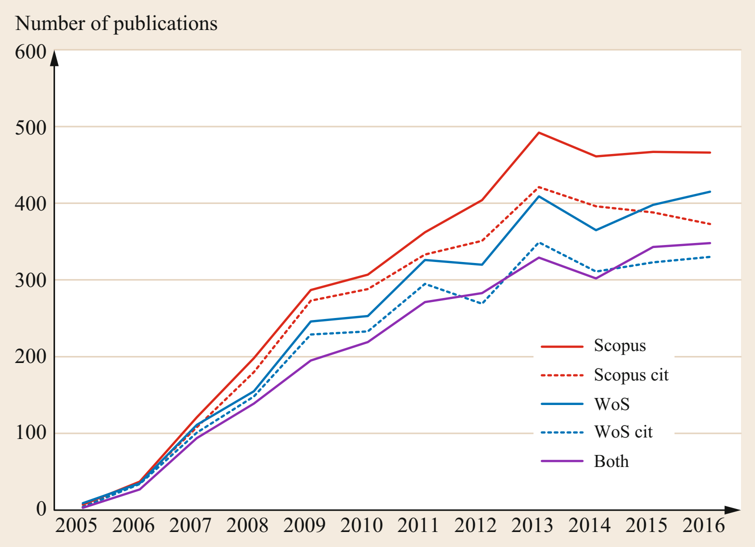

Fig. 12.2 The annual number of h-index-related documents (total and citation-based) in the Web of Science and the Scopus bibliographies and of documents contained in both databases

explained by the fact the PDF link does not point to Placzek's classic paper but to an unpublished manuscript: M. Cardona, W. Marx: Georg(e) Placzek: a bibliometric study of his scientific production and its impact. arXiv:physics/0601113 with references to both Placzek's and Hirsch's papers.

12.3.4 Microsoft Academic

After several years of seeming lifelessness, Microsoft Academic (MA) has lately been revived [12.36, 37] to become a strong competitor of GS.

A citation search for Hirsch's paper for the period 2005–2016 resulted in 3205 citing documents. Unfortunately, it is not possible to produce a complete (or even an incomplete but extensive) list of the citing items (not even with the Publish or Perish software).

We compared the 120 most cited items of the 3205 citing documents with the WoS, Scopus and GS lists. There were 12 items in the MA list not included in any other list: seven were published only on the internet, and three were conference materials. Two papers [12.38, 39], although included in the MA list, did not appear to contain any reference to Hirsch's paper.

12.4 A Bibliometric Overview of the *h*-Index Literature

12.4.1 Document Types

Although some of the document type categories bear different names in the WoS and the Scopus databases, the general features of the composition of the two bibliographies are evident (Fig. 12.3).

Articles
With a share consistently around 70%, the article is by far the leading article type in both the WoS and the Scopus bibliographies. Among articles, the overlap of the two databases is rather high as well: 92% of WoS and 78% of Scopus items are shared.

Conference Materials
In the WoS, conference materials are categorized as either *article; proceedings paper* (those published in regular journals or other serial issues), *proceedings paper* (published in standalone proceedings volumes) or *meeting abstracts* (in journals). These three categories make up the 12% of the WoS bibliography of *h*-index-related papers. The share of conference papers is almost identical in Scopus, but the overlap here is much lower than in the case of articles: 45% of WoS and 32% of Scopus items are shared. The selection in both databases seems to be rather haphazard. Quite frequently, the conference materials, in identical or slightly altered form, were also published as journal articles.

About two-thirds of the *h*-index-related conference papers in the WoS were computer science-related, and 1/4 of them fell into the category of information science & library science.

Editorials, Letters
The relatively high percentage of editorials is no surprise, since the editors of journals, regardless of research area, are those who are most concerned with the standing of their journal or, more generally, the actors (actors, institutes, etc.) in their field. Similarly, the interest (or sometimes anger) of the research community in evaluation-related questions is expressed in letters. This assumption is underscored by the fact that almost 20% of the impact factor-related literature consists of editorials; letters constitute about 4%. For comparison, in the

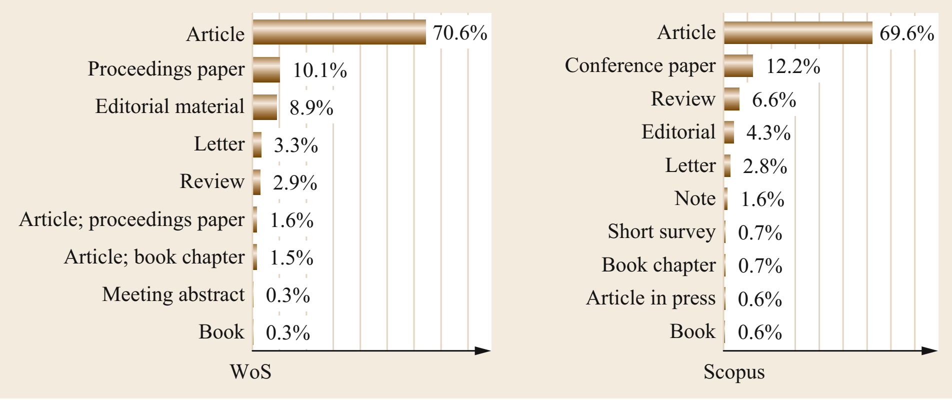

Fig. 12.3 The document type composition of the WoS and the Scopus bibliographies

literature of more neutral topics such as PageRank, percentile or network centrality, editorials are around 0.5% or less, and letters are around 0.1% or less.

Reviews

There appears to be a significant difference in the percentage share of reviews between the WoS and Scopus bibliographies: 2.9 and 6.6%, respectively. However, the difference is by and large illusory. Actually, almost 80% of the reviews found in Scopus can also be found in WoS but are not categorized as reviews. About half of Scopus reviews are articles or editorial materials in WoS.

Books

To our knowledge, no book devoted specifically to the h-index has yet been published.

Two books mentioned earlier [12.2, 3] contain extensive and useful sections on the topic. Neither is included in either of the two databases.

The WoS bibliography includes nine items of document type *book* and 46 *article; book chapter* items; in Scopus, 22 *book* and 27 *book chapter* items are included. The overlap is only around 20%.

Three books, included in both databases, may have special relevance for those interested in the application of the h-index: [12.40–42].

12.4.2 Sources

The 3042 documents of the WoS bibliography are dispersed among 1272 source titles, the 3608 Scopus items among 1584. About 75% of both lists contain only a single item. Almost 90% of the documents in the bibliographies were published in journals.

The top 18 journals with 10 or more papers in the WoS bibliography are shown in Table 12.2.

As the last column of the table shows, the first 10 positions are identical between the two databases. Scopus contains one title among the top producers not covered by WoS: Wuhan Daxue Xuebao (Xinxi Kexue Ban)/Geomatics and Information Science of Wuhan University, with 12 h-index-related publications.

Most of the top titles are as expected. The high activity of some surgery and neurosurgery journals is surprising, but the titles of the papers suggest real interest, even if at times mixed with doubt: "The use of the Hirsch index in benchmarking hepatic surgery research", "Application of the h-Index in Academic Plastic Surgery", "The Hirsch Index; Imaginary Number or High Value Currency?", "Use of the h index in neurosurgery", "Survey of the h index for all of academic neurosurgery: another power-law phenomenon?", etc. The top position of PLoS ONE, while not surprising, is remarkable.

The most productive non-journal sources are the proceedings of the biennial international conferences of the International Society for Scientometrics and Informetrics (ISSI), with 69 papers. The series Lecture Notes in Computer Science (including the subseries Lecture Notes in Artificial Intelligence and Lecture Notes in Bioinformatics), covered only by Scopus, published 64 h-index-related papers.

12.4.3 Subject Categories

Papers of both bibliographies can be assigned to subject categories according to the subject classification

Table 12.2 Journals publishing the greatest number of h-index-related papers in the WoS bibliography

WoS rank	Journal title	#	Scopus rank
1	Scientometrics	440	1
2	Journal of Informetrics	232	2
3	Journal of the Association for Information Science and Technology (formerly JASIST)	151	3
4	PLoS ONE	83	4
5	Current Science	36	5
6	Online Information Review	29	6
7	Malaysian Journal of Library & Information Science	21	7
8	Research Evaluation	20	8
9	Information Processing & Management	17	9
10	Journal of Neurosurgery	14	10
11	Profesional de la Informacion	13	13
12	Proceedings of the National Academy of Sciences of the United States of America	12	12
13–16	Journal of Information Science	11	15
13–16	Revista Espanola de Documentacion Cientifica	11	22
13–16	Scientific Reports	11	17
13–16	World Neurosurgery	11	11
17–18	Journal of Surgical Education	10	16
17–18	Nature	10	35

of the source journals. For the WoS, the Essential Science Indicators (ESI) Journal List [12.43] was used, and for Scopus, the Scopus Source List [12.44] was used. The main difference between the two categorization schemes is that ESI assigns each journal to a single category, while Scopus allows for multiple assignments.

The subject composition of the two bibliographies is shown in Fig. 12.4.

Because of the differences in the philosophy of categorization and in the categories themselves, the comparison is difficult and somewhat misleading.

The striking difference in the position of computer science can be attributed to two factors: (1) While in the ESI most of the information science journals are categorized into *social sciences, general*, in Scopus, most of them are assigned *computer science* as a secondary category. (2) A significant portion of the surplus conference papers in Scopus (as compared to the WoS coverage) are computer science-related.

Mathematics also has its strong position in Scopus because of its frequent occurrence as a secondary category.

Table 12.3 Countries publishing the greatest number of *h*-index-related papers in the WoS bibliography

Rank	Country	Code	Papers	Scopus rank
1	United States	US	700	1
2	China	CN	279	2
3	Spain	E	252	3
4	United Kingdom	UK	249	4
5	Germany	G	217	5
6	Belgium	B	168	8
7	Italy	I	166	7
8	Australia	AU	158	6

19	Greece	G	43	18
20	Malaysia	MY	37	20

[a] Including Nablus in the Palestinian territory

12.4.4 World Map of the *h*-Index Literature

The documents in the bibliographies were authored by researchers from about 100 countries. A visual overview of the geographical distribution of authors in the WoS bibliography is given in Fig. 12.5. The detailed national productivity data are given in Table 12.3.

In the Scopus bibliography, Iran takes the 16th position in place of Israel.

12.4.5 Authors and Institutes

More than 6000 authors contributed to the literature on the *h*-index published between 2005 and 2016. The distribution is extremely skewed: about 80% of the authors contributed only a single paper. The most productive authors of the WoS and Scopus bibliographies are listed in Table 12.4.

The two rankings are fully coherent. The top three positions cause no surprise; they are occupied by well-known, prominent researchers of the topic. The subsequent several names are, however, somewhat bewildering. The authors ranked 4–8 do not belong to the mainstream scientometrics community. Their contribution is in the application rather than the development or interpretation of the concept of the *h*-index. As this is a hot topic, such types of publications may also be successful. Their usefulness can even exceed that of many *amelioration* or *clarification* attempts.

Prof. Jean Anderson Eloy and Peter F. Svider are practicing physicians at the Rutgers School of Biomedical and Health Sciences, Department of Otolaryngology and Head & Neck Surgery, Newark, NJ, USA. Among their 95 joint publications (mainly in otorhinolaryngology journals), there are numerous articles oriented toward science policy and research evaluation. Their most highly cited paper is [12.45].

Prof. Waleed M. Sweileh, Sa'ed H. Zyoud and Samah W. Al-Jabi are pharmacologists-toxicologists at the Faculty of Medicine and Health Sciences, An-Najah National University, Nablus, Palestinian territory. They have published 56 joint papers in 38 different journals. A great share of these involve bibliometric analysis of various pharmacological or health-related issues. Their most-cited paper also belongs to this category [12.46].

The authors of the documents in the bibliographies were affiliated with more than 2000 institutions. Again, more than half of the institutions are represented by only one article in the bibliography. Another rather high percentage is represented by more than one paper, but only by one or a very small number of researchers interested in the topic. To further complicate the situation, some authors (among whom are the two most

30–33	Sawalha A.F.	14	17–18

productive authors, Leo Egghe and Ronald Rousseau) regularly indicate two or three institutional affiliations in the byline of their publications.

We think, therefore, that for an institutional comparison, it is useful to complement the number of papers with some other indicators. The number of authors indicating the institution as their affiliation is an obvious choice. An h-type indicator can also be calculated: the number, h, of authors each having at least h publications. The size of the h-core is the total number of authors each having at least h publications. It is not necessarily equal to h because of the possible ties. (For a more detailed discussion of the theory and application of the concept of h-core, several excellent papers can be suggested [12.47–49].) The indicators of the 12 most productive institutions in the Scopus bibliography are given in Table 12.5.

Table 12.5 Indicators of the 12 most productive institutions of the Scopus bibliography

Rank	Institute	Papers	Authors	h-Index	h-Core
1	Universiteit Antwerpen	74	6	3	3
2	KU Leuven	71	26	3	5
3	Universiteit Hasselt	61	3	3	3
4	Universidad de Granada	53	62	4	7
5	An-Najah National University	37	16	4	6
6	University of Sydney	36	65	4	7
7	Katholieke Hogeschool Brugge-Oostende	36	1	1	1
8	Rutgers New Jersey Medical School	35	68	5	6
9	Universidade de Sao Paulo	33	58	3	5
10	Indiana University	33	69	5	8
11	ETH Zürich	33	26	4	4
12	Hungarian Academy of Sciences	32	7	3	3

The four indicators together can give a more articulate picture of the author community of the institutions than any single indicator alone. At one extreme, KH Brugge is a "one man band" (Rousseau). Achievements of Antwerpen, Hasselt and the Hungarian Academy of Sciences are produced by isolated small teams. At the other end, in Indiana, Sydney and Granada, 7–8 core authors can attract a considerable number of local coauthors.

12.4.6 Citations

The 3042 publications of the WoS bibliography received a total of 37 451 citations (12.31 citations per paper) from 16 734 citing papers. The h-index of the set of papers is 69.

Twelve papers were cited at least 200 times (Table 12.6).

The h-index is the main topic of seven of these top-cited papers (#2, #3, #6, #8, #9, #10 and #11), has a *supporting role* in #7 and is mentioned only passingly in #1, #4 and #5. In all of these papers, Hirsch's origi-

nal paper is formally referenced (in #2, Hirsch's paper itself, the arXiv variant).

Paper #1 in Table 12.6 is a real citation superstar, a comprehensive review of the state of the art of network theory in 2006 based on 888 references. Reference [551] is Hirsch's paper cited as "J.E. Hirsch, physics/0508025 (2005)". It is cited together with *Ball*'s paper [12.20] in the context

> recently the power law behavior of the in-degree distribution suggested the introduction of a new indicator (the index h) quantifying the impact of a scientist on the modern scientific community.

It was able to be retrieved as citing document to Hirsch's paper in GS and WoS, but not in MA or Scopus. In MA it was not identified as a linked reference; in Scopus, the references were recorded as "Hirsch JE (2005) 1" without title or source.

The Boccaletti et al. paper was co-cited with Hirsch's paper seven times.

The h-index was used as citation indicator for authors and journals, respectively (Tables 12.7 and 12.8).

Both the author and the journal rankings clearly show strong similarities to and characteristic differences from the productivity rankings (Tables 12.4 and 12.2, respectively). To facilitate comparison, the productivity rank is given in the last column.

12.4.7 References

The 3042 publications of the WoS bibliography contained more than 100 000 references to approximately 50 000 documents. Among the references, 18% were made to 3% of the documents: to about 1500 items

of the bibliography itself. Not surprisingly, the papers receiving the greatest number of citations from the bibliography items were also among the most highly cited papers of the bibliography (Table 12.6).

The 20 references receiving the greatest number of citations from the WoS bibliography items are listed in Table 12.9. The number of citations received from the bibliography items is supplemented with the total number of citations and the paper's rank in the citation-ranked list of the bibliography (Table 12.6), provided that it was included in it. The overwhelming majority of the citations of the bibliography items came from other bibliography items, indicating the high degree of coherence of the h-index-related literature.

All five papers in the top-20 list not included in the bibliography (they are italicized in Table 12.9) dealt with the impact factor. Three were published well before Hirsch's paper.

The oldest work co-cited with Hirsch's paper is Johannes Kepler's Astronomia Nova from 1609. The citing work is [12.50].

Among the co-cited authors, one may find Newton, Swift, Adam Smith, Hume, Lavoisier, Humboldt, Darwin and even Karl Marx (with his Communist Manifesto) [12.51].

12.5 Application of the h-Index Concept Within and Outside the Realm of Bibliometrics

In his paper [12.1], *Hirsch* definitively set forth the purpose of the h-index: "to quantify an individual's scientific research output". The index, however, soon outgrew the original intent, becoming a useful statistical indicator for variables and conditions quite different from the original settings. The differences include various types, as follows:

1. Citations to publications not of an individual but of groups, institutions, journals, countries, etc. are considered (e. g., h-index for journals in SCImago).
2. Citation and publication windows are limited (e. g., Google Scholar's h5-index: the h-index for articles published within the last 5 complete years.
3. Citation and publication numbers are adjusted (e. g., discount of self-citations, partial credit to co-authors).
4. Variables other than citations to publications (e. g., visits to a web page) are considered.
5. The algorithm for determining the index value is modified (e. g., Kosmulski's $h^{(2)}$-index: the highest natural number such that the author's $h^{(2)}$ most

cited papers received each at least $(h^{(2)})^2$ citations [12.52]).

There is no consensual naming convention for these types of variants. *Boell* and *Wilson* introduced the term *h-like index* for indices using the same rationale (algorithm) as the h-index but which are not based on citations [12.53]. This proposal, however, did not gain wide acceptance. *Harzing* [12.34], for instance, calls Schreiber's multi-authored h-index [12.54] an h-like index, although it is clearly citation-based. In *Vitanov*'s book [12.2], the term *h-like index* is used in a vague sense to refer to indices resembling or related to the h-index.

Our modest proposal is as follows: reserve the name h-index (or Hirsch index) for the index that complies with Hirsch's original intentions (citation-based measure for individuals according to Hirsch's algorithm); call all indices using Hirsch's original algorithm h-type indices (within this category one can distinguish citation-based from non-citation-based indices); and refer to indices as h-related indices whenever the algorithm itself is modified (again, with citation-based and non-citation-based subcategories).

12.5.1 Application of the *h*-Index (in the Strict Sense)

Following Hirsch's example of listing top physicists by their h-index, a vast array of publications have included h-ranked lists of eminent researchers of various fields, as *Meyer* describes: from "the psychologists of Italy [...] to the chemists of Peru, not to forget the library scientists of Hungary" [12.55].

Publication of h-index-based lists of individuals does not necessarily meet with unequivocal positive acceptance. Henry Schaefer and Amy Peterson of the University of Georgia, GA, USA, published an h-index ranking of living chemists [12.56]. The list was first announced in April 2007 [12.57], and was regularly updated until December 2011. In compiling their rankings, Schaefer and Peterson manually combed through data from several databases in an attempt to match papers to authors and ensure the accuracy of their data set. Due to constant fierce criticism, however, they eventually decided to abandon the project [12.58].

In the face of potential critics, the Webometrics website in its January 2017 edition published a list that includes both living and deceased authors of all research fields ranked by their h-index [12.59] on the basis of Google Scholar data. According to this list, the all-time champion of the h-index is Sigmund Freud, with an h-index of 269.

12.5.2 Application of Citation-Based *h*-Type Indices

Levels of Aggregation

At higher-than-individual level, the h index has been used to quantify the research output of research groups [12.60–62], institutions [12.63–67], countries [12.68, 69] and journals [12.11, 70, 71].

A considerable body of literature has been published on the application of the h-index for journals in various disciplinary and geographical areas, often in comparison with the impact factor. Some examples are compiled in Table 12.10.

Direct comparisons with the impact factor generally favor the h-index:

> h-index would be a better citation-based metric for evaluating the quality and contribution of scholarly journals than other metrics such as the impact factor (IF) or the number of cites per paper (cpp). [12.75]

> h-index provides a better alternative for journal rankings than the ISI JIF. It does not suffer from the same statistical limitations as the JIF and is more suitable to measure a journal's wider economic or social impact rather than its impact on an academic audience only. As such we argue it provides a more accurate and more comprehensive measure of journal impact. [12.79]

Table 12.10 Application of the h-index for journals in various disciplinary and geographical areas

Area	Reference

Soil research	[12.91]
Toxicology	[12.92]

> *h*-index [...] may be more useful than the Journal Impact Factor, as a measure of journal quality, and in providing a basis to rank journals. [12.80]

> despite certain flaws and weaknesses, [the *h*-index] is considerably better than using a journal's impact factor. [12.87]

> *h*-index represents an important complement, and perhaps improvement, to the use of impact factors as a way to assess journal quality. [12.90]

As specific advantages, its robustness and its good correlation with peer evaluations is generally stressed.

From a more balanced perspective:

> *h*-index is a useful supplementary indicator, enrichment for the bibliometrics toolset but it is certainly not suited to substitute advanced indicators (JIF) which have long ago become standard in bibliometric research. [12.89]

A paper with a title that appears contradictory to the superiority of the *h*-index [12.93] actually deals with a quite different question: whether the impact factor of a journal or the *h*-index of its first author is a better predictor of the citation future of a paper.

The *h*-index can be determined for any aggregate of publications, not only for groups of researchers or papers of a journal. Not long after the publication of Hirsch's paper, *Banks* applied the concept to chemical compounds and scientific topics [12.94]. Papers of a selected set of compounds and topics were compiled, and the citation-based *h*-index of the sets was determined. Considering the publication year of the paper (2006), it is not surprising that C_{60}, fullerenes and carbon nanotubes dominated both the chemistry and the physics scenes, challenged only by magnetoresistance and quantum dots in physics.

McIntyre and colleagues put the idea into action by using the topic-based *h*-index as a proxy for the impact of human and domestic animal pathogens [12.95–97]. A strong correlation was found between burden of disease (in log10-transformed disability-adjusted life years (DALYs)) and *h*-index scores. *Escherichia coli* was found to be the highest-impact pathogen in Europe in both humans and domestic animals, followed in humans by the HIV1 and HIV2 and the hepatitis C virus. *McIntyre* later extended the method to salmon pathogens, where sea lice and furunculosis were found to be key diseases [12.98].

The top three pathogens in swine were *Escherichia coli*, porcine reproductive and respiratory syndrome virus, and porcine circovirus type 2, with *h*-indices of 106, 95 and 85, respectively [12.99].

Time Periods

It is common practice to contrast the short-term impact measured by the impact factor with the lifetime impact measured by the *h*-index. Although it is undeniably true if we compare the impact factors of the *Journal Citation Reports* (JCR) back in the twentieth century with Hirsch's original proposal, both indicators have turned out to be much more flexible than that. The present-day JCR contains 5-year impact factors, and Google Scholar offers the *h*5, a similar 5-year *h*-type index. The substantial difference, however, lies in the algorithm: the impact factor is a sample mean, while the *h*-index is determined using the specific algorithm proposed by Hirsch. Consequently, the impact factor is size-independent, while the *h*-index is dependent on the sample size.

12.5.3 Application of Non-Citation-Based *h*-Type Indices

Unweighted Graphs

There is an obvious application of the *h*-index concept independent of any actual representation or implementation: its use as a network indicator. To each node of a graph, the vector of the degrees of its neighboring nodes can be assigned, and after arranging the vector in decreasing order of degrees, the *h*-index of the node can be determined. From the vector of *h*-indices of the nodes of a graph, analogously, the *h*-index of the whole graph can be determined. There is an obvious analogy with the various graph centrality concepts, where the centrality distribution of the nodes determines the centralization of the graph.

The idea was so self-evident that it was almost simultaneously published in two independent versions [12.100, 101]. A more elaborate introduction of the index was published soon after the scientometrics-oriented application in the *Korn* et al. paper [12.100] under the name *lobby index* [12.102]. The lobby index of a node x is the largest integer k such that x has at least k neighbors with a degree of at least k.

The role of the photo-finish camera is taken nowadays by preprint services. The first version of the *Korn* et al. paper [12.102] was posted on arXiv as arXiv:0809.0514v1 [physics.soc-ph] 2 Sep 2008 (the final version as arXiv:0809.0514v6 [physics.soc-ph] 26 Jan 2009), while the *Eppstein–Spiro* paper [12.101] was posted as arXiv:0904.3741v1 [cs.DS] 23 Apr 2009 (first and final version).

The *Eppstein–Spiro* paper [12.101] was later published as a journal article [12.103].

Both versions were cited several times, although in different contexts: the *Eppstein–Spiro* paper mainly in the context of subgraph problems [12.104–107], and the lobby index considered rather as an alternative to the traditional centrality measures. To our knowledge, the two sources have never been cited together—until this chapter.

The application of the *h*-type network centrality measure, whether named lobby index or not, is rather diverse and usually successful. It has been used, for example, in:

- Bibliometric network analysis [12.49]
- Designing information-forwarding algorithms in social networks, where "Lobby Influence outperformed Bubble Rap and Epidemic routing algorithms in terms of message delivery and speed" [12.108]
- Proteomics [12.109]
- Information search on complex networks [12.110]
- Improving multimedia content delivery, where "the use of the Lobby-index score metric results in higher hit ratio percentages compared to the equivalent HITS score cases" [12.111]
- Building a conceptual framework for characterizing the ego in a network [12.112].

The relation of the *h*-type network index to other centrality measures was also studied in detail [12.113].

The application of the *h*-core of clusters in local clustering to the delineation of core documents also deserves mention here [12.49].

Weighted Graphs

The generalization of the network *h*-index (lobby index) to weighted graphs is straightforward. Let us define the strength of a node in a weighted network as the sum of the weights of all its links. Then, the *h*-degree of node n in a weighted network is equal to h if h is the largest natural number such that n has at least h links each with strength at least equal to h [12.114].

The *h*-degree was successfully used in finding basic structural patterns in weighted networks [12.115, 116].

A typical weighted graph in scientometrics is the co-author network, where the weights are the number of occasions a pair of authors had joint publications. *Abassi* defined seven new measures for network nodes, and tested them on co-authorship networks [12.117]:

- Definition 1. The al-index of a node is the average degrees of the top k neighbors of the node that each has at least k links (degree of k).
- Definition 2. The gl-index of a node is the largest number such that the top k neighbors of the node have together at least k^2 links (connections).
- Definition 3. The a-degree of a node is the average weights of the top k links of the node that have minimum weight of k.
- Definition 4. The g-degree of a node is the largest number such that the top k links of the node have together a minimum weight of k^2.
- Definition 5. The Hw-degree of a node is the largest number such that the top k neighbors of the node have each at least nwD of k (the *neighbor-weighted degree* (nwD) is the degree of each neighbor multiplied by the weight of the link between that neighbor and the node).
- Definition 6. The Aw-degree of a node is the average of the nwD of the top k neighbors of the node that have nwD of at least k.
- Definition 7. The Gw-degree of a node is the largest number such that the top k neighbors of the node have together at least a nwD of k^2.

Searching for correlation between the authors' centrality measures and their bibliometric performance measures, the author found that "the average based centrality measures (a-degree and Aw-degree) show better correlation with performance".

A further step in generalization is the directed *h*-degree in directed, weighted networks [12.118]. The in-*h*-degrees and out-*h*-degrees are defined in line with *h*-degrees in undirected graphs [12.114]:

- Definition 1. In a directed weighted network, the in-*h*-degree of node n is equal to h if h is the largest natural number such that n has at least h in-links each with strength at least equal to h.
- Definition 2. In a directed weighted network, the out-*h*-degree of node n is equal to h if h is the largest natural number such that n has at least h out-links each with strength at least equal to h.

The prototype of directed graphs in scientometrics is the citation network. The in-*h*-degree/out-*h*-degree concept was tested on the citation network of 46 library & information science journals. JASIST was found to be the most central journal of the field with regard to both the in- and the out-*h*-degree.

A special case of the *h*-degree was defined as the PartnersHIp Ability Index (PHI, φ) [12.119]. A partnership comes about between two actors through a joint action. An actor is said to have a partnership ability index, φ, if the φ of his/her n partners had at least φ joint actions each, and with the other $(n-\varphi)$ partners, had no more than φ joint actions each. The basic properties of the indicator are as follows:

- The partnership ability is 0 if and only if the actor has no joint action with any other actor.
- The partnership ability is 1:
  (a) if the actor had an arbitrary number of joint actions with the very same partner,

(b) if the actor had an arbitrary number of partners with no more than one joint action with each, or
(c) if the actor had an arbitrary number of joint actions with the very same partner AND an arbitrary number of partners with no more than one joint action with each [12.120].

- In all other cases, the partnership ability is an integer larger than 1.
- The use of the index is exemplified in the paper by a co-authorship example, but it is stressed that

> the possible use of the φ-index is far not restricted to scientometrics. As suggested in the definition, actors in all kind of co-activity network can be characterized this way. The word 'actor' may be, e. g., taken literally [... by] the analysis of the Internet Movie Database (IMDb). A delicate possible area of application might be that of sexual encounter networks widely studied nowadays to understand and control the propagation of sexually transmitted diseases [12.119].

The application of the φ-index was tested at a much larger scale as well: on the co-authorship network of over a million Data Bibliography and Library Project (DBLP) authors [12.121].

Along with some further co-authorship network examples [12.122–124], the φ-index was also applied for characterizing the partnership ability of jazz musicians [12.125].

A similar but somewhat different measure, the collaboration index or communication centrality or c-index, was defined to characterize *collaboration competence* [12.126] or *communication ability* [12.127]. The c-index of node x is the largest integer c such that the node x has at least c neighboring nodes satisfying the condition that the product of each node strength and the strength of the edge linked with node x is not less than c (cf. the definition of h-degree [12.114]).

Other Miscellaneous Applications

Social media is an inexhaustible source of network analysis, and obviously, h-type indices have found their way to this area as well [12.128–131]. One remarkable idea, for example, is measuring the controversial nature of a post with an h-type index of the comments (as "publications") and replies (as "citations")—originally proposed for Slashdot [12.128] but easily extended to other social media.

An h-type index characterizing chemical compounds was already mentioned earlier [12.94]. It was, however, a citation-based index derived from the bibliometric analysis of the literature of the compounds under study. An h-type index concerning the concentration of the chemicals was proposed as a tool for compound prioritization in environmental monitoring [12.132]. In order to make the idea work, the concentration values had to be properly rescaled to make them commensurate with the ranks in the ordered list (actually, normalization to 100 is used in the paper). A general scheme of rescaling the h-index for whatever purpose [12.133], and a special h-type index for distributions of percentage-valued variables [12.134], can also be found in the literature.

Sports is a typical training ground for all kinds of statistical exercises. Apart from the historical example of cycling mentioned earlier, it is surprisingly difficult to find a good sports-related example of h-type indices. The first one, to our knowledge, concerned cricket [12.135].

An analogy was found between the h-index and the rule for fixing the size of the group of athletes a National Olympic Committee (NOC) may select for each individual event at the Olympic Games [12.136].

12.5.4 Application of h-Related Indices

In a recent review of the literature on citation impact indicators [12.137], *Waltman* formulated four recommendations—not specifically for the h-type and h-related indices, but for all citation-based indicators:

- Recommendation 1: Do not introduce new citation impact indicators unless they have a clear added value relative to existing indicators.
- Recommendation 2: Pay more attention to the theoretical foundation of citation impact indicators.
- Recommendation 3: Pay more attention to the way in which citation impact indicators are being used in practice.
- Recommendation 4: Exploit new data sources to obtain more sophisticated measurements of citation impact.

In view of the proliferation of h-related literature in general, and h-related indices in particular, these recommendations seem to be more apt than ever.

In the review by *Alonso* et al. [12.21] and its somewhat updated web version [12.22], 47 different h-related index versions were compiled. In the recent handbook of *Todeschini* and *Baccini* [12.3], 59 such indicators are listed, partly overlapping with the previously mentioned compilation. In Appendix 12.B, a unified alphabetical list of the h-related indices included in these two sources is given. The original sources of these indices can only be partially found in the references of this chapter; as to the rest, the reference lists of the two mentioned review sources may be visited.

As a matter of fact, although most of these indices claim to remedy some real or perceived deficiency or weakness of the original h-index (adjustments for multi-authorship, self-citation, disciplinary differences, etc.), very few of them have ever been used in real-life situations. If they have ever been cited, it is self-citation or inclusion in reviews or other compilations. Frankly, we did not want to add to the number of these idle citations.

Instead, we cite a very important lesson from one of the h-related editorials:

> Is the h-index a more useful metric than the [impact factor]? That depends: more useful for what purpose? The point is not to argue in favor of the h-index but rather to reiterate one of the most fundamental lessons ...: namely, the methods used ... should be foremost informed by the question we are asking. The close corollary of this lesson is that without a clear question, we cannot evaluate the adequacy of the methods, much less their results. [12.138]

The message can be readily transferred to the comparison of the h-index and its variants. The h-index has several features. It is a combined measure of publication output and citation impact. It is not sensitive to outstanding citation rates. It is not sensitive to a massive amount of uncited or poorly cited papers. Its statistical behavior is not as straightforward as, say, an average, but—as we will soon see—can be treated sufficiently with appropriate statistical tools.

It is the question we are asking that determines whether these features are positive or negative, whether the h-index is a proper measure to answer the question. And if the answer is that it is not, then there is still an arsenal of existing bibliometric indicators (see, e. g., the *Handbook of Bibliometric Indicators* [12.3]) from which to find a more suitable one. Even if the question is clear and well defined, the introduction of a new indicator is not justified by its mere superiority to the h-index (what might well be completely unsuitable in certain cases) but by its superiority among all existing and well-established indicators. This is what is painfully lacking from a substantial number of the attempts to introduce new h-related indicators.

Without doubt, the most cited h-related index (WoS: 582, Scopus: 705, GS: 1401, MA: 1107), which is also frequently used in evaluation practice, is Leo Egghe's g-index.

> A set of papers has a g-index g if g is the highest rank such that the top g papers have, together, at least g^2 citations. This also means that the top $g+1$ papers have less than $(g+1)^2$ papers. [12.139]

The rationale behind the use of the g-index instead of the h-index is to take the actual citation rate of the top-cited papers into account. At the same time, this is the source of its main weakness: its sensitivity to outliers. The g-index can be equivalently defined as the largest number n of highly cited articles for which the average number of citations is at least n [12.140]. This definition can easily be extended from the arithmetic average to other (geometric, harmonic, etc.) averages [12.141], the median or other statistical measures [12.142]. By choosing the averaging function, the sensitivity of the indicator can be fine-tuned as needed.

12.6 Mathematical Models of the *h*-Index

The introduction of the h-index was met with a certain degree of incomprehension because of the obvious difficulties in categorizing the index into the systematics of orthodox statistics. Some would have excommunicated it as inappropriate, others—just as unjustly—glorifying it as something independent of the traditional bibliometric indicators.

Several papers have attempted to find a place for the h-index in the edifice of mathematics. Others tried to relate it to existing, well-known indicators.

12.6.1 Hirsch's Model

In his original paper, Hirsch gives only very simplistic models of the relation of the h-index to the number of publications and citations. His assumptions are admittedly oversimplified (e. g., constant annual rate of publications of an author or constant annual rate of citations to a paper), and obviously serve as only a rough approximation. Nevertheless, the simple relation $h = (N_{c,\text{tot}}/c)^{1/2}$ (where $N_{c,\text{tot}}$ is the total number of citations and c is an empirical constant found by Hirsch to range between 3 and 5) is often referred to in the literature as the one-parameter Hirsch model of the h-index [12.143–146].

12.6.2 The Lotkaian Framework

The concept of Lotkaian informetrics was introduced by *Leo Egghe* [12.147]. The idea is simple. Since many of the informetric distributions are fat-tailed, i. e., their tails are bounded by an inverse power function (rather than an exponential function, as is the case for most of the distributions in the physical sciences), an informetrics model was constructed where all variables were postulated to have an exact power function distribution, $F(x) = x^{-\alpha}$; $f(x) = \alpha x^{-(\alpha+1)}$. In the discrete case, this is equivalent to *Lotka*'s law [12.148]. In this model, many informetric (or, formally equivalently, bibliometric or scientometric) quantities, relations or laws can be described by simple, closed formulae, which might be considered a zeroth approximation of more complete, multiparameter models.

A critical question in such cases is the structural stability of the model: whether small perturbations of the model may lead to indefinite deviations in the results. If the model is not structurally stable, then no conclusions can be extended beyond its strict limits. We are unaware of any attempt to study the structural stability of Lotkaian informetrics.

Egghe's book was published before Hirsch's paper, so it could not contain the Lotkaian interpretation of the h-index. This was remedied by the paper [12.149]. Using the Lotkaian model, the authors concluded that $h = T^{1/\alpha}$, where T is the total number of sources (in the original example of Hirsch, the number of papers of an author). No empirical test of the result was attempted in the paper.

Later attempts [12.146, 150] revealed that the statistical performance of the Lotkaian model, unsurprisingly, fell behind that of its more sophisticated competitors. In the words of *Burrell*:

> This is not to say that Egghe and Rousseau are mathematically incorrect—they do indeed derive the h-index for the mathematical functions that they consider. The practical problem is that these mathematical functions seem not to be appropriate for the actual context of interest as originally presented by Hirsch. [12.145]

12.6.3 Extreme Value Theory

Glänzel [12.151] recognized that the h-index can be related to the so-called Gumbel characteristic extreme values of a probability distribution.

Extreme value theory is of utmost importance whenever not the *typical* but rather the *exceptional* behavior of a statistical variable is considered. Typical examples are prediction of floods or sport records. Extreme value estimators are not (asymptotically) consistent in the statistical sense: as the sample size increases indefinitely, the resulting sequence of estimates does not converge in probability to a finite value. All records will be broken someday. Being closely related to extreme values, this *inconsistency* of the h-index is an inherent property that evoked initial aversion in some.

Let X be a random variable. In our case, X represents the citation rate of a paper. The probability distribution of X is denoted by $p_k = P(X = k)$ for every $k \geq 0$, and the cumulative distribution function is denoted by $F(k) = P(X < k)$. Put $G_k = G(k) := 1 - F(k) = P(X \geq k)$. Gumbel's r-th characteristic extreme value (u_r) is then defined as

$$u_r := G - 1\frac{r}{n} = \max\left\{k : G(k) \geq \frac{r}{n}\right\},$$

where n is a given sample with distribution F. The theoretical h-index, h^*, can consequently be defined as

$$\begin{aligned} h^* &:= \max\{r : u_r \geq r\} \\ &= \max\left\{r : max\left\{k : G(k) \geq \frac{r}{n}\right\} \geq r\right\}. \end{aligned}$$

If there exists such an index r that $u_r = r$, then we obviously have $H := r$ and we can write $H := u_H$.

Let us now consider an important special case, namely, the discrete Paretian distributions with finite expectation. Most distributions used for modeling publication activity and citation processes belong to this category.

We say that the distribution of a random variable X is Paretian if it asymptotically obeys Zipf's law, i.e., if $\lim_{k\to\infty} G_k k^{-\alpha} = \text{constant}$. Asymptotically Pareto-distributed random variables obviously meet this definition, since $p_k = P(X = k) \approx \gamma(\beta + k)^{-(\alpha+1)}$ if $k \gg 1$; $\alpha > 1$, where β and γ are positive constants. In what follows we will deal with this family of distributions. For $k \gg N$ we obtain $p_k = P(X = k) \approx \gamma k^{-(\alpha+1)}$ and $G_k = P(X \geq k) \approx \gamma_1 k^{-\alpha}$, where γ_1 is a positive constant. Hence, we have

$$E(X) = \sum_{k=0}^{\infty} k p_k = \sum_{k=0}^{\infty} G_k < \infty \quad \text{if} \quad \alpha > 1\,.$$

By elementary manipulation of the cumulative distribution function, we obtain the following approximation from the above definition of Gumbel's r-th characteristic extremes.

$$u_r \approx c_1 \left(\frac{n}{r}\right)^{1/\alpha},$$

where c_1 is a positive constant. Applying the Hirsch condition to this approximation results in the property

$$h^* = u_{h^*} \approx c_1 \left(\frac{n}{h^*}\right)^{1/\alpha}, \quad \text{if} \quad n \gg 1\,.$$

Hence, we have

$$h^* \approx c_2 n^{1/(\alpha+1)}\,, \quad \text{if} \quad n \gg 1\,,$$

where $c_2 = c_1^{\alpha/(\alpha+1)}$ is a positive constant. In verbal terms, the h-index is approximately proportional to the $(\alpha+1)$-th root of the number of publications.

The next question is whether and how the h-index of a journal is determined by the parameters of its citation distribution (first of all, of its expected value, the mean citation rate) and the sample size: the number of papers published in the corresponding journal.

In the case of a two-parameter Pareto distribution with parameters β, α, the expected value, x, is

$$x = \frac{\beta}{\alpha - 1}\,,$$

while the constant, c_1, above is $c_1 = \beta$. Hence,

$$h^* = u_{h^*} \approx c_1 \left(\frac{n}{h^*}\right)^{1/\alpha} \approx \beta^{\alpha/(\alpha+1)} n^{1/(\alpha+1)}\,.$$

In the special case of $\alpha = 2$, which corresponds to a Lotka distribution with exponent 3, we have $x = \beta$; hence, we finally obtain

$$h^* = cn^{1/3}x^{2/3}\,, \tag{12.1}$$

where c is a positive real value of order 1.

Although clearly dependent on several precarious conditions, (12.1) proved to be surprisingly general and stable.

It was first tested on the citation distributions of more than 6000 journals over 2 years (2001 and 2002) from the Web of Science database [12.71]. The empirical and calculated values were strongly correlated ($r^2 \approx 0.95$), and the value of the constant was $c \approx 0.75$.

A comparison of 40 countries [12.68] yielded a correlation with $r^2 \approx 0.99$ and $c = 0.93$.

Later, the model was successfully applied for various samples.

It was tested, for examples:

- On the most actively publishing Moroccan scientists (1997–2006) with $r^2 \approx 0.95$ and $c = 0.91$ [12.152].
- On the top 10 journals and institutions (ranked by h-index) from the Web of Science [12.143]. The author compared three models: that of *Hirsch*'s original paper [12.1], the model of *Egghe* and *Rousseau* [12.149], and the Glänzel–Schubert model. The author found that with $c = 0.9$ for journals and $c = 1.0$ for institutions, the Glänzel–Schubert model gives by far the best fit, with Pearson correlation coefficients of 0.995 and 0.885, respectively. The same author later repeated the comparison on a set of universities based on Essential Science Indicators (ESI) data (1999–2009) [12.144]. He found that

  > the Glänzel–Schubert estimation corresponds best to real data. This is confirmed by calculating both Pearson and Spearman correlation coefficients (as the Pearson coefficient measures a linear relation and the Spearman correlation measures whether ranks correspond, we use both coefficients for synthetic measures) between the estimates and the real h-indices.

  The Pearson coefficient was 0.986 and the Spearman coefficient was 0.976. The value of the constant was not reported.
- On Italian analytical chemists with $r^2 = 0.980$ and $c = 0.80$ [12.153].
- On Malaysian universities with $r^2 = 0.98$ and $c = 0.97$ [12.154].

Some authors varied also the α values to find an optimal fit:

- On a selected set of journals and institutes, the size dependence of the h-index was found to be $n^{0.4}$; that corresponds to $\alpha = 1.5$ [12.155, 156].
- On a sample of 50 pharmacology and 50 psychiatry journals (the top 50 journals of an impact factor-ranked list), the optimal choice was $\alpha = 2.2$, when $r^2 = 0.92$ and $c = 0.71$ [12.85].
- On a sample of 134 ecology and 54 forestry journals, parameters $\alpha = 1.77$; $c = 0.70$ and $\alpha = 1.97$; $c = 0.78$ were found, respectively. Instead of linear correlation, the authors used more sophisticated goodness-of-fit tests to conclude:

  > With regard to their fit, we observe that the Glänzel–Schubert model under a Gaussian distribution provides the best fit to the two sets of data [12.146].

Equation (12.1) serves well for non-citation-based h-type indices too.

For the co-author network h-indices of 36 journals in the field of Dentistry & Oral Medicine, the actual h and estimated h^* index values showed a correlation of $r^2 = 0.56$ and $c = 0.60$ [12.100].

Similar to the co-author network, a network of jazz musicians playing in joint sessions was established [12.125]. The estimated collaboration h-indices of the musicians fitted well to the actual values ($r^2 = 0.88$, $c = 0.81$).

The PartnersHIp Ability Index (PHI, φ) also obeys (12.1). The φ-indices of the 34 awardees of the George Hevesy medal (the premier international award of excellence to honor outstanding achievements in radioanalytical and nuclear chemistry) were determined, and tested with the result: $r^2 = 0.85$, $c = 0.96$ [12.119].

A test on a vastly larger sample was also successful. The co-authorship network of over a million Data Bibliography and Library Project (DBLP) authors was analyzed, and actual and estimated φ-indices were correlated, with the result: $r^2 = 0.87$, $c = 0.67$ [12.121].

A h-type measure of product popularity in e-commerce was also defined and modeled by (12.1) [12.157]. A fairly good fit was found ($r^2 = 0.74$, $c = 0.53$). The fit was substantially improved by changing the α from 2 to 0.6 ($r^2 = 0.91$, $c = 0.35$).

Equation (12.1) was also the starting point for several innovative ideas in h-index-related indicators research.

Prathap proposed using the rough estimate of the h-index, $n^{1/3}x^{2/3}$, as an indicator in its own right. He very aptly called the indicator the *mock* h*-index* [12.135]. It is rather useful when a synthetic indicator is needed for characterizing the number of publications and the citation rate simultaneously, but only the sample size and the average citation rate and not the full citation distribution is known. Although *Prathap* soon renamed the indicator the p-index (for performance) [12.158] and fitted it into a thermodynamic framework [12.159], the basic idea remained unchanged, and found its way to real-life analyses, at least in the author's home country [12.160, 161].

Iglesias and *Pecharromán* built an original theoretical framework based on power law distribution and the stretched exponential distribution in order to compare h-indices among different scientific fields [12.162]. Their result, nevertheless, was admittedly consistent with Glänzel's model. Although the paper is highly cited, real-life practical applications are difficult to find [12.163]. With the explicit use of (12.1), the result of *Iglesias* and *Pecharromán* was later generalized to allow for field normalization, change of time frames or any other changes in measurement scales [12.133].

Glänzel further developed his model by:

- Introducing the z-statistics for the analysis of the tail properties of Pareto-type distributions [12.164]
- Finding the formula

$$\left\{h_1^{(\alpha+1)} + h_2^{(\alpha+1)}\right\}^{\frac{1}{(\alpha+1)}}$$

  for the concatenation of two h-indices with the same α but different sample sizes [12.165]
- Finding the relation of the h-index to the method of characteristic scores and scales [12.166].

12.6.4 Fuzzy Integrals

Torra and *Narukawa* [12.167] found that the h-index could be considered a Sugano integral, a type of so-called fuzzy integral.

Let us consider measures and integrals with respect to a finite reference set $X = \{x_1, \ldots, x_N\}$, e.g., we can consider a set of published works.

Definition 12.1
A set function $\mu\colon 2^X \to \mathbb{R}_+$ is a fuzzy measure if it satisfies the following axioms:

i) $\mu(\emptyset) = 0$ (boundary conditions)
ii) $A \subset B$ implies $\mu(A) \le \mu(B)$ (monotonicity).

A measure is additive when $\mu(A \cup B) = \mu(A) + \mu(B)$ for $A \cap B = \emptyset$.

Definition 12.2
Let X be a reference set. Then the additive fuzzy measure $\mu\colon 2^X \to \mathbb{R}_+$ defined as $\mu(A) = |A|$ is called the counting measure.

Definition 12.3
The Sugeno integral of a function $F\colon X \to \mathbb{R}_+$ with respect to a fuzzy measure μ corresponds to $\max_i \min(f(x_{\sigma(i)}), \mu(A_{\sigma(i)}))$, where $A_\sigma(k) = \{x_{\sigma(i)} | j \le k\}$, and when σ is a permutation such that $f(x_{\sigma(i)}) \ge f(x_{\sigma(i+1)})$ for $i \ge 1$.

Definition 12.4
A researcher has an h-index h if h of his papers have received at least h citations and the rest fewer than h citations.

Using X_r and f as above, this can be expressed as: the h-index of researcher r corresponds to $h_r = \max_i \min(f(x_{\sigma(i)}), i)$, where $\{\sigma(1), \ldots, \sigma(N)\}$ is a permutation of $\{1, \ldots, N\}$ such that $f(x_{\sigma(1)}) \ge f(x_{\sigma(2)}) \ge \ldots \ge f(x_{\sigma(N)})$.

Proposition 12.1
The h-index corresponds to the Sugeno integral of f with respect to the counting measure μ.

The authors claim that the interpretations presented "permit one to apply those results obtained in the field of fuzzy integrals and aggregation to analyze current indexes as well as to define new ones," namely:

1. Index that stresses the importance of active researchers.
2. Index that takes into account publisher credibility. To make matters simple, one may define publisher credibility as the impact factor of the journal.
3. Index that takes into account the impact of related papers.

These potentials do not seem to be realized as yet.

M. Bras-Amorósa et al. [12.168] used the Sugano integral to introduce their unique idea of counting the citations to a paper only from authors who had previously never collaborated with the author(s) of the paper in question. It is not the fault of the Sugano integral concept but rather the difficulties in implementing the indicator and the doubts regarding its interpretation (all honestly revealed in the paper) that prevented its wider adoption.

Mesiar and *Gagolewski* [12.169] recently used the Sugano integral framework to introduce some modifications into the h-index to compensate for its insensitivity to a large number of papers with relatively small numbers of citations and with respect to a large number of citations received by a small number of papers, as well as its complete lack of taking uncited publications into account. They also called attention to the connection of the h-index to another fuzzy measure: "the h-index is the Ky Fan metric computed with respect to the 0 vector".

In summary, fuzzy integrals seem to serve as a rather elegant and general framework within which to find a place for the h-index and related constructions in the edifice of mathematics, but so far without much practical significance.

12.6.5 Axiomatics

It is always a great challenge for mathematicians to find the bare skeletons of an intellectual construction in the form of basic postulates or axioms. Axioms of ranking in general, and citation-based ranking in particular, were well known before the appearance of the h-index [12.170, 171]. The roots of all these attempts lead back to *Arrow*'s work [12.172, 173].

The axiomatization of the h-index apparently began with *Woeginger* [12.174], who formulated "five fairly natural axioms that capture certain desired elementary properties of a scientific impact index $\mathrm{f}: \mathrm{X} \to \mathbb{N}$":

A1. If the $(n+1)$-dimensional vector y results from the n-dimensional vector x by adding a new article with $f(x)$ citations, then $f(y) \leq f(x)$.

A2. If the $(n+1)$-dimensional vector y results from the n-dimensional vector x by adding a new article with $f(x)+1$ citations, then $f(y) > f(x)$.

B. If the n-dimensional vector y results from the n-dimensional vector x by increasing the number of citations of a single article, then $f(y) \leq f(x)+1$.

C. If the n-dimensional vector y results from the n-dimensional vector x by increasing the number of citations of every article by at most one, then $f(y) \leq f(x)+1$.

D. If the $(n+1)$-dimensional vector y results from the n-dimensional vector x by first adding an article with $f(x)$ citations and afterwards increasing the number of citations of every article by at least one, then $f(y) > f(x)$.

In the spirit of Arrow's impossibility theorem, it was proved that "no scientific impact index can simultaneously satisfy all five axioms A1, A2, B, C, and D".

As to the h-index, the main result was the characterization theorem: "A scientific impact index $\mathrm{f}: \mathrm{X} \to \mathbb{N}$ satisfies the three axioms A1, B, and D, if and only if it is the h-index".

As a by-product of the axioms, the author defined the dual of the h-index, referred to as w-index. The duality is elucidated by the pair of definitions:

- The h-index is the scientific impact index $h: X \to \mathbb{N}$ that assigns to vector $x = (x_1, \dots, x_n)$ the value $h(x): \max\{k : x_m \leq k \text{ for all } m \geq k\}$.
- The w-index is the scientific impact index $w: X \to \mathbb{N}$ that assigns to vector $x = (x_1, \dots, x_n)$ the value $w(x) := \max\{k : xm \leq k - m + 1 \text{ for all } m \geq k\}$.

The dual of the theorem concerning the h-index is: "A scientific impact index $\mathrm{f}: \mathrm{X} \to \mathbb{N}$ satisfies the three axioms A1, B, and C, if and only if it is the w-index".

It is important to note that although five axioms are set, the h-index is characterized by only three of them.

In a subsequent paper [12.175], *Woeginger* replaced axiom B in the characterization theorem with the more appealing symmetry axiom (axiom S). For any publication vector x, the "reflected publication vector" $R(x)$ was defined as $R(x)_i = |(k : x_k \geq i)|$. Then,

S. For any $x \in X$ we have $f(x) = f(R(x))$.

The characterization theorems are now as follows:

- A scientific impact index $f: X \to \mathbb{N}$ satisfies the three axioms A1, S, and D, if and only if it is the h-index.
- A scientific impact index $f: X \to \mathbb{N}$ satisfies the three axioms A2, S, and C, if and only if it is the w-index.

Woeginger's axiomatics were further extended to other h-related indices [12.176, 177].

In a paper submitted almost simultaneously with Woeginger's first paper, and therefore obviously unable to acknowledge it, *Marchant* characterized the ranking according to the h-index using six axioms (i. e., it is a ranking according to the h-index if and only if it satisfies these six axioms) [12.178]. He later compared his results with those of *Woeginger* [12.179].

Using Woeginger's monotonicity axiom (axiom D) and two other axioms, *Quesada* characterized the h-index in the domain of all non-negative real-valued indices [12.180]. He subsequently published several characterizations without the monotonicity axiom [12.181, 182].

Hwang retained two of Woeginger's axioms (A1 and B) and replaced monotonicity by expansion consistency [12.183]. He was apparently unaware of Quesada's characterizations without using the monotonicity axiom.

Miroiu summarized several existing characterizations and introduced some new ones [12.184].

12.6.6 Statistical Reliability

A statistical indicator is virtually useless if its reliability cannot be assessed, at least as a rough approximation. The h-index is often criticized for being an integer, and several *improved* versions were proposed to make it a real number to allow for *greater resolution*. No one, however, can answer the question as to whether an index value of 15.3 differs significantly from 15.7. It is not easy to say, either, that an h-index value of 15 differs significantly from 17, but for the h-index there exists some error estimations and reliability tests.

Table 12.11 Confidence intervals for the h-index ($p = 0.95$, $\alpha = 2$)

h-Index	Lower-bound	Upper-bound
20	18	23
25	22	28
30	27	33
35	32	39
40	37	44
50	46	54
100	94	106

Based on the results of *Beirlant* and *Einmahl* [12.185], *Barcza* and *Telcs* [12.186] and his earlier papers [12.164, 166], *Glänzel* determined the confidence interval for an empirical h-index for any confidence level and any α [12.187]. In Table 12.11, the confidence intervals are given for the most generally used confidence level, 0.95, and the typical α value of 2.

It can be seen that the statistical uncertainty of the empirical h-value is decreasing with increasing h-index but not below $\pm 6\%$. The claim to create *higher-resolution* indices is, thus, illusory.

From a similar premise, using a somewhat different statistical apparatus, *Cerchiello* and *Giudici* [12.188] reach a similar conclusion: in the range of h between 10 and 20, at a confidence level 0.90, the confidence interval is about $\pm 25\%$.

Fiorenzo et al. [12.189] used the Egghe–Rousseau model [12.149] and Monte Carlo simulation to find the effect of the error in citation data to the error of the h-index. They found that 1% error in the citation distribution data may cause 3–5% error in the h-index.

12.7 Closing Remarks

In the Web Ontology Language (OWL) [12.190], the *citation function* class contains the following subclasses and members [12.191]:

- Factual function: cites as authority, cites as data source, cites as evidence, cites as metadata document, cites as source document, cites for information, compiles, contains assertion from, documents, gives background to, gives support to, includes excerpt from, includes quotation from, is cited as authority by, is cited as data source by, is cited as evidence by, is cited as metadata document by, is cited as source document by, is cited for information by, is compiled by, is documented by, is plagiarized by, is updated by, obtains background from, obtains support from, plagiarizes, provides assertion for, provides conclusions for, provides data for, provides excerpt for, provides method for, provides quotation for, updates, uses conclusions from, uses data from, uses method in.
- Negative rhetorical function: corrects, critiques, derides, disagrees with, disputes, is corrected by, is critiqued by, is derided by, is disagreed with by, is disputed by, is parodied by, is qualified by, is refuted by, is retracted by, is ridiculed by, parodies, qualifies, refutes, retracts, ridicules.
- Neutral rhetorical function: cites, cites as recommended reading, cites as related, describes, discusses, extends, has reply from, is cited as recommended reading, is cited as related by, is cited by, is

described by, is discussed by, is extended by, is reviewed by, is speculated on by, replies to, reviews, speculates on.
- Positive rhetorical function: agrees with, cites as potential solution, confirms, credits, is agreed with by, is cited as potential solution, is confirmed by, is credited by, is supported by, supports.
- Rhetorical function: cites as authority, cites as evidence, contains assertion from, gives background to, gives support to, is cited as authority by, is cited as evidence by, obtains background from, obtains support from, provides assertion for.

After spending many, many hours studying the h-related literature, the authors of this chapter came to the conclusion that practically all members of this list are represented among the citations to Hirsch's paper [12.1].

Blessing or curse, fad or fashion, Hirsch and his h-index left an indelible mark not only in scientometrics/bibliometrics/informetrics/webometrics, but also in quite distant areas such as network analysis, proteomics or environmental monitoring. The paper and the index thus appear to have a real and lasting impact, and the h-related literature will still provide work for analysts in years and decades to come.

Acknowledgments. One of the authors, András Schubert was supported by the European Commission through FP7 Grant No. 613202 (IMPACT-EV project).

12.B Appendix

Table 12.13 h-related indices included in references [12.3, 21] and in [12.22]

Index	Author	Year
Adaptive pure h-index	Chai JC, Hua P-H et al.	2008
A-Index	Jin BH, Liang LM et al.	2007
Amplitude-index	Valentinuzzi ME, Laciar E, Atrio JL	2007
AR-index	Jin B	2007
b-Index	Brown RJC	2009
ch-Index	Ajiferuke I, Wolfram D	2010
Citation speed s-index	Bornmann L, Daniel HD	2010
Citer h-index	Franceschini F, Maisano D et al.	2010
Complementary h-index	Batista PD, Campiteli MG et al.	2005
Contemporary h-index	Sidiropoulos A, Katsaros D, Manolopoulos Y	2007
Dynamic h-type index	Rousseau R, Ye FY	2008
e-Index	Zhang CT	2009
Environment hj-indices	Dorta-Gonzalez P, Dorta-Gonzalez MI	2010
f-Index	Tol RSJ	2009
f-Index	Katsaros D, Akritidis L, Bozanis P	2009
f-Index	Franceschini F, Maisano D	2010
First-author h-index	Opthof T, Wilde AAM	2009
Fractional g-index	Egghe L	2008
Fractional h-index	Egghe L	2008
Freshness indicator	Wu J, Lozano S, Helbing D	2011
Generalized h-index	Glänzel W, Schubert A	2009
g-Index	Egghe L	2006
$h^{(2)}$-Index	Kosmulski M	2006
h'-Index	Hirsch JE	2005
h^2-Lower, h^2-center and h^2-upper	Bornmann L, Mutz R, Daniel HD	2010
Harmonic p-index	Prathap G	2011

Table 12.13 (continued)

Index	Author	Year
h-Bar index	Hirsch JE	2010
h-Core citations	Rousseau R	2006
hg-Index	Alonso S, Cabrerizo FJ et al.	2010
h_{int}-Index	Kosmulski M	2010
h_{m}-Index	Molinari A, Molinari JF	2008
h_{m}-Index	Schreiber M	2008
hpd Index	Kosmulski M	2009
hpy Index	Kosmulski M	2009
hw-Index	Egghe L, Rousseau R	2008
if^2-Index	Boell SK, Wilson CS	2010
Impact vitality indicator	Rons N, Amez L	2009
Iterated weighted c-index	Todeschini R, Baccini A	2016
Iterated weighted g-index	Todeschini R, Baccini A	2016
Iterated weighted h-index	Todeschini R, Baccini A	2016
j-Index	Todeschini R	2011
k-Index	Anania G, Caruso A	2013
k-Index	Ye FY, Rousseau R	2010
Maxprod	Kosmulski M	2007
Mean h-index	Lazaridis T	2010
m-Index	Bornmann L, Mutz R, Daniel HD	2008
Mock h_{m}-index	Prathap G	2010
Modified h-index	Schreiber M	2008
Modified r-index	Panaretos J, Malesios C	2009
m-Quotient	Hirsch JE	2005
${}^{n}h_3$-Index	Vieira ES, Gomes JANF	2010
n-Index	Namazi MR, Fallahzadeh MK	2010
Normalized h-index	Levitt JM, Thelwall M	2007
Normalized h-index	Sidiropoulos A, Katsaros D, Manolopoulos Y	2007
Paper fractional g-index	Egghe L	2008
Paper fractional h-index	Egghe L	2008
p-Index	Prathap G	2010
Pure h-index	Wan JK, Hua PH, Rousseau R	2007
Pure r-index	Wan JK, Hua PH, Rousseau R	2007
q^2-Index	Cabrerizo FJ, Alonso S et al.	2009
Rational g-index	Guns R, Rousseau R	2009
Rational h-index	Ruane F, Tol RSJ	2008
RC- and CC-indices	Abbasi A, Altmann J, Hwang J	2010
R-index	Jin BH, Liang LM, Rousseau R, Egghe L	2007
Role based h-maj-index	Hu XJ, Rousseau R, Chen J	2010
Second-generation citations h-index	Kosmulski M	2010
Selectivity-index	Valentinuzzi ME, Laciar E, Atrio JL	2007
Self-citation-corrected $h^{(2)}$-index	Kosmulski M	2006
Self-citation-corrected h-index	Kosmulski M	2006
Seniority-independent Hirsch-type index	Kosmulski M	2009
Sharpened h-index	Schreiber M	2007
Sharpened modified h-index	Schreiber M	2009
Single paper h-index	Schubert A	2009
Specific-impact s-index	De Visscher A	2010
Tapered h-index	Anderson TR, Hankin KSH, Killworth PD	2008
Time scaled h-index	Mannella R, Rossi P	2013
t-Index	Tol RSJ	2009
Trend h-index	Sidiropoulos A, Katsaros D, Manolopoulos Y	2007

Table 12.13 (continued)

Index	Author	Year
v-Index	Riikonen P, Vihinen M	2008
w-Index	Anania G, Caruso A	2013
w-Index	Wohlin C	2009
w-Index	Wu Q	2010
wl-Index	Wan X, Liu F	2014
x-Index	Wan X	2014
π-Index	Vinkler P	2009
πv-Index	Vinkler P	2010
α-Index	Abt HA	2012

András Schubert

Library and Information Center
Hungarian Academy of Sciences
Budapest, Hungary
schuba@iif.hu

András Schubert, former Head of the Department of Scientometrics and Science Policy at the Library of the Hungarian Academy of Sciences, graduated as chemical engineer from the Budapest University of Technology and Economics. He switched to scientometrics in 1980. He is editor of the journal *Scientometrics*. Since retirement, he devotes much of his time to playing the clarinet and to literary writing, largely children's stories.

Gábor Schubert

University Library
Stockholm University
Stockholm, Sweden

Gábor Schubert studied chemical engineering at the Budapest University of Technology and Economics before becoming engaged with research in computational chemistry. In cooperation with his father, András Schubert, he has been involved in bibliometric studies since the mid-1990s. He is currently Head Bibliometrician of Stockholm University Library.

13. Citation Classes: A Distribution-based Approach for Evaluative Purposes

Wolfgang Glänzel, Bart Thijs, Koenraad Debackere

In this chapter, we describe a scientometric assessment tool that was first introduced as early as the second half of the 1980s, but due to the high computational requirements at that time, the method fell undeservedly into oblivion. The method is called Characteristic Scores and Scales (CSS) and is aimed at providing a more detailed picture of citation impact, with particular regard to the high end of performance. More than two decades after its introduction, the method experienced a revival as a consequence of the burning need for improved and versatile assessment tools, facilitated by the rapid development of information technology and the broad access to electronic data sources.

The first part of this chapter will describe the model, its background and the statistical properties underlying this approach, while the following sections will deal with its implementation within the framework of research evaluation at different levels of aggregation and in various disciplinary and multidisciplinary contexts. Special attention is paid to the applicability to various aggregation levels, such as national research performance, the comparative analysis of institutional research output, as a tool to assist the assessment of individual researchers and as journal impact measures. A graphical sketch of possible applications is used as a road map throughout the chapter to navigate the various methodological issues and fields of use. The chapter begins with a review of previous work, but also aims at presenting new insights and applications in a systematic manner. In addition to the presentation of new results, future perspectives and possible applications of this model within and outside traditional scientometrics will be sketched and highlighted.

13.1 General Introduction: The Need for Multilevel Profiling of Citation Impact

The continuing debate on the need for normalization of bibliometric indicators, and the experienced observation of phenomena that lead to serious biases, even distortions, of citation indicators at the institutional, research group and individual levels, has prompted bibliometricians to reform the traditional basic indicator system. The insufficiency in using a single indicator to depict quantitative aspects of research performance has long been experienced in our field. In particular, the disparity between standard models of regular performance versus outstanding performance as reflected by citation impact [13.1, 2] is another phenomenon that renders the expression of performance by a single indicator conceptually impossible. The objectives of improvement are thus to replace the concept of the *linearly structured* indicator model by more complex performance profiles, while ensuring the seamless integration of measures of outstanding and even extreme performance into the standard tools of scientometric performance assessment [13.3].

Therefore, a reduction of the original citation distribution to performance classes on the basis of *Characteristic Scores and Scales* (CSS), as introduced by *Glänzel* and *Schubert* [13.4], has been proposed as an alternative parameter-free solution for performance assessment. Before we introduce this method and describe its properties and various fields of application, we first have a look at the conceptual background of scientometric indicators, pointing to the main opportunities and limitations, followed by the mathematical basis required for the necessary soundness of the underlying methodology.

13.1.1 The Conceptual Background

When turning to quantitative methods in science studies, i. e., statistics, measures and indicators, to capture and express important and characteristic aspects on the basis of sufficiently large numbers of objects to analyze, we are usually faced with several important methodological and practical issues. Among these issues, we must stress the matter of *conceptual* robustness, reliability and validity. From a conceptual viewpoint, these are different from the statistical interpretation. First of all, these issues are related to the design of bibliometric methods, measures and tools, and imply that indicators can really be assumed to measure what they are intended to measure and are, by definition, not sensitive to marginal changes in the system or in the interpretation of data. *Bookstein* [13.5] has noted three (out of other) demons of measurement that are challenges to quantitative approaches in studies of scientific communication. All three of them have strong conceptual roots—and, of course, also statistical implications, as we will see later. The first demon refers to *randomness* (otherwise, a precondition of mathematical statistics), which concerns not only the variables to be measured but also the conditions of measuring and the *environment* of the variables. Scientific communication is subject to the influence of many intra- and extra-scientific factors that are difficult to capture, depict and model by mathematical methods. *Fuzziness* is reaching beyond probabilistic uncertainty; it is related to the impossibility of accurately representing concepts by traditional variable sets. Many properties that are assumed and investigated by quantitative science studies are only partially valid, that is, the assumption of considering full or absolute validity might bias the studies. The relevance of retrieved documents, the determination of (co-)authorship credits, and the subject assignment of publications might serve just as some typical and commonly acknowledged examples of fuzziness. According to Bookstein, *ambiguity* pushes the idea of fuzziness to its extreme. He argues that the conceptual basis for measurement is often weak, although we aim for accurate measurement and the development of techniques to derive precise results and statements, by often searching for relationships with similarly weak concepts. Finally, the adoption of related methods from other disciplines with similar concepts and changes in the application focus, such as the shift of bibliometrics from scientific information to research evaluation and science policy, increases the impact of ambiguity to the detriment of the required precision. According to Bookstein, all mathematical relationships are approximate. One way to cope with ambiguity is to create and apply models that are less sensitive to imperfect conceptualization. Following his ideas, it may also be important in this context to create and apply specific informetric laws that are based on probabilistic models and to ensure that uncritical adoption of models from other disciplines with similarly imperfect conceptual background is reduced to the possible minimum.

Apart from the above demons, which are also shared with other disciplines—above all in the social sciences and humanities—there are some specific challenges in bibliometrics that are related to the dissemination of information. Unlike interaction of matter as in the natural sciences, or trading of products, information need not be created again in order to transfer again, while dissemination also becomes increasingly independent of specific carriers. This effect, together with other particularities of social processes, results in two further demons to bibliometric measures. The first concerns a certain incommensurability of *masses* and elite as shown, e. g., by *Glänzel* and *Schubert* [13.4] and *Glänzel* [13.2] in the case of citation distributions. This effect has strong implications for finding general regularities and setting reference standards. The second issue relates to *outliers* that sometimes blow all reasonable limits and can be understood in the context of the *anathema* of seemingly unlimited dissemination of information, an effect that is also known in datamining [13.6]. *Waltman* et al. [13.7] have reported such observations in bibliometrics in the case of individual citation rates. As a consequence, otherwise statistically marginal numbers of observations can seriously bias, even distort, the reliability of indicators and thereby affect the rank statistics. Such phenomena, of course, compromise the usefulness of common traditional indicators in the sense of applicability and meaningfulness. At this point, conceptual issues turn into mathematical tasks and require concrete mathematical solutions. The effect of extreme observation, for instance, is not only a bibliometric issue. So-called censored data or extreme observations distorting empirical distributions are known in several other fields, e. g., in insurance mathematics [13.8], just to mention one example. This makes it possible to borrow methods from other, even unrelated, disciplines in a critical way and to search for more informetric solutions, the groundwork of which is to be discussed in the following subsection.

13.1.2 The Mathematical Background

The majority of traditional indicators in bibliometrics are based on simple statistical functions and some arithmetic relations of those. These include, for instance, sample means, shares and percentiles. Yet, the distributions underlying publication activity, co-authorship, citation impact and other bibliometric phenomena to be studied have specific properties that challenge the usefulness of these simple statistics in those contexts that have strong policy implications and financial consequences. In other words, reliability and validity questions emerge if (but not only if) the results of bibliometric studies are applied to the evaluation of research performance at various levels, to the allocation of research funding and the promotion of scientists. And, if bibliometric tools have an effect on decision-making in science policy and research management, this might have measurable repercussions on the scientists' behavior, notably in their scholarly communication, as has been described by *Glänzel* and *Debackere* [13.9].

Coming back to the properties that are partially at the roots of the above-mentioned issues, we must emphasize two specific features of bibliometric distributions. The first important property is that bibliometric distributions are typically (nonnegative) integer values with low medians and means, which prevents us from the approximation by continuous distribution models, since any small deviation from these two statistical functions can almost be considered qualitative rather than infinitesimal. This makes for a clear distinction between bibliometric distributions and those in other disciplines such as meteorology, sports, demographics, insurance mathematics or income distributions. The second property has to do with skewness and extreme values. Informetric distributions are characterized by having heavy (fat) tails and large extreme values, often with true outliers. In such situations, the use of means and medians raises serious issues. The median suffers from low discriminatory power because of the first property, and the mean is, although formally a legitimate statistic in these cases as well [13.10], clearly not representative for the underlying sample, because of the second property. These two specific features are accompanied by a third, not typically informetric issue, namely that of multidimensionality. A single indicator can hardly describe most bibliometric phenomena [13.11]. Citation distributions with practically the same mean (or median) may have different shapes, with different shares of cited papers [13.12]. Therefore, single-number indicators should preferably be replaced by indicator groups in order to obtain a more realistic insight, of course, with severe implications for ranking exercises, because these rely by nature on a linear approach [13.13].

Before we switch to the groundwork of setting up the performance classes for profiling citation impact, we refer to one of the bibliometric demons to measurement mentioned in the context of the *conceptual imperfections*. When dealing with the heavy tails of citation distributions, we often encounter a phenomenon that complicates the estimation of parameters considerably. We have observed significant imparity between standard models developed for describing *regular* performance, i. e., the citation impact attracted by the overwhelming majority of the authors and publications versus the ones designed to capture the outstanding performance achieved by a small elite that apparently obeys its own rules [13.2, 4]. And in this context we do not even speak of outliers. Pragmatically, we would need two different values for the same parameter of the distribution, one for the head and body, and one for the tail. *Glänzel* [13.2] therefore used mathematical-statistical methods such as QQ plots and extreme value distributions to analyze to what extent the high end of citation impact, as reflected by the tail of scientometric distributions, is in line with the *standard* citation impact attracted by the majority of scientific papers, and to what extent extreme values and outliers might be responsible for possible deviations and distortions of citation indicators [13.7].

While in several other fields outliers can be discarded as being exceptions, or can be treated as censored data and re-estimated by more realistic ones, in bibliometrics these extreme observations represent the high end of research performance and deserve special attention. This need argues against alternative solutions such as discarding or correcting extreme values. One possible solution is the use of QQ plots and tail parameters to supplement traditional citation-based performance indicators [13.2, 14]. The analysis of the tail can practically be uncoupled from the overwhelming rest of the empirical distribution. The estimation of the tail parameter from the Pareto model, which is most commonly used in scientometrics, can directly be obtained from subsets of order statistics. This approach also allows the construction of confidence intervals for its estimator. Nevertheless, as the above-mentioned studies have pointed to, the estimation of the tail index remains rather problematic, since most methods are still sensitive to the cut-off point for the tail. This is the reason why mathematicians have sought alternative and more robust solutions. This has, of course, strong implications for alternative methods and indicators that take this disproportion into account. Since already minute changes of the tail parameter might have significant consequences in an evaluative context, the recommendation in the study by *Glänzel* [13.2] was to favor a parameter-free solution for the assessment of outstanding performance. This might also help avoid parameter conflicts resulting from estimating parameters on the basis of different parts of the distributions, notably of the low and high ends of the distribution.

Given the above discourse on the multiple issues in bibliometric measurement that can result in biased, even heavily distorted and "interference-prone" indicators, we briefly summarize the desired properties of an alternative mathematical/informetric method that goes beyond the traditional metrics.

The proposed method should:

1. Provide a parameter-free solution for different performance classes
2. Avoid arbitrary or preset thresholds
3. Not be sensitive to or distorted by ties
4. Replace the concept of *linearly structured* indicators by performance profiles
5. Be applicable to various levels of aggregation and gauge observations against several standards
6. Ensure the seamless integration of measures of outstanding and even extreme performance into the standard tools of scientometric performance assessment.

In order to develop a method with such properties, two basic approaches could provide the required mathematical basis. One possibility is the use of quantiles. A solution using six percentile classes was proposed by *Leydesdorff* et al. [13.15]. Their model assumed a set of six rank percentages, which are derived from a reference distribution based on the entire population. The individual publications of the sample under study are then assigned to the corresponding percentile on the basis of their observed citations rates. This method is apparently insensitive to extreme values and outliers, since those will become just one object in the highest percentile class, that is, extreme values and outliers have the same score as any other highly cited paper independently of their actual citation rates. However, two problems arise from this approach, particularly the arbitrariness of preset percentiles and the ties present in both the reference distribution and the observations. *Waltman* and *Schreiber* [13.16] recently found a solution for solving the latter problem and for avoiding the otherwise inevitable ties.

Another solution is a reduction of the original citation distribution, where the individual observations—or, using the parlance of probability theory, the individual events—are grouped into a given number of classes. As a consequence, the distribution of citations over classes instead of individual values is considered. Similar to the previous approach, the reference distribution of the total population or a relevant subpopulation can be used to define the classes and to set the corresponding standards. If such assignment could be made self-adjusting and widely independent of the influence of the various factors typically affecting citation rates, one would obtain an almost universal tool for the evaluation of citation impact. The structure and properties of such a method will be described in the following section.

13.2 The Method of Characteristic Scores and Scales (CSS)

Grouping events and empirical observations into a limited number of certain classes can be done in different ways. In order to understand the background of our solution, we have to go back to some basics and results in probability and distribution theory. Therefore, we will briefly recall the probability-theory-related rudiments before we discuss their detailed statistical implementation.

13.2.1 The Stochastic Model Behind Characteristic Scores and Scales

Let X be a nonnegative random variable. If furthermore X takes, for instance, integer values, the variable might stand for publication activity or citation rates. Mathematicians have proven that conditional expectations, particularly left-truncated moments and their arithmetical combinations, under certain conditions, characterize the underlying distribution. In this context we refer, above all, to theorems by *Hamdan* [13.17], *Kotz* and *Shanbhag* [13.18] and *Glänzel* et al. [13.19]. According to a fundamental representation theorem for probability distributions, the conditional expectations $E(h(X)|X \geq x)$ with $x \geq 0$, where h is a real function defined on the support of X, characterize a large family of continuous and discrete distributions. Some special cases are of particular interest—for instance, the simplest case, if h is the identity function, i. e., $h(x) = x$, $E(X|X \geq x)$ is a linear function of x, if and only if X has an exponential or Pareto distribution of the second kind (also called Lomax distribution), or, in the discrete case, if, and only if X has a geometric or Waring distribution. Hence, the following idea arose: If this property holds for all nonnegative values x, then the property must also be true for particular x values, such as the expected value $b := E(x)$. Hence, we derived the following iteration

$$
\begin{aligned}
b_1 &:= b = E(X|X \geq 0)\;, \\
b_2 &:= E(X|X \geq b_1)\;, \\
b_3 &:= E(X|X \geq b_2)\;.
\end{aligned}
$$

Putting $b_0 := 0$, we have $b_k := E(X|X \geq b_{k-1})$ for all nonnegative integer values $k = 1, 2, \ldots$ For a Lomax/Waring distribution we obtain a very interesting property, specifically

$$
\begin{aligned}
b_k &= E(X|X \geq b_{k-1}) = ab_{k-1} + b_1 \\
&= N(a-1)\left(\sum_{i=0}^{k-1} a^i\right) = N(a^k - 1) \\
\text{with } a &= \frac{\alpha}{\alpha - 1}\;,
\end{aligned}
\tag{13.1}
$$

where N and α are the parameters of the distribution [13.4, 20] and $b_k = E(X|X \geq b_{k-1}) = b_{k-1} + b_1 = kb$ for the exponential/geometric case which is the limiting case of the previous distributions.

In other words, the iteration of truncating the distribution at its expectation to determine the following value results in a geometric series. This property could, of course, be used for parameter estimation, but because of the above-mentioned tail-parameter inconsistency (disproportion between trunk and tail), we refrain from this option. Instead, we use the b_k values to determine intervals that can be used to reduce the original distribution to a limited "state space" consisting of a finite number of classes. If we nevertheless talk about parameters, we then use those to point to some fundamental, albeit approximate, properties. The following one is maybe the most interesting. In a previous paper, *Glänzel* [13.20] showed that for the Lomax distribution, the class sizes depend only on the tail parameter and, in the case of the exponential distribution, which is a limiting case of the Lomax distribution, class sizes are independent of any parameter. In particular, for Lomax, we have the following property

$$
\begin{aligned}
&G(b_k) = 1 - F(b_k) = a^{-k\alpha} = \left(1 - \frac{1}{\alpha}\right)^{k\alpha} = q^k\;, \\
&\quad k = 1, 2, 3, \ldots \quad \text{with } q := a^{-\alpha}\;.
\end{aligned}
$$

The class sizes are then obtained as

$$
\begin{aligned}
&\Delta G(b_k) := G(b_{k-1}) - G(b_k) = q^{(k-1)}(1-q)\;, \\
&\quad k = 1, 2, 3, \ldots
\end{aligned}
$$

We will just mention in passing that if α tends to infinity and we obtain an exponential distribution, then $q = (1 - 1/\alpha)^\alpha \to \mathrm{e}^{-1}$; with that $\Delta G(b_k)$ becomes independent of parameters. In bibliometric studies, we often observe α values in the range 2.0–3.0 (i. e., $q = 0.25$–0.30– [13.20, 21]). We show the corresponding class sizes around this value as well as for the exponential case in Table 13.1. For $\alpha = 3.0$, we have a theoretical distribution of objects over classes 1 through 4 roughly following a 70%–21%–6.5%–2.5% rule. Later on, in the empirical part, we will check how realistic this rule is in real-life situations.

Because of the underlying approach, i. e., the determination of classes on the basis of the characterization by conditional expectations, and the important role of the characteristic tail parameter α for the thresholds and class sizes, it was called the method of *Characteristic Scores and Scales* (CSS) when it was first proposed by *Glänzel* and *Schubert* [13.4]. Apart from

Table 13.1 Class sizes in relation to the α parameter of the Lomax distribution

α	q	Class 1 (%)	Class 2 (%)	Class 3 (%)	Class 4 (%)	Total (%)
∞	0.368	63.2	23.3	8.6	5.0	100
4.0	0.316	68.4	21.6	6.8	3.2	100
3.5	0.308	69.2	21.3	6.6	2.9	100
3.0	0.296	70.4	20.9	6.2	2.6	100
2.5	0.279	72.1	20.1	5.6	2.2	100
2.0	0.250	75.0	18.8	4.7	1.6	100

the above-mentioned role of the characteristic parameter, the knowledge of its actual value is not required for the method. The method does, therefore, meet the first requirement addressed in the introduction [13.4, p. 4]. Also, the second condition is satisfied, since the b_k thresholds are not preset, but are generated by the procedure.

So far we have merely dealt with the stochastic background of this model and its properties. In the following subsection, we will have a closer look at the statistical implementation of this theory.

13.2.2 Statistical Implementation of the Model

The statistical implementation of the above method of CSS is a recursive procedure of iteratively truncating a sample at its mean value, recalculating the mean of the truncated sample, and continuing this procedure until it is stopped, when the preset number of thresholds is reached or no new scores can be obtained. The following formalized description was provided in a previous study by *Glänzel* [13.20, pp. 93–94] and reads as follows:

We proceed from a bibliometric sample. This could, for instance, be a set of n papers published in a given subject field. The number of citations received by the individual papers in a given period are denoted by X_i, where index i runs from 1 to n. The observations are then ranked in descending order $X_1^* \geq X_2^* \geq \cdots \geq X_n^*$, with X_1^* denoting the citation rate of the most frequently cited paper and X_n^* consequently the lowest number of citations a paper within the set has received. We first put $b_0 := 0$ and $\upsilon_0 := n$, where n is the sample size, i. e., in the case of citation, the number of papers. According to the stochastic model of the previous section, b_1 is then defined as the sample mean

$$b_1 = \sum_{i=1}^{n} \frac{X_i}{n} = \sum_{i=1}^{n} \frac{X_i^*}{\upsilon_0} \, .$$

The value υ_1, which represents the size of the truncated sample, is uniquely defined by the following inequality

$$X_{\upsilon_1}^* \geq b_1 \quad \text{and} \quad X_{\upsilon_1+1}^* < b_1 \, .$$

This procedure can be repeated till it is stopped or the sample cannot be truncated further, so that we have

$$b_k = \sum_{i=1}^{\upsilon_{k-1}} \frac{X_i^*}{\upsilon_{k-1}} \, ,$$

and we choose υ_k so that

$$X_{\upsilon_k}^* \geq b_k \quad \text{and} \quad X_{\upsilon_k+1}^* < b_k, \quad k \geq 2 \, .$$

Obviously, the b_k thresholds define a not strictly increasing sequence, i. e., $b_0 \leq b_1 \leq b_2 \leq \ldots$, while the υ_k values (not strictly) decrease: $\upsilon_0 \geq \upsilon_1 \geq V_2 \geq \ldots$ If no preset number of classes is given, the procedure comes to a natural end if no further classes can be defined. In line with the intervals of the theoretical model, the k-th class is now defined by the pair of threshold values $[b_{k-1}, b_k)$ and the number of papers belonging to this class amounts to $\upsilon_{k-1} - \upsilon_k$. The share of papers falling into this class is the statistical equivalent of the theoretical value $\Delta G(b_k)$ (cf. Sect. 13.2.1).

On the basis of the above iteration, we can now define our citation-impact classes. Usually, we stop the iteration at $k = 2$ or 3. In what follows, we will use $k = 3$ as the default option. The interval $[b_0, \infty)$ contains the complete set $\upsilon_0 := n$. We call the first class $[b_0, b_1)$ with $(\upsilon_0 - \upsilon_1)$ elements the set of *poorly cited papers* since its elements are less cited than the average. The second class $[b_1, b_2)$ is referred to as *fairly* cited and contains $(\upsilon_1 - \upsilon_2)$ elements; the $(\upsilon_2 - \upsilon_3)$ papers of the third class $[b_2, b_3)$ are called *remarkably* cited and, finally, $[b_3, \infty)$ forms the group of the υ_3 *outstandingly* cited papers. Class 3 and 4 together can be considered highly cited. Combining those would, of course, be identical with the choice of $k = 2$.

After this step has been taken, we have the tools for scoring individual citation rates or any subsets or samples. Benchmarking exercises can now be readily constructed in the following manner. The original paper set, on which the above scores have been determined, serves as the reference distribution with a reduced state space. Now, observed citation rates of papers of any subset or sample can be gauged against this reference standard. The observed citation rate of each paper is compared to the thresholds b_k of the reference distribution and assigned to the four classes (or three classes, if k is set to 2), depending on whether the actual citation rate is greater or less than b_k. Note that the assignment is unique. Because of the definition of scores and the classes, multiple assignments cannot occur, not even for ties. This means that the third requirement formulated in the introduction in Sect. 13.1.2 is also met.

The choice $k = 2$ proved useful for small samples such as the publication output of individuals or research groups, whereas $k = 3$ is a general-purpose choice for large-scale analysis with sufficiently large publication sets in the samples under study.

When all elements of the subset or sample are each assigned to one of the classes, the two distributions can be compared. We will just mention in passing that the choice of $k = 1$ would result in *classical* bibliometrics with a comparison of mean values. Consequently, the last requirement in the list in Sect. 13.1.2, the seamless integration into the standard tools of scientometric performance assessment, is also met. The last question in the list concerning robustness and stability, along with its applicability to various levels of aggregation and its ability to gauge observations against several standards, will be answered on the basis of empirical evidence in the next section.

13.3 Characteristic Scores and Scales in Research Assessment

The method of CSS *includes* two basic properties that predestine it for universal use. Firstly, the CSS method is parameter-free, that is, subject to random errors of parameter estimators, and, secondly, it is self-adjusting. In other words, no predefined thresholds or quantiles are needed to set up the scales. In contrast, for instance, to percentiles, this approach is *natively* not sensitive to ties. The method can be interpreted as a reduction of the original citation distribution to a distribution over a given number of performance classes. The only arbitrary value that is needed to build the performance classes is its number. In practice, four classes are usually sufficient. As we will later see, at lower levels of aggregation, where the number of underlying publications is rather low, even three classes could be a more appropriate choice, since the fourth class might not contain enough elements. The four classes represent "poorly cited" (class 1), "fairly cited" (class 2), "remarkably cited" (class 3) and "outstandingly cited" (class 4) papers. Papers in classes 3 and 4 can be considered highly cited. Furthermore, the integration of the method into the standard scientometric tools directly results from its definition. The choice of two classes instead of four would provide a normalized mean citation score.

13.3.1 General Properties of the Method

The most striking advantage is the more detailed picture that we get regarding the citation impact. If the reference distribution is properly chosen, then CSS thresholds can be considered *normalized*. Unlike in the case of traditional indicators, where we can only infer whether the impact of our publication set under study is above or below the benchmark value, be it a mean or median, CSS provides five major types of deviations from the reference standard. And also here one can decide whether the possible deviation should be considered significant or not. Since we deal with distributions, the application of a simple χ^2 test is probably the most straightforward method for that, but alternatively, other or supplementary and preferably nonparametric statistics could be used, e. g., Cramer's V for the calculation of the effect size. The five paradigmatic types of deviations are symbolically potted in Fig. 13.1. Type III in the figure is in line with the reference standard. Two types, here marked as types II and IV, show clear trends towards poorly and highly cited papers, respectively. Type IV represents the most advantageous situation. Its distribution of the four performance classes is more skewed than the reference distribution: less poorly cited papers here entail more highly cited papers. Type II reflects the opposite situation: the large share of poorly cited papers is to the detriment of high-impact papers. These two types still correspond to their classical coun-

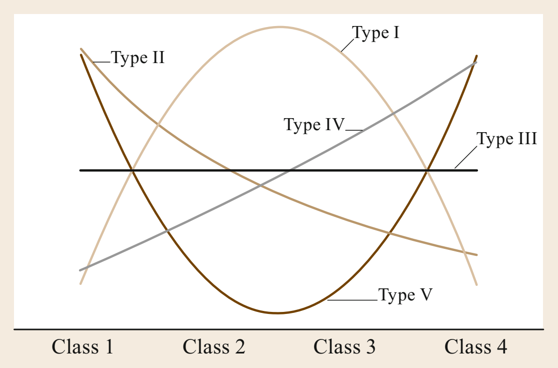

Fig. 13.1 The five different profiles according to their deviation from the reference standard (after *Glänzel* et al. [13.3])

terparts: high versus low (normalized) mean citation rates. Types I and II, however, represent completely different situations. Unlike type II, type I is characterized by the situation in which most papers are close to the average, and both poorly and highly cited papers are less frequent. Type V, finally, represents polarized citation impact. In such samples, poorly and highly cited papers are frequent and *average* papers are less frequent, as in the reference distribution. The latter two types are observable most notably at the level of individual scientists. The occurrence of these types thus depends on the level of aggregation, and the lower the level of aggregation, the more pronounced their shapes.

As already stressed by *Glänzel* et al. [13.3], a further advantage that this method shares with the percentiles approach is its insensitivity to outliers. An outlier is just one out of several publications that are assigned to the highest performance class. This prevents outliers from distorting the citation-impact indicators of the unit under study. As we mentioned in the methodological sections, the characteristic scores are obtained by iteratively calculating the mean value of a citation distribution and by subsequently truncating this distribution by removing all papers with fewer citations than the conditional mean. Although the method is based on mean values, the huge number of publications underlying the baseline, i. e., the complete database, guarantees that the influence of outliers remains marginal. From a statistical viewpoint, the publications that receive such striking citation rates form just a fraction of a thousandth of the population, i. e., the complete publication universe. The citation impact of this minuscule set of publications in the database that attracts this enormous amount of citations is easily absorbed by the total population. Nevertheless, these papers have been written and published by a rather small number of researchers, and if we assign the papers to statistics on these authors, their departments or even the institutes or organizations with which they are affiliated, the effect of the exceptional citation rates received by these papers can no longer be absorbed by the resulting samples. This was one of the main reasons why we replaced individual observations with performance classes. To give an example, we mention the case of the paper on the history of SHELX, which was published by a researcher at the University Göttingen. The extreme citation impact of this single paper is able to distort world university rankings if based on citation counts or means. *Waltman* et al. [13.7] first observed this effect. The paper in *Acta Crystallographica Section A* published in 2008 is still ranked first in the top list of the most cited papers during the last decade and is among the top ten most cited journal papers since 1955. We present the up-to-date citation impact of these ten most-cited papers just as an illustration (Table 13.2). Data have been sourced from Clarivate Analytics Web of Science Core Collection (WoS), but we stress that Elsevier's Scopus could be used as well. We will use the WoS throughout this chapter, so that we will explicitly indicate whenever an additional data source is referred to.

In addition to a review of our previous studies on CSS, the main objective of the remainder of the book chapter will be:

1. The demonstration of the applicability of the proposed method to various levels of aggregation, such as individual subjects on a large scale
2. The application to a combination of different subjects, including new results for journal assessment, and
3. The evaluation at the micro level.

The possibilities for applying the CSS method are manifold. In the following subsections, we will re-

Table 13.2 Extreme citation rates: the ten most-cited journal articles in the WoS displayed in descending order of citations received from publication year through 10.03.2017

1st author	Journal	Publication year	Volume	1st page	Citations

view them in a systematic way. The first group of applications comprises the assessment and profiling of publication sets according to their citation impact at various levels of aggregation. This concerns comparative analyses at the macro level (countries and regions), at the meso level, such as research organizations, universities, hospitals, university faculties and departments, and at the micro level, including research teams and individual scientists. A further opportunity provided by this method is the subject and journal analysis. We will just mention in passing that this is actually the field of application for which the method was originally designed [13.4]. Finally, the application to subject normalization was also soon discovered and implemented in a large compilation of journal–country indicators [13.22] and later used in the context of journal ranking [13.23]. The last option, which has not yet been frequently applied, is gauging citation classes against different reference standards that arise from several contexts. For instance, both the macro- and meso-level standard can be used to benchmark micro-level data, and at the same time, standard subjects or specifically delineated topics can be used to define the reference standards. A simplified overview of these fields of application is given in Fig. 13.2. The gray shapes on the left-hand side symbolize the most prominent domains of the assessment of research performance, while the three shapes in brown represent different aggregation levels of the underlying cognitive base. Although these three levels can also be studied independently of any national, institutional or individual research performance, even greater advantage can be gained if the results of the subject analysis are applied, for instance through improved subject/topic normalization, to research performance studies at different levels. In the following subsections, methodological and technical aspects will be discussed and illustrated by examples, where Fig. 13.2 will serve as a kind of road map throughout the chapter to navigate among the possible fields of application.

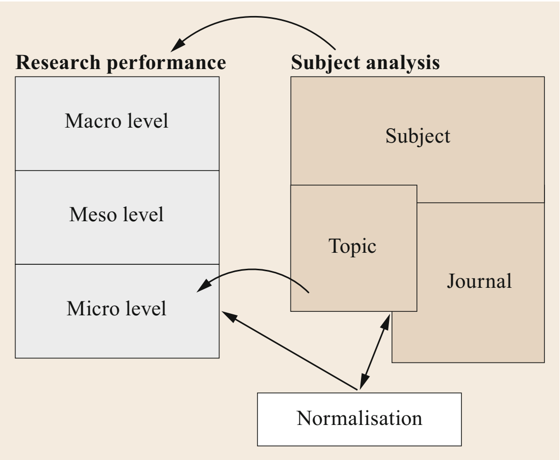

Fig. 13.2 Sketch of possible applications of Characteristic Scores and Scales

Before we explain in greater detail the methodological and technical aspects of the assessment of citation impact according to citation classes, we give empirical evidence of some important properties of CSS that are needed to properly interpret any results obtained from the application of this method. This concerns robustness with respect to subject matter, publication time and length of citation window. In the following subsection, we will give an illustration of these three aspects of robustness. Further evidence can be found in previous studies by the authors, notably in *Glänzel* [13.20, 23] and *Glänzel* et al. [13.24].

Finally, some words about the data sources. All calculations that have been made for the following (sub)sections are based on bibliographic data extracted from Clarivate Analytics Web of Science Core Collection. In order to study possible time dependence of CSS indicators, two volumes (2006 and 2013) of the WoS journal editions have been chosen. This choice allows for the calculation of citation measures for 3-year citation windows (i. e., 2006–2008 and 2013–2015, respectively) for both volumes and for a 5- and 10-year citation window for papers indexed for the 2006 volume (i. e., 2006–2010 and 2006–2015), since the last available volume for counting citations was 2015. Only *citable* papers, i. e., documents of type article, letter and review, have been selected for the chapter. All data were cleaned and processed for bibliometric use before the CSS indicators were built.

13.3.2 Empirical Properties and Disciplinary Characteristics of CSS

In order to shed light on subject-specific peculiarities, first, all documents extracted from the 2006 and 2013 volumes of the WoS database were assigned to the 74 individual subfields according to the modified Leuven–Budapest classification system (Fig. 13.3). *Glänzel* and *Schubert* [13.26] developed the first version of this scheme as a hierarchical system based on the Web of Science and Journal Citation Reports (JCR) subject categories. It was later modified [13.25] to provide a better categorization of the social sciences and humanities. In particular, the modification became necessary for the use with the *Book Citation Index* (BKCI) and the *Emerging Sources Citation Index* (ESCI) because of their larger coverage of the social sciences and humanities. Of course, this enhanced version is also fully compatible with the journal and proceedings editions,

THE LEUVEN-BUDAPEST CLASSIFICATION SCHEME FOR THE SCIENCES, SOCIAL SCIENCES AND HUMANITIES

0. MULTIDISCIPLINARY SCIENCES
- X0 multidisciplinary sciences

1. AGRICULTURE & ENVIRONMENT
- A1 agricultural science & technology
- A2 plant & soil science & technology
- A3 environmental science & technology
- A4 food & animal science & technology

2. BIOLOGY (ORGANISMIC & SUPRAORGANISMIC LEVEL)
- Z1 animal sciences
- Z2 aquatic sciences
- Z3 microbiology
- Z4 plant sciences
- Z5 pure & applied ecology
- Z6 veterinary sciences

3. BIOSCIENCES (GENERAL, CELLULAR & SUBCELLULAR BIOLOGY; GENETICS)
- B0 multidisciplinary biology
- B1 biochemistry/biophysics/molecular biology
- B2 cell biology
- B3 genetics & developmental biology

4. BIOMEDICAL RESEARCH
- R1 anatomy & pathology
- R2 biomaterials & bioengineering
- R3 experimental-laboratory medicine
- R4 pharmacology & toxicology
- R5 physiology

5. CLINICAL AND EXPERIMENTAL MEDICINE I (GENERAL & INTERNAL MEDICINE)
- I1 cardiovascular & respiratory medicine
- I2 endocrinology & metabolism
- I3 general & internal medicine
- I4 hematology & oncology
- I5 immunology

6. CLINICAL AND EXPERIMENTAL MEDICINE II (NON-INTERNAL MEDICINE SPECIALITIES)
- M1 age & gender related medicine
- M2 dentistry
- M3 dermatology/urogenital system
- M4 ophthalmology/otolaryngology
- M5 paramedicine
- M6 psychiatry & neurology
- M7 radiology & nuclear medicine
- M8 rheumatology/orthopedics
- M9 surgery

7. NEUROSCIENCE & BEHAVIOR
- N1 neurosciences & psychopharmacology
- N2 psychology & behavioral sciences

8. CHEMISTRY
- C0 multidisciplinary chemistry
- C1 analytical, inorganic & nuclear chemistry
- C2 applied chemistry & chemical engineering
- C3 organic & medicinal chemistry
- C4 physical chemistry
- C5 polymer science
- C6 materials science

9. PHYSICS
- P0 multidisciplinary physics
- P1 applied physics
- P2 atomic, molecular & chemical physics
- P3 classical physics
- P4 mathematical & theoretical physics
- P5 particle & nuclear physics
- P6 physics of solids, fluids and plasmas

10. GEOSCIENCES & SPACE SCIENCES
- G1 astronomy & astrophysics
- G2 geosciences & technology
- G3 hydrology/oceanography
- G4 meteorology/atmospheric & aerospace science & technology
- G5 mineralogy & petrology

11. ENGINEERING
- E1 computer science/information technology
- E2 electrical & electronic engineering
- E3 energy & fuels
- E4 general & traditional engineering

12. MATHEMATICS
- H1 applied mathematics
- H2 pure mathematics

13. SOCIAL SCIENCES I (GENERAL, REGIONAL & COMMUNITY ISSUES)
- Y1 education, media & information science
- Y2 sociology & anthropology
- Y3 community & social issues

14. SOCIAL SCIENCES II (ECONOMIC, POLITICAL & LEGAL SCIENCES)
- L1 business, economics, planning
- L2 political science & administration
- L3 law

15. ARTS & HUMANITIES
- K0 multidisciplinary journals
- K1 arts & design
- K2 architecture
- K3 history & archaeology
- K4 philosophy & religion
- K5 linguistics
- K6 literature

Fig. 13.3 The modified version of the Leuven–Budapest hierarchical classification scheme based on the WoS subject categories according to *Glänzel* et al. [13.25]

while major fields and subfields in the sciences of the previous version are not changed. The modified classification scheme is presented in Fig. 13.3.

The reason why we decided to use the second hierarchical level of the scheme results from experience. While major fields often prove too coarse—that is, subjects within the same major field might represent different standards in publication and citation behavior, for which mathematical & theoretical physics and particle & nuclear physics may serve as an example—

the choice of the lowest level, i. e., of the WoS subject categories, would result in a superposition of the multiple assignments of papers to subjects, which, to solve, requires an extensive combination of fractionating and weighting by subjects. Nevertheless, at the micro level, this would be—alternatively to the delineation of specific topics—the preferred solution, as lower levels of aggregation always need higher granularity.

Citation patterns are strongly influenced by subject characteristics. This effect is a well-known characteristic of citation indicators. Papers in mathematics, engineering and social sciences exhibit distinctly lower citation impact than their counterparts in the natural or life sciences. Even within major fields of the sciences and social sciences, communication patterns may vary considerably. *Peritz* [13.27] showed this in her study on the intradisciplinary differences in citation impact of theoretical, methodological and empirical papers in sociology in three prestigious sociology journals. In the sciences, theoretical subjects usually have a lower impact than experimental and applied ones. *Marx* and *Bornmann* [13.28] point to a further reason for subject-specific differences originating from the different coverage of the literature in multidisciplinary databases, which in turn is only partially a result of the scientists' distinct publication activities in the different disciplines. For these reasons, citation measures are—without proper subject normalization—not appropriate for cross-field comparisons. In order to illustrate this property, we show the aggregate impact factors (AIF) of 20 selected subject categories according to the 2015 sciences and social sciences edition of the Clarivate Analytics Journal Citation Report in Table 13.3. The selected categories represent the high end, the medium range and the low end of citation impact. The difference between the highest and the lowest impact extend to one order of magnitude.

As a consequence, the actual b_k values of the characteristic scores are also strongly influenced by the disciplines in which papers have been published. The subject dependence of characteristic scores, notably the enormous variation in the $b_3$values, has already been pointed out in earlier studies [13.20, 23, 24]. The underlying citation window is the second important factor that affects citation indicators, in general, and characteristic scores in particular. It goes without saying that larger citation windows provide the opportunity to attract and receive more citations than shorter ones. In order to illustrate both effects, we have fixed one publication year and selected a number of disciplines from different science and social science fields. The b_k values for the WoS 2006 volume and a range of subject fields in three different citation windows are given in Table 13.4. In particular, we have selected 18 of the 74 total subfields, two each from biosciences, internal and noninternal medicine, chemistry, physics, engineering and the social sciences, and one each from mathematics, geo- and space sciences, neuroscience and biology. The number of papers assigned to these disciplines 2006 ranges from roughly 10 000 to 60 000.

Data sourced from Clarivate Analytics Journal Citation Report

The b_k values ($k = 1, 2, 3$) are arranged by citation window in three columns each (Table 13.4). The first three columns corresponding to citations received in 2006–2008 are completely in line with the AIF presented in Table 13.3, and thus confirm the general trend of subject-specific characteristics in citation indicators, although the AIF is a synchronous indicator with fixed citation year and variable publication years. Mathematics and social sciences are found at the low end, while biosciences, notably cell biology, are at the top surrounding the natural sciences, medical sciences and psychology. The high and the low ends are separated by one order of magnitude, as in the case of CSS. Increasing the citation window yields considerable changes in all b_k values. The increase by 2 years (5-year window 2006–2010) results in roughly doubling of the corresponding values. Further enlarging the citation window to 10 years (2006–2015) yields another doubling. This trend is proportional. Although this is not important for

Table 13.4 Characteristic scores for 18 selected subfields in 2006 according to the Leuven–Budapest scheme

any field of application of CSS scores, it reveals an interesting empirical property. A simple linear regression analysis shows a very strong correlation with r^2 values ranging from 0.97 to 0.99 for all citation windows and k values, while the slope varies from 2.0 to 2.1 for the extension of the citation window from 3 to 5 years, and takes values between 2.1 and 2.4 for the extension by an additional 5 years. Although there is no theoretical model or rationale that could explain these values, from an application viewpoint, this simple factor of around 2 could potentially be used for time-based normalization of citation indicators.

In contrast to the characteristic scores, the distribution of citations over the four classes that are defined by the b_k scores is strikingly insensitive to both the citation window and the underlying discipline. This kind of robustness is in line with the observations published in the above-mentioned studies by *Glänzel* [13.20, 23] and *Glänzel* et al. [13.24]. This stability is maintained even if the citation window is further extended to 20 years, on the basis of the 1980 volume of the Science Citation Index (SCI) and a 21-year citation window. The share of those papers that have received at least b_k but not reached b_{k+1} citations (with $b_0 = 0$ and $b_4 = \infty$) for all papers published in each of the 74 Leuven–Budapest subfields in 2006 was calculated for the three periods 2006–2008, 2006–2010 and 2006–2015. Table 13.5 gives the corresponding values for the same selection of disciplines as above. The class-percentage values are very similar, although not identical, independent of the discipline and the citation window. The conclusion drawn from these empirical distributions is completely in line with both our Paretian model (Sect. 13.2.1) and the empirical observations made by, e. g., *Albarrán* and *Ruiz-Castillo* [13.29] and *Glänzel* et al. [13.24]. According to these results, the share of papers cited less frequently than the average (class 1) amounts to roughly 70%, the share of those assigned to class 2 to about 21%, and the share of papers in the upper two classes is 6%–7% and 2%–3% of all papers, respectively.

Apart from just showing empirical properties of CSS thresholds and classes, there is also a straightforward application of these results. The shares of papers falling into classes 1 through 4 can be used as a benchmark for any sample drawn from a population or for any other subset of papers in the corresponding subfield. The three corresponding thresholds (b_k scores) then serve as the criteria of assignment for the papers in the subset under study. If this subset were the true mirror of the entire population, its share in all four classes would be identical to that of the reference standard. Any deviation from this standard indicates a specific profile. Possible paradigmatic profiles have already been sketched in Fig. 13.1 (Sect. 13.3.1). In particular, individual profiles might be more or less skewed with higher or lower shares in the lower classes, respectively, or more or less polarized as the lower/higher share of lower-class papers is compensated by a higher/lower share of upper-class papers. This makes comparison with benchmark values or reference stan-

dards more complex than the usual higher/lower than expected as known from traditional bibliometric exercises. In order to infer significance of deviation from the reference standard, a simple χ^2 homogeneity test with three degrees of freedom can be applied. In this context, it is also important that the sample size is large enough, that is, it should amount to at least 20–30 items (*Vincze* [13.30] mentions a minimum of 40 items for the Welch test, which requires slightly larger sample sizes). In order to illustrate how to use CSS for sample profiling, we give the following example.

We have taken four nonrandom subsets of publications, one each for cell biology (B2), psychiatry & neurology (M6), analytical, inorganic & nuclear chemistry (C1) and pure mathematics (H2). The papers were published in 2006, while the citation window is 2006–2008. The sample sizes of these subsets range from 100 to 329 and are thus sufficiently large. Applying the χ^2 homogeneity test, we obtain $\chi^2 = 7.99$ for cell biology, $\chi^2 = 38.30$ for psychiatry & neurology, $\chi^2 = 5.23$ for the chemistry discipline and $\chi^2 = 4.32$ for mathematics. The critical value at a confidence level of 95% is 7.81. According to these results and the CSS-class distributions of the samples and the reference standard, we can conclude that the distribution of papers over CSS classes of the first sample (B2) differs significantly from that of the benchmark, and thus follows profile type II. This type reflects a quite unfavorable situation, with more less-cited papers and fewer papers in the upper classes. The deviation from the reference standard is even more striking in the second sample (M6), but here the deviation points in another direction. The share of poorly cited papers lies distinctly below the standard, while the percentage of fairly and highly cited papers in all classes is above the corresponding benchmark value. This situation corresponds to type IV, which reflects the most advantageous situation. The paper set in analytical, inorganic & nuclear chemistry (C1) would be an excellent example of type I. However, the deviation from the standard is not significant. Finally, the fourth subset (H2), because of its relatively small size, also does not differ significantly from the standard. Its CSS profile by and large follows the benchmark distribution and is of type III. The four distributions with the χ^2 test values are displayed in Table 13.6.

13.3.3 Application of Characteristic Scores and Scales in Comparative Macro- and Meso-Level Studies

Using a dataset reflecting a properly delineated homogeneous subject profile as the reference standard is, of course, one of the possible applications for the impact analysis of research output, and we will, therefore, deepen this further in this section. However, the typical task in quantitative research evaluation is the assessment of rather heterogeneous publication sets, such as the multidisciplinary output of a research unit or a country. It is, of course, possible to process each discipline separately and assess research performance in each dis-

Table 13.6 Four samples to illustrate benchmarking according to CSS classes (publication year: 2006, citation window: 2006–2008)

Subfield	Subfield reference standard				Subset					χ^2
	Class 1	Class 2	Class 3	Class 4	Class 1	Class 2	Class 3	Class 4	N	
B2	69.9	21.5	6.0	2.6	79.6	17.5	2.2	0.7	137	7.99

H2	70.4	18.5	7.8	3.3	69.3	16.7	11.4	2.6	228	4.32

Data sourced from Clarivate Analytics Web of Science Core Collection

cipline, but real-life situations relate rather to output of inter- and multidisciplinary research results, which preferably should not be disaggregated into individual subjects. Referring to Fig. 13.2, the subject of analysis of the previous subsection was located at the upper-right corner of the diagram. We now move to the left-hand side, where macro- and meso-level publication output is usually not assignable to single disciplines and thus requires more sophisticated approaches. *Glänzel* et al. have described such an approach [13.24].

Even if CSS are applied in multidisciplinary environments, all publications that are subject of the analysis need to be assigned to individual disciplines. The reason is that the *unique* assignment of publications to performance classes is an indispensable precondition for the applicability of CSS. We illustrate this problem using the following example. Bibliographic databases allow and apply multiple assignments of indexed items to subject classification, independent of whether the assignment is made on papers directly (e. g., MathSciNet) or through the journal in which it is published (e. g., WoS, Scopus). Let us now assume that a paper is assigned to two subjects, here denoted by S1 and S2. Both subjects usually have their own specific publication and citation standards. As we could observe in Table 13.4, the two subjects might have distinctly different b_k ($k = 1, 2, 3$) thresholds. Let us further assume, without loss of generality, that the citation standard of S1 is higher, that is, its b_k values are higher than their counterparts of S2. This means that the paper in question might be assigned to class 3 in subject S1 and to class 4 in S2, since its citation rate does not exceed b_3 in S1, but it is greater than the corresponding threshold b_3 in S2. Directly combining the two subjects or applying a simple average of b_k would not solve this problem or provide any acceptable solution, as this solution would lack any theoretical background or justification. We have solved this problem by applying a proper subject-based fractionation such that each publication is gauged against only one individual standard and b_k threshold value for each $k = 1, 2, 3$. The basic idea behind this solution was developed in the context of traditional indicators. Unlike the journal-based expected citations rates of individual papers, discipline-based expectations are subject to the same methodological problem of setting unique reference standards. As argued in a previous study by *Glänzel* et al. [13.31], one consequence of multiple assignments is the necessity of fractionation by all individual subjects to which the paper is assigned, and this has to be followed by the calculation of proper weights for the corresponding individual subject-expected citation rates. This must be done by defining correct weights such that the sum of the individual subject-based expectations over all publications in the system equals the citation total of the database in the combination of these fields. As a result, one obtains an "implicit" classification with standards that are different from those given in Table 13.4, since the corresponding thresholds are influenced by the combination of individual co-assignments to disciplines. As a consequence, we do not have *common* thresholds for all papers assigned to the same discipline. In order to distinguish the two types of scores, we denote the common scores in subsection 3.1 by b_k and the individual ones according to this procedure by b_k^*.

Also, this procedure is iterated to determine all CSS scores needed to define the four classes. This is done in the following manner. The first step is identical to the procedure for calculating subfield-expected citation rates [13.31]. A first fractionation applies to the calculation of the citation means of the disciplines. This is done on the basis of the respective number of subfields to which a publication is assigned. In this step, publications as well as citations are fractionated. After this is done, the individual expectation denoted by b_1^* is calculated for each paper, which is simply the mean value of the fractionated subfield standards. As we did this before in the disciplinary approach in Sect. 13.3.1, all papers that received fewer citations than their individual expectation are removed from further calculation. The above procedure is then repeated on the remaining set. This way we obtain the individual thresholds b_2^*. In total, the procedure is applied three times to obtain the three individual characteristics scores ($k = 1, 2, 3$) for each paper. After this is finished, papers can be uniquely assigned to one of the four classes. We would like to stress that this model is an extension of the previous single-disciplinary model. In particular, if the underlying paper set consists only of publications from a single discipline, fractionation and weighting would result in a trivial solution that would be identical to the unfractionated solution described in the previous subsection. The individual b_k^* thresholds in this case are identical to the common characteristic scores b_k.

In order to illustrate this procedure at the macro and meso levels, we have first selected 25 countries from among all regions in the world. We have selected two publication years, 2006 and 2013. The choice of the first year (2006) allows the calculation of indicators, i. e., of CSS scores, and the corresponding classes for citation windows up to 10 years. The second publication year allows for a comparison of the values of the same indicators shifted over 7 years to monitor their evolution. When selecting the countries, we aimed at both sufficiently large publication sets underlying the statistics in the two publication years and an acceptable geographic and geopolitical coverage. We have included papers of document type article, letter and review published in any subject category. The authors have published similar results by using the publication years 2007 and 2009 with a 5- and 3-year citation window, respectively [13.24]. This also gives us the opportunity to compare part of the new results with the previous, but differently structured results, since the overlap of the country selection is quite large. This comparison could confirm or argue against the robustness of the method.

First, we present the distribution of papers over CSS classes for the 25 selected countries. We have used the three-letter ISO codes for the country names; the key can be found in the Appendix. Table 13.7 gives the percentages along with the size of the underlying dataset. The last row displays the reference standard. According to the results published in our previous study, the reference standards for 2007 with a 5-year citation window and 2009 with a 3-year citation window amounted to 69.8% (class 1), 21.5% (class 2), 6.3% (class 3) and 2.4% (class 4), and 69.7% (class 1), 21.4% (class 2), 6.4% (class 3) and 2.5% (class 4) [13.24]. The

present results are very similar, although we can observe a slightly more skewed situation with a 10-year citation window. Comparing these distributions, most notably those for 3- and 5-year citations windows, we can again confirm the overall robustness of the method, with a class distribution of roughly 70%–21%–9% (class 1, class 2 and class 3&4), which has also been confirmed by *Albarrán* and *Ruiz-Castillo* [13.29]. Even more interesting, the CSS distribution of the selected countries shows the same robustness, while national characteristics become obvious. At the macro level, one cannot expect very polarized patterns (type I or V according to Fig. 13.1), and indeed, most shapes follow types II, IV or roughly type III. A χ^2-test is omitted here since, as a consequence of the large datasets at this level, almost all small deviations from the benchmark are to be considered significant. The strikingly large share of highly cited papers in Switzerland, Denmark, the Netherlands, the USA and Belgium has already been mentioned by *Glänzel* et al. [13.24]. The CSS classes of these countries are the most striking examples of type IV distributions. The type IV distribution of Singapore is not so pronounced as in the case of the above-mentioned countries, but is somewhat surprising. This is contrasted with the clear type II shapes of several countries including Russia, Brazil, India, China and Poland, but Japan and South Korea also belong to this group. Among the larger Eastern European countries, only the Czech Republic and Hungary (not displayed in Table 13.7) are close to the standard type III. Their patterns remain stable if the citation window is enlarged.

The following example shows CSS distributions of the same country sets for papers published in 2006 and 2013, each with a 3-year citation window. This underpins the comparison of the same indicators over a temporal distance of 9 years. Instead of the presentation of indicators in tables, we chose a visualization in stacked bars. Since percentages summed up over the four classes give 100%, we have omitted the lowest class. We must stress that a similar share of class 1 papers does not imply the same distribution over the upper classes. Figures 13.4 and 13.5 show the distribution over classes 2–4 of the 25 countries, along with the corresponding reference standard. The bar at the right-hand side represents the world standard. The results are very clear, although a detailed interpretation of the bars is not straightforward.

Essential changes cannot be observed, but those were not expected. China, Korea and India have gained citation impact; most notably, Singapore's share of

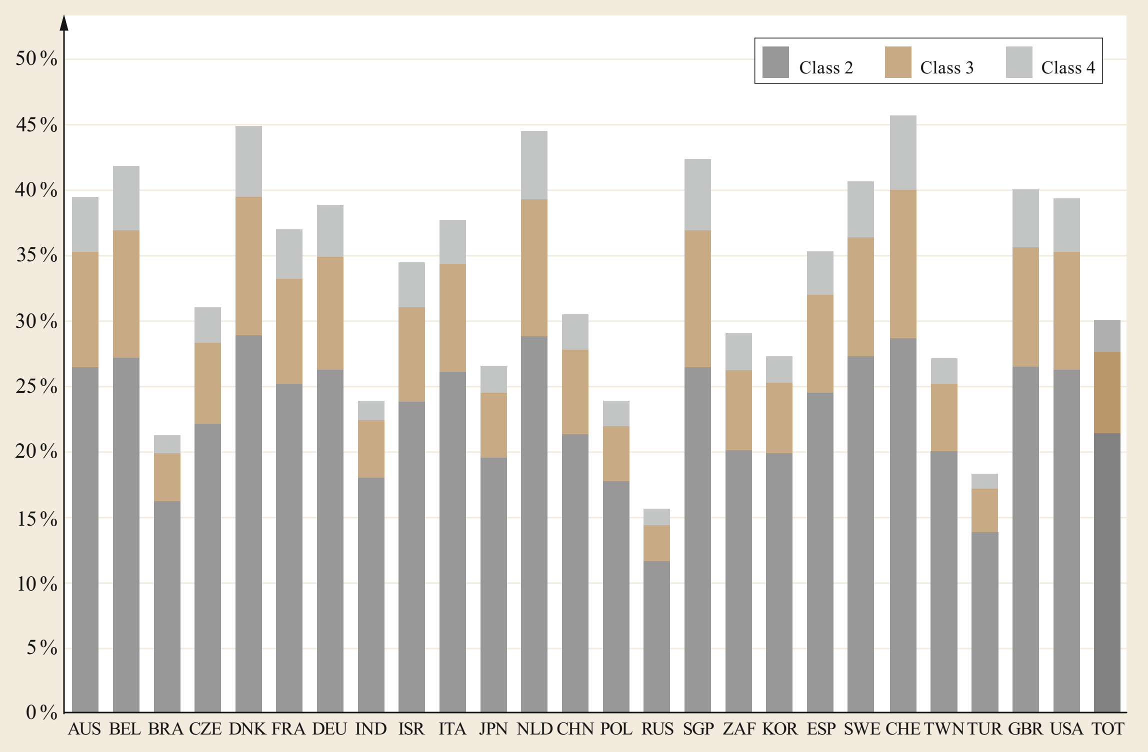

Fig. 13.5 Distribution of national shares of 25 selected countries in the upper reference CSS classes in 2013 in all fields combined (citation window: 2013–2015) (Data sourced from Clarivate Analytics Web of Science Core Collection)

fairly and highly cited papers has grown considerably, reaching the level of the most developed European and North American countries in 2013. By contrast, Russia, Brazil, Taiwan and Japan slightly lost impact during these 9 years. The overall picture obtained reflects stability.

To conclude this subsection, we illustrate the applicability of CSS scoring to the institutional level. For this purpose we have selected two universities each from 10 European countries. Here we have two reference standards, the national one for each country and the benchmark on the basis of the complete population. Of course, one would expect that the universities' profiles should mostly mirror the national patterns, but we can also find situations that differ from the respective national standard. These might be more or less favorable than the corresponding national profile.

Figure 13.6 shows the university profiles along with their national and the world reference standards for 2013, with a 3-year citation window. The respective Belgian, German, Italian, Swedish and British universities reflect slightly or even distinctly more favorable profiles than their national reference standard. In the other sample countries we also find universities with less favorable profiles. In addition to the large multidisciplinary universities, we have selected large medical (HU1 and SE2) and technical universities (DK2, DE2 and NL2). The high standard of technical universities again provides evidence of the subject independence of the method, since the applied and technical sciences generally attract fewer citations than the natural sciences, most notably the life sciences. Further examples can be found in the aforementioned study by the authors [13.24].

13.3.4 Application of Characteristic Scores and Scales to Micro-Level Studies

While bibliometric macro- and meso-level studies generally represent quite similar situations in terms of subject profiles (multidisciplinarity) and sample sizes (statistical reliability), studies of research teams face two specific issues. The first concerns the specific research and publication profiles of individual scientists or research teams. These profiles often cannot be captured by the standard subject categories of disciplines. Here, specialization and interdisciplinarity are the predominant models, and their fields of activities might be characterized by distinctly different citation behaviors from the standard subjects. This requires a proper

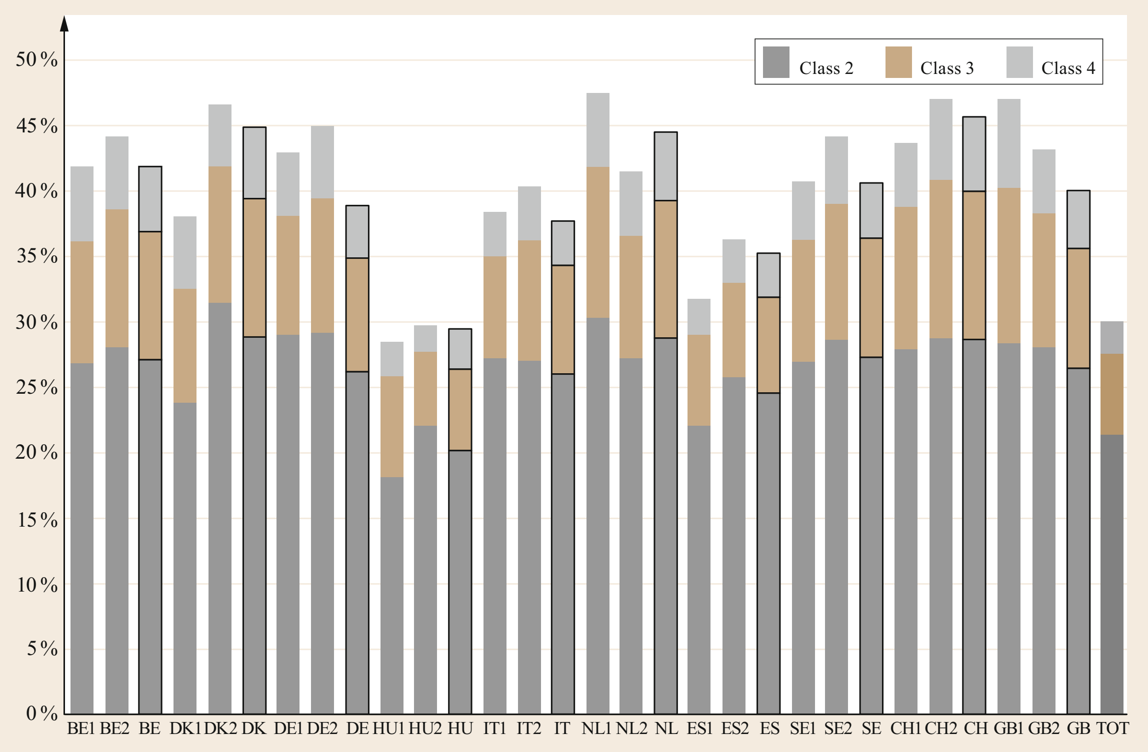

Fig. 13.6 Distribution of shares of publications of ten selected universities and countries in all fields combined over the upper reference CSS classes in 2013 (citation window: 2013–2015) (Data sourced from Clarivate Analytics Web of Science Core Collection)

subject delineation and determination of benchmarks according to the researchers' profiles. According to Fig. 13.2, we have to go back to journals and research topics in order to find the appropriate normalization for CSS benchmarking at this level of aggregation. The other issue is a consequence of the small sample sizes. Not all researchers (or teams) active in the field under study have published a sufficient number of papers to be included in the comparison group, and more prolific scientists (or teams) generally achieve higher visibility and impact than single-paper authors or less active scientists. This may result in built-in biases if the publication sample for individuals originates from the output of the more active authors [13.32]. In other words, the selection of topics and reference groups might determine different reference standards and baseline distributions for the publication set under study. Furthermore, at this level, outliers and observations differ distinctly from their expectation and distort traditional indicators to a greater extent. That is why micro-level studies require extremely stable and robust solutions. Again, we will show that the CSS-based method meets these requirements. As with any application of bibliometric methods to the micro level, i. e., to the level of individual scientists and research teams, the CS remains a challenging task [13.33]. According to multiple evidence-based statements, evaluation criteria should never rely on quantitative methods alone and should always be combined with appropriate qualitative methods. Furthermore, if the underlying data set is not sufficiently large, quantitative methods should not be applied at all.

The selection of a proper benchmark is another challenge. While we can use a sufficiently fine-grained subject classification at the meso and macro levels, the research assessment of individuals and teams requires personalized solutions. Typically, we have two different approaches at this level, the bottom-up and the top-down. The top-down approach proceeds from a given topic which is largely different from any predefined substructure of the subject-classification schemes that come with or are derived from bibliographic databases. Then, one has to identify the actors, i. e., authors and/or research teams who are active in this topic. Finally, indicators—in our case CSS scores—must be calculated for the topic and the authors' citation distributions gauged against this standard. One drawback of this solution is that only those papers of relevant authors/teams that fall within the topic are taken into account. If authors are also active outside this topic, that part is thus ignored. This approach, which represents a topic–author (topic–team) combination, is nevertheless the easier way compared with the bottom-up approach, which has not always been a unique solution. The authors are given, and their research topics must be delineated on the basis of their publication activity. The broadness of the subjects, be it ready-made subject categories or individually delineated tailor-made topics, is normally determined in collaboration with the agency or authority that commissions the bibliometric study. Preserving the authors' anonymity, we chose the first option (top-down approach) to illustrate the application of the CSS method to individual scientists. We have chosen the topic *scientometrics*, a subject we are very familiar with. Since we also know the actors, we can readily judge the correctness of inference from the data. We have collected publication data from 1998 to 2012 and applied 3-year citation windows, shifted by publication year. This citation window is admittedly short, but permits the inclusion of quite recent papers, which is an important aspect for a growing topic like scientometrics. In order to delineate the field, we have used core journals, including *Scientometrics* and *Journal of Informetrics*, along with a combination of a large range of keywords, including sciento-/biblio-/infor/web(o)-metric*, (co-)citation analysis*, bibliographic coupling, co-authorship and network/analysis. The total number of relevant papers amounts to 11 514. Smaller disciplines or specialized topics that form a subpart of a discipline, or the papers that are assigned across several disciplines but not fully covered by those, usually produce biased citation-impact baselines, if standard subject classification is used [13.34].

In the case of scientometrics, the argument against the use of standard fields is that papers in this topic exhibit, on average, higher citation rates than other papers in information and library science. Many relevant papers are published in journals outside this subject category, notably in multidisciplinary and specialized journals, practically in all fields of the sciences and social sciences. However, if we determine the CSS reference distribution of the citations received by the bibliometric papers and ignore any subject assignment, we obtain a class distribution of 67.6%–23.1%–6.4%–2.9%, which is again in line with the general distribution rule. This again substantiates robustness, most notably if one takes the large publication period of 15 years into account. If we exclude authors with fewer than ten papers each, we obtain a distribution of 54.0% (class 1), 31.1% (class 2), 9.7% (class 3) and 5.3% (class 4), which again illustrates the strong bias towards prolific authors [13.32]. We also see that the profiles of the most prolific authors, i. e., of the 22 authors with at least 30 papers each, tend to have profiles according to type IV. We have assigned identifiers to all authors who appeared as co-authors in publications collected for the scientometrics dataset. Only one author among the 22 persons displayed in Table 13.8 has a type I profile, due to the large share of fairly cited papers (#654). Authors whose profiles proved not to deviate significantly from the reference standard are automatically considered to have a type III profile.

Two issues need to be mentioned in the context of inference from CSS statistics at this author-level aggregation. First, authors with about 40 papers need only a single class 4 paper to get in line with the expectation, since this amounts to $\approx 2.5\%$, and second, co-authorship has a strong effect on the high end of the CSS class distribution here. This is the reason we recommend the application of three CSS classes (with $k = 1, 2$) only. The five profile types are still distinguishable using three classes. Alternatively, a χ^2 test could be applied with two degrees of freedom and the corresponding critical value of 5.99. In this context, we again must stress the necessity of context analysis required at the micro level, which also includes seniority and career analysis, citation context and analysis of co-authorship networks [13.33, 35].

13.3.5 Application of Characteristic Scores and Scales to Journal Assessment

Moving further to the right-hand side of Fig. 13.2, we arrive at the journal area. From a historical viewpoint, the use of the CSS in the context of journal assessment was the first application, and this was actually the application for which the method was designed [13.4, 22, 36]. Unlike subject assignment or the profiles of individuals and research units or countries, journals do not require multiple assignments of papers. Journals form a true partition of the document space that is covered by a bibliographic database and also of any paper set under study. If papers are to be assigned to journals on the basis of where they have been published, assignment is always unique, and thus no fractionation is needed. This property essentially simplifies the application of bibliometrics to journal indicators. On the other hand, journal analysis is still an important methodological topic in scientometric research and an indispensable fundamental for supplementing bibliographic databases by journal metrics (cf. Journal Citation Reports (JCR), Scimago Journal Ranking (SJR), Scopus CiteScore metrics). As long as journals serve as the basis for subject classification, journal indicators remain essential issues in bibliometric studies.

Table 13.8 Distribution of papers over performance classes by individual authors with at least 30 scientometric papers in 1998–2012. The χ^2 test is based on four CSS classes

Author ID	Papers	Class 1 (%)	Class 2 (%)	Class 3 (%)	Class 4 (%)	Class 3&4 (%)	χ^2	Type

Data sourced from Clarivate Analytics Web of Science Core Collection

In our first applications in 1987 and 1988, mean citation rates for chemistry journals were calculated for a 5-year publication period, with the same citation window, and then gauged against the CSS standards set by subfields of chemistry. The share of uncited papers was still used as an additional class 0 below the poorly cited articles. Thus three characteristic scores provided five classes, class 0 though class 4. We later refrained from this solution because of a lack of robustness. The share of uncited papers strongly depends on both the citation windows, i. e., it decreases as the window increases, and the subject matter. The reason for the instability is that this is the only class that is defined on a fixed criterion (i. e., uncitedness), while all other classes are based on variable thresholds that depend on time window and research topic. The basic idea at that time was to provide additional information about the journals' position in a discipline beyond the usual ranking exercises. *Schubert* et al. [13.22] already applied CSS to journals on the basis of two scores only and with the purpose of gauging national contribution to journal impact but not to compare class distributions by journals. Now we will use the CSS class distributions as an alternative to journal ranking.

This also demonstrates a new and completely different application context. Although this type of application does not allow any linear ranking, and the interpretation of CSS class distributions is not always straightforward, the added value of the information and the more detailed picture of citation impact that we obtain compensates for the greater complexity. The surplus of information results from two sources that have been addressed many times in the scientometric literature: first, the subject-specific peculiarities of citation impact, and second, the various shapes of citation distributions underlying journal impact. *Glänzel* and *Moed* [13.11] and *Glänzel* [13.12] have given examples of journals with almost identical mean citation rates but different distribution shapes. We have computed mean citation rates (denoted by MCR) and CSS class distribution for all journals in 2013 using a 3-year citation window. We have applied the fractionation process for subjects according to the procedure described in Sect. 13.3.2, since many journals have multiple subject assignments. Table 13.9 gives the mean citation rate values of five selected journal pairs with almost identical citation impact (MCR) each but distinctly different profile types according to their CSS class distribu-

Table 13.9 Examples of mean citation rates (MCR) of selected journal pairs with almost identical citation impact but distinctly different profile types in 2013 with 3-year citation window according to *Glänzel* and *Thijs* [13.37]

Data sourced from Clarivate Analytics Web of Science Core Collection

tions. We have chosen journals representing different *standards* to illustrate that this phenomenon might occur in all impact classes ranging from high to low standards.

Now we have a closer look at CSS profile types at the journal level. Also, for scientific journals, which correspond to the meso level in bibliometric practice, we can clearly distinguish all five types. The annual number of citable papers (articles, letters, notes, reviews) published in journals ranges from less than 10 to almost *industrial* quantities of several thousand in the major chemistry and physics journals, led by PLOS One with more than 30 000 papers in 2013. We have excluded the 5688 out of 12 386 journals with fewer than 50 papers each. Journals whose profiles did not deviate significantly from the reference standard in 2013 (70.0%–21.4%–6.2%–2.4%) were considered to be of type III. The distribution of journals over CSS profile types is thus as follows: 400 (type I), 3037 (type II), 1748 (type III), 1499 (type IV) and 14 (type V). Type V is thus extremely rare at this level too. Table 13.10 shows a sample of 30 journals across several subject fields per type in alphabetical order. While *Physical Review C* follows the reference standard almost perfectly, the deviation from this standard may be enormous as, e. g., *Accounting Review*, with quite homogeneous citation patterns, and *Prenatal Diagnosis*, with extremely polarized citation rates, clearly illustrate. We have not displayed the MCR values in order to avoid biased interpretation caused by mean citation rates. Nevertheless, type IV represents the most advantageous profile and type II the least favorable situation. Type III simply means general conformity to the subject-based standard. Figure 13.7 presents data on a selection of five triplets of the journals displayed in Table 13.10 just to visualize the variety of profiles at the journal level.

13.3.6 Application of Characteristic Scores and Scales to Citation-Impact Normalization

In an earlier paper, *Schubert* et al. [13.22] had observed that the difference $b_2 - b_1$ was a very close proxy for the standard deviation of the underlying distribution. This observation was based on a mere empirical finding, in particular, with the important property that the approximation improves with increasing sample size. However, the basic idea behind this formula is the fact that mean values of empirical Pareto-type distributions are approximately normally distributed, provided that the characteristic parameter α is greater than 2 [13.10]. Now, if we assume the very simple model in which the underlying distribution is approximately a Pareto-type distribution of Lomax type, then $\Delta\ b_k = b_k - b_{k-1} \approx ba^{k-1}$, and thus we have $b_2 - b_1 \approx ba$, where $a = \alpha/(\alpha - 1)$. In verbal terms, $b_2 - b_1$ is a linear function of b, where the slope depends only on α that is on the tail property of the underlying distribution. Yet the standard deviation of a Lomax distribution is $b\{a/(2-a)\}^{1/2}$. Both expressions are proportional to b and, if α is around 3, the coefficients amount to 1.5 and 1.73, respectively. The small deviation of the two values is less relevant, if all samples share the same α, as the most important property is the proportionality to b. On the basis of both the empirical evidence and the theoretical explanation, the following standardization of mean citation rates seems to be justified

$$u = \frac{x - b_1}{b_2 - b_1}\,, \tag{13.2}$$

where x represents the actual mean citation rate, and the u value is called the *unified citation score*. *Schubert* et al. [13.22] have introduced the unified citation score

Data sourced from Clarivate Analytics Web of Science Core Collection

in the context of the comparative analysis of national research performance. Obviously, the expectation of the unified citation score is 0 if the expected value of x is identical to that of the population, i. e., with b_1. If we prefer scores that take only nonnegative values, we can simply use the following random variable u^* instead of u. Then the same scaling effect is maintained, but the effect of uncitedness results in the value of zero as the lower bound of the normalized distribution,

$$u^* = \frac{x}{b_2 - b_1} \,. \tag{13.3}$$

Glänzel [13.20, 23] showed the robustness of this transformation for subfields and journal impact using examples of different publication years and citation windows, ranging from 3 to 21 years. Here we do not further deepen the issue of subject normalization using CSS, since scientometric research has come up with new, more sophisticated normalization solutions regarding a priori and a posteriori, i. e., cited- and citing-side normalization [13.24, 38–43]. Therefore, we mention the above property rather as one of the possible alternatives to a posteriori normalization and, most notably, as important evidence of the consistency of the Characteristic Scores and Scales method. However, with this issue, we arrive at the bottom of Fig. 13.2, which indicates the possible application of this kind of normalization in the context of research evaluation, and within that area, above all, at the lower aggregation levels.

13.4 Characteristic Scores and Scales in New Environments? Some Future Perspectives

In light of the foregoing, the question arises as to possible application of the CSS method in new, emerging environments. The so-called altmetrics, and more generally Scientometrics 2.0 [13.44, 45], are not only new challenges to bibliometricians; they also bring us new fields of application of methods previously devised and designed for their application contexts in the traditional "Scientometrics 1.x" [13.46]. In principle, the CSS method or its modifications or derivatives could be applied to any field that deals with similar phenomena of long-tailed Pareto-type distributions and statistics that might be biased by extreme values and outliers. The question as to how far the principles, rules and methods of Lotkaian informetrics [13.47, 48] also hold in their extension to altmetrics and social metrics is still to be answered. *Chi* and *Glänzel* [13.49] recently found that CSS could be applied to usage statistics provided by Clarivate Analytics (formerly Thomson Reuters) Web of Science Core Collection. According to *Pringle* [13.50, p. 1]:

> This count measures the level of interest in a specific item on the Web of Science platform. The count reflects the number of times the article has met a user's information needs as demonstrated by clicking links to a full-length article at the publisher's website (via direct link or OpenURL) or by saving the metadata for later use.

Unlike altmetrics indicators, which are designed rather to measure communication with an impact on the general public, usage counts focus again on communication among scholars [13.50]. In the above-mentioned pilot study by *Chi* and *Glänzel* [13.49], five disciplines from the life sciences, the natural sciences and the social sciences according to the Leuven–Budapest classification scheme and three countries were chosen to study whether usage and citations show similar patterns and to what extent these patterns might correlate at this level of aggregation. Again, the Characteristic Scores and Scales approach has shown the expected stability, with CSS class distributions very close to the usual 70%–21%–6.5%–2.5% rule.

Furthermore, the question arises of whether the observed properties of the Characteristic Scores and Scales method can be found in completely different contexts, for instance, in the context of degree distributions in network analysis or in graph models, or possibly in other fields of the sciences and socials sciences as well. Imaginable application fields outside informetrics could, for example, be economics, insurance mathematics or quantitative linguistics, i. e., fields where the (generalized) Waring distribution already plays an important role in modeling, identifying and processing a small quantity of outstanding and extreme observations, which in turn is contrasted by the otherwise overwhelming share of *low-profile* observations. We sincerely hope that the methods discussed in this chapter will help to tackle the pending and upcoming, yet unresolved, questions in both Scientometrics 2.0 and other contexts, wherever a power law, or even more generally a Paretian model, can be assumed to underlie the phenomena under study.

Wolfgang Glänzel

ECOOM and Faculty of Economics and Business
KU Leuven
Leuven, Belgium
wolfgang.glanzel@kuleuven.be

Wolfgang Glänzel is Director of the Centre for R&D Monitoring (ECOOM) and Full Professor at KU Leuven. He is also affiliated with the Department. Science Policy and Scientometrics at the Library of the Hungarian Academy of Sciences in Budapest (Hungary). Wolfgang Glänzel studied mathematics at Eötvös Lorand University (ELTE) in Budapest. He holds a Doctorate in Mathematics from ELTE, obtained in 1984, as well as a PhD in the Social Sciences obtained from Leiden University (The Netherlands) in 1997.
His research activities comprise probability theory and mathematical statistics, quantitative science studies, and research policy. Wolfgang Glänzel has published numerous journal articles, proceedings, and book chapters, and has co-authored/co-edited several books. He is Secretary-Treasurer of the *International Society for Scientometrics and Informetrics* (ISSI), *Editor-in-Chief of the international journal Scientometrics, and Academic Editor of the multidisciplinary OA journal PLoS ONE.*

Bart Thijs

ECOOM
KU Leuven
Leuven, Belgium
bart.thijs@kuleuven.be

Bart Thijs is a Senior Researcher in Bibliometrics at KU Leuven – ECOOM. His research focusses on the identification of global and local network structures within scientific communication and on the development and application of citation-based indicators. He combines a background from Mathematical Psychology (Master's degree from KU Leuven) and Social Sciences (PhD from Leiden University) with professional experience as a statistical consultant in his work.

Koenraad Debackere

ECOOM and Faculty of Economics and Business
KU Leuven
Leuven, Belgium
koenraad.debackere@kuleuven.be

Koenraad Debackere is a Professor of Innovation Management and Policy at KU Leuven. He is Promotor-Coordinator of ECOOM. His research has focused on the development and use of indicators measuring the effects of science and innovation policy, the role of entrepreneurial universities in economic development and the management and growth of knowledge-intensive companies.

14. An Overview of Author-Level Indicators of Research Performance

Lorna Wildgaard

The purpose of this chapter is to present a critical overview of author-level indicators of research production (ALIRP), discuss their appropriate application and provide a tool to support the informed use of ALIRP. A brief history of the development of ALIRP begins with a chronological discussion of the major trends in indicator development, which documents the quick adaptation of ALIRP in evaluation practice, and consequently sets the argument for the need to monitor and evaluate present-day indicator production, which is the major theme of this chapter. The characteristics and common mathematical properties of ALIRP are used to highlight the challenges we face in applying appropriate ALIRP in evaluation. The construction and validity of 69 ALIRP are analyzed, and the results presented in table form for easy reference. These tables are also available as interactive tables provided as e-material to this chapter. This analysis, combined with the deconstruction of indicators in the chapter sections, argues that ALIRP are mathematical models, and the numerical values they produce should never be confused with the reality they are trying to model in evaluation practice.

14.1 A Brief Introduction to Author-Level Indicators

The author-level indicator market is a crowded marketplace. Since the introduction of the *h*-index in 2005 [14.1], the number of indicators that measure some aspect of the individual researcher's published output continues to grow exponentially. However, few have attempted to systematically create an overview of the indicator products available in this market [14.2–6]. The proliferation of indicators is well intentioned but not always well informed. Indicators can be ill-applied in practice, leading to distrust of bibliometrics as an evaluation method. The purpose of this chapter is to present a critical overview of author-level indicators of research performance (ALIRP), with particular emphasis on newer developments toward disciplinary- and seniority-specific indicators, and the practical challenges we face in the context of their application. The chapter does not consider alternative quantitative author-level indicators such as Altmetrics, econometrics or network metrics, nor does it address qualitative evaluation indicators of individual performance. This approach can perhaps be regarded as a narrow view that does not fully reflect the plurality of the indicator research. It is nonetheless a realistic view addressing the

Electronic supplementary material The online version of this chapter (https://doi.org/10.1007/978-3-030-02511-3_14) contains supplementary material, which is available to authorized users.

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_14

practical application of indicators, and highlights the pressing matter of indicator validation. Accordingly, it is important to start off this chapter by defining ALIRP and what they are considered to measure—or, importantly, not measure—and refer briefly to the ongoing discussion in the bibliometric and research evaluation community.

According to *van Raan* [14.7]

> An indicator is a measure that explicitly addresses some assumption. [...]. Indicators cannot exist without a specific goal in mind, they have to address specific questions, and thus they have to be created to gauge important *forces*. [...]. Indicators must be problem driven, otherwise they are useless.

The aim of indicators is to provide a better understanding of how science works, how it can be measured and the extent to which indicators can inform evaluation practice. Hence, bibliometric indicators are designed to answer specific questions at specific aggregation levels. Aggregation can occur at the level of the individual author, group of authors, institutions, journal, field or country, among others. As each level of aggregation has its own inherent properties, it is possible to distinguish indicators designed for these successive levels of aggregation from one another. Author-level indicators of research performance (ALIRP) are a set of quantitative indicators developed to capture aspects of quality, impact and prestige at the aggregation level of the individual researcher. The desired properties of ALIRP are suggested by *Todeschini* and *Baccini* [14.8, pp. 24–25] as follows:

1. Univocal mathematical definition
2. Rank top and young researchers in a balanced way
3. Sensitive to number and distribution of citations and papers
4. Robust to small variations in citations and papers
5. Ability to rank researchers (low degeneracy)
6. Preserve sensitivity also for top researchers
7. Easily computable from the available data.

At higher levels of aggregation, the consistency properties are different [14.9]. *Waltman* et al. draw our attention to the fact that the consistency properties of indicators applied at different levels of aggregation are not merely of interest theoretically, but also have significant practical relevance [14.9]. The practical relevance of ALIRP is an extremely important discussion. Not only are ALIRP used to summarize a researcher's set of papers and citations and to assess their contribution to a specific research community; the resulting values are also used as performance benchmarks within and across disciplines and seniority levels in research evaluation, hiring, promotion and funding decisions. The basic data used to compute the indicators are counts of the number of citations and publications, and they are value-laden data. What is defined as a publication or set of papers differs from research area to research area [14.10, 11]. Different types of publications represent different research methods, which in practice render comparisons of counts among different publications unfeasible [14.12]. Some consider publications as simply a discrete set of objects that can be counted in aggregate [14.13], while others maintain that publications must be limited to output indexed in citation databases for indicators to make sense [14.14]. Similarly, citations are open to interpretation—from recognition of intellectual debt [14.15], indications of authority [14.16], or markers of scientific communication [14.17] or cognitive influence [14.18], to simply "a quantitative and computer manipulable measure of *something or other*" [14.19]. Further, citations do not necessarily measure the extent to which important scientific output is communicated and used: as authors, we fail to cite, we cite to criticize, and we fail to acknowledge ideas/intellectual influence [14.20, p. 127]. Both publications and citations have different values with regard to paradigmatic and social norms [14.21, 22], but when publication and citation counts are combined in bibliometric indicators, they produce numeric values that we *assume* tell us *something* about the researcher's past performance, *partially* inform us of scientific progress and/or produce a statement of *impact*. There is yet no consensus as to what these indicators are in fact measuring and, consequently, what we can claim. There is agreement, however, that in the realm of evaluation, publications are just *one* measurable aspect of scientific productivity and, together with citations, claim a role as intermediary devices in assessments of *aspects* of scientific quality. So, even before we discuss the construction and mathematical foundations of ALIRP, we have encountered the core problem that has vexed the bibliometric community for years. How do we define a publication, a citation or even an author, and operationalize these concepts as countable variables in performance indicators? Clear definition does not just ensure robust and valid operationalization of variables included in ALIRP. Clear definition ensures responsible interpretation of the numbers these indicators produce and enables informed statements about the relations between an individual's productivity, impact, collaboration and prestige, among other qualities.

The methods we use to count and combine publications and citations are not neutral techniques. Even the databases from which we harvest bibliometric data originate from Northern European scientific communities, and thus primarily reflect the practice characteristics of the natural sciences in these regions. In the construction of author-level indicators, specifically as instruments to measure performance, we must be aware of the strengths and limitations of applying indicators as a positivistic approach to research evaluation. The strength of the positivistic approach is that it is intended to prevent confusion, rejecting as meaningless all concepts that cannot be verified by experiment and logical analysis. In indicator development, this means that indicators use what can be counted to verify clearly defined *partial* aspects of an individual's performance. What is countable is regarded as empirical fact. The first main weakness of the positivistic approach is that the sociological and theoretical variables of researcher output and activity that do not produce quantifiable data remain invisible. In strict adhesion to the positivistic ethos, these should be considered meaningless at any rate. Common sense tells us this is not so. Philosophical and sociological discourse is essential in legitimate performance evaluation, but the research on indicator development presented in this chapter does illustrate a clear demarcation between indicator development and indicator application in practical research assessments. Secondly, confusion does not appear to be prevented. There is great tension between detail and accuracy: an inverse relationship perhaps between the precision of the bibliometric data and the substantiation of the indicator [14.23]. The bibliometric community appears divided between those that develop indicators and those that apply indicators in evaluation practice. This division is not necessarily a bad thing; it sparks the creativity of the inventors of indicators and encourages critical use in the application context, as we will explore further in the next sections.

14.2 Brief Review: Trends in Indicator Development

In the 1960s and 1970s, Derek J. de Solla Price published a number of books and articles that, together with the development of Garfield's Science Citation Index, laid the foundation for the emerging field of quantitative science studies as a research program [14.24]. Yet it was only after the journal *Scientometrics* was founded by Tibor Braun in 1978 that publications of studies on how to measure science were truly liberated from traditional information, technology and computer science journals. That same year saw an introduction of best practices in exploring broad, new perspectives and possibilities for science indicators, published in a book by *Elkana* et al. [14.20], featuring the writing of leading historians, philosophers of science and social scientists. The authors emphasize the importance of practice standards, particularly with respect to taking data seriously in a historical context in order to produce responsible indicators based on science, rather than on group politics under the guise of science. These are the same principles that would be reiterated nearly 30 years later in the Leiden Manifesto [14.25] and in the Metric Tide [14.26]. In the context of ALIRP, *Elkana* et al. [14.20, p. 132] discuss the duality of applying mechanistic indicators in what they argue should be primarily a humanistic evaluation of individual researchers. Researchers are viewed as complex systems of human activity and relationships that together result in scientific products and services. Generalizations, therefore, based on the history and sociology of science and theoretical approaches to measuring science break down when tested on individual cases and examined in sufficient detail. Humanistic explanations are far more powerful than those furnished by quantitative indicators at the individual level, and certainly human activity should be explained humanistically rather than interpreted through mechanical, numerical concepts. Measuring science mechanistically, counting production for example, directs the evaluation to the authority of the techno-structure rather than the authority of the evaluand (the person under assessment). The evaluation is focused on the network of managers, policymakers and administrators who control procedural decisions, strategies and economies both within and beyond the realm of the individual. It is distanced from the interests of the researcher and their goals, potential, consumers, or the fusion of their scientific production and wisdom. In a mechanistic approach, indicators may only be of value in monitoring and planning science *if* they are used with an awareness that they are but one of many inputs in an evaluation program. They alone do not reflect the vigor or potential of the researcher.

Nevertheless, the continued desire to use algebraic models in a mechanistic approach to quantify and compare the production, vigor, prestige, outreach and potential of researchers and to counterbalance the role of peer review in evaluation has fueled the creation of an enormous number of indicators. Already in 1978, a call for caution was sent out by *Elkana* et al. [14.20], along with a plea for prioritizing responsible and creative science indicators to inform science policy. Figure 14.1 illustrates the growth in papers concerning the development of ALIRP, (reference search in Web of Science, Scopus

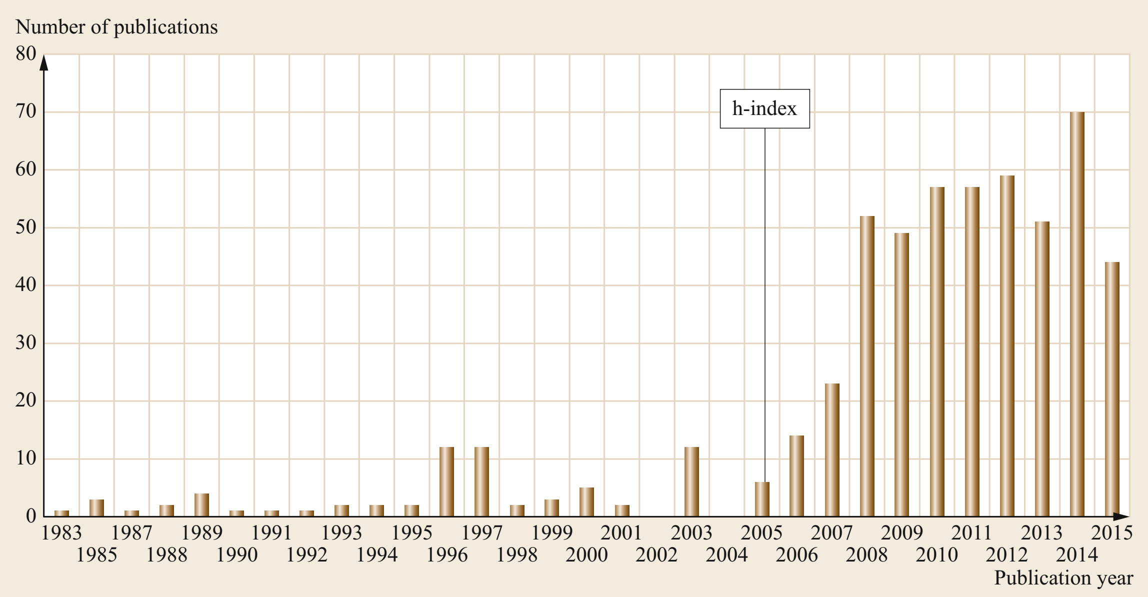

Fig. 14.1 Development of ALIRP, 1980–2015

and Google Scholar, 1980–2015, undertaken December 2016).

The more or less immediate response of the bibliometric community in the 1980s was the development of ALIRP that concentrated on the correlation between bibliometrics and peer judgment [14.27–30], and on how to account for the differences between researchers in different disciplines in scholar rankings and performance evaluation [14.31–33]. In the mid-1990s, bibliometricians argued that although citation indices provided a logical starting point for measuring production and citation effect, the limitations of these sources could leave a void in the coverage of citations to an author's work, a void that must be explicitly recognized in evaluation. Consequently, a heated debate ensued regarding how to improve citation indexing to ensure the future role of the indices in responsible evaluation of individual researchers [14.34–36], leading to a number of exemplary investigative studies, though still primarily in the hard sciences [14.37–40]. Some fundamental questions were also being addressed—importantly, the performance of ALIRP in science and technology in order to analyze the dynamics between patents, publications and the movement of researchers between research institutions [14.41, 42], as well as the role of citations in communication theory, building upon earlier work [14.43–45].

The second half of the 1990s saw the blossoming of a discussion on author-level bibliometrics as a paradigm [14.45]; specifically, during this period, the groundwork was laid for the standardization of bibliometric terminology and indicators [14.46–49], and the operational definitions of authorship and collaboration in indicator development were heavily debated [14.50–53]. The potential for indicators to capture collaboration from a research evaluation and policy perspective is a recurrent theme to the present day [14.54–57], specifically the extent to which inter-institutional and international collaboration is beneficial for an individual's research production and career trajectory. Ultimately, the 1990s ended with its own call for a unified indicator theory [14.58–60] to ensure that the hunger for metrics from science administrators and policymakers was satisfied with robust and valid metrics. However, the call was not heeded. Instead, there was a shift away from theoretical discussions and the operationalization of citations in the development of ALIRP, towards the application of ALIRP by governmental agencies to measure innovation and demonstrate the value of productivity in management and funding policy strategies [14.61, 62]. Accordingly, the validation of indicators as appropriate measures of individual researcher performance became a major concern within the bibliometric community [14.63–66], who, in response to the increasing institutionalization of indicators and their somewhat unconstrained application in research evaluation, argued for the correct contextual application of indicators and the need for data quality assessment methods [14.10, 67–70]. Consequently, the bibliometric literature became increasingly concerned with the potential and limitations of alternative sources of bibliometric data as a supplement to or replacement for traditional citation indices at the individual level [14.71, 72]. Of particular interest was the potential of the recently established Google Scholar database as a citation index [14.73–75], as the influence of the scope of the citation index on author-level indicator values is not inconsequential in rankings [14.76–80].

Throughout the 1980s to mid-2000s, the development of ALIRP was strongly considered by researchers as *blasphemous* and by bibliometricians as a practice that should be avoided, because such indicators would be inadequate for evaluation and would lead to erroneous conclusions [14.81]. The cardinal rule of indicator development was that "the biases and deficiencies of individual citers are repaired to a tolerable degree by the combined activity of the many" [14.82], that is, small sets of bibliometric data, those representing individual researchers, would lead to statistical problems that would distort indicator values [14.83]. However, a fundamental change in the basic concepts and experimental practices in indicator development was heralded with the publication in 2005 of the h-index [14.1], a type of indicator never before seen, developed by a different kind person from outside the field of bibliometrics! A Hawkinesque indicator, a single unifying equation that would explain everything, able to balance the quantity of an individual's publications with impact, quality, prestige and rank among peers, the h-index quickly captured the attention of the scientific world, policymakers and the media, gaining legitimacy and acceptance as a useful measure from leading scientific journals [14.84]. Bibliometricians were quick to criticize the h-index for oversimplifying the conundrums inherent in the development and application of ALIRP, encouraging users to substitute mathematical rules for judgment in evaluation [14.3, 85]. But they were just as quick to cast off their previous reluctance to develop ALIRP, producing a barrage of new ALIRP, each claiming to be more robust, valid and sophisticated than the last [14.2, 86–88]. However, with no advisory boards, common standards or contextual assessments, the indicators were largely incomparable, laboratory experiments. They appeared theoretically unfounded, the methodological and operational origins often concealed from the users. Validity tests, if any, were conducted only on small choice sets of bibliometric data [14.81, 89].

The rapid adoption of ALIRP in research policy continues to steer the direction of indicator development to the present day [14.90–92]. First, the operationalization and institutionalization of ALIRP in hiring, reappointment, tenure and funding decisions [14.90, 93–97] has led to experiments with indicators that can objectively account for gender [14.98–100], seniority [14.101, 102] or disciplinary bias [14.103–106]. Second, the added value that ALIRP bring to evaluations has been investigated, especially when they are used as a supplement to traditional input–output investment indicators [14.107–110] in the evaluation system, along with their influence in the processes of researcher/departmental development. These advances into the political arena have forced the bibliometric community to readdress guidelines for meaningful evaluation at the individual level—a need first called for but fundamentally ignored in the 1990s [14.45–47, 49, 111]—and to communicate guidelines for the practical implementation of indicators for users outside the core bibliometric community [14.112–117]. Not surprisingly, the increased interest in the use of ALIRP in policy and evaluation has led to an increased demand for assessment of the validity and reliability of indicators at the individual level [14.90, 118–122]. As a result, a number of studies have investigated the psychological effects that bibliometric evaluations can have on the researcher, and reactive changes in publication behavior [14.123–127]. A process-oriented rather than diagnostic approach to accommodating change is seen in the current development of indicators, such as the benefits of publishing alone or in groups in evaluation of productivity, how to compare *mass* production to quality production, strategies in the author-byline hierarchy, and the challenges of name disambiguation in the attribution of credit [14.128–132]. Validation of indicators appears to have defined a shift in recent bibliometric literature, which seems to have turned increasingly introspective, examining whether the *appropriate* methodology is being used by bibliometricians to explain and predict trends in bibliometric analyses [14.133, 134]. In earlier years, this topic was limited to peripheral discussions [14.135–139]. Drawing on knowledge from the field of statistics, *Schneider* [14.133, 134, 140] and others [14.141–146] challenged the overreliance of the bibliometric community on sample statistics and false precision to argue the strength of the findings in bibliometric experiments. Bibliometrics is not a pure science, and at the individual level, indicator values cannot be detached from the person under evaluation. The shortcomings of the mechanistic approach and the strength of the humanistic approach suggested in 1978 by *Elkana* et al. are being revisited. ALIRP cannot be dissociated from the scientific and cultural materials the individual produces, as they are produced in a social system through complex relationships for the sake of science, not for the sake of a statistical method of measurement [14.147]. Determining which concepts are operationalized in indicators and how they are operationalized, where the data come from, what is missing and how sociological concepts can be interpreted without a theoretical framework constitutes a real problem [14.148–150]—a more important problem than sophisticated statistical calculations.

And so the literature has gone full circle, back to 1978 and the call for practice guidelines and fidelity to historical data [14.20]. The growth and interest in ALIRP has evolved at an astonishing rate, with a recent focus on developing responsible metrics and good practice guidelines for consumers of ALIRP. Concerns with practical implementation has perhaps taken attention away from the equally important need for theoretical and methodological frameworks that support the development of robust ALIRP and reduce the production of ad hoc ALIRP. Such frameworks could have a huge influence on how indicators are constructed and how indicators designed specifically for analysis at the individual researcher level are legitimized.

14.3 General Characteristics of Author-Level Indicators

In the previous section, prominent themes driving the development of ALIRP were discussed chronologically. This brief review led us to the current state of indicator development, where there is strong consumer demand from research administration and policymakers for quantitative measures to inform decisions. To support decision-making in science policy scenarios, ALIRP could be considered as *customer-value* models, which are data-driven representations of the worth, in mathematical terms, of the researcher under evaluation. To learn more about the robustness and validity of ALIRP in informing practice and decisions, it is crucial to have a shared understanding of how these customer-value models are built and the characteristics that define them.

14.3.1 Interdisciplinary Collaboration in the Development of ALIRP

Developers from outside the bibliometric research community are highly visible in the production of ALIRP. They use their disciplinary expertise to suggest indicators specifically designed to fit the characteristics of their field to inform responsible evaluation. In Fig. 14.2, which is adapted from *Wildgaard* [14.89, Ch. 6], the disciplinary partnerships among developers of 57 ALIRP are mapped. These developers represent 125 research specialties, which were determined using the authors' own keywords from their biographies, their CVs or institutional webpages. For simplification, these specialties are collapsed into 17 broad fields of study, represented by the circular nodes on the sociogram. Counts are not fractionalized, meaning that a developer can belong to more than one research area. The figure illustrates the extent to which ALIRP are produced through collaborative design, i. e., teams of developers with varying skill sets and expertise from different research areas, who work together on the design of an indicator to capture aspects unique to a field, specialty or academic profile in the indicator model. The *IQP* indicator, for example, is grounded in the fields of psychology, economics and leadership, whereas the *b*-index is developed in the field of chemistry. In practice, it may be wise to be mindful of the worldview of the developer, as this could determine field-specific goals of the indicator and the types of publications, authors and sources, for example, that are operationalized in the indicator model.

14.3.2 The Immaturity of Indicators

The greatest shared characteristic of ALIRP is their immaturity, both those presented in the bibliometric literature and those published in other disciplinary journals, blogs or publication channels. The majority of ALIRP remain tentative proposals, untouched from the day they were put forward, not tested in follow-up empirical studies. This has left us with a large set of indicators that remain theoretical. Theoretical indicators are important, as they help us gain greater knowledge of paradigmatic mathematical laws and properties of bibliometric distributions, e. g., hw, *dynamic h* and *tapered h* (hT), that in turn could eventually inform the development of ALIRP. Yet practical application of these theoretical (or new or unestablished) indicators in empirical studies is vastly neglected. We need to learn more about the suitability of indicators in different application contexts and the ability of the indicator, in combination with other evaluation measures, to capture the heterogeneity of scholarship. Empirical follow-up research has been published on the extent to which some indicators build on, overlap or supplement one another, primarily with regard to the robustness of the *h*-index [14.80, 88, 91, 109, 151–154] and suggestions for multiple design variants of *h* for specific disciplines and seniority levels [14.3, 86, 88, 101, 135, 153, 155]. However, this is far from sufficient to establish a practice of validation and verification of the many indicators we have at our fingertips. Further, these variants themselves represent suggested improvements that require verifica-

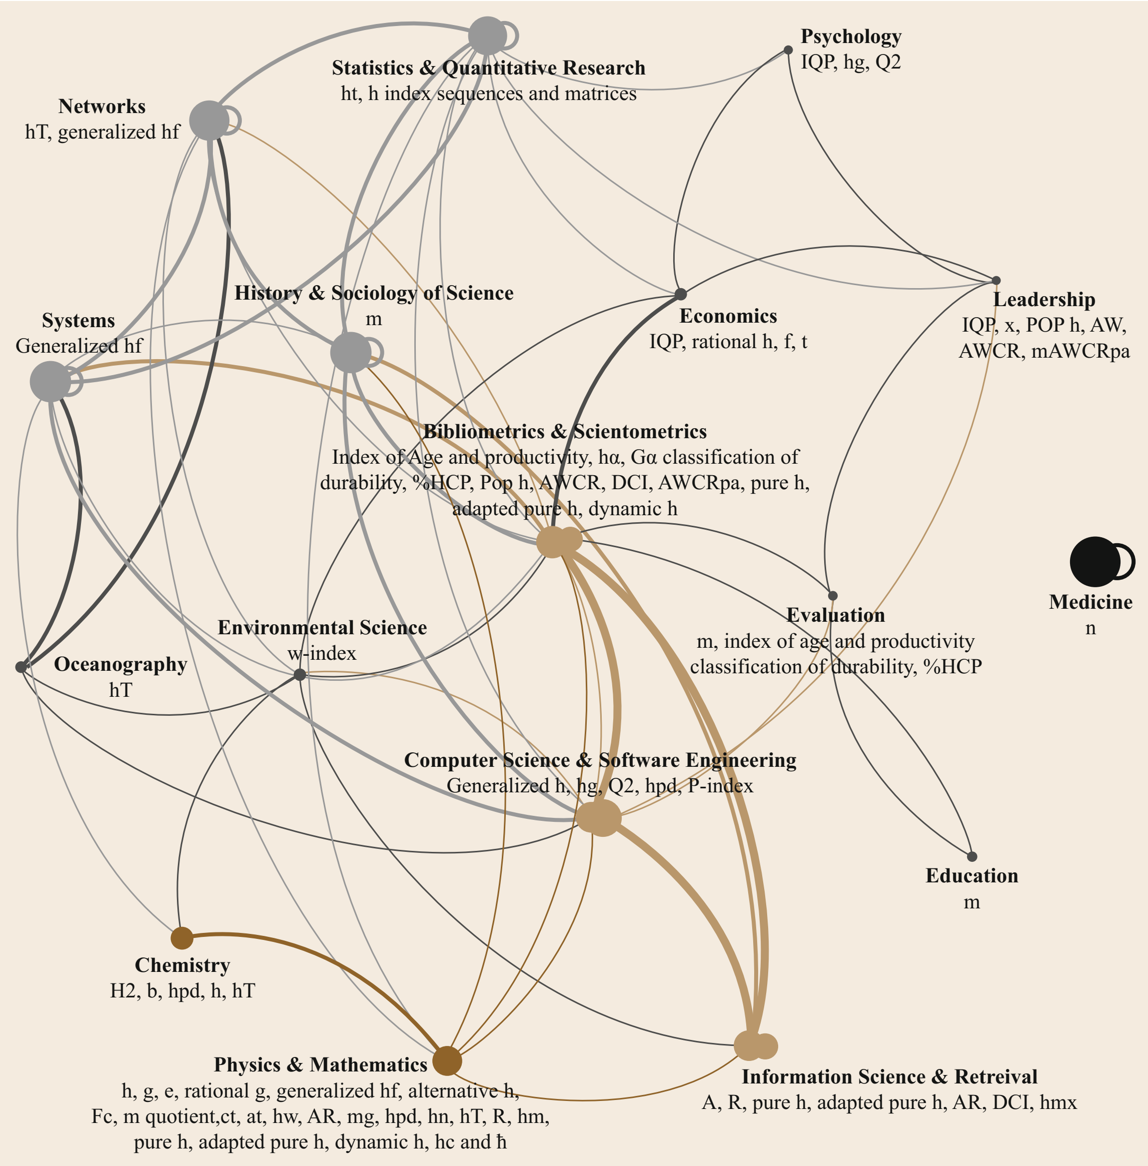

Fig. 14.2 Map of interdisciplinary collaboration between developers of 57 ALIRP

tion and validation, which means that caution should be exercised if they are applied in their present state in *real-life* evaluations.

14.3.3 Conceptual Operationalization and Model Validity

Methodological clarity is a basic requirement for the construction of all mathematical models. As models, ALIRP are representations of *something*, an analogy to help us visualize something such as an effect or impact, something that cannot be directly observed. As such, they are "a system of postulates, data and inferences presented as a mathematical description of an entity or state of affairs" [14.156]. Accordingly, they are cognitive activities that use mathematical concepts and language to describe how something behaves in real life. Therefore, it is important to validate them, to know how and when to use them, and to know when their use is limited. This entails 1) identifying how the developer(s) of the indicator conceptualized, defined and operationalized the variables in the indicator model (most commonly author, publication and citation, but there are others including time, seniority and gender), and 2) ascertaining how these variables are combined through different arithmetic functions to measure a specific aspect of research performance. Homogeneity and consistency, as discussed by *Gingras* [14.157], are central to ALIRP, in that every indicator we use must be dimensionally homogeneous and dimensionally consistent. The following is an example of the common-sense validation technique devised by *Gingras* [14.157]. The h-index is defined by *Hirsch* as a measure of the importance, significance and broad impact of an individual's overall research output, and is a composite measure of productivity (number of published articles) and citation effect (number of citations) [14.1]. This means that every term in the h-index should describe a relation to these two concepts, and should operationalize the total dimensions of importance and significance. Yet the design of the indicator is inconsistent with our understanding of the relationship between the quantity of papers and citations and the concepts of importance and significance. Also, the h-index claims to be an index designed to *quantify* a researcher's scientific *output*, and as such we expect an increase in h equal to the increase in the importance/significance of a researcher's work, and likewise a decrease if there is a decrease in the importance/significance of the researcher's work. Many studies have shown flaws in the inertia of h, situations where the lower h-index hides the better-quality researcher.

There is no doubt that mathematical models have been successfully developed and applied in scientometrics at higher levels of aggregation, providing insight, for example, into disciplinary production and the direction of research at a national level. Doubt remains, however, as to whether ALIRP can model events successfully at the individual researcher aggregation level, because the situation of the individual is incredibly complex or, as exemplified with the h index, because the models are intractable. For ALIRP, it is essential to be able to defend the relations among four basic facets of the indicator model. These are:

1. The aim of the indicator, i. e., the aspect of performance the indicator is designed to evaluate
2. The context of the person under evaluation (typically operationalized as an author)
3. The data (publications and citations)
4. The calculation methods (Fig. 14.3).

Figure 14.3 (first published in [14.89, Ch. 6]) illustrates the different approaches adopted by 51 ALIRP in operationalizing the variables of author, publication and citation, and the concept that the 51 indicators claim to measure. Full insight into the data is given in the electronic supplementary material that is provided with the online version of this chapter. Developers argue the adequacy of the indicator through the definitions and operationalization of author, publication and citation. Naturally, the definition and operationalization of these core variables vary, as indicator developers are attempting to capture different aspects of research performance in a very heterogeneous landscape. Similarly, the ALIRP could still measure what it is intended to measure even though the definitions of these variables are poorly articulated. It would be a mistake to conclude that an indicator that cannot isolate these variables of measurement has a certain level of defect. Poor articulation does not mean that the indicator should be dismissed as irrelevant or misleading. Rather, it highlights the need for developers and consumers of ALIRP to learn to evaluate the description, objectives and components of indicators, not just the indicator's strengths and weaknesses in evaluation contexts. The author concept informs us regarding the individual for whom the indicator model is designed (Fig. 14.3), be it an award winner, a scientist, someone who has published or someone who has both published and been cited. The concept of citation informs us as to how the developers interpret citations, and varies from indicator to indicator, whether as part of a reward system, recognition of use over time, quality, popularity or transference of ideas. The concept of publication informs us as to the specific type of output counted in the indicator, be it papers that have been cited, papers indexed in specific citation indices or papers from other resources. Some ALIRP are designed to include all of a researcher's publication output, while others advocate the practical usefulness of restricting papers to those in a citation index such as the Web of Science (WoS). Papers in WoS are argued to have an implicit aspect of quality that can be utilized in ALIRP to say something about some aspect of quality of the researcher's work, and enable comparisons of output among similar researchers. To be included in the citation index, papers have passed peer review and are published in mainstream disciplinary journals that have a certain level of citation, and further, the papers are represented by a bibliographical record that makes the paper searchable and verifiable. Likewise, the number of works citing a paper are also registered and details of these are indexed as well, enabling quantitative studies of scientific communication (for additional detail, see *Moed* [14.18, pp. 35–50]).

Together, the concepts of author, citation and publication are operationalized to measure something—the currency, the excellence, the growth, the quality and quantity of an individual's work—or to produce rank-

Fig. 14.3 Definitions of concepts and measures in 51 ALIRP

ings of similar researchers. When performing indicator calculations, the use of types of author, resource or publication form that differ from those recommended by the developers of the indicator may in turn affect the performance of the indicator. Consequently, results similar to those demonstrated by the developers cannot be guaranteed. Therefore, if we diverge from the qualities of the author, publication and citations as defined by the developer, what implications will this have for the application and interpretation of ALIRP and for the researcher under evaluation? Is the correlation between the variables and the measure that the ALIRP is purported to produce strengthened or weakened? Are there consequences for our confidence in the reliability of the indicator values?

14.3.4 Mathematical Construction

ALIRP can be percentile-based, depicting the prestige of the researcher's publications based on their position within the citation distribution of their peers. More commonly, ALIRP are based on an assumption of averages.

The percentile of a publication or set of publications is determined by creating a citation frequency distribution for all of the publications in the same year, subject category and document type. The papers are arranged in descending order of citation count, and the percentage of papers at each level of citation is determined, i. e., the percentage of a researcher's papers cited more often than their significant peers as in the *IQP* index and *DCI*. It is also possible to come up with an informed estimate of the researcher's performance if they place lower or higher than expected. As percentiles can be normalized for subject area and time, proportions of publication percentiles can be compared between subjects and periods [14.158]. Further, percentile-based indicators are not dependent on the calculation of the arithmetic mean, which is commonly used in ALIRP, as the arithmetic mean should not be used for skewed data—a typical characteristic of bibliometric data at the individual level of aggregation [14.142]. However, percentile indicators can be strongly biased by different methods of setting the decile limits, defining the peer set for comparison and treating tied papers in the evaluation of the percentage of highly cited publications.

Alternatively, average-based indicators tell us something about the central distribution of citations to publications. At high levels of aggregation, such indicators are appropriate as long as they roughly describe performance patterns. Conflicts arise at low levels of aggregation, when such indicators are used to compare individual researchers on a mathematically fabricated average, creating insecurity in both interpretation and expected performance. Average-based indicators that attempt to indicate an overall citation impact are problematic [14.18, 159], because a single statistic of centrality may not adequately summarize the asymmetries of skewed citation distribution, as some publications will have scored the average number of citations, some will have scored higher and some lower. At this lower level of aggregation, we need precise models, and the requirement for precision often leads to complexity in model design. The concept of averages, estimates of centrality, varies greatly in ALIRP depending on the type of mean estimate used—harmonic (f-index), arithmetic (A-index), geometric (t-index), median (m-index) or mode (h-index)—and importantly, the spread, concentration and proportion of the data used in the model. Needless to say, in the evaluation context, different estimates of the average result in very different snapshots of the average performance of a researcher. The arithmetic mean assumes that the distribution of citations to publications is approximately Gaussian (normal), and as the distribution becomes less Gaussian (either by not being symmetric or due to the presence of outliers), the arithmetic mean becomes a worse description of the distribution. The arithmetic mean returns a higher average value than the geometric mean, as the geometric mean gives larger weight to smaller values in a positively skewed distribution. The geometric mean in turn returns a higher value than the harmonic mean, which is the recommended mean estimate when there are extreme outliers. The harmonic mean in turn returns a higher value than the median. To apply average-based indicators successfully, just as in any other statistical test, the bibliometric data must meet important assumptions of normality. One first needs to determine the distribution of the data and assess whether it approaches a normal distribution before applying indicators based on the chosen mean. Doing this will radically reduce the number of indicators that are appropriate for use. Indicators based on the arithmetic mean, the *CPP* for example, will produce inaccurate results if applied to data that are highly skewed, as the data violate the assumption of normality, which is the essential characteristic needed in the data for this statistical test. Not fulfilling assumptions consequently contaminates the conclusion of the indicator and interpretation of the results. Therefore, indicator developers recommended supplementing such fixed-average indicators with other ALIRP that calculate performance in the tail ends of the distribution, such as the e-index and $\hbar$-index. An alternative, perhaps more intuitive and simpler solution when working with skewed data at the individual-level, is to indicate the average performance by describing the number of citations to papers using the *median*, and reporting the minimum and maximum values to calculate the range or interquartile range where appropriate.

As a researcher's citations and publications increase and decrease over time, they are by no means static. Fixed indicators do not capture this evolution; therefore, testing the stability and robustness of dynamic but mathematically complex indicators such as the *generalized h*, *adapted pure h*, *rational h*, *rational g*, *hT*, *hα* and *gα* can drive indicator design, sometimes superseding the applicability of the indicator in practice. These indicators require the establishment of parameters that represent publication and citation practices in specific fields (note: these parameters are not standardized or consensual, but are experimental) or require special software to compute the indicator, as in the *tapered h*, and *h-sequence and matrices*. The *hw* and *dynamic h*-indicators exemplify Lotkanian informetrics in that they utilize a theoretical approach to bibliometric indicators, building on the Lotka power law of mechanisms of size and frequency. Such dynamic indicators attempt to capture how the distribution between citations and publications can give rise to new phenomena in the interpretation of physical referencing behavior and bibliometric distributions, and hence question how they should be studied rather than how to evaluate researchers [14.160]. They utilize the concepts of size and rank frequency to provide steady patterns of the evolution of papers, for example, in the *h*-core over time, i. e., interpreted as quality papers, indicating that no publication can instantly become a highly cited one, thus implying that in dynamic indicators, the well-known inconsistencies of *h* cannot occur [14.161]. Further, this power law approach is used to develop indicators that use citations as a constant rank-frequency function in the mathematical model to increase the granular precision of scholar rankings, as can be seen in the proposal of the *tapered h-index* [14.162]. These same indicators in tests show their superiority over the *h*-index and other simple indicators by correcting for mathematical consistencies, providing granular comparisons between researchers and embodying the inertia of the objects they are designed to measure. However, their application in practice is severely limited due to their complexity. Simple indicators—of which there are many—may be coarser or even mathematically flawed, but when used wisely, and in combination with one another, they offer great potential for well-rounded author-level bibliometric assessments.

The correlation between publications, citations and effect or impact is not a perfect line. Capturing this relationship in a mathematical model is complicated. The order is not perfect, publications and citations can be concentrated, and the distribution can be skewed. Therefore, applying the wrong mathematics is still wrong, even if the methods are well known, as in *CPP* and *h*. Different weights and parameters included in the indicator model may lead to different conclusions about researcher performance. Indicator values can be highly affected by the researcher's publishing and citing behavior, or based on a system of proportional representation where such behavior is not considered important, leading to a loss of detail.

All models can lead to mistaken observations and conclusions about the performance of the researcher within the boundaries of the evaluation system, but understanding the math and applying the mathematical models to data that fit the underlying assumptions will greatly improve the validity of our estimates of researcher performance.

14.3.5 Families of Indicators

ALIRP are a specific species of bibliometric indicator, and because this chapter advocates the application context, families of ALIRP are presented in the following taxonomy (Fig. 14.4) based on what they are designed to measure rather than a genus taxon based on math. The order of the families in the taxonomy depicts the increase in indicator complexity, reading from left to right, the simplest counting models closest to the raw output [14.2]. There are no hard and fast rules for describing or recognizing a family, branches or any taxon. One could take different positions regarding taxonomic descriptions, and I do not claim that Fig. 14.4 is *the* correct depiction. Figure 14.4 increases our awareness of the families and relationships in the community of ALIRP.

Starting with the light blue family, these indicators count a researcher's output. These are models of how to count different types of scholarly and scientific works, published or unpublished depending on the unit of assessment, adjusting for publication channel, bibliographic database and co-authorship. These are closely linked to the green family of indicators that measure the citation effect of the researcher's output by counting whole citations or by counting fractional citations to adjust for collaboration behavior. This family contains two main branches of indicators of the citation effect of a researcher's output. In the first branch, citations are normalized to publication type or a specific field to enable comparison with standardized benchmarks. On the second branch, citations are normalized to certain publications within the researcher's portfolio of work or to the age of the citation to identify work that is actively being used. Indicators that qualify output using journal impact factors are depicted in yellow. In this family, the first branch of indicators measure the impact of a re-

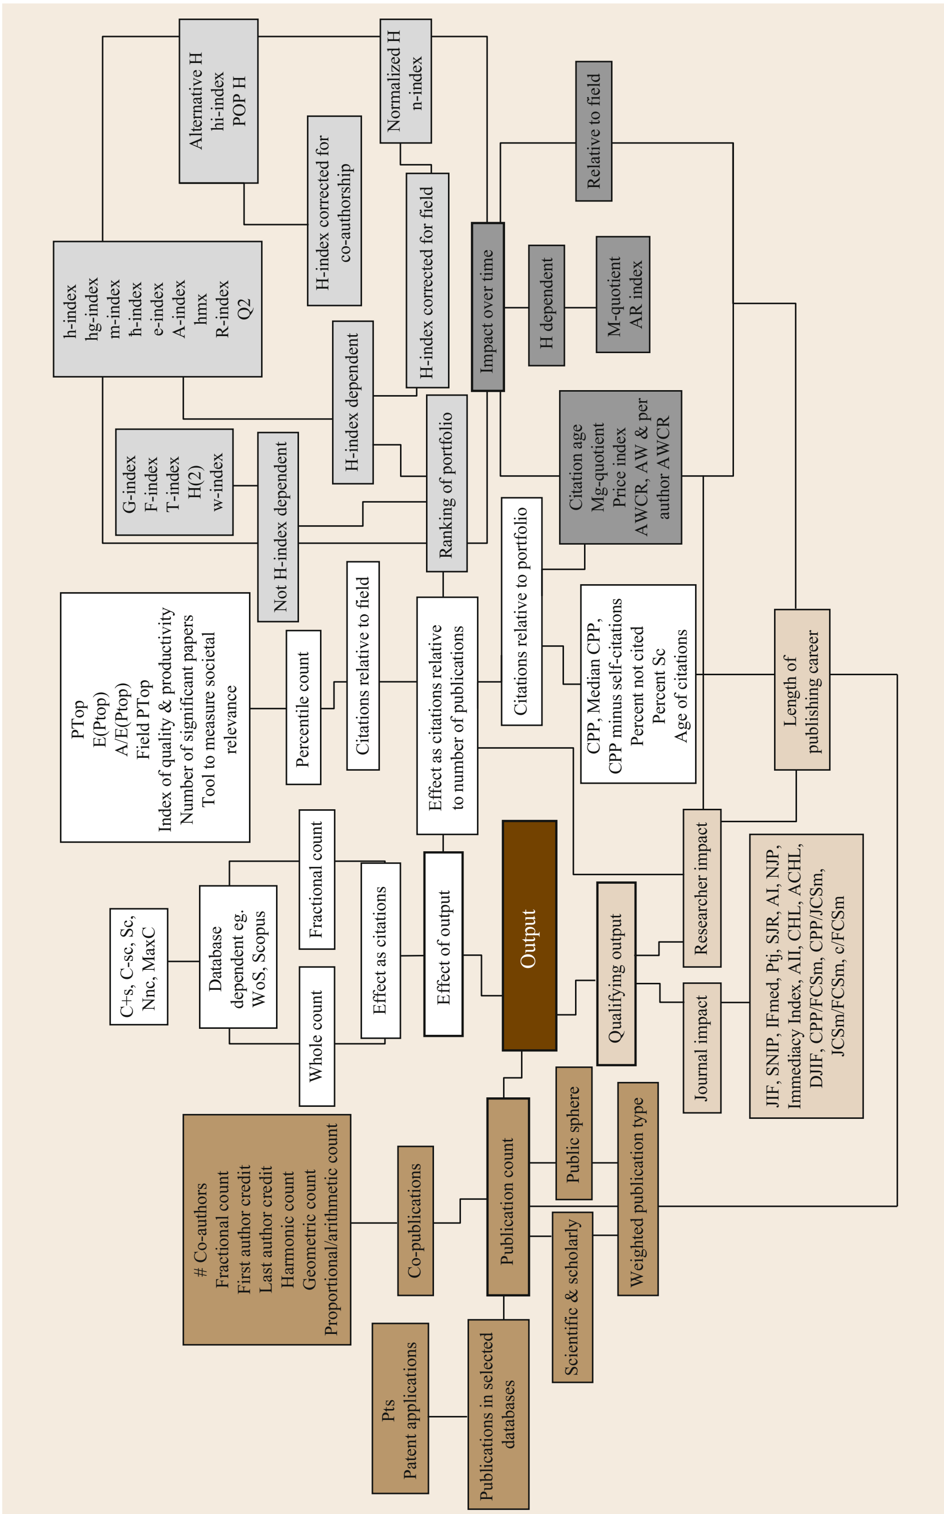

Fig. 14.4 Taxonomy of 51 ALIRP

searcher's articles in chosen journals, where the impact of the journals themselves is used to formally suggest the potential visibility of the researcher's work in the field in which he/she is active. The second branch, researcher impact, suggest the impact of the researcher's portfolio of work by using a combination of indicators from the output and effect families to formally suggest the researcher's productivity and visibility of work in the field in which he/she is active. Typically, these indicators are used in combination with a narrative, e. g., *IQP*, *index of age and productivity*, and the *Classification of Durability*, to situate the indicator values in the context of the researcher. In this family, indicators qualify output by normalizing for the length of a researcher's publishing career. The purple family of indicators, on the far right, contains indicators that measure and rank the portfolio of the individual, typically to promote the top-performing publications, or in an evaluation, to promote the researchers themselves. These indicators rank publications by the number of citations each publication has received and establish a mathematical cutoff point for what is and is not included in the ranking. The indicators are subdivided into two branches, h-dependent and h-independent. The h-dependent indicators include the calculation, or a variation thereof, of the h-index in their construction in order to denote something about the importance or significance of a researcher's work or to rank researchers. Additionally, the indicators can adjust h to account for the characteristics of research areas or co-authorship. Secondly, there are the h-independent indicators that do not include h in their construction. They provide an alternative to h, attempting to avoid the flaws of h while still producing values that denote something about the importance or significance of a researcher's work or that rank researchers, adjusted to field or co-authorship. Finally, the orange family of indicators of impact over time denote something about the extent a researcher's output continues to be used or the decline in use. This family includes indicators that set the researcher in the context of his or her research area (relative to the field) and include h-type indicators that identify the use of the active core of the researcher's work over time.

Figure 14.1 illustrates quite simply the many groups of indicators we have at our disposal, those that share common characteristics and where they differ. We can now begin to get an idea of which indicators could complement and supplement one another in an extensive analysis that could capture the diversity of the production and performance of a researcher's output.

We still have much to learn about the extent to which ALIRP supplement one another in practice, whether they become redundant when used together, produce too much or conflicting information, or whether they do indeed contribute with unique information that tells us something highly individual about the researcher's output and the extent of its use. In application contexts, the first step is to understand the conceptual design and mathematical construction of each applied indicator. This will help us discern what and how we measure, and whether we are indeed measuring what we value, or are just measuring what we can easily measure and thus valuing what we (can) measure [14.163]. Like any other mathematical model, ALIRP are dependent on the quality and configuration of the data used to compute them as well as our expertise in interpreting the model. Different weights and parameters included in the indicator model may lead us to different conclusions about the researcher's performance. Selecting appropriate indicators involves making explicit choices about how to account for diversity. One indicator alone cannot possibly encompass all the requirements of an assessment or capture the similarity, disparity and balance between researchers and the objects being measured. Determining the most appropriate indicators to use in practice depends on the goal of the evaluation and the context of the researcher. Therefore, methodological transparency is essential. This includes describing the data and sources used in the calculation of the indicators as well as an interpretation of the math to show the properties of what you are measuring, i. e., how you are using the model to provide an interpretation of a researcher's production and effect. It is quite acceptable to use different models and different math in evaluations, as these result in different perspectives of interpretation of a researcher's performance.

In summary, this section argues that the choice of indicator must be substantiated through critical reflection on the conceptual design and mathematical construction of the indicator models before application in practice. The rationale is simple: to provide valid answers to questions about the production and use of a researcher's work, we need good measures. To better understand the quality of the measures we have, this chapter began with a description of the evolution of ALIRP and a discussion of the general characteristics of ALIRP. The discussion included a description of the mathematical and theoretical foundations of ALIRP, their conceptual clarity, validity and intended purpose, and their strengths and weaknesses. These discussions culminate in the following section in the form of three extensive tables that explicitly define the design, mathematical model, advantages and limitations of ALIRP. The purpose of the tables is to provide an overview of the ALIRP discussed above and to enable consumers of ALIRP in evaluation processes to assess the appropriateness of the indicators and consider whether the use of the indicator is valid in an evaluation context.

14.4 Schematizing the Indicators

In the following sections, the common features of 69 indicators designed for use at the individual level are summarized in table form. The aim is to illustrate the diversity of the indicators and the potential we have for multidimensional bibliometric analyses.

14.4.1 Introducing the Tables

Table 14.1 presents indicators that count publications, Table 14.2 provides indicators that count citations, and Table 14.3 lists hybrid indicators (offspring of publication and citations counts that combine elements of publication and citation performance with other components and mathematical manipulations). In total, 69 suggested ALIRP are schematized with regard to six criteria, which appear as column headings in the tables. The indicator name/acronym is presented in the first column, followed by the concept the indicator is design to capture in the next. In the third column, a brief description of how to compute the indicator is introduced. The fourth column contains the definition of the indicator, which is taken from the developers' own description of the purpose of the indicator in their original published papers. This is followed in the next two columns by a brief presentation of the advantages and disadvantages of the indicator as discussed in the bibliometric literature, supplemented by additional comments in the final column. The bibliographic references to each indicator, where available, are found in an additional reference list in the appendix of this chapter. The 69 indicators in Tables 14.1–14.3 are systematically assessed in order to better understand the unique approach of each indicator and its suggested use in evaluating an individual researcher. In this respect, the tables are designed to support an informed choice across a range of ALIRP by examining the strengths and weaknesses in indicator construction that can enhance or hinder their effective use in evaluation.

With no advisory boards, common standards or contextual assessments, comparing indicators is problematic, and this can both impede the development of the field and cause consumers of ALIRP to be distrustful of the results of evaluations [14.49]. On the other hand, without the restrictions of advisory boards, common standards or contextual assessments, creativity in indicator development is unfettered. Professor *Yves Gingras* addressed this duality in 2014, and suggested that developers, administrators and researchers need to learn how to better evaluate indicators [14.157]. He provides three validity criteria:

(C1) The adequacy of the indicator for the object/concept it measures

(C2) The sensitivity to the intrinsic inertia of the object/concept being measured, i. e., that there are no important changes without cause and that the indicator increases proportionally in relation to the concept

(C3) The homogeneity of the dimensions of the indicator, e. g., ensuring that the units in the mathematical model are consistent on both sides of the equal sign, as in $CPP = C/P$, and that the indicator is not combined with arbitrary weights. Homogeneity can tell us whether the math is incorrect, but cannot tell us if the math is definitely correct.

It is important to remember that even ALIRP that fulfill all three criteria could still produce invalid results in an application context if the scope or precision of the data collection process is flawed.

Each of the 69 indicators, presented in the tables in the following sections, was assessed using the validity criteria. This assessment adhered to the guidance for critical reflection provided by *Gingras* [14.157], which involved reviewing the literature about the construction of each indicator (summarized in previous chapters and illustrated in Fig. 14.3) and learning about the strengths and weakness of the indicator in practical applications (summarized in Tables 14.1–14.3). This approach has resulted in a qualitative analysis attempting to determine the exact meaning of each indicator. In the text supplementing the tables of indicators, the results of this analysis are presented not as the infallible truth, but to spark the reader's own critical reflections on the potential validity of the indicators before applying them in practice.

All three tables may be downloaded as Excel files that are made available together with the online version of this chapter. The tables are extensive, detailing the evaluation criteria and the complexity of each indicator.

14.4.2 Indicators that Count Publications

Ten common publication indicators are presented in Table 14.1. The strength of publication count models lies in their easy adaptability by consumers to count only publications from specific sources or to include the type(s) of publications deemed important for the evaluation or discipline. This can be done without compromising the properties of the specific indicator. *Cognitive orientation*, *publications in selected sources*, *P* and *weighted publication count* are examples of the aforementioned and are indicators that clearly correspond to the concept they are defined to measure (C1). They

Table 14.1 Indicators that count publications

Indicator	Measure	Computation	Definition	Advantages	Disadvantages	Comment
Cognitive orientation	Cognitive orientation	Aggregates papers in scientific subfields in which the individual publishes or is cited	How frequently a scientist publishes, is cited in various fields	Relatable to the position a researcher holds in the community	Limited to the database definitions of scientific fields. Journal-based, more applicable in some fields than others	Useful for identifying future areas for collaboration and production
App proportional	Contribution	Author with rank R in a byline with n co-authors ($R = 1 \ldots n$) receives score $n + 1 - R$	Shared authorship of papers, first author weighted highest and last author lowest	Rewards level of contribution to a paper	Indicator cannot be used if authors listed alphabetically or where authors alternate first authorship	Can be normalized in such a way that the total score of all authors is equal to 1
App geometric	Contribution	Author with rank R with N co-authors receives credit of $2N - R$	Assumes that the rank of authors in the byline accurately reflects their contribution	The first few authors receive most of the credit	Allotted authorship credit rapidly approximates asymptotic values as N increases	Asymptotic values lose their validity with small sample size
App harmonic	Contribution	Ratio of credit allotted to i-th and j-th authors is $j : i$ regardless of total number of co-authors	First author gets twice as much credit as the 2nd, who gets 1.5 times that of the 3rd, who gets 1.33 times that of the 4th etc.	Representation of perceived quantitative norms of byline hierarchy	Applies only in areas where unequal co-author contributions are the norm	Tested in the natural sciences
FA	Contribution	Only first of n authors of a paper receive credit equal to 1	Credit given to first author only	Simple method of crediting publication to the assumed main contributor	Does not give an accurate picture of the relative contribution of the authors	Unfair when authors are ordered alphabetically or practice *noblesse oblige*
Noblesse oblige	Contribution	Last author receives 0.5 credit, other $N - 1$ authors receive $1/(2(n-1))$ each	Indicates the importance of the last author for the project behind the paper	Last author gets credit for contributing with resources (funding, network, expertise) and ensuring the article was written	There is no way to identify actual level of contribution apart from authors' statements	This is one of many suggested counting schemes for noblesse oblige
Fp	Independence	Each publication divided by number of authors, limited to max. 10 authors	Shared authorship of papers gives less weight to collaborative works than non-collaborative ones	Accounts for differences in publishing behavior among fields and level of multi-authorship	Favors secondary authors by allocating equal credit to all authors	Criticized for lack of fit between credit scores and contribution
Publications in selected sources	Production in selected sources	Count of publications in predefined sources	Important sources defined by scholars, institute, field or evaluation committee	Reflects output in sources deemed locally important	Provides a distorted or incomplete picture of production	Provides only a snapshot of productivity
P	Production of papers in journals and academic books	Sum of publications	Count of production used in formal communication	Potentially, all types of output can be included or selected with regard to theme of evaluation	Does not measure importance, impact of papers, duration or volume of research work	Counts vary across disciplines due to nature of work and conventions for research communication
Weighted publication count	Production of specific types of publications	Applies a weighted score to the type of output	Distinction between different document types	Importance of different publication types for communication within a field	Has to be designed for individual specialty/field	Enables comparison of like with like if agreement of importance is reached

are homogeneous indicators (C3) and fulfill the inertia criteria (C2), that is, the indicator value increases in a manner consistent with an increase in the concept that the indicator measures. All 10 indicators are simple to calculate and make sense; however, caution is advised when interpreting the *Fp*, *noblesse oblige*, *FA*, *App harmonic*, *App geometric* and *App proportional* indicators. These indicators work with the concept of contribution, that is, the substantive intellectual contribution to a paper an author has made can be mathematically deduced from his or her position on the author byline of a paper. There is no way to identify the actual level of contribution apart from gathering statements of authorship. These indicators instead offer a complementary insight into the impact of an author, adjusting for potential biases of (excessive) co-authorship. As a set, the publication indicators presented in Table 14.1 supplement one another, in that they provide unique insights into the quantity of publications an individual has produced.

14.4.3 Indicators that Count Citations

Eight citation-counting models are presented in Table 14.2. Five are considered to correspond to the concept they are defined to measure (C1), fulfill the inertia criteria (C2) and are homogeneous (C3). They are as follows: *C*, *database-dependent citation count*, *C-sc*, *%nc* and *%sc*. These indicators are also simple to calculate, and what they measure is unambiguously clear. They are independent indicators, in that they provide information about different aspects of a researcher's citation count. The indicators *SIG*, *Sum pp top prop* and *Fc* have obvious flaws in their conception, but because they are so intuitively simple, they could still be appropriate measures for evaluation. *Fc* attempts to give less credit to collaborative works, leading to fairer evaluative comparisons. However, credit is calculated in *Fc* as a single unit that can be distributed evenly, making the share dependent on the number of authors, thus assuming that the contribution of the author can be equally rewarded. *SIG* and *Sum pp top prop* are coarse indicators of significant works, and these significant works are defined as top papers in the context of a database's indexing policy and classification system. When interpreting these indicators, it is wise to draw the consumer's attention to that fact that the paper with the greatest number of citations is not necessarily a researcher's most academically/scientifically significant paper. Further, the indexing policies and classification systems in databases can have both geographic and disciplinary biases and resource bias, which further distorts the interpretation of the indicator [14.10, 164].

14.4.4 Hybrid Indicators

Fifty-one hybrid indicators are analyzed in Table 14.3. Ten of these are identified as relatively simple to compute, correspond to the concept they are defined to measure (C1), fulfill the inertia criteria (C2) and are homogeneous (C3). They are as follows: f, t, *index of age and productivity*, π, $c(t)$, $a(t)$, *Price index*, *Classification of Durability*, *AWCR*, and *IQP*. The commonality of the these 10 ALIRP is that they cannot stand alone. They all demand a narrative to set the indicator values in the context of the researcher and of the calculation—the *IQP* is an excellent example. The narrative is a brief description showcasing the informed use and informed interpretation of the bibliometric indicators, and the expertise and influence of the researcher in the context of their demographic information, specialty and academic seniority. These indicators have been tested empirically in WoS and other databases and are recommended as suitable for implementation in different disciplines (for more information, please refer to the bibliographic references to these indicators at the end of this chapter). Further, there is no redundancy among these 10 indicators when they are used together, as each indicates different facets of the citation effect of a researcher's publications. They can be used together, within the context of the citation index, to indicate:

- The currency and relative currency of the researcher's work ($c(t)$, $a(t)$, *Price*, *Classification of Durability*)
- The average effect of a researcher's work (f, t)
- The cumulative effect of the researcher's body of work, (*AWCR*)
- The excellence of the researcher's work compared to subjectively defined specialty standards that are based on the researcher's publication habits (*IQP*, *Index of Age and Productivity*).
- Comparison with peers, across fields (π).

The remaining 41 ALIRP fail on one or more of Gingras' evaluation criteria (please refer to the tables provided as e-material to this chapter for more detail). Thirty of these indices are corrections to the h-index, using the principles of h in their calculation. Eight are alternatives to the h index that do not use h in their calculation, and three are diverse ALIRP that indicate the average number of citations to all papers, top papers and the currency of a researcher's work: the *CPP, %HCP* and *DCI*.

The 38 h-type ALIRP attempt to correct for the inherent inconsistency problem in h, in that h performs in rankings in a counterintuitive way [14.135]. With consistent indicators, it is ensured that if two authors

Table 14.2 Indicators that count citations

Indicator	Measure	Computation	Definition	Advantages	Disadvantages	Comment
C	Times cited	Sum of citations, including self-citations	Number of citations for whole period of analysis	Reflects social side of research and cumulative growth of knowledge	Quality and timeliness of citation not considered	Self-citations affect the reliability and validity of the measure on small amounts of data in assessments
Database-dependent citation counting	Times cited in specific sources	Number of citations recorded in a specific database	Citation number is dependent on the database used to collect citation information	Shows that coverage of researcher in database can affect calculation of indicators and performance of researcher	Many indicators and field benchmarks are reliant on WoS and cannot be compared with data from other sources	Scope, validity, reliability and cost of the citation collection is dependent on choice of citation index
C-sc	External citations	Sum of citations, minus self-citations	Measure of external citations	Reflects social side of research and the cumulative growth of knowledge	Quality and timeliness of citation not considered; what is a sc: cites of oneself, a co-author or institutional colleague	Does not account for older articles being more cited and variation in citation rates between document types and fields
Sig	Most significant work	The paper with the highest number of citations	The most significant paper	Simple indicator of the most important and influential research	The most significant paper is not necessarily the paper with the most citations	Most highly cited paper can have the largest number of authors, be longer than the average article and have more references
Sum pp top prop	Most significant work	Proportion of papers in the top 10% in the world	Identify scholars' papers that are rated top of their field	Simple indicator of most cited papers in the field	Uses WoS subject categories to define field	Does not compare like with like
%nc	Work that has not been cited	The number of uncited papers divided by sum of citations, multiplied by 100	Percentage of papers that have not been cited	Used to contextualize other indices, e. g., CPP, related academic age	Papers may not be recorded as cited due to citation database indexing policy	Illustrates the types of publications that, although important, do not receive citations, i. e., technical reports, guidelines
%sc	Self-use	Self-citations divided by sum of citations multiplied by 100	Percentage of self-citations	Illustrates how work builds on previous findings. Advertises the work and the author	Unclear what a self-citation is: cites of oneself, a co-author or institutional colleague	Self-citation rate is highly variable among individuals and their contribution highly variable
Fc	Citations scholar would have received if worked alone	Citations to a paper divided by the number of authors. Limited to max. 10 authors	Removes the dependence of co-authorship on citation count	Less weight given to collaborative works	Regards credit as a single unit that can be distributed evenly across a number of authors	Comparison to field norm unwise, as citations to the publications may not be representative of the field, but biased toward the highly or poorly cited

Table 14.3 Hybrid indicators

Indicator	Measure	Computation	Definition	Advantages	Disadvantages	Comment
f	Average effect	Harmonic mean of citations to papers	Highest number of articles that receive f or more citations on average	An additional citation to an infrequently cited paper counts more than an additional citation to an often-cited paper	Both f & t indices are maximum if every paper is cited the same number of times. The f-index deviates much faster from this maximum than the t-index	More discriminatory power than h- and g-indices, as the nonlinearity of the harmonic mean is more sensitive to small differences between researchers
t	Average effect	Geometric mean of citations to papers	Highest number of articles that received t or more citations on average	Geometric mean does not place much weight on the distribution of citations	Sensitivity to small differences between researchers is stronger with harmonic mean (f-index) than geometric mean	It is not sufficient to determine the function and value of citations using indices; their cognitive background should also be taken into consideration
CPP (CPAY)	Average number of citations per paper	Sum of citations divided by sum of papers (alt. number of years since first publication registered in citation index)	Trend of how cites evolve over time	Enables comparisons of scientists of different ages and different types of publications	Tells nothing of the timeliness, origin or quality of the cite (positive or negative)	Citations can be hard to find, reward low productivity & penalize high productivity
w-index	Broad impact of masterpieces	w is the highest number of papers that have at least 10w citations each	Impact of researcher's most excellent papers	Accurately reflects the influence of a scientist's top papers	Tendency to describe quantity of the productive core	w-index of 1 or 2 = someone has learned the rudiments of a subject; 3 or 4 = mastered the art of scientific activity, *outstanding individuals* have w-index of 10
Index of age & productivity	Career	Mean number of documents by age and CPP (3-yr citation window) in 4-year age brackets, adjusted to field	Effect of academic age on productivity and impact	Identifies the age at which scholars produce their best work and the extent of the decline of their production	Mean impact declines with age regardless of quality of researcher's body of work	If used independently, fosters practice of quantity over quality. Difficult to maintain high values of impact with increasing rates of production
Hn (Normalized h)	Comparison across fields	hn = h/papers(Np), if h of its Np papers have at least h citations each, and the rest (Np − h) articles received no more than h citations	Normalizes h to compare scientists achievement across fields	Accounts for scientists different publication and citation habits in different fields.	Hn can only be used with h-index; rewards less productive but highly cited authors	Gives paradoxical results for junior researchers with few papers

Table 14.3 (continued)

Indicator	Measure	Computation	Definition	Advantages	Disadvantages	Comment
π index	Comparison across similar fields	π is one hundredth of the number of citations received by the top square root of the total number of papers ranked by decreasing number of citations	Production and impact of scholar	Comparative assessment of scientists active in similar subject fields. Sensitive to citedness of top papers	Value depends on citation rate of papers in the elite set (top-cited papers); the elite set is scaled by an arbitrary prefactor	Can be calculated on a small number of papers. Unique index as it is defined in terms of the summed number of citations rather than the square root of the sum or the average
hf	Comparison to peers	Citations of each article normalized by average number of citations per article in the subject category of the article under observation	Comparison to peers by correcting each article's citation rate for field variation	Makes scientists of different scientific age comparable	Difficult to determine the correct publication/citation window in construction of the matrix	Calculation is not easy, making it a nominal index and not a pragmatic one
H index of sequences and matrices	Comparison to peers and domain	Calculates h-sequence by continually changing the time spans of the data. Constructs h-matrix based on a group of correlative h-sequences	Identifies significant variations in individual scientists' citation patterns across different research domains	Makes scientists of different scientific ages comparable	Difficult to determine the correct publication/citation window in construction of the matrix	Only tested on 11 well-established physicists
n index	Comparison within specialty & across fields	Researcher's h-index divided by the highest h-index of the journals of his/her major field of study	Enables comparison of researchers working in different fields	Can surmount the problem of unequal citations in different fields	Still awaiting validation	Calculation based on Scopus definition of h and SCImago Journal and Country Rank website for journal information
c(t)	Currency	c(t) is the difference between the date of publication of a researcher's work and the age of citations referring to it	The age of citations referring to a scholar's work	The entire distribution of the citation ages of a set of citing publications provides insight into the level of obsolescence or sustainability	Measuring aging by means of citation counting is disputed. Does not account for effect of literature growth, availability of literature and disciplinary variety	Usage and validity are not necessarily related
a(t)	Currency	a(t) is the difference between ct and $c(t+1)$	Aging rate of a publication	Allows for translation of diverse factors influencing aging into parameters that can be estimated from empirical data with a specified margin of error	A corrective factor is required if citation rates are to be adjusted for changes in the size of citing population and discipline	For individual documents, stochastic models are preferable. The simplest model to study aging is the exponential decay of the distribution of citations to a set of documents

Table 14.3 (continued)

Indicator	Measure	Computation	Definition	Advantages	Disadvantages	Comment
Hc	Currency	Articles assigned decaying weight depending on age. The weighting is parameterized gamma = 4 and delta = 1	Currency of articles in the h-core	Accounts for active versus inactive researchers	An old article gradually loses its "value", even if it still receives citations; thus newer articles are prioritized in the count	Identical to hpd, except measured on a 4-year cycle rather than a decade
Price index	Currency	PI = (n1/n2) × 100. n1 = number of cited references with a relative age of less than 5 years. n2 = total number of references	Percentage references to documents, not older than 5 yrs, at time of publication of citing sources	Accounts for differing levels of immediacy characteristic of the structurally diverse modes of knowledge production in the different sciences	Does not reflect the age structure in slowly aging literature	In calculation of PI it is unclear whether the year of publication is year 0 or year 1. It is unclear whether this year is included
A	Distribution of citations	Arithmetic average number of citations to articles in the h-index	Magnitude of scholars' citations to publications, supplement to h	A-index can increase with increase in citations, even if h-index remains the same	A is h-dependent and has information redundancy with h. When used together, h masks the real differences in excess citations of different researchers	A-index involves division by h and punishes researchers with high h-index; sensitive to highly cited papers
$\hbar$	Distribution of citations	Square root of half the number of total citations to all publications	Overall structure of citations to papers. Enables comparison across field and seniority	Includes papers h ignores, i. e., most highly cited and the body of articles with moderate citations	Difficult to establish the total citation count with high precision	$\hbar$ is only roughly proportional to h
Classification of Durability	Durability	Percentile distribution yearly citations to a document, accounts for all document types and research fields	Durability of scientific literature	Aids study of individuals from general perspective using composite indicators. Discriminates between normal, flash in the pan and delayed publications	Minimum 5-year citation history threshold for reliable results. Empirically investigated in WoS using journal subject categories	Can be applied to large sets of documents or documents published in different years; documents can be classified in more than one field and can be updated yearly or monthly
hT index	Effect of all papers	Using Ferrers graph, h-index is calculated as equal to the length of the side of the Durfee square assigning no credit to all points that fall outside	Production and impact index that takes all citations into account, yet the contribution of the h-core is not changed	Evaluates the complete production of the researcher, all citations, giving to each of them a value equal to the inverse of the increment that is supposed to increase the h-index one unit	The relative influence of the interpolation will be stronger for smaller values of the indices; therefore, utilize the generalized indices when comparing many data sets with very small values of h	Shows smooth increase in citations, not irregular jumps as in h-index. Conceptually complex

Table 14.3 (continued)

Indicator	Measure	Computation	Definition	Advantages	Disadvantages	Comment
Q2	Effect of all papers	Square root of (h multiplied by median number of citations to papers in h index)	Relates two dimensions in productive core: the number and impact of papers	h-index' measurement of papers in core, correcting for distribution of citations to papers	h- and m-index have to be obtained before calculation of Q2	Geometric mean is not influenced by extreme higher values. Fuses the information provided by the aggregated values in a balanced way
AWCR	Effect of all papers	(Citations to all papers, divided by age of paper)/number of publications	AWCR = number of citations to all papers, adjusted for age of each individual paper	Sum over all papers represents the impact of the total body of work. Younger, less cited papers contribute to AWCR	Field norm has to be decided to account for field characteristics, e. g., expected age of citations, "sleeping beauties" and delayed recognition	AWCR offers by default empirical insight into research seniority and career age
AW	Effect of all papers	Square root of AWCR	Square root of AWCR avoids punishing researchers with few very highly cited papers	AW approximates the h-index if the mean citation rate remains constant over the years. Includes younger and yet less cited papers	It is more rigorous to assign weights to each of the publications, calculate the average weighted citations (arithmetic mean), and normalize that result to one of the publications	Square roots are appropriate for data that grows exponentially. Gives consistent results, though this is not the same as giving correct results
m-quotient	Effect of best papers	h-index divided by years since first publication	h normalized for academic age	Comparisons between academics with different career length, as h is approximately proportional to career length	m stabilizes later in career; small changes in h can lead to large changes in m; first paper not always an appropriate starting point	m-quotient adds time as a weighting factor. It does not counter the major disadvantages of the h-index
mg-quotient	Effect of best papers	g-index divided by years since first publication	g normalized for academic age	Comparisons between academics with different career length. g is approximately proportional to career length	First publication is not necessarily the appropriate estimate of the start of the researcher's career	mg and m discriminate against part-time researchers/career interruptions
m	Effect of best papers	Median citations to publications included in h-index	Reduces impact of highly cited papers	Accounts for skewed citation distribution. Median is used as measure of central tendency	Median may be a better measure of central tendency, it can be chronologically unstable	Reduces impact of heavily cited papers
%HCP	Excellence	Publications cited above the 80th percentile in respective research areas	Indicates papers among the 20% most cited in research area, i. e., relative impact	Indicator of excellence understood as citation count reflect the extent to which an academic's work affects the work of his/her peers	Indicates only one facet of excellence and no reflection of the impact of the work on society	Difficult to maintain high values of relative impact with increasing rates of production

Table 14.3 (continued)

Indicator	Measure	Computation	Definition	Advantages	Disadvantages	Comment
IQP	Excellence	A = (mnjs × Pyrs x p + 1)/2. B = A/number of papers C = Received citations IQP = C/B + nPapers, C = calculate field impact per papers x number of papers	Expected average performance within field; number of papers cited more frequently than average and how much more these papers are cited	Corrects citation count for scholarly productivity, author's academic age, and field-specific citation habits. IQP Calculator: [14.165]	Tested in natural sciences, medicine and psychology. Dependent on WoS field specific journal impact factors	Correlates better with expert ratings of excellence than h index. Puts papers in low cited fields on same scale as papers in highly cited field to improve comparison
e	Excellence	Defines total citations to articles in h-index. Subtract h^2 from total citations (e^2). Square root of e^2 is e	Production and effect of highly cited papers	The combination h and e provides complete citation information	e can only be calculated if h is given	More precise in evaluation of highly cited scientists and comparing group of scientists who have identical h
H2	Excellence	Cube root of sum of citations	Cumulative achievement. Weights most productive papers	Reduces precision problem as only a small subset of the researcher's papers used to calculate H2	Difficult to discriminate high H2 indices between scientists with different numbers of publications and different citation rates	Suffers from same intrinsic disadvantages as other indices based on citations, i. e., it is not comparable across fields or academic age
b index	Excellence	b = integer value of the author's external citation rate (non-self-citations) to the power three quarters, multiplied by h	Number of papers i that belong to the top n% of papers in a field; Effect of self-citations on h	Field-specific reference standard for scientific excellence used as cutoff value for including or excluding publications in productive core	Difficult to implement because of the computations needed to obtain the measure. Difficulty in obtaining accurate data from bibliographic databases	The b index depends on the year in which it is determined, the period under consideration and the database
Rational g	Excellence	Interpolates between g and g + 1 based on the piecewise linearly interpolated citation curve	Indicates the distance to a higher g-index	It is not a complementary index requiring first the determination of g, but rather follows from a self-consistent definition	Relative influence of the interpolation is stronger for smaller values of the indices. Utilize generalized indices when comparing many data sets with small h values	As every citation increases interpolated g, the index is sensitive to self-citations
AR	Growth	Square root of sum of the average number of citations per year of articles in the h-core	Citation intensity and age of articles in the h-core,	AR is necessary to evaluate performance changes. Supplements h	The decay of a publication is very steep and insensitive to disciplinary differences	AR increases and decreases over time. AR is not convincing as a ranking metric in research evaluation

Table 14.3 (continued)

Indicator	Measure	Computation	Definition	Advantages	Disadvantages	Comment
Hpd	Growth	Hpd is highest number of papers that have at least hpd citations per decade each and other papers have less than hpd + 1 citations per decade each	Compares the output of scholars of different ages. Seniority-independent h-type index	hpd of a mature scientist is nearly constant over many years, and hpd of an inactive scientist slowly declines whereas h-index increases in time	Using scaling factor of 10 to improve granularity between researchers is an arbitrary number. Randomly favors or disfavors individuals	Can be modified for multi-authored papers. A paper's cites per year is divided by the number of co-authors to indicate contribution of each co-author
R	Growth	Square root of the A-index	Magnitude of scholars' citations to publications	Adjusts for punishing the researcher with a high h-index	R-index involves division by h and punishes researchers with high h-index	Supplement to h. Easier to calculate than g index, but not as elegant
Hm	Independence	Hm is the reduced number of papers that have been cited hm or more times	Softens influence of authors in multi-authored papers	Does not push articles out of the h-core; each paper is fully counted allowing for a straightforward aggregation of data sets	Precision problem is enhanced, as additional papers enter into the hm-core	Uses fractional paper counts instead of reduced citation counts. Uses inverse number of authors to yield a reduced or effective rank
Alternative h	Independence	Alternative h = h-index divided by mean number of authors in the h publications	Number of papers a researcher would have written along his/her career if working alone	Rewards scientists who work alone from authors that work in groups. Accounts for differences in co-authorship patterns, discipline and self-citations	Mean is sensitive to extreme values and could penalize authors with papers with a large number of authors	Might decrease when a paper with many authors advances into the h-core by attracting additional citations and reduces size of the h-core
POP h	Independence	Divides number of citations by number of authors for that paper. Normalized citation counts used to calculate h	Accounts for co-authorship effects	Gives an approximation of the per-author impact, which is what the original h-index set out to provide	Normalization by mean number of authors of publications in the h-core leads to reduction of the index	Also considered multiple authors by computing g and h indices using a fractional crediting system
AWCRpa	Independence	Citations to a paper/age of paper. Result for each paper divided by the number of authors per paper. Summed over all papers	Normalizes AWCR to the number of authors for each paper	Accounts for co-authorship to give a more approximate individual author impact	Giving less weight to collaborative publications than non-collaborative publications is undesirable	Rankings using AWCRpa agree with those that rely heavily on citations per year data
Pure H	Independence	Hp = square root of h/normalized number of authors and credit to their relative rank on the by-line of h-core articles	Corrects individual h-scores for number of co-authors	Reduces effect of collaboration in multi-authored, highly cited paper	Results vary depending on method of distributing credit to authors—fractional count, arithmetic to determine h	More refined index is to use the number of collaborators, rank in the byline and the actual number of citations (pure R)

Table 14.3 (continued)

Indicator	Measure	Computation	Definition	Advantages	Disadvantages	Comment
Adapted pure h	Independence	h is interpolated rank value between papers (fractionally counted) and citations (counted as square root of equivalent number of authors)	Finer granularity of individual h-scores for number of co-authors by using a new h-core	Alters h-core to be less biased than Hp with respect to authors with many multi-authored papers	Precision is an issue and difficult to calculate	Leads to a more moderate correction of authorship than h_i as divides citation count by the square root of author count rather than full author count
Ht	Pioneer research	Each citation of an article is assigned an exponentially decaying weight, which is expressed as a function of the *age* of the citation	Age of article and age of citations	Identifies pioneering articles that set out new line of research and still cited frequently. For researchers with a long career behind them	The weighting is parameterized, and for gamma = 1 and delta = 0, this metric is the same as the h-index	Estimates impact of researchers' work in a particular time instance, i. e., whether articles still receive citations by looking at the age of the cites
hw	Quality	Hw = square root of total weighted citations (Sw) received by the highest number of articles that received Sw/h or more citations	Quality of a scholar's publications (h value weighted by citation impact)	Improves sensitivity to the number of citations in h-core	Does not use h-table in calculation and is therefore not an acceptable h-type measure	Hw can be misleading and a contradiction of h
DCI index	Quality	Sum of weighted count of citations over time to a set of documents divided by the logarithm of the impact in past time intervals	Devalues old citations in a smooth and parameterizable way	Gives more weight to highly cited publications as these are assumed to be quality works. Weights citations by the value of the citing publication	Difference caused by weighting: some authors gain impact while others lose	Rewards an author for receiving new citations even if the publication is old
h	Quality and quantity	Publications ranked in descending order after number of citations. Where number of citations and rank match, this is h	Cumulative achievement (productivity and impact)	h is a simple but rough measurement of quality of work	Once a paper is in h-core, the number of citations it receives is disregarded. Loss of citation information means comparisons based on the h-index can be misleading	Arbitrary cutoff value for including or excluding publications from productive h-core
x index	Quantity and quality in cross disciplinary comparisons	x is a researcher's absolute score divided by a reference score	Describes quantity and quality of the productive core and comparison with peers	Uses the journals the researcher publishes in as reference, not field classification, to account for multi/interdisciplinary research	x is based on (5 year) Impact Factor which has well-documented limitations; x is also vulnerable to scale issues	Using a measure based on citation counts would permit a more meaningful assessment of scientific quality

Table 14.3 (continued)

Indicator	Measure	Computation	Definition	Advantages	Disadvantages	Comment
Hα	Quantity OR quality	The value of hα is equal to N papers with at least αhα citations each and the other $n - H\alpha$ papers have fewer than $\leq \alpha h\alpha$ citations each	Cumulative achievement, advantageous for selected scientists	Greater granularity in comparing scientists with same h; α can be set to the practices in a specific field, allowing for fairer comparison between fields	No agreement on the value of parameter α. The appropriate choice of α requires more study and is field-dependent. Sensitivity of hα to α needs investigating	Small α: ranks scientists based on papers with at least one citation (quantity measure, advantageous for productive scientists who are not highly cited) Large α: measures number of citations of most-cited paper (quality)
Dynamic h	Rank	Builds on three time-dependent elements: $R(T) \times vh(T)$, where R(T) is the R-index computed at time T and vh is the h velocity	Accounts for size and contents of the h-core, number of citations received and the h-velocity	Ideal where two scientists have the same h index and the same number of citations in h-core, where one has no change in h and the other h is on the rise	H-dependent. To define vh, it is better to find a fitting for hrat(t), not for h(t). This function is more similar to a continuous function than the standard h-index	For evaluation purposes, self-citations should be removed
hmx	Rank	Ranks academics by their maximum h (hmx) measured across WoS, Scopus and Google Scholar	Ranking of the academics using all citation databases together	Accounts for missing citations, lack of correlation between databases and disparities in h across databases	Assumes that the differences in h across the databases are due to false-negative errors and that these were negligible	An examination of the overlaps of citations and publications between the databases will provide a better estimate
Gα	Rank AND quality	$g\alpha =$ highest rank the first gα papers have together, at least number of citations	Allows for fractional papers and citations to measure performance at a more precise level	gα-index puts more weight on the quality aspect of scientific performance than the hα-index	No agreement on the value of parameter. The appropriate choice of Gα requires more study and is field-dependent	Empirical research needed to determine whether the gα provides better results than the g-index in practice
g	Rank of scholar	Publications ranked in descending citation order. Cumulative sum of citations is calculated. g is where the square root of the cumulative sum is equal to rank	Cumulative achievement, highly cited papers included, to distinguish between and rank scientists	Corrects h by weighting highly cited papers to make subsequent citations to highly cited papers count in calculation of the index	Can be disproportionate to average publication rate. g of a scientist with one big hit paper and a mediocre core of papers could differ significantly from scientists with a higher average of citations	Ignores the distribution of citations

Table 14.3 (continued)

Indicator	Measure	Computation	Definition	Advantages	Disadvantages	Comment
Rational h	Rank of scholar	hrat = (h + 1) − (nc/2h + 1). h = h-index, nc = number of citations needed to make a h-index of h + 1 and 2	Indicates distance to a higher h by interpolating between h and h + 1. h + 1 = maximum number of cites needed to increase the h index one unit	Increases in smaller steps than h, providing greater distinction in ranking of individuals	Same limitations as for rational g	Interpolated indices have the advantage that one does not have to wait so long to see one's index growing
hg	Rank of scholar	The square root of (the sum of h multiplied by g)	Comparison of scholars with similar h and g indices	Accounts for influence of large successful papers on g-index. Achieves balance between the impact of an author's best papers and the very highly cited ones	Combining h and g does not improve discriminatory power	hg has no direct meaning in terms of papers and citations of a scientist and can lead to hasty judgments

show the same relative or absolute performance, they do not rise or drop in rank position [14.148]. This is not the case with *h*, and already in 2005 *Moed* pointed out that authors with very different citation distributions can have the same *h*-index [14.18], just as many people with very different citation distributions can have the same *CPP*. Consequently, developers continue to suggest new indicators to correct for the inconsistencies in *h*, and use different mathematical manipulations to overcome this. For example, *hw* and *dynamic h* attempt to identify quality papers by applying the Lotkanian approach to concepts of size and rank frequency, aiming to provide steady patterns of the evolution of papers in the *h*-core over time. Thus, no publication can instantly become highly cited, implying that with dynamic indicators, the *h* inconsistency cannot occur [14.161]. However, as can be seen in Table 14.3, many of these hybrid ALIRP are clearly exploratory, in that they raise important questions rather than provide answers for indicator developers. The requirements for data collection and calculation are also more demanding, and this increased complexity does not necessarily correlate with an increase in the validity of the indicator. Further, the focus is not on the practical evaluation of researchers, but on studying the equations within the indicator and the theoretical interpretations of bibliometric laws, stimulating further study [14.160]. These indicators are still experimental, with their own caveats and inconsistencies. As the following examples illustrate, they are not application-ready unless detailed explanations of their shortcomings are provided in evaluation reports. The *h2* [14.166] is an indicator of excellence, but it has a consistency problem, which means that it cannot determine excellence, as it does not discriminate between scientists having different numbers of publications with quite different citation rates for relatively high *h2* indices [14.135]. The *Q2* index [14.167] takes the square root of the sum of the *h*-index multiplied by the *m*-index [14.91] to provide an estimate of the average effect of a set of productive papers. However, *Q2* values are closer to *h* than to *m* (median number of citations to papers in the *h* core), and this can be interpreted as a penalty associated with the *m*-index for researchers where *h* is very low. The *Q2* indicator suffers from the same inconsistency problems as *h* [14.168]. Similarly, the *e*-index [14.169] computes the square root of the surplus of citations in the *h*-set beyond h^2 as a supplement to *h* to indicate excellence. Consequently, *e* only makes sense when *h* is given, which as we know is inherently flawed. Finally, *hg* [14.170] adapts *h* to calculate the square root of the sum of *h* multiplied by the *g*-index to give granular rankings of researchers with similar *h* and *g* indices. Consequently, it includes in its calculation an arbitrary threshold of citations, creating a fractional size–frequency function, and it can be disproportional to the average publication rate [14.3, 171]. This means that the *hg*-index of a scientist with one big hit paper and a mediocre core of papers could increase significantly in comparison to that of scientists with a higher average number of citations. Perhaps the discussion around the validity of ALIRP in this section is too academic, not rooted in real life. Perhaps it is unnecessary to go into so much mathematical detail, and instead to look at the indicator in question and simply consider whether it makes sense. Therefore, taking *CPP* and *%HCP* as examples, they are clearly flawed because of their respective reliance on the arithmetic mean or on WoS disciplinary classifications, but because they are simple to calculate and their failings easily understandable, they are still appropriate for evaluations *if* supplementary indicators and, of course, a narrative are provided. In comparison, the *DCI* index is a highly sophisticated indicator. However, it is so complicated that problems with the indicator are hidden. The difference in *DCI* values can be caused by the weighting parameter, resulting in some authors scoring well on this indicator while others score poorly, with no connection to the currency of their body of work, let alone the quality of their work, which is the concept this indicator is attempting to capture.

The analyses in Tables 14.1–14.3 and discussions in the previous sections show that identifying the appropriate indicator for specific situations is complicated. In bibliometrics, we rely less on anecdotes and favor data, the idea being that numbers tend to lie less than people do when evaluating an individual's academic reputation and career path. However, the demands we place on these numbers must be supported by transparency in the purpose of the evaluation, the robustness of our methods and the validity and clarity of our models, an awareness of what may bias the indicator scores, and openness regarding the limitations of ALIRP. Determining the appropriate application of ALIRP is challenging, and it is the author's hope that Tables 14.1–14.3 will make choosing an ALIRP at least a *little* less complicated.

Assessing the composition and validity of the indicator can help us identify potential structural problems even before application of the indicator in practical evaluation. Coherence in indicator design is a major challenge. One way to improve this situation is to update our understanding of model-building in bibliometrics for both developers of indicators and consumers. This includes the need for clear statements of definition and operationalization of concepts by indicator developers, frank discussion concerning the constraints of indicators, and addressing the technical problems and resource challenges we face in gathering data and computing indicator values in practice. In particular, we as a bibliometric community must address the ad hoc nature of indicator development and provide guidance for the validation and application of indicators to promote coherent evaluation and to prevent conflict. Most importantly, we must strengthen the weak follow-up of indicator development. Not a short list by any means, but this handbook is a practical step in the right direction.

14.5 The Appropriateness of ALIRP and the Application Context

ALIRP are tricky, as they present different bibliometric pictures of researcher performance, and the numerical values demand conscientious interpretation. From a researcher perspective, indicators that are interpreted as portraying them in the most flattering light might be the most useful, but from the evaluator's point of view, indicators that are informative to a particular question are the most useful. This is why the current chapter explores the appropriateness and not the usefulness of ALIRP, as usefulness can differ greatly depending on the end user's needs.

We cannot assume that those responsible for applying an indicator will not be self-serving, manipulating the indicator to appear ineffective or unreliable, or vice versa. The commonality in the application of an indicator, regardless of the end user, is that the interpretation of the ALIRP affects our interpretation of researcher performance. Further, the same indicator can be subject to a variety of interpretations, often based on the many diverse values of the administrators, the culture of the researcher's affiliated organization and the purpose of the evaluation. Therefore, the need for indicators that are valid measures is fundamental to the process of evaluation. But how is validity addressed in the application context? ALIRP are surrogates, measurements taken with the intent to gain insight into something that can be impractical to measure directly or, in principle, impossible to measure, such as a researcher's potential. Impact and influence are common bibliometric measures that have little meaning in and of themselves, but are used to provide insight into the profile of a researcher. With a direct and uncomplicated causal relationship, surrogate measurements are as good as direct measurements. The difficulty arises at the level of the individual, as the relationship between the researcher and the impact, significance or importance of their work is not uncomplicated. Measuring prestige, impact, effect or quality by counting publications and citations is neither a direct nor causal measure, but rather an illusory one. Hence, the need to apply indicators critically and explicitly argues for their validity.

Elkana et al. [14.20], The Acumen Collaboration's portfolio [14.172], and more recently *Belter* [14.173] and *Wilsdon* et al. [14.26], suggest that the way forward is to adopt a balanced approach and discuss a researcher's achievements in terms of spheres of activity, or *domains*. This knowledge is set in a narrative and used to fit appropriate qualitative and quantitative indicators to the situation of the researcher. In the first domain, a manpower and diversity framework for the department in which the researcher is employed is described to set the context and indicate the extent that this environment stimulates the researcher's performance or works against it [14.174]. This includes, among other factors, the size of the department, programmaticity (clearly defined goals and matching strategies, organizational structures, and managerial procedures and abilities that reflect them), the freedom to shift direction and pursue whatever leads appear promising, the hours the researcher must spend teaching, the hours dedicated to research, and perhaps somewhat controversially, the scientific vigor and promise shown by the researcher (documentation of working on weekends and after hours). In the second domain, researchers describe their managerial responsibilities and academic duties, such as reviewing for journals, contributing to internal and external committees, and organizing conferences. The third domain is an explanation of how researchers devote their time to students, what courses they have developed, and supervisory and other responsibilities they have taken on. Fourth, the researchers describe their research work including a description of scientific management (timelines, economy, completion) and the foresight of research, their role in research projects, be it as collaborators, technicians, fund-raisers or project managers, and the publications produced by these projects. *Elkana* et al. [14.20] suggest further fragmentation of this fourth domain, with indicators of how well the individual fits new findings together with previous findings, topic-related indicators, formulation of new questions and solving outstanding questions. Fifth, entrepreneurship and community outreach are described, which can include digital communication of research allowing for the use of web- and altmetrics, taking part in radio broadcasts, invited talks, and holding open house science days for members of the public. Each domain presents the potential for a great variety of indicators and the opportunity to produce rich, contextual information about a researcher's competencies, their innovation and creativity, managerial capabilities, technical skills, methodological strengths, ability to attract funds, social outreach, and economic and pedagogical impact, to name but a few. For each domain, a different palette of indicators is appropriate—including both qualitative and quantitative as well descriptive and evaluative indicators. This evaluation framework puts the role of ALIRP into perspective: note that only one of the aforementioned domains is based on counting scientific publications and citations. ALIRP are thus a small part of a comprehensive program of metrics that work on baseline values of very different value systems, and only together can describe the scholarly and scientific activities of the researcher. This program of indicator application promotes the participation of those affected, and in this way the validity of the chosen metrics is confirmed through collaboration between the evaluator and the evaluand, as recommended in the evaluation principles by *Hicks* et al. [14.25].

14.6 Conclusions

In this chapter, the meaning, methodology and problematic issues associated with ALIRP have been presented. The chapter highlighted the pressing need for monitoring and evaluation of present-day indicator production and improved articulation of the concepts that are operationalized in ALIRP. Constraints and technical problems were exemplified, and the weak follow-up of indicator development was questioned. It was of great value to isolate and deconstruct ALIRP in this chapter, because choosing the appropriate ALIRP is difficult. ALIRP that are valid and suitable for one application may be invalid or of little use in another. If ALRIP are to be used for evaluation, the indicators we choose and how we apply them is important.

Even though no one set of quantitative indicators is in itself sufficient for evaluation or without flaws, that is not to say that such indicators are not necessary or helpful. ALIRP have a role in research evaluation frameworks, as they present a multiplicity of methods, and they increase in value when set in a narrative or with other types of indicators. ALIRP produce numbers, and this numerical information must have context; otherwise, indicators become vulnerable to manipulation and meaningless numerology. The numbers produced by

ALIRP are used as political bricks in a foundation, as a baseline for decision-making. They are considered evidence of a researcher's performance and effect, and as such, their interpretation must not be deduced post hoc. ALIRP are inductive processes that are constantly changing not only with respect to the researcher within the research environment, but also with methods of research administration. Therefore, to be successful, the use of ALIRP must be informed by follow-up research from the bibliometric community, and continued feedback from administrators and from those under evaluation. Successful evaluation with ALIRP is realized in interpersonal contracts between evaluator and evaluand, so trust is essential. It is not our place as bibliometricians to use ALIRP to judge researchers for what they may or may not have done. It is our job to contribute with indicators that can help support meaningful truths in evaluations. ALIRP are only models. They are designed as a numerical representation of something real or something conceptual that is relevant for evaluating a researcher's performance [14.175]. However, as models, they are abstractions, proxies, and they should never be confused with the reality they are trying to model. Thus, if the behavior measured by the ALIRP does not reflect what we see, or if the model does not capture the true aspects of the researcher's performance, it is the model that needs to be fixed—not the researcher.

Lorna Wildgaard is a Data Management Specialist at the Royal Library, researcher services at Copenhagen University. She obtained her PhD in bibliometrics in 2015. Her research areas include bibliometrics andresearch evaluation, medical informatics, research methods, information seeking, communication of information through visualmedia, and the potential of eyetracking in understanding the communication of information. She is passionate about teaching, co-organizer of DST4L2016, and co-founder of a new data science network in Denmark for librarians.

15. Challenges, Approaches and Solutions in Data Integration for Research and Innovation

Maurizio Lenzerini, Cinzia Daraio

In order to be implemented by policy makers, science, technology, and innovation (STI) policies and indicator building need data. Whenever we need data, we need a method for data management, and in the era of big data, a crucial role is played by data integration. Therefore, STI policies and indicator development need data integration. Two main approaches to data integration exist, namely procedural and declarative. In this chapter, we follow the latter approach and focus our attention on the ontology-based data integration (OBDI) paradigm. The main principles of OBDI are:

(i) Leave the data where they are.
(ii) Build a conceptual specification of the domain of interest (ontology), in terms of knowledge structures.
(iii) Map such knowledge structures to concrete data sources.
(iv) Express all services over the abstract representation.
(v) Automatically translate knowledge services to data services.

We introduce the main challenges of data integration for research and innovation (R&I) and show that reasoning over an ontology connected to data may be very helpful for the study of R&I. We also provide examples by using *Sapientia*, an ontology specifically defined for multidimensional research assessment.

15.1 The Role of Data Integration for Research and Innovation

In the last years, the amount of data available for research and innovation (R&I) is growing, in particular thanks to data collections and other initiatives of international and national organizations. While the availability of data stored in current information systems and the processes making use of such data are exponentially increasing, turning this data into information and governing both data and processes are still great challenges in the context of information technology (IT) [15.1–3]. These issues arise from the proliferation of data sources and services both within a single organization and in cooperating environments. Data integration and data interoperability, which have been important in the last decades, are even more important today, in the big data era (see, for instance, two recent books on big data integration [15.4, 5]). Some of the theoretical issues that are relevant for data integration and data interoperability are modeling a data integration application, extract-

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_15

ing and exchanging data from relevant sources, dealing with inconsistent data sources, and processing and reasoning on queries [15.6].

According to *Parent* and *Spaccapietra* [15.7], interoperability is the way in which heterogeneous systems talk to each other and exchange information in a meaningful way. They recognized three stages of interoperability, from the lowest based on no integration, to an intermediary stage in which the system does not guarantee consistency across database boundaries, to a higher stage, which has the objective of developing a global system embracing the existing systems, in order to deliver the desired level of integration of the data sources.

Two main approaches to data integration exist, namely procedural and declarative. In the procedural approach, also called bottom-up approach, for every *information need*, one figures out which data are needed and how they can be accessed, and the goal is to design and realize the corresponding service. On the other hand, in the declarative approach, also called top-down approach, one defines a global representation structure that is valid for the domain of interest underlying the data sources, links this structure to the actual data, lets the user use this structure to specify the *information needs*, and the goal is to automatically extract the right data from the sources. In this chapter, we follow the latter approach and focus our attention to the ontology-based data integration (OBDI) paradigm, which is a recently introduced declarative paradigm for data integration and governance. OBDI uses knowledge representation and reasoning techniques for a new way of integrating and governing data. The principles at the basis of OBDI can be summarized as follows:

(i) Leave the data where they are.
(ii) Build a conceptual specification of the domain of interest, in terms of knowledge structures; such a conceptual representation is called ontology.
(iii) Map such knowledge structures to concrete data sources.
(iv) Express all services over the abstract representation.
(v) Automatically translate knowledge services to data services.

An OBDI system is thus constituted by three main components: the ontology, which represents a conceptual description of the domain; the data sources, where the actual data are, and the mappings that link the data sources to the ontology. Additionally, the ontology is expressed in a form that is both computational and logical. The computational form allows the ontology not only to be understood by humans, but also to be manipulated by the computer, to aid human and machine agents in their performance of tasks within that domain. The logical form is instrumental in enabling additional properties to be inferred by logical reasoning. More generally, reasoning can be used for different goals, such as verification, validation, analysis, synthesis, and exploitation of the latest development in automated reasoning.

The main benefits of the OBDI approach for R&I, as we will see in the examples reported in the following, are related to the opportunity of reasoning over the conceptual structure of the domain (the ontology), reasoning over the mappings of the data sources to the ontology, and reasoning over the data and indicators, for their consistency analysis, their validation, and their data quality assessment (see also the conclusions for an extended summary).

Data integration for R&I is a challenging issue because R&I activities are complex and their assessment is complex too. This is because it requires a systemic approach in which research activities are considered together with education and innovation activities. Moreover, the development of models of indicators or metrics requires a comprehensive framework that includes the specification of the underlying theory, methodology, and data dimensions. Models of metrics are necessary to assess the meaning, validity, and robustness of metrics [15.8]. The complexity of R&I assessment also arises from the consideration of the *implementation* problem according to this three-dimensional framework (see [15.8] for more details).

A workshop organized during the *15th International Conference on Scientometrics and Informetrics* held in Istanbul (Turkey) on 29 June–4 July 2015 discussed the Grand Challenges in Data Integration for Research and Innovation (R&I) Policy. The grand challenges identified were: handling big data, coping with quality issues and anticipating new policy needs.

The analysis of data integration for R&I policy was framed on a groundwork scheme composed by four main areas of intervention and a list of critical issues [15.9]. The main four areas of intervention are:

- Data collection/project initiatives
- Open data, linked data, and platforms for STI
- Monitoring performance evaluation
- Stakeholders, actions, options, costs and sustainability.

The identified critical issues, without being fully comprehensive, are:

- Data quality (considered as *fitness for use* with respect to user needs, see [15.10]) issues – completeness, validity, accuracy, consistency, availability and timeliness

- Comparability problems related to heterogeneous definitions of the variables, data collection practices and databases
- Lack of standardization
- Lack of interoperability
- Lack of modularization
- Problems of classification
- Difficulties in the creation of concordance tables among different classification schemes
- Problems and costs of the extensibility of the system
- Problems and costs of the updating of the system.

Interestingly, many of these issues were already discussed in a Special Session of the ISSI Conference in 1995 in Chicago [15.11]. Moreover, the need for harmonization and standardization of data in R&I is discussed in *Glänzel* and *Willems* [15.12]. It seems that the need for "a clear and unambiguous terminology and specific standards" [15.13, p. 176] is still relevant and timely nowadays.

As described in *Daraio* and *Glänzel* [15.9], the complexity of R&I systems requires a continuous information exchange. This process is due to the communication and interaction process among all actors and agencies involved in the production, processing, and application of knowledge. All data entries, all processing, development, and application of data relevant for research, technology, and innovation have their own rules and standards.

Figure 15.1 shows some elementary rules of interferences expressed in terms of data definition and standard setting in the process of data integration for different purposes, including process monitoring, input–output monitoring, and ex-ante and ex-post evaluation. The application of appropriate standards and data harmonization is crucial to achieve the interoperability of heterogeneous sources of data.

The chapter unfolds as follows. The next section presents the problem of data integration and data governance in a general way. Section 3 describes a formal framework for ontology-based data integration. Section 4 presents the ontology *Sapientia* and the OBDI system developed for multidimensional research assessment. Section 5 presents some illustrative examples of reasoning over *Sapientia*, while Section 6 summarizes the main points and concludes the chapter.

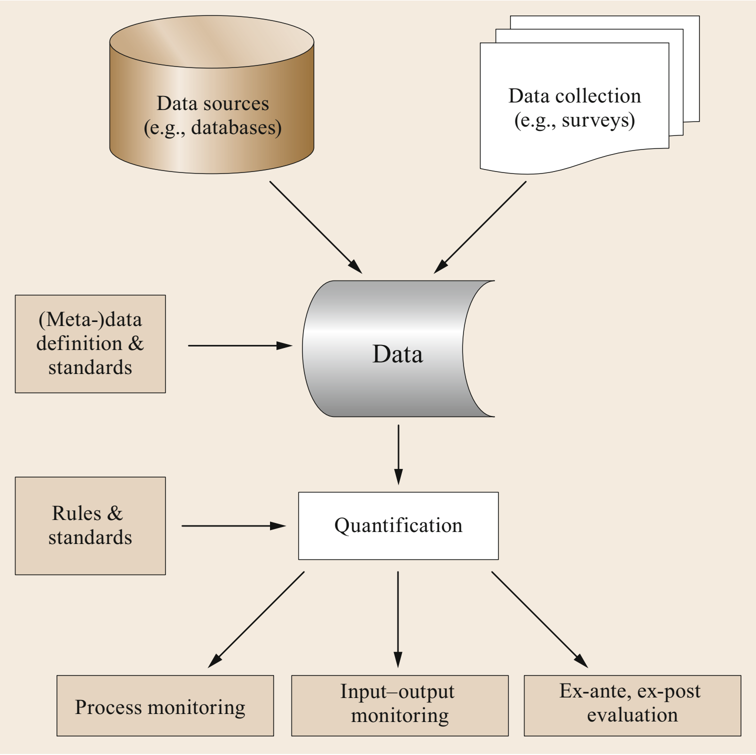

Fig. 15.1 Data integration in use for different purposes with interference points for standardization (after *Daraio* and *Glänzel* [15.9])

15.2 The Problem of Data Integration and Data Governance

Big data management and analysis form a key technology for the competitive advantage of today's enterprises and for shaping the future data-driven society. However, after years of focus on technologies for big data storing and processing, many observers are pointing out that making sense of big data cannot be done without suitable tools for conceptualizing, repairing, and integrating data (http://www.dbta.com/). A common opinion in technology observers is that big data are ready for analysis; one should simply access, select, and load data from big data sources, and magically gain insight, discover patterns, and extract useful knowledge. As pointed out in [15.14], this is not the case; loading a big data platform with quality data with enough structure to deliver value is a lot of work. Thus, it is not surprising that data scientists spend a comparatively large amount of time in the data preparation phase of a project. Whether you call it data wrangling, data preparation, or data integration, it is estimated that 50–80% of a data scientists' time is spent on preparing data for analysis. If we consider that in any IT organization, data governance is also essential for tasks other than data analytics, we can conclude that the challenge of identifying, collecting, retaining, and providing access to all relevant data for the business at an acceptable cost, is huge. If we specialize the above observation to the domain of interest in this chapter, namely R&I, we can state that one of the most challenging tasks for carrying out quantitative studies in the realm of R&I is to identify, collect, integrate, organize, govern and access all relevant data.

Although data integration is one of the oldest problems in data management, the above observations show that it is a major challenge today. As we said in Sect. 15.1, in principle, there are two main approaches to this problem: procedural and declarative. In the procedural approach, sometimes called bottom-up approach, whenever an information need arises that requires accessing the integrated data, a specific program is coded, so as its execution produces the required information. In some sense, with this approach, integration is achieved on a query-by-query basis. In the declarative approach (top-down), one defines a priori an integration database structure, and in order to satisfy an information need one can simply pose a query over such a structure (Fig. 15.2 illustrates these notions relative to R&I). So, with this approach, integration is achieved independently from a specific query (or a specific set of queries).

In this chapter, we focus on the declarative approach and we refer to the typical architecture underlying this approach, which is based on three components [15.6, 16]: the global schema, the sources, and the mapping between the two. The sources represent the repositories

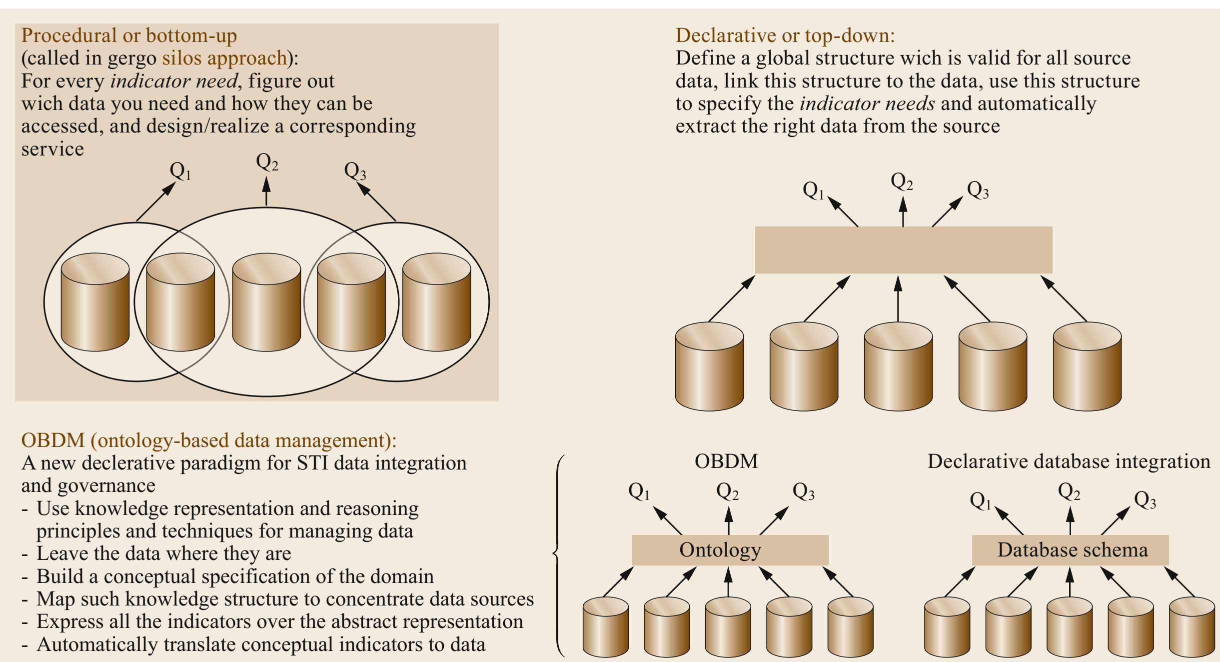

Fig. 15.2 Approaches to data integration for STI (after [15.15])

where the data are; the global schema, also called mediated schema, represents the unified structure presented to the clients; the mapping relates the source data with the global schema. The most important service provided by the integration system is query answering, i. e., computing the answer to a query posed in terms of the global schema. Such computation involves accessing the sources, collecting the relevant data, and packaging such data in the final answer.

Formal, declarative approaches to data integration started in the 1990s [15.6, 16–18]. Since then, many aspects of the general problems have been the subject of detailed investigations both in academia and in industry.

Among them, in this chapter, we want to focus on the idea of using semantics for making data integration more powerful. As illustrated in [15.14], using semantics here means conceiving data integration systems where the semantics of data is explicitly specified and is taken into account to devise all the functionalities of the system. Over the past two decades, this idea has become increasingly crucial to a wide variety of information-processing applications and has received much attention in the artificial intelligence, database, web, and data mining communities [15.19].

As we said before, we concentrate on a specific paradigm for semantic data integration, OBDI. This new paradigm was introduced about a decade ago, as a new way for modeling and interacting with a data integration system [15.20–23]. According to such paradigm, the client of the information system is freed from being aware of how data and processes are structured in concrete resources (databases, software programs, services, etc.) and interacts with the system by expressing her queries and goals in terms of a conceptual representation of the domain of interest, called ontology. An OBDI system is an information management system maintained and used by a given organization (or a community of users), whose architecture has the same structure as a typical data integration system, with the following components: an ontology, a set of data sources, and the mapping between the two. The ontology approach as outlined in the following paragraphs was originally published in [15.24].

The ontology is a conceptual, formal description of the domain of interest to the organization, expressed in terms of relevant concepts, attributes of concepts, relationships between concepts, and logical assertions formally describing the domain knowledge. The data sources are the repositories accessible by the organization where data concerning the domain are stored. In the general case, such repositories are numerous and heterogeneous, each one managed and maintained independently from the others. It may be even the case that some of the data sources are not under the control of the organization and can be accessed remotely, e. g., via the web. The mapping is a precise specification of the correspondence between the data contained in the data sources and the elements of the ontology, where by element we here mean concepts, attributes, and relationships. The main purpose of an OBDI system is to allow information consumers to query the data using the elements in the ontology as predicates. In the special case where the organization manages a single data source, the term *ontology-based data access* (OBDA) system is used instead of the OBDI system.

The notions of OBDA and OBDI were introduced in [15.20–22] and originated from several disciplines, in particular, information integration, knowledge representation and reasoning, and incomplete and deductive databases. OBDI can be seen as a sophisticated form of information integration, where the usual global schema is replaced by an ontology describing the domain of interest. The main difference between OBDI and traditional data integration is that in the OBDI approach, the integrated view that the system provides to information consumers is not merely a data structure accommodating the various data at the sources, but a semantically rich description of the relevant concepts in the domain of interest, as well as the relationships between such concepts. In general, such a description is formally defined in logic and enriches, generalizes, and relates the vocabularies of different data sources, thus providing a *common ground* for the domain knowledge. Also, the distinction between the ontology and the data sources reflects the separation between the conceptual level, the one presented to the client, and the logical/physical level of the information system, the one stored in the sources, with the mapping acting as the reconciling structure between the two levels. Notably, this separation is also instrumental for recovering the possibility of access to legacy systems, which are often excluded from the possibility of being used in interesting analyses carried out by the organization on its own data.

From all the above observations one can easily see that the central notion of OBDI is the ontology, and, therefore, reasoning over the ontology is at the basis of all the tasks that an OBDI system has to carry out. By reasoning, we mean the ability to derive all the implicit knowledge on the domain that is logically implied by the explicitly asserted facts in the ontology. In particular, the axioms of the ontology allow one to derive new facts from the source data, and these inferred facts greatly influence the set of answers that the system should compute during query processing. In the last decades, research on ontology languages and ontology inferencing has been very active in the area of knowledge representation and reasoning. Description logics (DLs) [15.25] are widely recognized as appropriate logics for expressing ontologies and are at the basis of the W3C standard ontology language OWL. These logics permit the specification of a domain by providing the definition of classes and by structuring the knowledge about the classes using a rich set of logical operators. They are decidable fragments of mathematical logic, resulting from extensive investigations on the trade-off between expressive power of knowledge representation languages and computational complexity of reasoning tasks. Indeed, the constructs appearing in the DLs used in OBDI have been carefully chosen taking into account such a trade-off.

As we said before, the axioms in the ontology can be seen as semantic rules that are used to complete the knowledge given by the raw facts determined by the data in the sources. In this sense, the source data of an OBDI system can be seen as an incomplete database, and query answering can be seen as the process of computing the answers logically deriving from the combination of such incomplete knowledge and the ontology axioms. Therefore, at least conceptually, there is a connection between OBDI and the two areas of incomplete information [15.26] and deductive databases [15.27]. The new aspect of OBDI is related to the kind of incomplete knowledge represented in the ontology, which differs both from the formalisms typically used in databases under incomplete information (e. g., Codd tables) and from the rules expressible in deductive database languages (e. g., logic programming rules).

Once we are able to reason about the ontology, we can take advantage of the OBDI system in many interesting and relevant ways. Some of these are referred to below:

1. As already noticed, we can take into account all inferences over the ontology in processing the queries. In other words, the quality of the query answering service is potentially much higher than in the traditional setting, because all the knowledge about the domain represented by the ontology is exploited in computing the answers.
2. We can carry out the task of data source profiling again by relying on the knowledge about the domain. This allows the data designer to describe, maintain, and document the content of the various data sources in a much richer way than in traditional systems, because (s)he can now specify the characteristics of the sources in terms of the vocabulary and the metadata sanctioned by the ontology.
3. We can check and assess the quality of the data sources by comparing their content and their structure with the ontology, and, therefore, singling out inconsistencies, incompleteness, and inaccuracies of the data sources with respect to the domain knowledge.
4. We can set up new interesting services realized through the integration system. One notable example is open data publishing. The presence of the ontology makes it simple and effective to annotate the published data with the concepts and the relationships that are relevant in the domain of interest, so as to provide a conceptual description and a meaningful context of the published datasets.

15.3 Formal Framework for OBDI

The previous section introduced the notion of OBDI as a new paradigm for data integration. In this section, we provide the fundamental elements for a formalization of OBDI, illustrating the form of an OBDI specification, and presenting the semantics of an OBDI system. We closely follow the exposition in [15.14]. In the formal framework, we assume that the OBDI system can access the data sources through a single SQL (Structured Query Language) interface, which presents the various data as if they were in a unique database. In other words, we talk about a single data source, which is a database obtained as an abstraction for a variety of (possibly heterogeneous) data sources. This is not a real limitation, because in practice, such a database might be obtained through the use of an off-the-shelf data federation tool, which presents the sources through a schema of a single database as a wrapping of the source schemas expressed in terms of a unique format.

Given this assumption, an *OBDI specification* I is as a triple $\langle O, S, M \rangle$, where O is an ontology, S is a relational schema, called source schema, and M is a mapping from S to O. As already stated, O represents the general knowledge about the domain (i. e., relative to classes and relationships, rather than to specific objects that are instances of concepts), expressed in some logical language. Typically, O is a lightweight DL TBox [15.20], i. e., it is expressed in a language ensuring both semantic richness and efficiency of reasoning, and in particular of query answering. The mapping

Fig. 15.4 Relational tables of the source schema of the example

M is a set of mapping assertions, each one relating a query over the source schema to a query over the ontology.

Example. We now present an example of an OBDI system extracted from a real integration experiment involving data from different sources in use at Sapienza University of Rome. The ontology is defined by means of the OWL 2 assertions shown in Fig. 15.3.

It is, in fact, a portion of the Lehigh University Benchmark (LUBM) ontology, an ontology that is commonly used for testing ontology-based applications in the Semantic Web. In particular, the global schema contains the classes *Person*, *Student*, *Professor*, *Organization*, *College*, *Dean*, and *Course*, and the object properties *headOf*, *worksFor*, *takesCourse*, and *advisor*. For the sake of simplicity, we do not report in this example assertions involving data properties (i. e., attributes), but they are obviously allowed in our framework. The source schema is a set of relational tables resulting from the federation of several data sources of the School of Engineering of the Sapienza University of Rome, and the portion that we consider in this example is constituted by the relational tables shown in Fig. 15.4.

As for the mapping, referring to the global and source schemas presented above, we provide some sample mapping assertions in Fig. 15.5.

The mapping assertion M_1 specifies that the tuples from the source table *students* provide the information needed to build the instances of the class *Student*. In particular, the SQL query in the body of M_1 retrieves the code for students whose date of birth is before 1990; each such code is then used to build the object identifier for the student by means of the unary function symbol "st". Similarly, the mapping M_2 extracts data from the table *degree*, containing information on the student's Master's degree, such as the year of the degree, the title of the thesis, and the code of the advisor. The tuples retrieved by the query in the body of M_2, involving only degree titles earned after 2000, are used to build instances for the object property (relationship) advisor; the instances are constructed by means of the function symbols "pr" and "st". Finally, the mapping assertion M_3 contributes to the construction of the domain of the advisor, taking from the source table exam only codes of students who have passed the exam of courses that were not assigned to any professor before 1990.

```
M1: SELECT ID
    FROM students
    WHERE DOB <= '1990/01/01' }                      →  SELECT ?st(ID)
                                                        {?st(ID) rdf:type Student }
M2: SELECT STUD_ID, PROF_ID
    FROM degree  WHERE YEAR > 2000 }                 →  SELECT ?st(STUD_ID) ?pr(PROF_ID)
                                                        {?st(STUD_ID) advisor ?pr(PROF_ID)}
M3: SELECT STUD_ID
    FROM exam
    WHERE course CODE NOT IN
      (SELECT COURSE_CODE
       FROM assignment WHERE YEAR < 1990) }          →  SELECT ?st(STUD_ID)
                                                        { ?st(STUD_ID) advisor ?X }
```

Fig. 15.5 Mapping assertions of the example

An *OBDI system* is a pair (I, D), where I is an OBDI specification and D is a database for the source schema S, called source database for I. The semantics of (I, D) is given in terms of the logical interpretations that are models of O (i. e., satisfy all axioms of O, and satisfy M with respect to D). The notion of mapping satisfaction depends on the semantic interpretation adopted on mapping assertions. Commonly, such assertions are assumed to be sound, which intuitively means that the results returned by the source queries occurring in the mapping are a subset of the data that instantiate the ontology. The set of models of I with respect to D is denoted with ModD(I).

As we said before, in OBDI systems, the main service of interest is query answering, i. e., computing the answers to user queries, which are queries posed over the ontology. Such service amounts to return the so-called certain answers, i. e., the tuples that satisfy the user query in all the interpretations in ModD(I). Query answering in OBDI is thus a form of reasoning under incomplete information and is much more challenging than classical query evaluation over a database instance.

It is well known that carrying out inference tasks, such as answering queries in OBDI systems, may be computationally expensive. From the computational perspective, query answering depends on:

1. The language used for the ontology
2. The language used for user queries, and
3. The language used to specify the queries in the mapping.

In the following, we consider a particular instantiation of the OBDI framework, in which we choose each such language in such a way that query answering is guaranteed to be tractable with respect to the size of the data.

From the general framework we obtain a computationally tractable one by choosing appropriate languages as follows:

- The ontology language is *DL-Lite*$_{\mathrm{A}}$ or its subset *DL-Lite*$_{\mathrm{R}}$ [15.22].
- The mapping language follows the *global-as-view* (GAV) approach [15.6].
- The user queries are unions of conjunctive queries [15.16].

In the following, we discuss each of the above choices.

15.3.1 Ontology Language

DL-Lite$_{\mathrm{A}}$ [15.22] is essentially the maximally expressive member of the *DL-Lite* family of lightweight DLs [15.20]. In particular, its subset *DL-Lite*$_{\mathrm{R}}$ has been adopted as the basis of the OWL 2 QL profile of the W3C standard OWL. As usual in DLs, *DL-Lite*$_{\mathrm{A}}$ allows for representing the domain of interest in terms of *concepts*, denoting sets of objects, and *roles*, denoting binary relations between objects. In fact, *DL-Lite*$_{\mathrm{A}}$ also considers *attributes*, which denote binary relations between objects and values (such as strings or integers), but for simplicity, we do not consider them in this chapter. From the expressiveness point of view, *DL-Lite*$_{\mathrm{A}}$ is able to capture essentially all the features of entity-relationship diagrams and UML (Unified Modeling Language) class diagrams, except for completeness of hierarchies. In particular, it allows for specifying ISA ("is a") and disjointness between either concepts or roles, mandatory participations of concepts into roles, and the typing of roles. Formally, a *DL-Lite*$_{\mathrm{A}}$ TBox is a set of assertions obeying the syntax

$B_1 \sqsubseteq B_2$	(positive concept inclusion)
$B_1 \sqsubseteq \neg B_2$	(negative concept inclusion)
$R_1 \sqsubseteq R_2$	(positive role inclusions)
$R_1 \sqsubseteq \neg R_2$	(negative role inclusions)
(funct R)	(role functionalities)

where:

- B_1 and B_2 are basic concepts, i. e., expressions of the form A, $\exists P$, or $\exists P^-$.
- R, R_1, and R_2 are a basic roles, i. e., expressions of the form P, or P^-.
- A and P denote an *atomic concept* and an *atomic role*, respectively, i. e., a unary and binary predicate from the ontology alphabet, respectively.
- P^- is the *inverse* of an atomic role P, i. e., the role obtained by switching the first and second components of P.
- $\exists P$ (or $\exists P^-$), called existential unqualified restriction, denotes the projection of the role P on its first (or second) component.
- $\neg B_2$ (or $\neg R_2$) denotes the negation of a basic concept (or role).

Assertions of the form (funct R) are called role functionalities and specify that an atomic role, or its inverse, is functional. *DL-Lite*$_A$ poses some limitations on the way in which positive role inclusions and role functionalities interact. More precisely, in a *DL-Lite*$_A$ TBox an atomic role that is either functional or inverse functional cannot be specialized, i. e., if (funct P) or (funct P^-) are in the TBox, no inclusion of the form $R \sqsubseteq P$ or $R \sqsubseteq P^-$ can occur in the TBox. *DL-Lite*$_R$ is the subset of *DL-Lite*$_A$ obtained by removing role functionalities altogether.

A *DL-Lite*$_A$ *interpretation* $J = (\Delta^J, \cdot^J)$ consists of a non-empty set constituting the *interpretation domain* Δ^J and an *interpretation function* $\cdot^J$ that assigns to each atomic concept A a subset A^J of Δ^J, and to each atomic role P a binary relation P^J over Δ^J. In particular, for the constructs of *DL-Lite*$_A$, we have (symbol \ is used to denote set difference):

- $A^J \subseteq \Delta^J$
- $P^J \subseteq \Delta^J \times \Delta^J$
- $(P^-)^J = \{(o_2, o_1) | (o_1, o_2) \in P^J\}$
- $(\exists R)^J = \{o | \exists o'.(o, o') \in R^J\}$
- $(\neg B)^J = \Delta^J \setminus B^J$
- $(\neg R)^J = (\Delta^J \times \Delta^J) \setminus R^J$

Let C be either a basic concept B or its negation $\neg B$. An interpretation J satisfies a concept inclusion $B \sqsubseteq C$ if $B^J \subseteq C^J$, and similarly for role inclusions. Also, J satisfies a role functionality (funct R) if the binary relation R^J is a function, i. e., $(o, o_1) \in R^J$ and $(o, o_2) \in R^J$ implies $o_1 = o_2$.

15.3.2 Mapping Language

The mapping language in the tractable framework allows mapping assertions of the following the forms:

- $\varphi(x) \rightarrow A(f(x))$
- $\varphi(x) \rightarrow P(f_1(x_1), f_2(x_2))$

where $\varphi(x)$ is a domain-independent first-order query (i. e., an SQL query) over S, with free variables x, A and P are as before variables in x_1 and x_2 also occur in x, and f, possibly with subscripts, is a function.

Intuitively, the mapping assertion of the first form, called the concept mapping assertion, specifies that individuals that are instances of the atomic concept A are constructed through the use of the function f from the tuples retrieved by the query $\varphi(x)$. Similarly for the mapping assertion of the second form called the role mapping assertion. Each assertion is of type GAV [15.6], i. e., it associates a view over the source (represented by $\varphi(x)$) to an element of ontology. However, differently from traditional GAV mappings, the use of functions is crucial here, since we are considering the typical scenario in which data sources do not store the identifiers of the individuals that instantiate the ontology, but only maintain values. Thus, functions are used to address the semantic mismatch existing between the extensional level of S and O [15.22].

Formally, we say that an interpretation J satisfies a mapping assertion $\varphi(x) \rightarrow A(f(x))$ with respect to a source database D, if for each tuple of constants t in the evaluation of $\varphi(x)$ on D, $(f(t))^J \in A^J$, where $(f(t))^J \in \Delta^J$ is the interpretation of f(t) in J that is, f(t) acts simply as a constant denoting an object. Satisfaction of assertions of the form $\varphi P(f_1(x_1), f_2(x_2))$ is defined analogously. We also point out that *DL-Lite*$_A$ adopts the unique name assumption (UNA), that is, different constants denote different objects, and thus different ground terms of the form f(t) are interpreted with different elements in Δ^J.

15.3.3 User Queries

In our tractable framework for OBDI, user queries are conjunctive queries (CQs) [15.16] or unions thereof. With q(x), we denote a CQ with free variables x. A Boolean CQ is a CQ without free variables. Given an OBDI system (I,D) and a Boolean CQ q over I, i. e., over the TBox of I, we say that q is *entailed by* (I, D), denoted with $(I, D) \models q$, if q evaluates to true in every interpretation $J \in \mathrm{Mod}_D(I)$. When the user query $q(x)$ is non-Boolean, we denote with $\mathrm{cert}_D(q(x), I)$ the *certain answers* to q with respect to (I, D), i. e., the set of tuples t such that $(I, D) \models q(t)$, where q(t) is the Boolean CQ obtained from q(x) by substituting x with t.

15.3.4 Query Answering

Although query answering in the general framework may soon become intractable or even undecidable, depending on the expressive power of the various languages involved, the tractable framework has been designed to ensure tractability of query answering. We end this section by illustrating the basic idea to achieve tractability.

In the tractable OBDI framework previously described, one can think of a simple chase procedure [15.28] for query answering, which first retrieves an initial set of concept and role instances from the data source through the GAV mapping, and then, using the ontology axioms, *expands* such a set of instances deriving and materializing all the logically entailed concept and role assertions; finally, queries can be evaluated on such an expanded set of instances. Unfortunately, in $\textit{DL-Lite}_A$ (and in $\textit{DL-Lite}_R$ already) the instance materialization step of the above technique is not feasible in general, because the set of entailed instance assertions starting from even very simple OBDA specifications and small data sources may be infinite.

As an alternative to the above materialization strategy, most of the approaches to query answering in OBDI are based on query rewriting, where the aim is to first compute a query q' representing a reformulation of a query q with respect to an OBDI specification I, and then evaluate q' over the source database. Actually, the above described OBDI framework allows for modularizing query rewriting. Indeed, the current techniques for OBDI consist of two phases, namely the phase of *query rewriting with respect to the ontology*, and the phase of *query rewriting with respect to the mapping*:

1. In the first phase, the initial query q is rewritten with respect to the ontology, producing a new query q_1, still over the ontology signature; intuitively, q_1 *encodes* the knowledge expressed by the ontology that is relevant for answering the query q.
2. In the second phase, the query q_1 is rewritten with respect to the mapping M, thus obtaining a query q_2 to be evaluated over the source data. Thus, the mapping assertions are used for reformulating the query into a new one expressed over the source schema signature.

Thus, following the above method, computing the certain answers of a query Q over I is reduced to a simple evaluation of a suitable query over the source database, thus relying on the technology of relational databases, including the possibility of adopting well-established query optimization strategies.

15.4 *Sapientia* and OBDI for Multidimensional Research Assessment

Sapientia is the ontology of multidimensional research assessment developed by an interdisciplinary group of scholars funded by Sapienza University of Rome in the framework of its Research Awards (two main research projects). It models all the activities relevant for the evaluation of research and for assessing its impacts. For impact, in a broad sense, we mean any effect, change or benefit, to the economy, society, culture, public policy or services, health, the environment, or quality of life, beyond academia.

The first version of *Sapientia* was closed on the 22 December 2014. It consisted of 14 modules of around 350 concepts, roles and attributes (Fig. 15.6). Figure 15.7 illustrates the organization of the main components of an OBDI system including *Sapientia*.

15.4.1 *Sapientia*'s Philosophy and its Main Principles

Sapientia's mission is being comprehensive and try to model everything related to the evaluation of research and its impacts. As we stated in Sect. 15.1, the evaluation of research, is a complex activity. It requires a systematic view and has its base on the interplay between theory, methodology, and data. To accomplish its mission, we designed *Sapientia* to be at the heart of a flexible knowledge infrastructure ("robust networks of people, artifacts, and institutions that generate, share, and maintain specific knowledge about the human and natural worlds" [15.29]) for the multidimensional assessment of research and its impacts. By flexible we mean a knowledge infrastructure characterized by being an open and evolving infrastructure.

The principles followed in the design and development of *Sapientia* are the following:

- We started with a top-down modeling approach, with subsequent bottom-up refinements and cyclical improvements. We describe and model the domain from a conceptual point of view, without considering the existing data and its specificity.

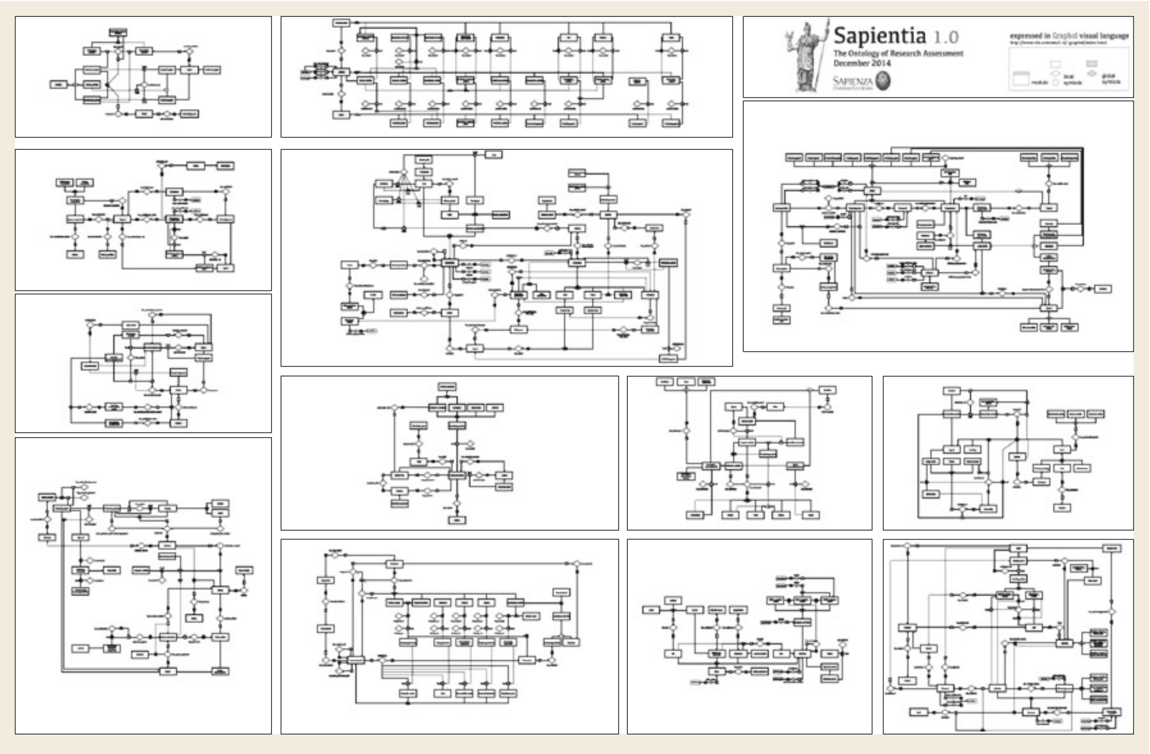

Fig. 15.6 An illustration of *Sapientia* (the ontology of multidimensional research assessment) 1.0

- We left outside the scope of the ontological commitment all the methodological consideration about choice of the methods for the assessment of research. This is because we want that our ontology being the common ground for experimenting and testing different methods and approaches.
- We left outside the scope of the ontological commitment the implementation problem and the consequences of evaluation. Again, this is for keeping our ontology as a common ground, a shared language or vocabulary, to build a cooperative and open discussion about evaluation approaches considering the interaction of different stakeholders with different points of view and interests.
- We pursued a modeling approach based on processes, which are conceived as collections of activities. A process is composed by inputs and outputs.
- Individuals and activities are the main pillars of the ontology.
- We followed a modeling approach based on a modularization of the system. Our ontology is organized in modules. As we shall see later, we have two kind of modules: functional modules and structural modules. By functional modules we mean modules that model the main agents and activities of our domain (namely Agents, Activities, R&D, Publishing, Education, Resources and Review). By structural modules, we mean those modules that represent the constituent elements of the ontology to ensure its long lasting and general-purpose functionality (namely, Taxonomies, Space, Representations, and Time).

We consider the building of descriptive, interpretative, and policy models of our domain as a distinct step with respect to the building of the domain ontology. In the following part of this section, we will reproduce the findings that we previously published in *Daraio*, *Lenzerini*, et al. [15.24]. However, the ontology will intermediate the use of data in the modeling step and should be rich enough to allow the analyst the freedom to define any model she considers useful to pursue her analytic goal.

Obviously, the actual availability of relevant data will constrain both the mapping of data sources on the ontology and the actual computation of model variables and indicators of the conceptual model. However, the analyst should not refrain from proposing the models that she considers the best suited for her purposes and to express, using the ontology, the quality requirements, the logical, and the functional specification for her ideal model variables and indicators. This approach has many merits, in particular:

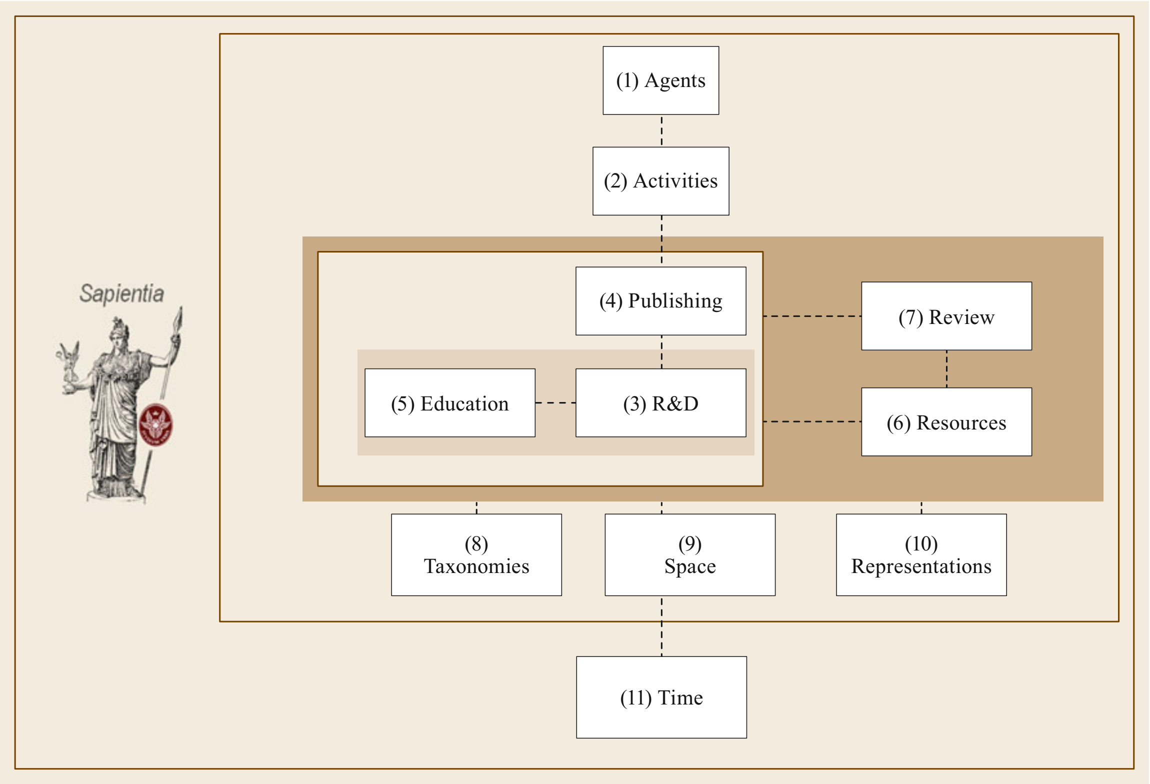

Fig. 15.7 Modules of Sapientia 3.0

- It allows the use of a common and stable ontology as a platform for different models.
- It addresses the efforts to enrich data sources, and verify their quality.
- It makes transparent and traceable the process of approximation of variables and models when the available data are less than ideal; it makes use of every source at the best level of aggregation, usually the atomic one.

More generally, this approach is consistent with the effort of avoiding "the harm caused by the blind symbolism that generally characterizes a hasty mathematization" put forward by *Georgescu-Roegen* in his seminal work on production models and on methods in economic science [15.30–32]. In fact, one can verify the logical consistency of the ontology and compute answers to unambiguous logical queries.

Moreover, the proposed ontology allows us to follow the Georgescu-Roegen approach also in the use of the concept of process. We can analyze the knowledge production activities at an atomic level, considering their time dimension and such funds as the cumulated results of previous research activities, both those available in relevant publications and those embodied in the authors' competences and potential, the infrastructure assets, and the time devoted by the group of authors to current research projects. Similarly, we can analyze the output of teaching activities, considering the joint effect of funds such as the competence of teachers, the skills and initial education of students, and educational infrastructures and resources. Thirdly, service activities of research and teaching institutions provide infrastructural and knowledge assets that act as a fund in the assessment of the impact of those institutions on the innovation of the economic system. The perimeter of our domain should allow us to consider the different channels of transmission of that impact: mobility of researchers, career of alumni, applied research contracts, joint use of infrastructures, and so on. In this context, different theories and models of the system of knowledge production could be developed and tested.

15.4.2 Requested Investment and Modularity of the System

In an OBDI approach, the modular design and its implementation requires an initial *large scale investment* into the formal definition of the main relevant concepts (and relationships among them) of the domain of interest but is facilitated by suitable graphical tools (which we will see below) that allow an easy modularization and updates of the relevant domain. The following paragraph is taken from *Daraio*, *Lenzerini*, et al. [15.33].

Following a real options approach in investment theory [15.34], we can conceive a data platform as an asset allowing repeated use. In this context, investment costs are made by front-up costs for the platform, maintenance costs, and recurring costs for projects. The revenues instead are the gains from better decisions in policy making (e.g., the possible use for performance-based allocation of public resources, the possible use for strategic priorities in S&T, or to set up public subsidies to firms for industrial R&D). A real options analysis in this context should follow a modular engineering design perspective [15.35] in which a quantitative model to describe the economic forces that push a design towards modularization and the consequences of modularity on the business environment are described. In this context, value creation is the goal of the modularization process, and real options theory offers a natural framework to evaluate the modularization of the design of the system.

There are also criteria to assess the decomposition of systems into modules. In modular design, the main criteria to assess the decomposition of systems into modules are those of cohesion and coupling. The principal rule to assess the quality of the modularization of a system, attributed to *Parnas* [15.36] even if the paper does not contain the terms cohesion and coupling, is of *high cohesion within modules and loose coupling between modules*.

Cohesion refers to the degree to which the elements of a module belong together and, hence, it is a measure of how strongly related each piece of a module is. Modules with high cohesion tend to be preferable, because high cohesion is associated with several desirable properties including robustness, reliability, reusability, and understandability.

Coupling is the manner and degree of interdependence between modules; a measure of how closely connected two modules are. Low coupling is often a sign of a well-structured system and a good design, and when combined with high cohesion, supports the general goals of high readability and maintainability. Modularity is a property of quasi-decomposition of hierarchical systems, based on the minimization of the interdependence of subsystems [15.37].

The modification of subsystems does not require the re-design of the entire system. Making the design of products modular requires a large front up investment in conceptual design. The standardization of interfaces is necessary. However, the design of successive versions of the product and/or re-design becomes cheaper.

The current version of *Sapientia*, *Sapientia* 3.0, includes around 600 concepts, roles, and attributes and is organized in 11 modules (Fig. 15.7). Another module on skills is going to be included. Its aim is to model all the competences involved in the assessment of research and its impacts.

The *central* modules of *Sapientia* are Agents (no.1) and their Activities (no.2), which are expanded into the five *main* process-based modules: 3 R&D, 4 Publishing (ancillary module of R&D), 5 Education, 6 Resources, 7 Review. These are connected to the four *auxiliary* modules (also defined as *structural* modules): 8 Taxonomies, 9 Space, 10 Time and 11 Representations, which support the modeling of the main modules from 1 to 7.

The module Agents (1) models the subjects involved in the world of research, carrying out the activities described in module 2 (Activities). Activities models, overall, the relevant actions carried out by agents and their products. Module 3 (R&D) models Research and Development (R&D) activities, those that allow the scientific community to advance the state of the art of knowledge. The module Publishing (4) models the publishing activities, those that allow people to communicate (and disseminate) the results of the R&D activities carried out. Education (5) models the educational activities, those that allow people to improve their knowledge and to acknowledge the improvements made by other people. Resources (6) models the resources and the activities carried out for their management. Review (7) models the reviewing activities for assessing the R&D activities and their results. Taxonomies (8) models the nomenclatures that classify the several elements of the domain. Space (9) models the regions of space where agents and activities are located and their roles. Representations (10) models the representations of the objects of the domain according to a Source. A data source is a possible source, but also other sources, such as a theory may be a source. Time (11) models the depth of time of the domain and cut across all the other modules.

15.5 Reasoning over *Sapientia*: Some Illustrative Examples

Sapientia, the ontology introduced in the previous section, is an important element of an OBDI system introduced in the previous sections (Fig. 15.8).

An OBDI system allows us to reason on each component of the system, i. e., on the ontology, on the data sources, and on the mappings. In the following, we show some examples.

15.5.1 Reasoning over the Ontology

In this section, we illustrate an example of reasoning over the ontology *Sapientia* analyzing some extracts from the Module 3 (R&D). The R&D module aims at modeling the research activities of researchers and their products. The central concept of the module is the R&D activity that is linked to two important concepts, i. e., research product and research outcome.

In *Sapientia*, any research activity has:

- Its direct output (has_output), available without the contributions of any other activity.
- Its outcome (has_outcome): an output of any activity (not necessarily a research activity) participating a value chain where the research activity has an enabling role (i. e., without the research activity, that specific output would not be generated).

In *Sapientia*, a Publication aims at reporting empirical or theoretical work and describes the results obtained in some knowledge field. Publications are described in the Module Publishing (4), which concerns the activity that allows people knowing the results of research. The output of a publishing activity is a publication, which is a way to represent a content through some media. There are four kinds of contents in *Sapientia*: paper-like content (a content structured as for being published paper); book-like content (a content structured as for being published as monographs or edited chapters), patent-like content (a content structured as for being published as patent applications) and Project-like content (a content structured as being suitable to apply for a call).

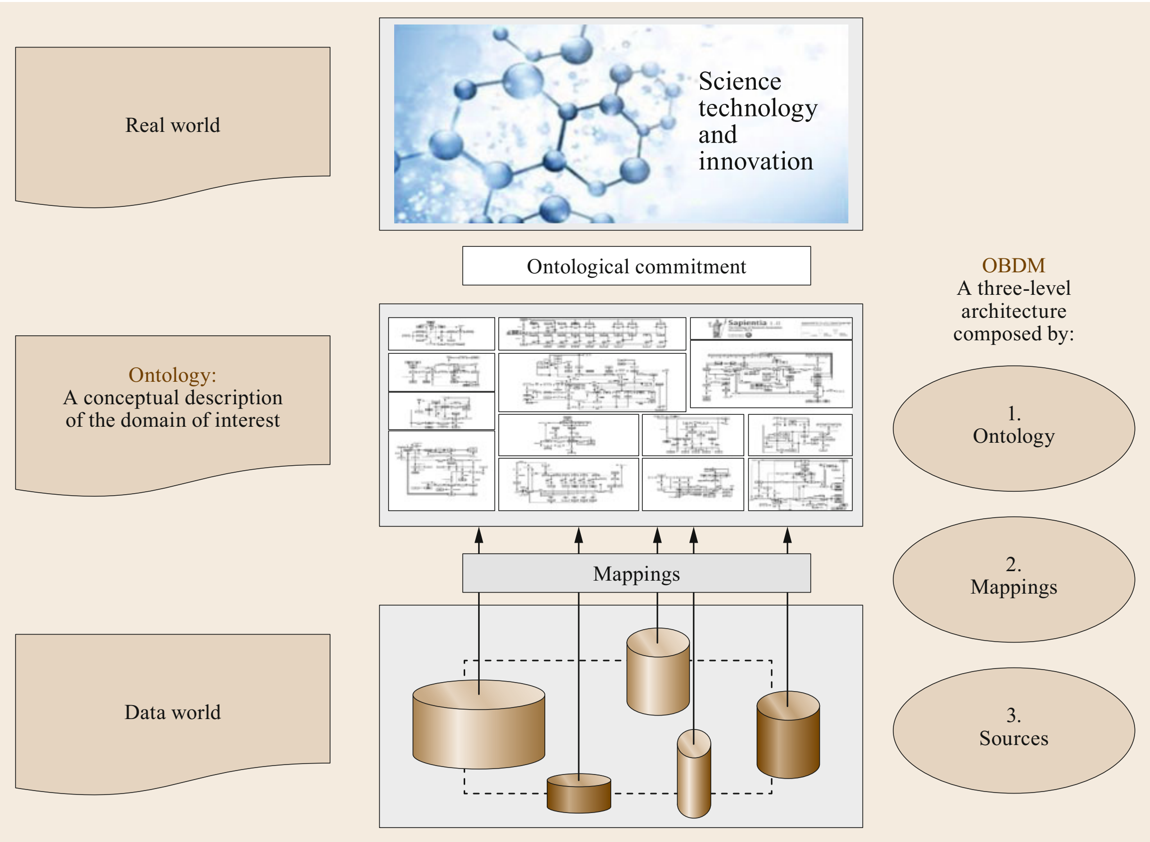

Fig. 15.8 Key components of an OBDI information system (after [15.15])

We point out that publication of research work is not considered an output of that research, because the output of the research work is the content of the publication. Publications, in fact, are the main concept of another module, the Module 4 (Publishing).

There are three kinds of agents involved in a publication:

- *Author*: An author of a publication is an agent that has contributed in writing the content of the publication (for instance, reporting the results of some research (s)he has carried out).
- *Editor*: An editor of a complex publication (where contributions of different authors need to be verified, harmonized, and combined) is an agent that oversees and coordinates the publication.
- *Publisher*: A publisher of a publication is the agent that provides some media to deliver and display a publication.

In *Sapientia* there are three kinds of publications:

- *Atomic publications*: A publication resulting from a unique, indivisible act of writing by one or more authors.
- *Collections*: A publication disseminating a group of atomic publications in a unique impulse, during a limited and short period of time.
- *Series*: Each disseminating a group of atomic publications during a long and (perhaps) unlimited period of time.

In *Sapientia*, a patent application is a possible publication, and is the output of an applied research. Notice that a patent is different from the other types of atomic publication; it is a right granted by a state which may concern a research output, not an output itself. A patent application follows its own path within the three levels of publications:

- It is an atomic publication itself.
- It is published in an issue (a collection).
- That issue appears in an intellectual property law journal (a series).

Note that there are no constraints between contents and publications where they can be published (for example, a patent_like_content can be placed in a part of a paper).

In Figs. 15.9 and 15.10, we show an example extracted from the Module R&D of *Sapientia* 3.0. Figures 15.9 and 15.10 display the path from Researcher to Publication in *Sapientia*. Figure 15.11 reproduces a legend to interpret the symbols used in the previous Figs. 15.9 and 15.10. Table 15.1 describes the main concepts and relations showed in Figs. 15.9 and 15.10. The language Graphol (http://www.dis.uniroma1.it/~graphol/) developed at the Sapienza university and implemented in the software Eddy [15.38, 39] is used in Figs. 15.9 and 15.10.

Graphol permits the expression of the axioms of an ontology as described in Sections 2 and 3 but in a more readable manner, in the form of a graph. This graphical representation of an ontology is very practical and useful to those who do not have a thorough knowledge of mathematical logic. Using the editor Eddy, it is possible to construct the corresponding chart ontology expressed in Graphol, which can be automatically translated (with a suitable translator downloaded from the website of Graphol) in a superset of OWL, or in a set of axioms OWL, possibly with the addition of some axioms that are not directly expressible in OWL (such as those of identification and denial of *DL-lite*). The graph expressed by Graphol illustrates and highlights the relationship between the various concepts and the various reports. The purpose of the graph is to offer a schematic view of the ontology, to focus attention on the concepts and how they are mutually linked in the representation.

The examination of Figs. 15.9 and 15.10 allows us to reason over the ontology about the path from researcher to publication. It clearly appears that the path from researcher to R&D activities to publication goes through *content*.

15.5.2 Reasoning over the Mappings

The mappings in an OBDI system play a crucial role. They bind the data sources to the ontology. The connection is made through the *materialization or staging* phase (Fig. 15.12). Different levels of materialization are possible, and the refreshing of the materialization can be different according to the data source. The realization of the mappings in the context of *Sapientia* and its OBDI system is an interesting peculiar case, because the problem of *disambiguation* is a very important problem in bibliometrics and affects the assessment of the research and its impacts.

The solution proposed so far for the implementation of the mappings of *Sapientia* to its data sources is based on the *balance* between the level of computation and the level of materialization. Therefore, *quality checks* on data sources can be carried out.

The connection with the entity resolution (ER) occurs at the *computation* level through *modularization*. This allows a high degree of flexibility; ER algorithms can be replaced and/or updated without modifying the overall system. This is a *computational* flexibility

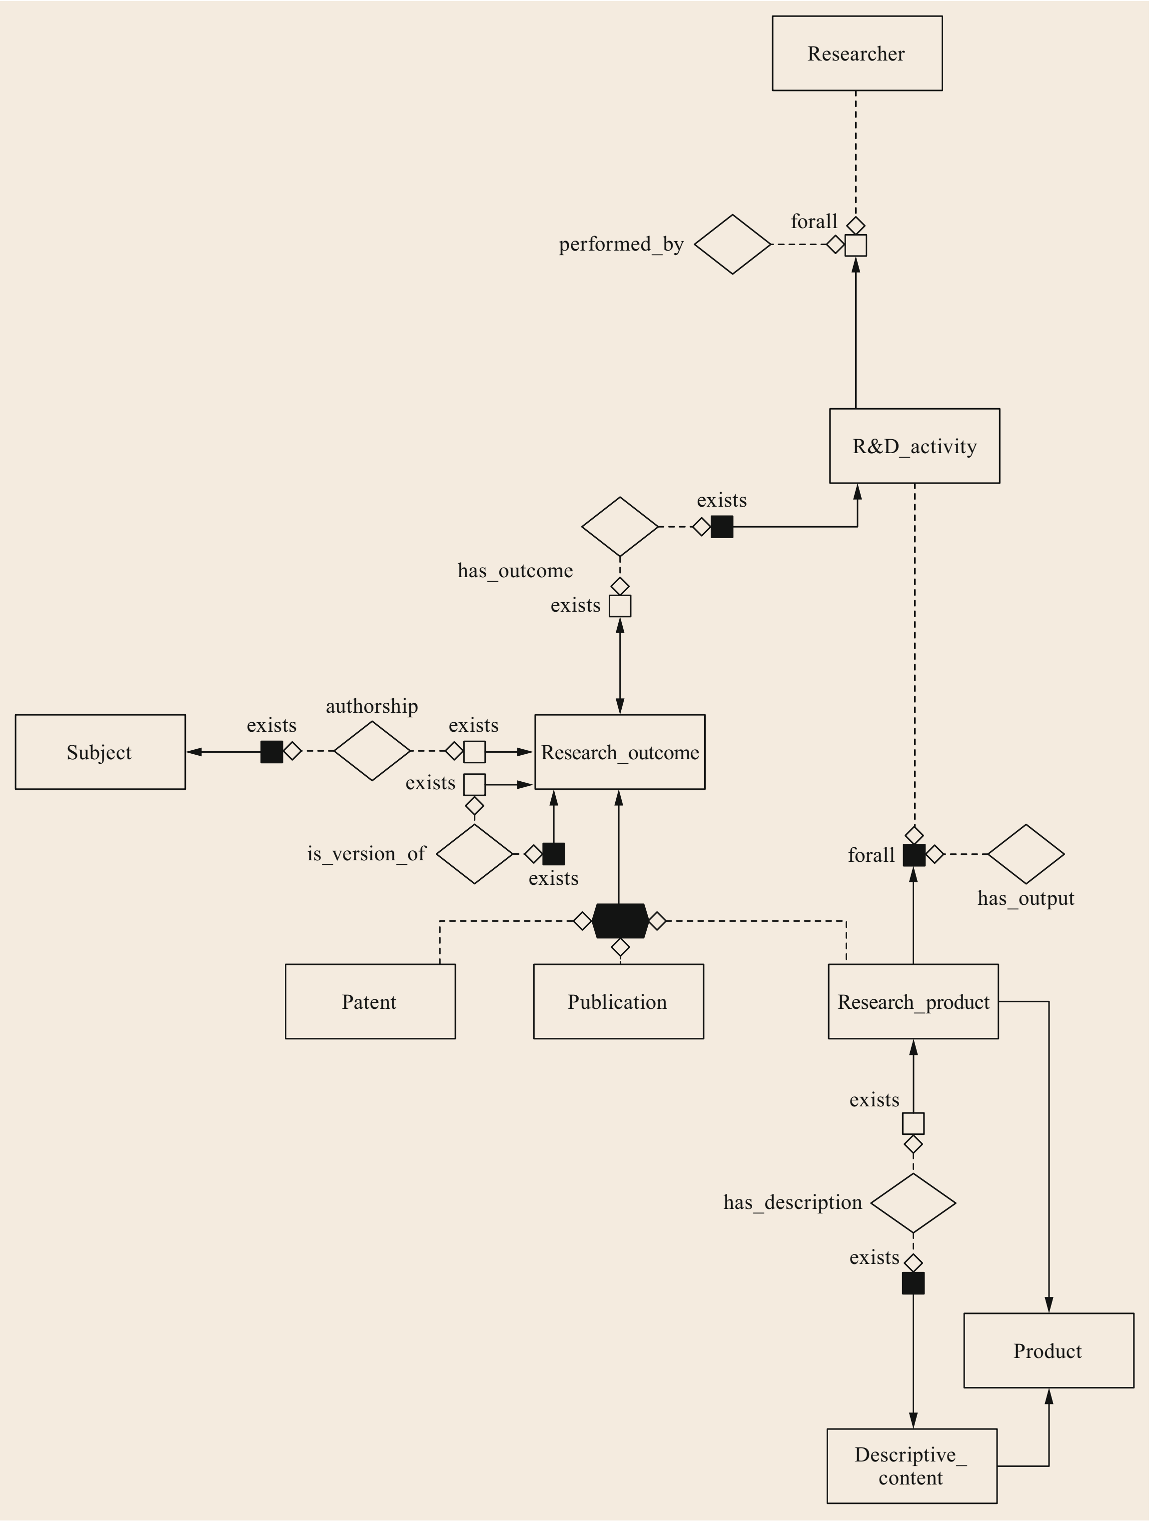

Fig. 15.9 An illustration of *Sapientia* from Module 3 R&D. Part I: from researcher to descriptive content

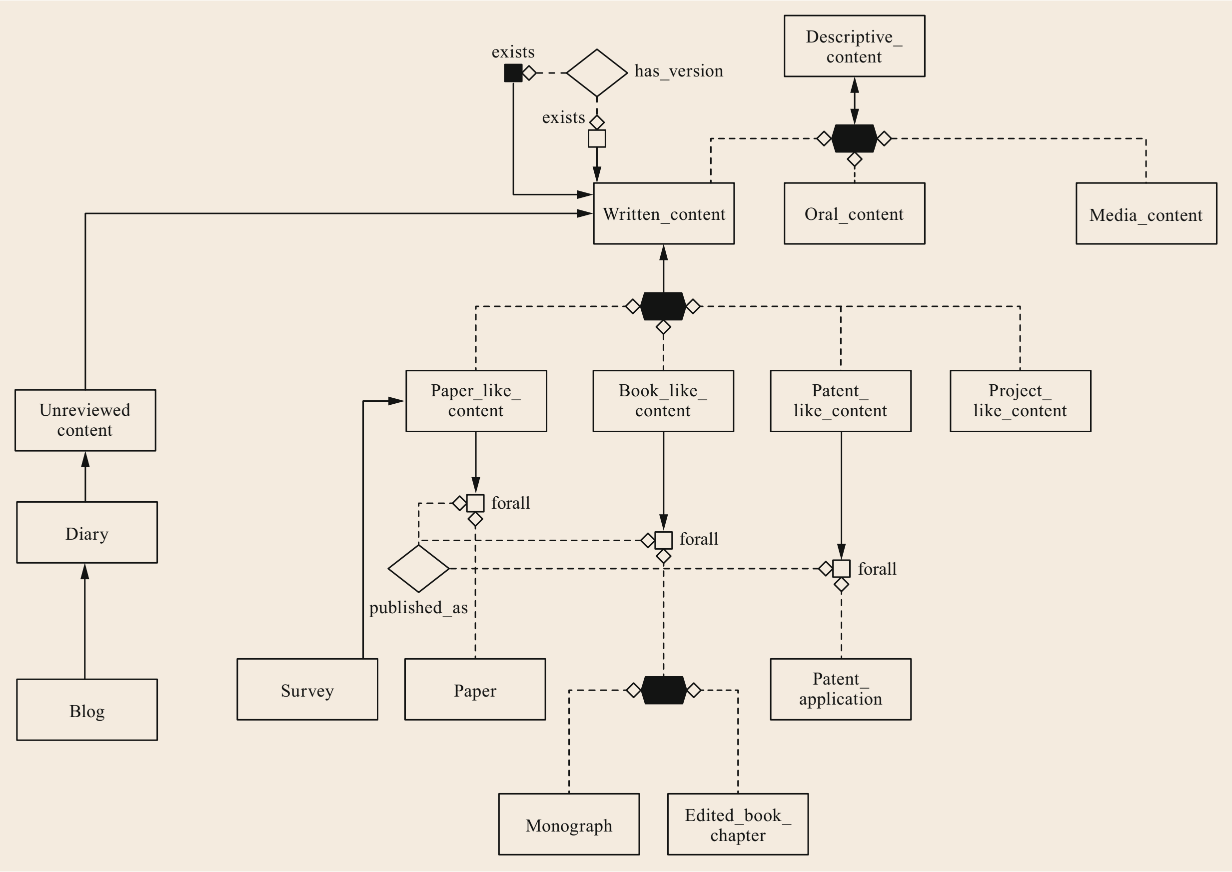

Fig. 15.10 An illustration of *Sapientia* from Module 3 R&D. Part II: from descriptive content to publications

with ER techniques through *modularization*. In addition, the ontological model offers the advantage of analyzing authors and affiliations together by means of a *conceptual* flexibility through the Module 11 Representations.

So far, we have implemented blocking mechanisms, mainly based on the Inverted Index. As with pairs of comparisons, blocking mechanisms are based on a common interface and specific implementations for single data sources. They act in a *spiral model* that will allow us to refine ER algorithms in subsequent iterations. In this respect, the ontology can be supportive to identify the strengths and weaknesses of the different ER algorithms that will be tested and implemented to our domain.

De Giacomo et al. [15.14] in the current challenges for OBDI mention “the problem of devising methodologies and tools for developing mappings for OBDI” and state that it “is largely unexplored.”

15.5.3 Reasoning over the Data and Indicators

Other possible reasoning tasks are those on data sources and on the indicators that may be built over the data. *Daraio*, *Lenzerini*, et al. [15.33] showed the usefulness of an OBDI system for R&I integration from a data quality perspective. *Daraio*, *Lenzerini,* et al. [15.42] showed that an OBDI approach allows for an unambiguous specification of indicators according to its four main dimensions: ontological, logical, functional, and qualitative (Table 15.2).

Reasoning over *Sapientia* permits the characterization of each indicator along its four dimensions listed above. This is extremely useful for studying the specification of indicators in the context of an *ontological approach* to the evaluation of research. The specification of the indicators within an OBDI framework aims to protect the analyst from the *risk of reductive conclu-*

Expression	DL-syntax	Graphol syntax

Fig. 15.11 Legend of the symbols illustrated in Figs. 15.9 and 15.10 (after [15.38, 39])

sions, which would focus on the logical and functional aspects of the specification, ignoring the ontological and quality assessment parts of the process.

In a broader perspective, *Daraio* and *Bonaccorsi* [15.43] identify two trends in indicator development:

- Trend towards *granularity* of indicators ("new indicators are explicitly requested to allow various kinds of aggregation and disaggregation, preserving desirable statistical properties, in order to address new policy needs"), detailing granularity in territorial, institutional and disciplinary areas.
- Trend towards *cross-referencing* ("the ability of indicators to be combined in meaningful ways, preserving their statistical properties").

Sapientia and its OBDI system may be a suitable infrastructure to develop indicators that satisfy the policy requirements of granularity and cross-referencing in a coherent and consistent way.

Table 15.1 Main concepts and roles illustrated in Figs. 15.9 and 15.10

Term	Type	Definition
Researcher	Concept	A researcher is an agent that carries out research activities allowing the scientific community to advance the state of the art of knowledge
R&D activity	Concept	A research and experimental development (R&D) activity, according to the Frascati manual [15.40, p. 28] "comprise creative and systematic work undertaken in order to increase the stock of knowledge—including knowledge of humankind, culture and society—and to devise new applications of available knowledge."
Research_product	Concept	A research product is a product that is an output of a research activity. In *Sapientia*, we included all the research products of the *Research Excellence Framework* [15.41].
Research_outcome	Concept	A research outcome of a research activity R is the output of an activity (not necessarily a research activity) participating a value chain where R has an enabling role (without R that output would not be generated).
Subject	Concept	A subject is any entity that can act as an agent and, playing such role, performs some activities. There are two types of subjects: natural persons and organizations.
Patent	Concept	A patent is a right that may be owned in an ownership, and shall confer to its owner the following exclusive rights: where the subject matter of a patent is a product, to prevent third parties not having the owner's consent from the acts of: making, using, offering for sale, selling, or importing for these purposes that product where the subject matter of a patent is a process, to prevent third parties not having the owner's consent from the act of using the process, and from the acts of using, offering for sale, selling, or importing for these purposes at least the product obtained directly by that process. Patent owners shall also have the right to assign or transfer by succession the patent and to conclude licensing contracts (Article 28 of the Trade-Related Intellectual Property Rights (TRIPS) Agreement administered by the World Trade Organization (WTO) that sets down minimum standards for many forms of intellectual property). Patents grant their owner a set of rights of exclusivity over an invention (a product or process that is new, involves an inventive step and is susceptible of industrial application). The legal protection conferred by a patent gives its owner the right to exclude others from making, using, selling, offering for sale or importing the patented invention for the term of the patent, which is usually 20 years from the filing date, and in the country or countries concerned by the protection. This set of rights provides the owner with a competitive advantage. Patents can also be licensed or used to help create or finance a spin-off company. It is therefore possible to derive value from them even if their owner does not have its own manufacturing capability (e. g., universities).
Publication	Concept	A publication is a particular kind of product consisting of an atomic or complex media including some content. There are three kinds of publications: atomic, collections and series.
Product	Concept	A product is an output of an activity, an entity (that might satisfy a want or need expressed by someone—or something—different from the agent who carried out the activity) which appears in the domain as consequence of an activity. Notice that the activity does not need to be finished at the time one of its products appears.
Descriptive content	Concept	A descriptive content is an interpretable object from which a human or an artificial intelligence can capture a meaning. It can use linguistic expressions and or media content.
Written content	Concept	A written content is a set of resources suited to be included in a single publication. These can be texts, technical drawings, diagrams, photographs and so on. These resources come together with their organizations (chapters, paragraphs, index). The linguistic parts of the resources are written in one or more natural languages (has_language).
Oral content	Concept	A descriptive content is oral if is the content of a speech.
Media content	Concept	A descriptive content is a media content whether it represents the way one or more events stimulate human sight and/or hearing.
Paper-like content	Concept	A paper like content is a written content suitable to become a paper, with respect to its internal organization, its length, its illustrations (technical drawings and diagrams, for example) and so on. Every paper has its content but not every paper-like content is published as a paper (for example it exists before the publication).
Book-like content	Concept	A book like content is a written content suitable to be published as (a part of) a book, with respect to its internal organization, its length, its illustrations (technical drawings and diagrams, for example) and so on. Every book has its content but not every book-like content is published as a book (for example it exists before the publication).

Table 15.1 (continued)

Term	Type	Definition
Patent-like content	Concept	A patent like content is the a written content suitable to a patent application, with respect to its internal organization, its length, its illustrations (technical drawings and diagrams, for example), and so on. Every application has its content but not every patent-like content is published as an application (for example, if it exists before the application).
Project-like content	Concept	A project-like content is written content suitable to apply to answer a call with respect to its internal organization, its length, its illustrations (technical drawings and diagrams, for example), and so on. A project like content is not, in general, an object of publication.
Survey	Concept	A paper-like content is a survey if it is an attempt to summarize the current state of understanding on a topic or a knowledge area.
Paper	Concept	A paper is an atomic publication. It contains original research results or reviews existing results. Before publication, the content of the paper has undergone a process of *peer review* by one or more referees (who are experts of the same field) who have checked that the content of the paper is suitable for publication in the journal. Such content may undergo a series of reviews, revisions, and re-submissions before finally being accepted or rejected for publication.
Monograph	Concept	A monograph is an atomic publication. Although a monograph has, in general, a structure, all its parts share the same group of authors. A monograph can be physically distributed in more volumes.
Edited_book_chapter	Concept	An edited book chapter is an atomic publication that is a part of an edited book with specific authors.
Unreviewed_content	Concept	It is a written content that has not been reviewed.
Diary	Concept	A diary is a record (possibly in handwritten format) with discrete entries arranged by date reporting (typically) on what has happened over the course of a day or a period.
Blog	Concept	A blog (a truncation of the expression weblog) is a discussion or informational site published on the World Wide Web and consisting of discrete entries (*posts*) typically displayed in reverse chronological order (the most recent post appears first). Blogs often cover a single subject. A blog is a diary, since the posts are arranged by date.
Published_as	Relation	Binds a written content to the publication which disseminates it (if any)
Has_version	Relation	Binds a written contents to its new versions (if any)
Has_description	Relation	Binds a research activity with descriptive content that descriptive it (if the activity has descriptions); notice that the descriptive content of a research activity may not be one of its outputs, and an output of a research activity may not be a description of the activity itself
Has_output	Relation	Binds any activity to its outputs; an activity may produce its outputs at any time when it is operative.
Authorship	Relation	Binds a research outcome to the subject which is responsible for it
Has_outcome	Relation	Binds a research activity to any output of any activity (not necessarily a research activity) participating in a value chain where the research activity has an enabling role (without the research activity that output would not be generated). The figure shows chains schemes that justify the outcome of the research activity shown in the left. The arrows represent the role has_output.
Performed_by	Relation	Binds an activity to the agent who performs it

Table 15.2 Main indicator dimensions and their role in the process of indicator development

Dimension	Description	Role
Ontological	Conceptual characterization (knowledge representation) of the domain of the indicator	Conceptual definition (*meaning*) of the indicator (a benchmark for the qualitative dimension)
Logical	Logical specification of the query(-ies) needed to retrieve all the information (data) needed to calculate the indicator	*Data* definition: selection of the relevant information through the query
Functional	Mathematical expression of the indicator (to be applied to the results of the queries)	*Mathematical* definition: related to the selected method of calculation of the indicator (most relevant for the user: the user is interested in the value of the indicator!) Note that the method is outside the ontological domain
Qualitative	Ontological questions related to the meaningfulness of the indicator.	Definition of the criteria for the *assessment* of the obtained result (degree of meaningfulness of the indicator)

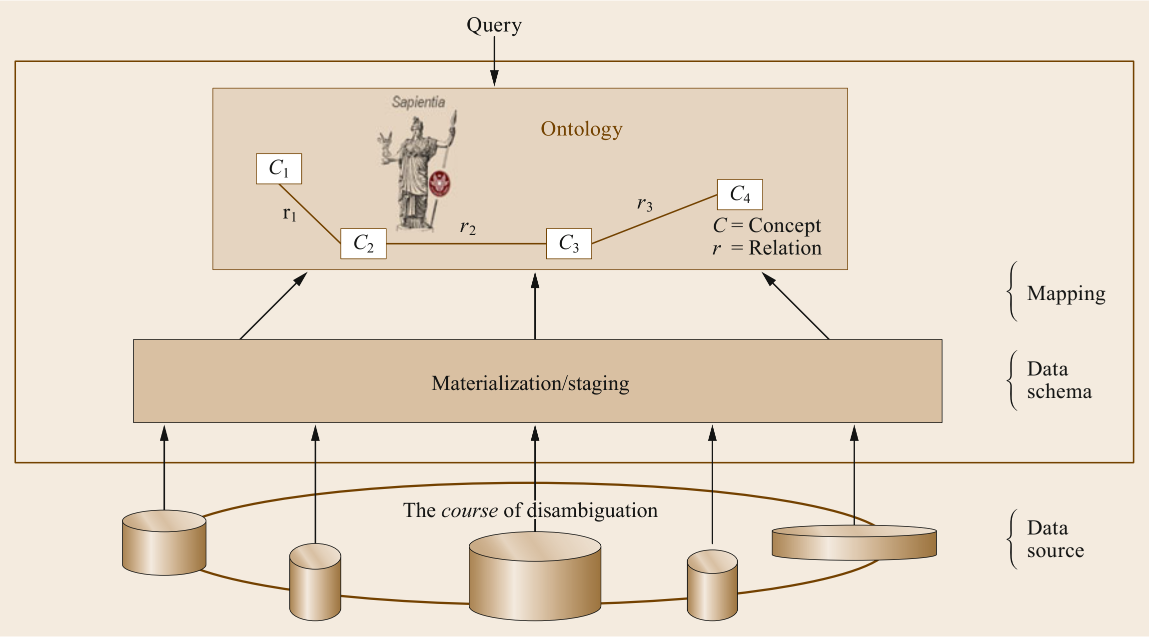

Fig. 15.12 Illustration of the materialization phase in an OBDI system

15.6 Conclusions

In this chapter, we introduced the main challenges in data integration for R&I. We discussed the two main existing approaches to data integration, namely procedural and declarative. We followed the latter approach and focused the subsequent analysis on the OBDI approach. The key idea of OBDI is to resort to a three-level architecture, constituted by the ontology, the sources, and the mapping between the two.

Daraio, *Lenzerini*, et al. [15.42] introduce the OBDI approach to coordinate, integrate and maintain the data needed for science, technology, and innovation policy and illustrate its potentials for specifying STI indicators and developing *science of science* policies. They outline the main advantages of OBDI with respect to the traditional silos-based approach to data integration, namely: *conceptual access to the data*, *re-usability*, *documentation and standardization*, *flexibility*, *extensibility*, and *opening of the system* (Table 15.3).

The three main advantages of OBDI for research and innovation analysis [15.33], which encompass and further expand those listed in Table 15.3 are: *openness*, interoperability, and data quality.

An OBDI approach may be an adequate platform/infrastructure to embrace and coordinate in an effective way (i. e., ensuring interoperability and high level of data quality standard), the many initiatives that are going on in research and innovation data collections.

Table 15.3 Main advantages of an OBDI approach over a traditional *silos*-based approach (after [15.42])

Advantage	Short description
Conceptual access to the data re-usability	Users can access the data by using the elements of the ontology.
Documentation and standardization	The mapping layer explicitly specifies the relationships between the domain concepts and the data sources. It is useful for documentation and standardization purposes.
Flexibility of the system	You do not have to merge and integrate all the data sources at once which could be extremely costly.
Extensibility of the system	You can incrementally add new data sources or new elements (ability to follow the incremental understanding of the domain) when they become available.
Opening of the system	Provide a conceptual framework that can be used as a common language by the community.

Figure 15.13 shows an outline of the main component of an open OBDI infrastructure.

An open STI data platform may encourage and support new research developments in the generation of new indicators carried out by scientists, which exploit the accessibility and transparency of data. In this way, there may be opportunities for the creation of new indicators beyond the short-term needs of policy-makers. The open-data framework, offers the possibility of full documentation on data and explicit articulation of logical linkages. It makes the traditional training and accreditation approach obsolete, in which users of indicators were dependent on the training provided by the owners of the data. Communities of users can, in fact, contribute to the improvement of the documentation and identify pitfalls and shortcomings of indicators. *Sapientia* and OBDI are two technologies to operationalize the consideration of data as infrastructural resources, as they are "shared means to many ends" that satisfy the three criteria of infrastructure resources [15.44]: a) non-rivalrous goods; 2) capital goods; and c) general-purpose inputs. *Sapientia* and OBDM could, indeed, be two *enabling technologies* to improve the exploitation of data for supporting growth and well-being, as proposed by OECD [15.45], and pushing towards the realization of an open science [15.46].

As we have showed in this chapter, the application of OBDI for the integration of data in R&I can be an interesting technology to further explore and exploit. However, it is important to point out that OBDM is not a *panacea* able to solve all the main challenges in data integration for R&I. Nevertheless, it can be a useful tool for *reasoning* over the assessment of research and innovation for different purposes and may lead to a more aware and careful specification of data and indicators useful in the evaluation process. *Sapientia* and its OBDI system may be at the heart of an open and collaborative platform around which to build a knowledge infrastructure for the assessment of research and its impacts.

Besides, the field of OBDI in computer science is far from being stable and consolidated. It is a dynamic and evolving field. *De Giacomo* et al. [15.14] discuss the main challenges related to OBDI that currently deserve investigation, namely querying rewriting optimization, meta-modeling, and meta-querying, non-relational data sources, OBDI methodology and tools, OBDI evolution, and going beyond data access. This is to say that the field of OBDI introduced in this chapter is a relatively new discipline to apply to interesting and complex issues, such as the evaluation of research and innovation, to corroborate the existing methodologies, and develop new and appropriate tools and solutions for data integration in these fields.

We conclude this chapter, recalling the final observation of *Daraio* and *Glänzel* [15.9]:

> One of the main Grand Challenges that remains to address is the exploitation of data availability, Information Technology and current state of the

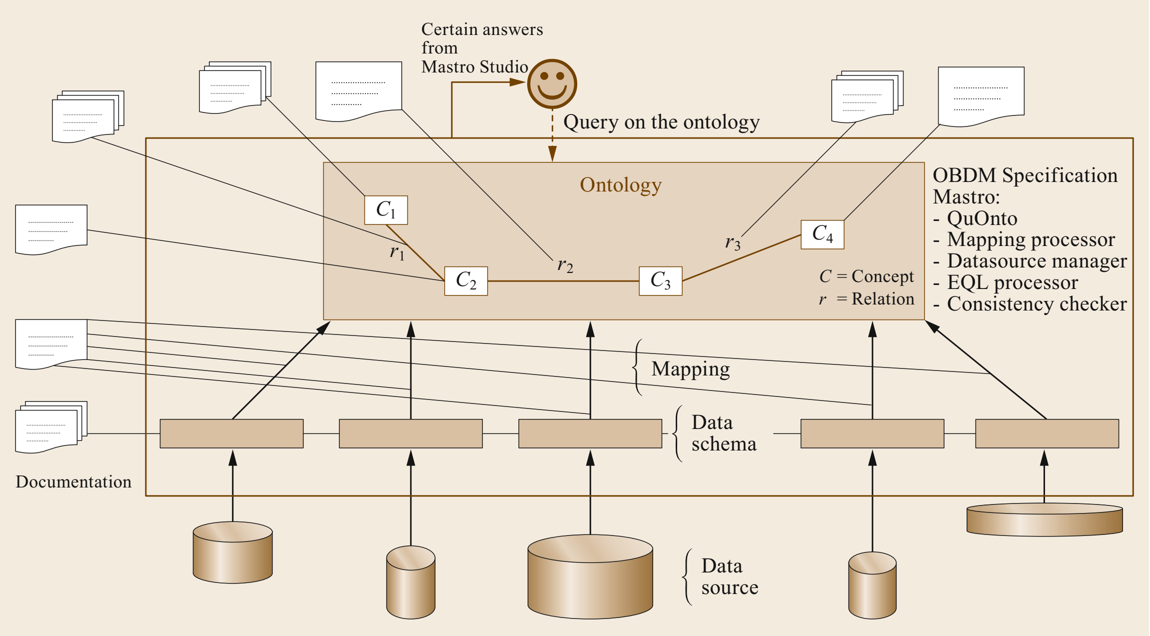

Fig. 15.13 Illustration of an open OBDI information system (after [15.33])

art in science and technology for the dynamical setting of standards in a data integration framework in use for multiple purposes.... Within this framework, to deal with this Grand Challenge, the interaction with stakeholders for ensuring an efficient and effective sustainable model is crucial. It depends also on the ability to successfully address, in a systematic way, the other problems highlighted above.

What would be needed to deal with this Grand Challenge and interact with stakeholders in order to develop and implement an OBDI approach for the integration of research information systems and the building of indicators upon them is a *long term investment* in the technology behind the OBDI and its related research. As recalled above, it is a relatively new discipline, which is worth further exploration and exploitation to address the existing challenges in data integration for R&I.

Acknowledgments. Financial support from the Project Sapienza Awards 2015 n. C26H15XNFS and the Project FILAS RU 2014-1186 is gratefully acknowledged.

She has authored more than 150 publications.

16. Synergy in Innovation Systems Measured as Redundancy in Triple Helix Relations

Loet Leydesdorff, Inga Ivanova, Martin Meyer

The Triple Helix (TH) of university–industry–government relations can first be considered as an institutional network. However, the correlations in the patterns of relations provide another topology: that of a vector space. Meanings are provided from positions in this latter topology and from the perspective of hindsight. Meanings can be shared, and sharing generates redundancy. Increasing redundancy provides new options and reduces uncertainty; reducing uncertainty improves the innovative climate, and the generation of options (redundancy) is crucial for innovation. The knowledge base provides an engine of the economy by evolving in terms of generating new options. The trade-off between the evolutionary generation of redundancy and the historical variation providing uncertainty can be measured as negative and positive information, respectively. In a number of studies of national systems of innovation (e.g., Sweden, Germany, Spain, China), this TH synergy indicator has been used to analyze regions and sectors in which uncertainty was significantly reduced. The quality of innovation systems can thus be quantified at different geographical scales and in terms of sectors such as high- and medium-tech manufacturing or knowledge-intensive services (KIS).

16.1 The Triple Helix Model of Innovations

The Triple Helix of university–industry–government relations emerged as a research program from a confluence of *Henry Etzkowitz*'s longer term interest in the entrepreneurial university [16.1–4] with *Loet Leydesdorff*'s interest in the evolutionary dynamics of science, technology, and innovation. Etzkowitz contributed a chapter entitled *Academic-Industry Relations: A Sociological Paradigm for Economic Development* to the book *Evolutionary Economics and Chaos Theory: New directions in technology studies* [16.5]. Leydesdorff argued in the Epilogue of this book that more than two interacting dynamics are needed for studying technology and innovation from an evolutionary perspective. Trajectories can be stabilized historically as a result of *mutual shaping* between two dynamics, but a third dynamic can be expected to disturb (destabilize) this tendency toward equilibrium and contribute to shaping a next-order (globalized instead of stabilized) regime. Different from an observable trajectory structuring behavior, a technological regime structures the expectations [16.6].

The sociologist *Simmel* noted already in 1902 that the transition from a dyad to a triad is fundamental to systems formation [16.7, 8]. A triad can be commu-

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_16

tative: are the friends of my friends also my friends? The order of the communications in a triad can be expected to generate asymmetries: two loops in one direction and one in the other may lead to a path different from that resulting from one loop in the first direction and two in the opposite. This system thus becomes path-dependent: one cannot go back without friction to a previous state, as in an equilibrium. An innovation system develops historically along trajectories. The triadic overlay has a dynamic different from the sum of the bilateral relations. It provides an emerging selection environment at the next-order level of an emerging regime.

Etzkowitz and *Leydesdorff* [16.9] considered this emerging operation as a *communication overlay*. *Ivanova* and *Leydesdorff* [16.10, 11] characterized the resulting communication system as a *fractal manifold*: the bilateral arrangements can be broken open (at all scales) by the third along each side of the triangle. A fractal manifold is scale-free because it develops endogenously in terms of reconstructions (which are needed because of the fractioning). The triads are nested at different levels and along different axes. In other words, a complex system can be expected to develop which is both horizontally and vertically differentiated [16.12].

The TH has hitherto focused on horizontal differentiation and integration among universities, industries, and governments as institutional spheres. In this chapter, we report on the further elaboration of the institutional model of university–industry–government relations into an evolutionary model of innovations as a vertical differentiation. We shall argue that the knowledge base evolves in terms of providing new options by making distinctions possible [16.13]. Increases (and decreases) in the number of options can be measured in terms of a trade-off between redundancy and uncertainty generation. We discuss the development of an instrument for the measurement of this balance in TH relations.

16.2 Institutional and Evolutionary TH Models

If sufficiently complex, institutional networks can carry the evolution of a knowledge base. However, the knowledge base develops with another dynamics on top of the institutional layer in terms of functions such as *supply*, *demand*, and *control* (Fig. 16.1).

These functions have to be specified at each level and sector. In a study of medical innovations, for example, *Nelson* et al. [16.15] distinguished among demand articulation for innovation in terms of diseases, supply in terms of new treatments, and control in terms of practical experiences and evaluations. *Petersen* et al. [16.14] measured these three dynamics in terms of medical subject headings (MeSH terms that are attributed by PubMed/MEDLINE). Branch *C: diseases* of this index can be considered as an articulation of demand, *D: drugs and chemicals* as supply, and *E: techniques and equipment* as conditioning the translations between supply and demand. Using the TH indicator—to be discussed below—windows of opportunities for new medical technologies were indicated.

The evolutionary and institutional dynamics are related in the events; for example, as coclassifications of publications by PubMed/MEDLINE. Unlike the TH model of university–industry–government *relations*, the evolutionary model includes both relations and nonrelations or, in other words, *correlations* among distributions of relations. The correlations span a vector space in which the relations and the carriers at the nodes occupy *positions*. In the case of three distributions, correlations between each two distributions can be spurious because of the third one. This latent dimension can contribute with either a plus or a minus sign. For example, university–industry relations in a nation or region may be excellent because of government policies or despite these policies.

In other words, each third helix can feedback or feedforward on the relations between the other two. From the perspective of this generalized TH model,

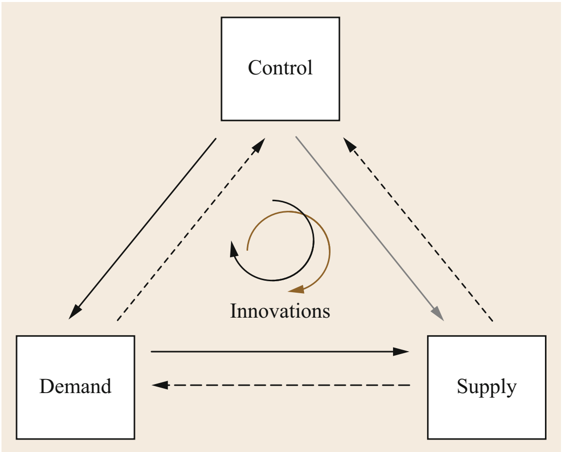

Fig. 16.1 The generalized Triple Helix model of innovations (after [16.14, Fig. 1, p. 667], with permission from Elsevier)

university–industry–government relations can be considered as the special case of focusing on institutional relations. From the evolutionary perspective, the analysis of relations is not a purpose but a means to study the potential synergy in new arrangements. The institutions and their relations develop historically and are therefore directly observable (*phenotypically*). However, functions can be specified as theoretically informed expectations (*genotypically*; [16.24]). The evolutionary TH model assumes that institutional arrangements evolve because of new options for:

(i) Knowledge production
(ii) Wealth generation, and
(iii) Regulation.

Table 16.1 summarizes the differences between the institutional and evolutionary model. The two models are intrinsically related as models for explaining emergence [16.25]. The institutional TH model focuses on relations [16.26, 27]. The relational interactions can be considered as first-order attributes to the nodes (in this case, institutions; e.g., *Etzkowitz* and *Zhou* [16.19]). Interactions among the relations in a triadic (or more-dimensional) configuration lead to a second-order dynamics among the first-order attributes (Fig. 16.2).

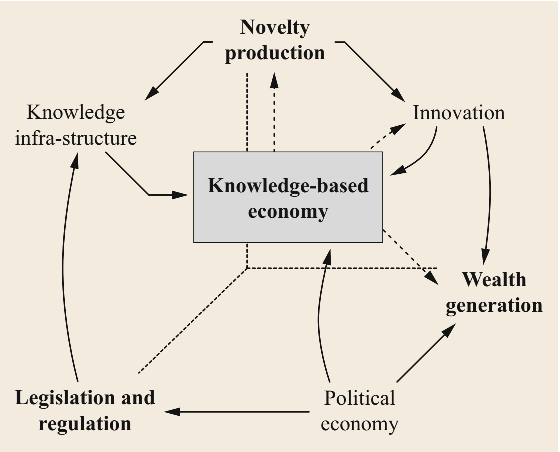

Fig. 16.2 Interactions among the first-order interactions generate a knowledge-based economy as a next-order system (after [16.28, p. 379], with permission from Wiley)

Whereas the functions of wealth generation and governance have been central to the analysis of political economy, the study of the knowledge-based economy includes the additional dynamics of innovations ([16.29]; see Fig. 16.2; [16.30, p. 186f.]; [16.31]). The trilateral interactions among the bilateral ones generate a feedback on the constituent helices and their bilateral relations *by providing an emerging selection environment*.

The institutional dynamics lead to path dependencies along historical trajectories. Between the historical variation and the selection mechanisms operating evolutionarily one can expect a nonlinear dynamics of creative destruction, agglomeration [16.32, 33], and reconstructions on the basis of competitive advantages [16.34]. The institutional restructuring is one of the relevant subdynamics of the complex dynamics of societal innovation and entrepreneurship. The relations and arrangements among institutions furthermore are sensitive to policy interventions. The objective, however, is the generation of synergy. The criterion of generating synergy in configurations of relations can provide a frame of reference for institutional reform since the lower the resulting uncertainty, the *smarter* specializations in terms of options can be.

In summary, the TH cannot be considered as a single method or model; it is a theme that binds together the transition of political economy into a knowledge-based economy as a macrodevelopment with the study of transitions at micro- and mesolevels based on and leading to knowledge-based innovations. The study of knowledge-based economic developments can be pursued at both institutional and functional levels. The institutional dynamics provide the social embedding to the evolving systems [16.35]. The model can be considered institutional insofar as the explanation is in terms of networked relations and interactions among institutional agents [16.26, 36]. The model is *neo*-evolutionary since more than a single selection is assumed and the selection environments can change and interact [16.37, 38]. The relational networks generate and retain the evolutionary dynamics [16.19, 25].

Knowledge-based innovation systems can be studied at macro-, meso-, or microlevels. Using the TH indicator, one is able to decompose the macro in terms of micro- and mesolevels. Thus, the issue of whether systems of innovation are national, regional, sectorial, etc., [16.39, 40], can be addressed empirically. A systemic development can be distinguished from nonsystemic (e. g., incidental) covariation. One can ask, for example, how much synergy is indicated at regional or national levels. Furthermore, one can quantify how much cross-border synergy the national level adds to the sum of the regional systems of innovation.

Note that the TH indicator provides a specific methodology which does not have to be used in a TH study. Much depends on the research questions and the kinds of data available. Crucial for the TH theme, in our opinion, is the extension of the economic and political analysis with attention to cognitive structuration [16.41]. Let us first specify the transition towards a knowledge-based economy in the macrohistorical context, and then proceed to discuss quantitative studies using contemporary data.

16.2.1 The Emergence of a Knowledge-Based Economy

In his time, Marx witnessed the prelude to the emergence of a knowledge-based economy. He was thoroughly aware of this. After studying in the British Library for almost a decade, in 1857 Marx published his rough draft of *Capital* under the title *Grundrisse: Foundations of the Critique of Political Economy* [16.42]. In this study, Marx considered the possibility of a knowledge-based economy as an alternative to the political economy that he criticized for ideologically accepting the extraction of wealth from labor, and thus condoning exploitation. As he put it (at p. 706):

> Nature builds no machines, no locomotives, railways, electric telegraphs, self-acting mules etc. These are products of human industry; natural material transformed into organs of the human will over nature, or of human participation in nature. They are *organs of the human brain, created by the human hand;* the power of knowledge, objectified. The development of fixed capital indicates to what degree general social knowledge has become a *direct force of production,* and to what degree, hence, the conditions of the process of social life itself have come under the control of the general intellect and been transformed in accordance with it. To what degree the powers of social production have been produced, not only in the form of knowledge, but also as immediate organs of social practice, of the real life process.

Note that Marx specified an indicator of this transition: *the development of fixed capital*. He discussed its operationalization at length (in the *Grundrisse*) and set himself the task to study the possibility that science and technology had become greater sources of societal wealth than labor. A model with two independent variables was not available in his time.

After another ten years of study, *Marx* [16.43] concluded in *Capital* that the main contradiction at the time remained the one between capital and labor. In the footnotes as a subtext (e. g., p. 393, note 89), however, Marx repeats that "the technology shows us the active relation of the human kind to nature, the immediate production process of our lives ..." If technology could enable us to free man from work sufficiently, the nature of capitalism would change, since "*the basis of this mode of production falls away*" (p. 709; italics in the original). In other words, Marx envisaged a regime change that is different from and an alternative for the communist revolution.

William Henry Perkin's research on dyestuffs in England during the late 1850s, for example, developed into an industry in Germany [16.44] [16.45, pp. 161f.] [16.18, p. 25]). However, *Noble* [16.46, p. 7] argued that "the major breakthroughs, technically speaking, came in the 1870s." He dated what he calls "the wedding of the sciences to the useful arts" as the period between 1880 and 1920. *Braverman* [16.45] introduced the concept of a *scientific-technical revolution* for indicating this same period when he formulated the regime change as follows (pp. 166f.):

> The scientific-technical revolution ... cannot be understood in terms of specific innovations—as is the case of the Industrial Revolution, which may be adequately characterized by a handful of key inventions—but must be understood rather in its totality as a mode of production into which science and exhaustive engineering investigations have been integrated as part of ordinary functioning. The key innovation is not to be found in chemistry, electronics, automatic machinery, aeronautics, atomic physics, or any of the products of these science-technologies, but rather in the transformation of science itself into capital.

The incorporation of science and technology into the production process makes the system evolve with a different dynamics [16.29]. Whereas both markets and political institutions can be considered as equilibrium-seeking [16.47], the nonequilibrium dynamics of the social production of knowledge makes evolution theory relevant to the analysis of innovation systems [16.48–51]. After WW II, the new field of *evolutionary economics* gradually emerged as central to innovation studies [16.52, 53]. However, it took until the 1980s before the debate about the knowledge-based economy and its institutional conditions became salient. Before that time, the confrontation between liberal and communist models of political economy dominated the Cold War. With the demise of the Soviet Union (1991) and the opening of China after 1989, this debate about political economy lost its prominence. The study of the emergence of a knowledge-based economy became urgent.

Using *Friedrich List*'s [16.54] model of national systems of political economy, *Freeman* [16.55] first proposed the model of *national systems of innovation* after studying Japan from a West-European perspective [16.56–58]. *Freeman* and *Perez* [16.35] further developed a macromodel of business cycles which updates Marx's dialectics of production relations and production forces. Using historical examples, these authors argue that long-term cycles (*technoeconomic paradigms*) are generated by *key factors* (such as oil in the previous cycle, or information in the current one) that can rapidly become abundant and thus cheaper. The structural crises between the new paradigm and existing institutions and industries call for adjustments. National innovation systems compete in terms of institutional reforms. The key factors which trigger next cycles, however, remained exogenous in this model, since the dynamics generating the *key factors* were not specified.

From a somewhat different perspective, *Nelson* and *Winter* [16.38, 59] called for evolutionary models of technological innovation that would endogenize the technological dimension. How is the knowledge base generated within the system? *Rosenberg* [16.60], for example, proposed to study selection in terms of focusing devices and inducement mechanisms. Under the condition of war, for example, national governments can be expected to invest in military technologies. Problems with the measurement of the knowledge base, however, seemed prohibitive in opening the black box further than in terms of historical descriptions [16.61, 62] or *history-friendly* models [16.50, 63]. How can one proceed from case descriptions and historical *phenotypes* to the specification of the evolutionary dynamics [16.52, 64]?

Within this program of studies, the issue of measurement became increasingly important. In his Presidential address to the American Economic Association, *Griliches* [16.65, p. 14] mentions the problem of measurement as a main constraint in research:

> After decades of discussion we are not even close to a professional agreement on how to define and measure the output of banking, insurance, or the stock market (see *Griliches* [16.66]). Similar difficulties arise in conceptualizing the output of health services, lawyers, and other consultants, or the capital stock of R&D. While the tasks are difficult, progress has been made on such topics.

How can one measure innovations and innovation systems?

For decades, *Freeman* and *Pavitt* curated a database of innovations at the Science Policy Research Unit (SPRU) of the University of Sussex [16.67]. In collaboration with Eurostat, in 1992 the OECD (Organization for Economic Co-operation and Development) developed the so-called *Oslo Manual* entitled *Guidelines for Collecting and Interpreting Innovation Data* [16.68]. The harmonization of national statistics is a first condition for making it possible to compare among national systems of innovation in terms of their strengths and weaknesses and perhaps to formulate best practices. However, neither innovation survey data nor patent data can be integrated easily—i. e., without additional assumptions—into the measurement of *national systems of innovation*. Patents, for example, are indicators of invention, and inventions are only proxies of innovation [16.65, 69, 70].

The focus on the national level was criticized by authors favoring regional perspectives [16.39] and resounded with the European Union's perspective on transnational and inter-regional innovation systems. The knowledge-based economy provided a metaphor which leaves the systems level open [16.40]. The economy is not defined institutionally, but functionally. At an expert meeting of the OECD in 1994 about developing indicators for the knowledge-based economy [16.71], however, *Carter* [16.72] warned that the measurement of knowledge had remained an unsolved problem [16.73]. *Andersen* [16.52] raised the question of *what is evolving?* in a knowledge-based economy as studied in *evolutionary economics*. Problems of operationalization and measurement thus came to the forefront.

During the second half of the 1990s, the OECD hosted a program about *the knowledge-based economy* [16.71, 74]. In an evaluation, *David* and *Foray* [16.75] cautioned that the terminology—knowledge-based economy—"marks a break in the continuity with earlier periods, more a 'sea-change' than a sharp discontinuity" [16.75, p. 9]. The authors noted that transformations can be analyzed at a number of different levels, and argued that *knowledge* and *information* should be distinguished more carefully by analyzing the development of a knowledge-based economy in terms of codification processes [16.76, 77].

Codification is a communication-theoretical problem: information can be provided with meaning, and specific meanings can further be codified as knowledge. The dynamics of the codification of information into knowledge are very different from the dynamics of government at different levels or the dynamics of markets in industrial sectors. The construction of knowledge-based systems is bottom-up, whereas retention of economic wealth from knowledge requires the downward arrow of control. How can the constructed advantages [16.34] be used for innovation? The theoretical challenge is to combine the perspective of codification with evolutionary and systemic perspectives [16.78].

16.3 The Operationalization of the Triple Helix

The Triple Helix model takes the challenges thus articulated, as starting points for further analysis and theorizing, but with the goal of operationalization and measurement. *David* and *Foray*'s [16.75] "break in the continuity with earlier periods" is appreciated as the new role and the transformative dynamics of the social organization of knowledge. This adds a third structural dynamic to the economy and to the political system regulating the economy. The dynamics of codification operate in terms of trajectories and regimes [16.6]. A regime has one more degree of freedom than a trajectory. Whereas trajectories are shaped in a landscape [16.63, 79], the knowledge-based regime is hypergeometrical. It can also be considered as the *genotype* of the observable *phenotypes* along trajectories.

The genotype of the technoeconomic evolution is not given like the DNA in biological systems. This *non-biological genotype* remains a construct that is open to partial reconstruction as knowledge is further developed [16.24]. In other words, *Andersen*'s [16.64] question of *what is evolving?* can now be answered: knowledge is a *cognitive* construct that evolves by generating new options. This evolving construct is socially retained and embedded along historical trajectories. The latter, however, are *social* constructs. Both dynamics are enacted and interact in events and actions generating and breaking relations.

Unlike the positive sciences which study domains that can be defined empirically, studies of sociocognitive systems develop cognitive means to study knowledge-based developments as their empirical domain. This raises questions of reflexivity [16.80–82]. The cognitive dimension cannot be observed as given naturalistically; it needs to be specified as a construct. The specification is performative in that it changes the expectations. (Expectations can be tested against observations!) Because of this constructivist constraint in the study of knowledge-based systems, the analysis remains at the edge of philosophy and develops what has been called an *empirical* [16.83, 84] or *concrete* philosophy of science [16.85, p. 159], [16.86]. This philosophy of science is concrete, since its status is one of hypothetical knowledge in need of the observation and testing of the contexts in which it is generated and which it transforms.

Do the observable instantiations inform us about the evolving system(s) by enabling us to improve our expectations? The measurement of science is nowadays further developed in the scientometric tradition. However, scientometricians are confronted with the same reflexivity problem—albeit from a different perspective—when the question is asked: what do the indicators indicate? When measuring, for example, the spectacular increases in international coauthorship relations in recent decades [16.87–89], does one indicate the growth of knowledge or only institutional expansion [16.90]? How do social relations reflect or perhaps interfere with cognitive constraints and opportunities? Can one infer from the one to the other dimension?

In an attempt to bridge the gap between qualitative theorizing and quantitative methods, *Callon* et al. [16.91] proposed juxtaposing the social, technical, and cognitive dimensions by considering networks of science and technology as heterogeneous. From this perspective, different units of analysis such as texts, authors, and cognitions are assembled in networks with a priori equal status (as actants). On the basis of the semiotic tradition, these actants are considered representations in a network whose dynamics can be mapped using cowords or other symbolic references, [16.92, 93].

Alternatively, one can distinguish among dimensions and relate networks of different character (e.g., [16.95, 96]. For example, one can use more-dimensional (n-mode) networks. Using Fig. 16.3, one

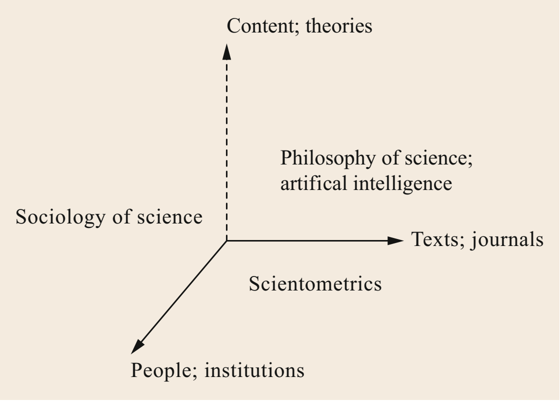

Fig. 16.3 Three main dimensions of science. Source: [16.94, p. 3]

of us proposed to distinguish in science studies more fundamentally among texts, people, and cognitions as three different units of analysis which cannot be reduced to one another. One can attribute texts to authors or vice versa, but the variation among the authors is different from the varieties among the texts. One can expect different—albeit interacting—dynamics along the three axes of cognitive content, social agency, and textual structures. Texts, for example, can be aggregated into journals or archives, whereas agents can be organized into institutions or groups. The dynamics of knowledge include, for example, the validation of new knowledge claims [16.97].

The three analytically distinguishable dynamics (in this case, social, cognitive, and textual) can also be considered as selection mechanisms operating upon one another. In a coevolutionary model, the variation-generating dimension (*helix*) can act as the selection mechanism at a next moment. Each two selection mechanisms operating upon each other can lead to *mutual shaping* along trajectories. A third selection environment, however, makes the system hyperselective [16.98]; one adds a *virtual order* or, in other words, "an absent set of differences, temporarily 'present' only in their instantiations, in the constituting moments of social systems" [16.41, p. 64]. One can expect skewed distributions in the outcome (e.g., scientometric distributions) because of selections operating upon one another [16.99].

In other words, we submit that the TH model can be appreciated in different topologies at the same time: the topology of the network of relations, and a vector space spanned by correlations providing structure in the background. In the latter, the zeros (nonrelations) are as important as the ones [16.100, pp. 3–9]. Structures operate deterministically at each moment of time, but over time the selection mechanisms operate upon one another, and thus structures are also at variance. Both relations and nonrelations can be considered as events that are selectively provided with meaning in the vector space. Meanings provided from different perspectives can be shared to differing extents.

The sharing of meanings generates overlap and redundancy, while the communications in terms of relations continuously generate variation containing (Shannon-type) information. Redundancy and information add up to the maximum entropy at each moment of time. However, the mechanisms of generating redundancy and information are different: information is generated historically, while redundancy is specified discursively in the knowledge base. The generation of redundancy—and not the generation of information—can make the system increasingly knowledge-based.

16.4 The Generation of Redundancy

Redundancy R was defined by *Shannon* [16.101] as follows

$$R = \frac{H_{\max} - H_{\mathrm{s}}}{H_{\max}} = 1 - \frac{H_{\mathrm{s}}}{H_{\max}} \,. \tag{16.1}$$

The maximum information content of a system ($H_{\max}$) is equal to the logarithm of the number of possible states N: i. e., $H_{\max} = \log(N)$. Equation (16.1) specifies that $H_{\max}$ is composed of two components: the system states hitherto realized ($H_{\mathrm{s}} = -\sum_i p_i \log(p_i)$) and the states which are possible given the definition of the system, but which were not (yet) realized: $H_{\max} - H_{\mathrm{s}}$.

For an innovation system, the number of options still available—that is, the redundancy—may be more important than the past record of already realized options; particularly when a system runs out of options. When additional redundancy is generated, the relative uncertainty $H_{\mathrm{s}}/H_{\max}$ decreases (ceteris paribus) because $H_{\max}$ increases. The exploration of new options (e. g., diversification) becomes less risky under the condition of less uncertainty [16.102]. The generation of redundancy, in other words, can be expected to improve the climate for entrepreneurship and innovation.

Shannon [16.101] deliberately abstained from the further specification of redundancy in terms of loops. From his perspective, redundancy and coding are needed for error-correction in the transmission (as "excess information"; [16.101]). Error-correction, however, assumes a norm and thus a social system. We note that meaning is provided from the perspective of hindsight and therefore against the axis of time. Insofar as meaning processing requires relationship and communication, Shannon-type information is generated, but at another level—that is, in the relational network space. The relational network can be rewritten as a matrix which can be analyzed in terms of eigenvectors. The focus on this vector space provides a different perspective on the same information contained in the distributions of historical events (e. g., relations).

Since *Shannon* [16.101] defined information as probabilistic entropy. (Shannon used H in Gibb's formulation of the entropy ($S = k_{\mathrm{B}}H$); k_{B} is the Boltzmann constant which provides the thermodynamic entropy S with the dimensionality Joule/Kelvin. However, H is dimensionless.) Because of the second law of thermodynamics, the development of information can only generate increasing entropy [16.103, 104]. The generation of redundancy, however, can be lead to either entropy increases or decreases depending on the feedback and feedforward loops in the meaning processing as different from information processing. Feedback and feedforward loops can be expected to propel information and meaning in clockwise or counter-clockwise cycles (Fig. 16.1), that is, with potentially opposite signs [16.10, 11, 105]. The relative information content of a message ($H_{\mathrm{s}}/H_{\max}$) can be enlarged or reduced by adding or constraining redundancy.

In other words, options other than those already realized are added or removed by mechanisms different from the second law. However, the number of options in a social system can increase much faster than their realizations. In a model, for example, the realizations are considered as special cases among possible states. As the models are refined, more distinctions and therefore options are made available. A knowledge-based economy seeks to exploit the increases of redundancy as a source of wealth.

16.5 The Triple Helix Indicator of Mutual Redundancy

How can redundancy be generated in relations among communication systems? Figure 16.4 visualizes a relationship between two sets as an overlap.

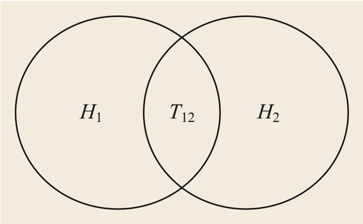

Fig. 16.4 Mutual information between two sets of messages

The formula for mutual information (or transmission T) follows according to the rules of set theory

$$H_{11} = H_1 + H_2 - T_{12} \,. \tag{16.2}$$

One subtracts the overlap (T_{12}) from the summation because otherwise one would count mutual information twice. However, if one sums the two sets as whole sets—accepting and including redundancy as surplus information—one obtains

$$\Upsilon_{12} = H_1 + H_2 + T_{12} \,. \tag{16.3}$$

Redundancy adds to the information content as "excess information" [16.101]. Comparing (16.2) and (16.3), mutual redundancy $R_{12} = -T_{12}$. Whereas T_{12} is Shannon-type information and therefore positive, R_{12} consequentially is expressed in terms of negative bits of information.

(16.2) can be rewritten in a more general format as follows

$$T_{12} = \sum_{i=1}^{n=2} H(x_i) - H(x_1, x_2) \geq 0 \,. \tag{16.4}$$

For more than two dimensions one can inductively generalize (16.4) as follows

$$\sum_{i=1}^{n=3} H(x_i) - H(x_1, x_2, x_3) = \sum_{ij}^{3} T_{ij} - T_{123} \tag{16.5}$$

$$\begin{aligned} &\ldots \\ &\sum_{i=1}^{n} H(x_i) - H(x_1, \ldots, x_n) \\ &\quad = \sum_{ij}^{\binom{n}{2}} T_{ij} - \sum_{ijk}^{\binom{n}{3}} T_{ijk} + \sum_{ijkl}^{\binom{n}{4}} T_{ijkl} - \ldots \\ &\qquad + (-1)^n \sum_{ijkl\ldots(n)}^{\binom{n}{n}} T_{ijkl\ldots(n)} \,. \end{aligned} \tag{16.6}$$

The left-side terms of (16.5) and (16.6) are positive because of the subadditivity of entropy (16.4). The alternation of the sign for mutual information in n dimensions (16.6)

$$(-1)^n \sum_{ijkl\ldots(n)}^{\binom{n}{n}} T_{ijkl\ldots(n)}$$

is an analytical consequence of this subadditivity. Taken apart, T_{ijk} and next-order terms can no longer be considered as Shannon-type information because of the sign changes [16.103, 104]. With the opposite sign, however, T_{ijk} can be considered as a measure of mutual redundancy. For n dimensions, the mutual redundancy R_n is

$$\begin{aligned} R_n &= -[(-1)^n T_{1234\ldots n}] \\ &= -\left[\sum_{i=1}^{n} H(x_i) - H(x_1, \ldots, x_n) \right] \\ &\quad + \left[\sum_{ij}^{\binom{n}{2}} T_{ij} - \sum_{ijk}^{\binom{n}{3}} T_{ijk} + \sum_{ijkl}^{\binom{n}{4}} T_{ijkl} - \ldots \right. \\ &\qquad \left. + (-1)^{1+n} \sum_{ijkl\ldots(n-1)}^{\binom{n}{n-1}} T_{ijkl\ldots(n-1)} \right] . \end{aligned} \tag{16.7}$$

R_n can be positive or negative: the first term on the right side of (16.7) is necessarily negative (because of the minus sign); but the second term is positive entropy in a set of relations. The outcome is balanced and therefore empirical. The more negative the sum, the more options are generated.

In other words, mutual redundancy is generated in a trade-off between selective structures and variable configurations of relations. A configuration can also be reorganized; for example, in terms of developing new institutional arrangements. The minimalization of the second (positive) term in (16.6) provides us with a criterion for the evaluation of changes in the relations. (We have hitherto not further elaborated this criterion.) The positive term is historically contingent, whereas the negative terms reflect the structure(s) in the system. As noted, these structures are not given naturally, but are (re)constructed. The technocultural evolution based on distinguishing [16.13] thus transforms the historical developments.

As new options are made available, the domain of what *Kauffman* [16.106] called *adjacent others*—diversification options at the border between historically realized and possible, as yet unrealized states—is changed. The shaping of new relations and loops changes the phase space first along historical trajectories. However, possibly unintended loops may emerge which feedback or feedforward on existing loops. Resonances among the loops can trigger a next-order cycle of redundancy generation, such as a change in a technological regime [16.107]. A change at the regime level implies a redefinition of the selection mechanisms in the vector space since another dimension is added. What *demand*, *supply*, and *control* mean may have changed after such a transition. For example, the demand for innovation in horse shoes changed after the introduction of the automobile. Although the automobile first emerged necessarily along a trajectory, the car system followed as a regime with many feedback loops. Feedback loops stabilize the system, whereas feedforward ones destabilize; but they enhance globalization beyond the boundaries currently given.

In summary, the information-theoretical perspective provides us with a model of technoeconomic evolution beyond the measurement instrument of the TH indicator. The regime level adds another selection environment reorganizing the trajectories [16.6, 108]. This selection environment—a communication field or overlay—emerges first as a second-order interaction term among bilateral relations (Fig. 16.2), but then becomes analytically different—as a knowledge base—from the selection environments from whose interactions and overlaps it emerged.

16.6 The Measurement

The TH indicator was first developed in the context of the institutional TH model as a quantification of the balance between bi- and trilateral relations among universities, industries, and governments [16.109, 110], [16.111, pp. 143 ff.]). The indicator can be derived using the Shannon formulas [16.112, 113] as

$$T_{123} = H_1 + H_2 + H_3 - H_{12} - H_{13} - H_{23} + H_{123} \,. \quad (16.8)$$

As noted above, T_{123} is not a Shannon measure since it can be negative. (The Shannon measure with a positive sign is $\sum_{ij}^{3} T_{ij} - T_{123} \geq 0$; (16.5) above). In the three-dimensional case, mutual redundancy $R_{123} = T_{123}$. In the two-dimensional case, however, $R_{12} = -T_{12}$. R measures mutual redundancy in a configuration of relations under study.

Figure 16.5, for example, is based on using all publications in the science citation index (SCI) with at least one South Korean address in the byline during the period 1973–2006. These publications carry 190 196 Korean addresses which were manually evaluated and then analyzed in terms of university–industry–government coauthorship relations using the TH indicator R_{123}. The figure shows the development of the interactions: whereas initially the system was state-controlled, the dictatorship regime relaxed gradually during the 1970s. This tendency was strengthened during the period of democratization in the 1980s. After the status of a more advanced economy is reached, the pendulum in the balance between uncertainty and redundancy generation swings back when Korea enters increasingly the world market, leading to full OECD membership in 1996. The internationalization of the research system uncouples from the national system of publications, and mutual redundancy thus decreases in absolute value (or, in other words, becomes less negative). Communication becomes more efficient or, in other words, less redundant.

On the basis of SCI data for the year 2011, Fig. 16.6 shows the strong integration at the national level in the

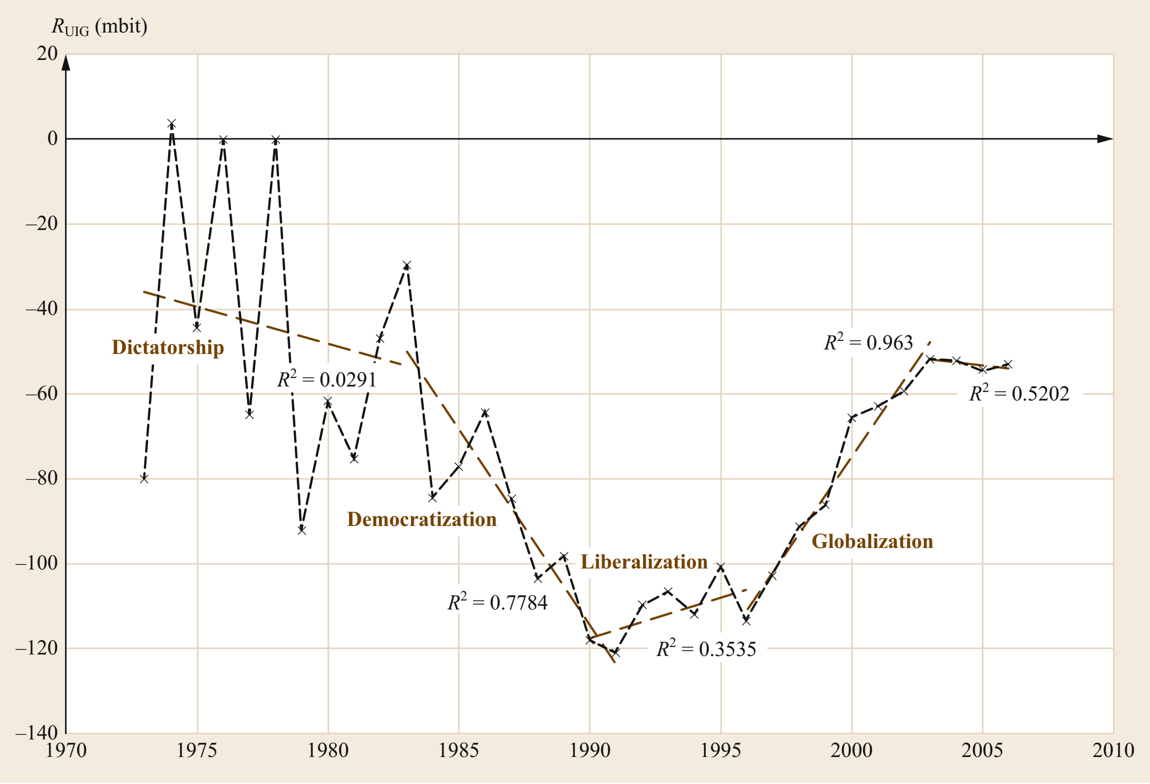

Fig. 16.5 The development of mutual redundancy in South Korean university–industry–government coauthorship relations during the dictatorship, the periods of democratization, liberalization, and globalization, respectively. (Adapted from [16.110, p. 645])

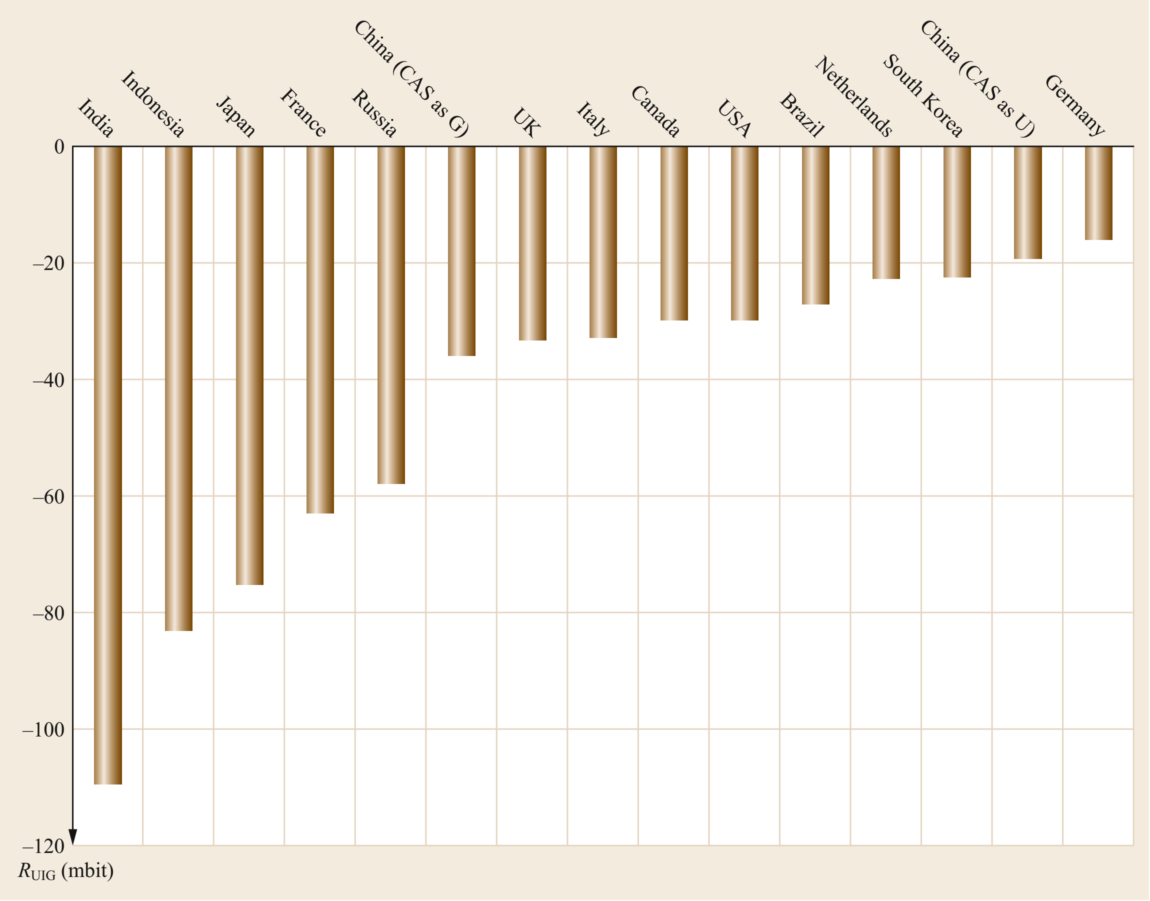

Fig. 16.6 University–industry–government coauthorship relations in 2011, evaluated in terms of mutual redundancy. Source: [16.114]. N of publications = 1 195 494 retrieved from the *Science Citation Index,* using an approximation developed by *Leydesdorff* [16.109, p. 458]; cf. *Park* et al. [16.115, 13 ff.]

case of some Asian countries (India, Indonesia, and Japan), whereas OECD member states (e. g., Germany and South Korea) are oriented more globally. The Chinese data provide us with an opportunity to consider publications of the Chinese Academy of Science (CAS) as either university or government.

The CAS is gradually making this transition [16.116]. When CAS publications are considered as university publications, the Chinese system can be compared with South Korea and Germany in terms of its local (national) versus global orientation. As government publications, however, CAS firmly anchors the Chinese publication system at the national level. The different patterns of TH configurations in developed versus developing nations have been further investigated by *Choi* et al. [16.117, 118].

16.7 Measuring the Knowledge Base of Innovation Systems

In studies focusing on university–industry–government relations, one can count seven instances (U, I, G, UI, UG, IG, and UIG) and then evaluate the combinations in the following three-dimensional cube of information (Fig. 16.7).

Note that the eighth option $\{U = 0; I = 0; G = 0\}$ is not counted in this (relational) model. Along each of the axes, however, one can refine the measurement. Instead of *university*, for example, one can distinguish among disciplines in terms of departments and faculties, given

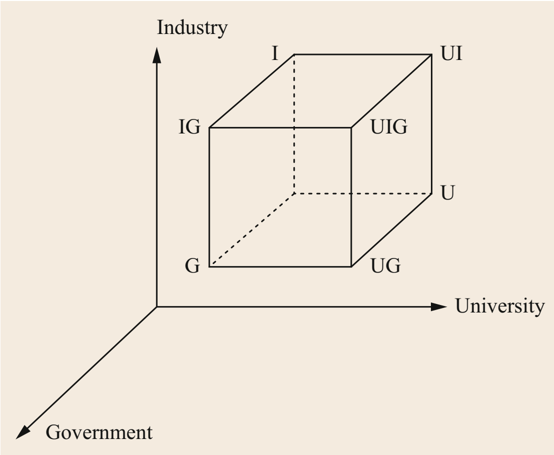

Fig. 16.7 University–industry–government relations and a three-dimensional vector space

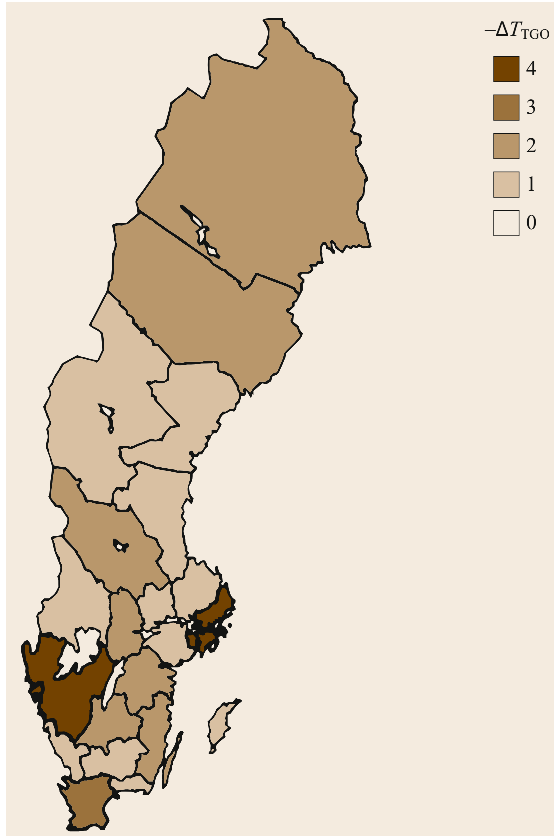

Fig. 16.8 Contributions to redundancy at the level of 21 Swedish counties (NUTS-3)

that university–industry relations are very different in biomedicine, engineering, or the social sciences. Similarly, industry can be differentiated among sectors (e. g., medium- and high-tech) and the dimension of government can be made more precise as national, regional, city, etc.

Using *Storper*'s [16.26] metaphor of a "holy trinity of technology, territory, and organization," one can organize firms in terms of technological classes, geographical addresses, and organizational size, and study the interactions among these three dimensions. Which regions or sectors contribute most to the generation of redundancy? In the case of Sweden, for example, the complete set of (micro) firm data for Sweden at Statistics Sweden was $N = 1\,187\,421$ in November 2011. This Swedish data contains address information in terms of 290 units at the lowest level of municipalities (NUTS5), a technology classification into 21 classes—concordant with the NACE classification of the OECD/Eurostat—and nine classes of numbers of employees which allow us to distinguish between small, medium-sized, and large companies using the TH calculator available at http://www.leydesdorff.net/software/th4 [16.119].

Figure 16.8 shows the results for the 21 counties in Sweden at the level NUTS-3. As could be expected, mutual redundancy is highest (in absolute value) for Stockholm (−3.49 mbit), Västre Gotalands län (−2.91 mbit), and Skåne (−2.31 mbit). These three counties host the major universities and dominate the picture within the nation; together they account for $(8.71/17.95 =)48.5\%$ of the summed redundancies of the regions at this geographical scale (NUTS-3).

One of the advantages of entropy statistics is that the values can be fully decomposed. Analogously to the decomposition of probabilistic entropy [16.120, 20f.], mutual redundancy in three (or more) dimensions can be decomposed into groups as follows

$$R = R_0 + \sum_G \frac{n_G}{N} R_G\,. \tag{16.9}$$

When one decomposes in the geographical dimension, R_0 represents redundancy generated between regions; R_G is the synergy generated at a geographical scale G; n_G is the number of firms at this geographical scale; and N the total number of firms in the aggregate ($N = 1\,187\,421$ in the Swedish case).

The between-group redundancy (R_0) can be considered as a measure of the synergy among regions. A negative value of R_0 indicates an additional synergy (i. e., redundancy generation) at the next level of national agglomeration among the lower-level geographical units. In the Netherlands and Sweden, for example, such a surplus was found at the national level; in Germany, this surplus was mainly found at the level of the federal states (*Länder*). Whereas one cannot compare the quantitative values of R_0 across countries—because these values are sample-specific—one is allowed to compare the indicator in terms of the positive or negative signs of R_0 and as percentages of the total synergy (R_{123}). The percentages of synergy which is generated above the regional level in the various country studies, for example, can be found in column (e) of Appendix 16.A.

Table 16.2 shows that in the case of Sweden, the surplus of the national system is -4.61 mbit (on top of the aggregation of the results at individual counties). This is 25.7% of the -22.56 mbit measured for Sweden as a national system. In other words, one quarter of the reduction of uncertainty in the national system is realized at a level higher than within the regions. At the next level of aggregation (NUTS2), an additional synergy of $(22.56-19.84) = 2.72$ mbit, or 13.7%, is realized. Among the three *Landsdelar* (NUTS1), however, only 0.5 mbit, or 2.2% of the national sum total, is reduced by this further aggregation. In other words, the Swedish national system is organized hierarchically, as indeed is suggested by most of the literature about Sweden.

Analogous to the geographical decomposition, one can also decompose redundancy in terms of industrial sectors or firm sizes. In a series of studies, we decomposed a number of national systems of innovation: Germany [16.122], the Netherlands [16.123], Sweden [16.121], Norway [16.124], Italy [16.125], Hungary [16.126], the Russian Federation [16.127], and China [16.128]. In the case of the Netherlands, Norway, Sweden, and China, the national level adds to the sum of the regions. In the Netherlands, the (inter-regional) highways to Amsterdam Airport (Schiphol) are probably the most important axes of the knowledge-based economy. In Sweden, the synergy is concentrated in three regions (Stockholm, Gothenburg, and Malmö/Lund); in China, four municipalities which are administered at the national level participate in the knowledge-based economy more than comparable regions. As noted, summary information about the various country studies is provided in the Appendices 16.A and 16.B. For more detailed information about data and methodology the reader is referred to the original studies. Here, we focus on the theoretical conclusions of these studies.

In Norway, foreign-driven investments along the west coast in the marine and maritime industries drive the transition from a political to a knowledge-based economy. The synergy in terms of the development of new options is larger in these coastal regions than in the regions with the traditional universities in Oslo and Trondheim. Hungary's western part is transformed by integration into the European Union, whereas the eastern part has remained a state-led innovation system. The capital Budapest occupies a separate position as a metropolitan system of innovations. The national level no longer adds synergy to the sum of the synergies in these three regional systems.

In a study of Italy, we first used the administrative units (NUTS2 regions) provided by Eurostat and the OECD. The data is the complete set of 4.5 million Italian firms registered at Statistics Italy in 2007. Figure 16.9 shows that the main division in this country is between the northern and southern parts of the country. (Sicily has a special position.) In other words, the pattern is opposite to the one for Sweden summarized in Table 16.2 above: the regions are administrative artifacts, while the country is organized in terms of two main innovation systems, each with a different dynamics. The aggregation among the lower level regions indicates the role of the national system, but this role is different in the northern and southern parts of Italy. The perspective on Italy in terms of regions [16.129] is not supported by these results.

One of the conclusions to be drawn throughout the studies of the more advanced economies, is that knowledge-intensive services do not contribute to the local synergy in regions because they are not coupled geographically. For example, if one offers a knowledge-intensive service in Munich and receives a phone call from Hamburg, the next step is simply to take a plane to Hamburg, or perhaps to catch a high-speed train. In other words, it does not matter whether one is located in Munich or Hamburg as knowledge-intensive services uncouple from the local economy. The main competitive advantage is proximity to an airport or train station.

In a study of the Russian Federation, however, the national level could be shown to disorganize synergy development at lower levels. Knowledge-intensive services (KIS) cannot sufficiently circulate in Russia because of their integration into the (localized) state apparatuses. Relative *foot-looseness* [16.130] of KIS can also be expected in the case of high-tech knowledge-

Table 16.2 Between-group synergy at different geographical scales in the Swedish innovation system. Source: [16.121]

Geographical scale	$\sum R$ (mbit)	R_0	R_0 as % contribution
NUTS0 (national level)	−22.56		
NUTS1 (3 Landsdelar)	−22.08	−0.48	2.2
NUTS2 (8 Riksområden)	−19.84	−2.72	13.7
NUTS3 (21 Counties)	−17.95	−4.61	25.7

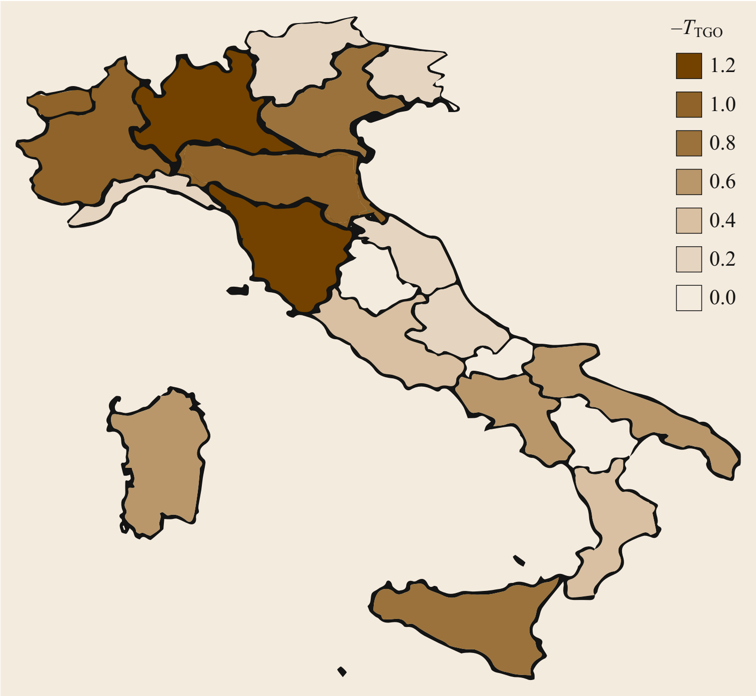

Fig. 16.9 Decomposition of Italy in terms of regions; n of firms $= 4\,480\,473$. Data: Statistics Italy (IStat), 2007. Source: [16.125]

based manufacturing; but the expectation is different for medium-tech manufacturing, because in this case the dynamics are often more embedded in other parts of the economy [16.131].

A number of policy implications follow from these conclusions and considerations. Footloose companies cannot be expected to contribute to the strengthening of the integration within a given region. High-tech knowledge-intensive services, however, may require a laboratory. One would expect medium-tech manufacturing to be more embedded and thus to generate more employment than high-tech.

In summary, the different country studies show that the patterns can be very different among nations as well as among regions within nations [16.132]. The dynamics are also different when comparing the sciences with markets: in publication systems uncoupling and international (that is, nonlocalized) orientation can be considered as improvements to the system, while in the case of regional developments the focus is on retaining *wealth from knowledge* and thus on developing local synergies. The discussion of the potential uncoupling from geographical locations by knowledge-intensive services illustrates how the different dynamics can also be interwoven. High-tech and knowledge-intensivity tend to induce globalization, including volatility, since stabilization is not a priority. The trade-off between the knowledge-based economy self-organizing at the global level and the lower-level organization in networked instantiations can be measured in considerable detail using the TH indicator.

Since the dynamics are complex, the results can be counter-intuitive because the a priori categories are being tested as hypotheses. Where are empirically the windows of opportunity for coupling self-organizing and differentiation with integration into organized forms and along trajectories? In a recent study of Spain, for example, Andalucia as a region (at the NUTS2 level) did poorly in generating mutual redundancy, but Sevilla as a town within this region (NUTS3) showed a different pattern [16.133]. In summary, one of the major functions of these studies is to revise and inform the categories used for making such assessments. Revision may make these categories more knowledge-based and thus enhance the visibility of new options.

16.8 Institutional Retention

Note that the TH indicator is a systemic indicator. Activities in a specific region (e. g., Linköping in Sweden; [16.134]) may have been very successful in terms of developing university–industry–government relations, but entrepreneurship is a form of action. One expects national governments and European policies to develop action plans to stimulate *less favored regions*. However, the TH-indicator informs us about the environments of these entrepreneurial activities. The chances of being successful as an innovative entrepreneur are statistically higher in Stockholm than in Linköping because of the relative reduction of uncertainty in the former region. This conclusion is not meant to discourage entrepreneurship in lagging regions. On the contrary, one may also conclude as a policy implication that some regions do not need support because the dynamics of the knowledge-based economy is already self-organizing in these regions.

Action, entrepreneurship, and local organization combine and integrate technical opportunities, market perspectives, and geographical resources (e. g., endowments). Selection mechanisms, however, differentiate on the basis of different criteria. Insofar as the criteria interact, redundancy may be generated. In other words, the complex dynamics is both differentiating and integrating. The neoevolutionary model focuses first on the *structural differentiation*: how is the system driven to change? The (neo-)institutional perspective on university–industry–government relations focuses on *integration in action*; for example, in terms of academic entrepreneurship.

From this perspective, the focus is on finding new ways to enhance innovation, such as the invention of venture capital. The cognitive dimension is endogenized into this model in the context of policy innovations. For example, priority programs at strategic research sites such as the emergence of new interdisciplinary fields (e. g., computer science) have been synthesized since the mid-20th century [16.135]. New fields are actively coconstructed as opposed to a previous model of branching into specialization [16.136].

Despite the intrinsic relations between the institutional and evolutionary models, the resulting research programs are different in important respects. A range of metrics have been developed from the institutional perspective on TH relations. These approaches do not present a single model for capturing *the Triple Helix*, but focus on different aspects of TH relations. Contributions link diverse themes ranging from conceptual work on entrepreneurial science (e. g., [16.2, 137]) and academic capitalism [16.138], or entrepreneurial universities [16.4] that can act as regional innovation organizers [16.139], to research on indicators such as university patenting and licensing [16.140, 141] and academic inventors [16.142, 143]. The theoretical frameworks of the empirical studies span a large domain including organization studies, business and management, network science, etc. It is beyond the scope of this chapter to review all these approaches which touch upon the TH theme.

We illustrate the diversity of theoretical backgrounds showing a coword map (Fig. 16.10) based on 139 keywords attributed five or more times to 492 documents retrieved from the Social Science Citation Index and the Arts & Humanities Citation Index on November 16, 2016 using the search string: `ts="Triple Helix" OR ts="university-industry-government relations"`. Seven clusters are distinguished, among them three major ones in red, green, and blue. `Triple-helix` as an adjective (with hyphen) is positioned in the blue-colored cluster on the left side labeled *entrepreneurial university*. `Triple Helix` as a substantive (without hyphen) is positioned in the green cluster on the right side labeled *systems dynamics*. The main cluster in red at the top relates the TH theme to studies of higher education and university policies. Scientometric indicators and social networks are indicated at the bottom with keywords that refer to new technologies such as *nanotechnology*.

A considerable number of contributions are concerned with capturing academic entrepreneurship [16.144]. Academic patenting has been debated in relation to the Bayh–Dole Act of 1980, which changed the intellectual property rights on academic inventions in the USA. *Mowery* et al. [16.145], for example, argued that the Bayh–Dole Act has been an important driver of university patenting and licensing activity. The entrepreneurial university has been another starting point for the development of indicators to measure Triple Helix relations [16.142, 146, 147]. *Narin* et al. [16.148, p. 317] considered the rapidly growing citation linkages between US patents and scientific literature as "useful evidence in arguing the case for governmental support of science."

Most of the scientometric contributions are method-driven; the TH is used as a metaphor in the theoretical background. Some authors argue for extending the metaphor to four or more helices, including for example the public, or the relation between developed and developing countries [16.149, 150]. The extension of the TH indicator of synergy to more than three dimensions is straightforward [16.119].

16.9 Concluding Remarks

The Triple Helix provides a metaphor which can be used in modeling the knowledge-based economy and innovation. The dynamics of a knowledge-based economy are complex [16.78, 151, 152]. We have argued that the challenges of modeling are not only theoretical. Systemness can be operationalized and measured in terms of the generation of new options. Without such operationalization, the notion of *system* tends to lead to reification; knowledge-based systems are not given, but constructed.

However, one can assume and test the possibility of emerging systemness. Can synergy be indicated and if so, at which level? From a communication-theoretical perspective, the not yet realized options can be considered as redundancy. Redundancy is developed by providing meanings from different perspectives to the same or similar events. A Triple Helix of university–industry–government relations provides these different perspectives.

In addition to horizontal differentiation among the three helices, we have operationalized vertical differentiation. The vertical differentiation finds its origin in the focus on relations in the neoinstitutional model [16.25, 27]: the nodes (in this case, the institutions) operate by relating; the relations relate in a second-order dynamics of possible relations. Meaning is provided from the perspective of hindsight to events invoking horizons of meaning that can be codified differently. The codes are generated by what has also been called institutional logics [16.153] or they can be considered as the eigenvectors in a vector-space [16.154]. A three-layered system is thus envisaged: information processing in relations at the bottom; meaning processing in a vector space based on correlations among distributions of relations; and thirdly, an interaction between meaning processing and codes of communication that opens horizons in which cognitive distinctions can be constructed. In other words, these cognitive constructs are embedded in social constructions such as networks and institutions.

New options are developed through cultural practices. The social structures carry the knowledge-based structures which are themselves carried by reflexive agents who infrareflexively have access to and can integrate representations in all three layers [16.81]. Agents are thus able to change structures; the structures mediate in layers of communication which transform events (including actions) into expectations and expectations into discursive knowledge [16.155]. Construction is bottom-up; control tends to be top-down. As a new selection environment is constructed, the locus of control can be expected to shift. As yet another selection environment, the knowledge base thus transforms the political economy in which it remains under construction.

Acknowledgments. We wish to thank Henry Etzkowitz, Han Woo Park, two anonymous referees, and the editors of the SPRU Working Papers Series (SWPS) for comments on previous versions.

Amsterdam, The Netherlands
loet@leydesdorff.net

Loet Leydesdorff (PhD Sociology, MA Philosophy, MSc Biochemistry) is Professor Emeritus at Amsterdam School of Communication Research (University of Amsterdam). He is Associate Faculty at the Science and Technology Policy Research Unit of the University of Sussex, Visiting Professor of the Institute of Scientific and Technical Information of China, and Guest Professor at Zhejiang University. He has published extensively in systems theory, social network analysis, scientometrics, and sociology of innovation. Clarivate Analytics lists him as highly-cited researcher since 2014.

17. Scientometrics Shaping Science Policy and vice versa, the ECOOM Case

Koenraad Debackere, Wolfgang Glänzel, Bart Thijs

It is difficult to imagine a world without science policy. Ever since Vannevar Bush published his seminal insights on the role of science in society, science policy has become deeply ingrained in public policy. Alongside this, the discipline of scientometrics developed. It started from library and information needs, helping the ever-growing scientific community to access, retrieve and disseminate its ever-increasing output. However, along the way, scientometrics developed into a powerful set of scientifically validated data, indicators and tools. It diffused across many disciplines in the social sciences. Over time, this evolution came to the attention of policymakers. The wealth of data and indicators developed in the field of scientometrics (later extended to informetrics and webometrics) elicited interest in their use for policy purposes. A symbiosis between scientometrics and science policy was born. Using the case of the Flemish Centre for Research & Development Monitoring (ECOOM), we describe and illustrate this coevolution between scientometrics and science policy, its opportunities and its challenges, and its do's and don'ts.

17.1 Scientometrics and Science Policy, a Symbiotic Relationship

Since the seventeenth century, journals have been the most important communication channel in biomedical, life and natural sciences, as well as in a growing number of social sciences. They offer a reliable and valid source of data on scientific methods and results so long as they are peer reviewed, i. e., their content is endorsed by means of expert qualitative judgments. Critical review by peers of the scientific insights developed and posited in papers became a central mechanism to check and support scientific progress since that era. Both the publication literature (and its channeling into scientometric or, synonymously, bibliometric applications) and the peer-review mechanism became cornerstones in the fields of science, technology and innovation policy.

Since the first half of the twentieth century, the bibliographic structure of journal papers has become highly predictable and standardized compared to other publication venues, making them the ideal target for the (semi) automatic extraction of metadata preliminary to their statistical analyses. *Derek de Solla Price* formalized the paradigm of quantitative science studies in his book *Little Science, Big Science* [17.1, p. xvi]:

> My approach will be to deal statistically, in a not very mathematical fashion, with general problems of the shape and size of science and the ground rules governing growth and behaviour of science-in-the-large … I shall not discuss any part of the detail of scientific discoveries, their use and interrelations. I shall not even discuss specific scientists … The method to be used is similar to that of thermodynamics, in which is discussed the behaviour of a gas under various conditions of temperature and pressure.

Bibliometrics would be just a counting game if matters of size were its only concern—at some point, quantity had to yield to quality, or in de Solla Price's

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_17

words (quoted in *The Encyclopaedia of Library and Information Science*):

> Who dares to balance one paper of Einstein on relativity against even a hundred papers by John Doe, Ph.D., on the elastic constant of the various timbers (one to a paper) of the forest of lower Basutoland?

The missing link was filled in the 1960s. The citation network developed by Eugene Garfield's science citation index (SCI) provided a welcome answer since: (1) authors cite in the bibliographies of their papers mostly (although not only) other documents/authors that have supplied some form of prior relevant art, e. g., tools, methods, ideas, reviews of previous studies, etc., and (2) the number of citations accrued to a document/author provides a true estimate of its usefulness to others, hence it is an indicator of its cognitive impact. These ideas were pioneered by *Garfield* [17.2] in his seminal paper *Citation Indexes for science: a new dimension in documentation through association of ideas*.

It must be mentioned that before the *invention* of the SCI, quantitative and qualitative analyses of science were performed along routes such as the compilation and rankings of eminent scientists and the descriptive statistics of bibliographic data for historical or library management purposes (statistical bibliography). The advent of the SCI and the possibility to track quantity and quality patterns in the network of published scientific literature marked the point of no return in bibliometrics, legitimizing its entrance into the science policy arena since the 1970s. Some reflections helped this legitimation. Peer review was judged to be subject to many (personal, social) biases whereas bibliometric measures are objective, or at least they seem to be. Hence, rankings of authors and institutions based on publication outputs and citation scores can complement the peer-review process in the allocation of scientific merit (tenure, promotions, funding, etc.) while the mapping of bibliographic links between scientific documents can help understand the cognitive structure and the dynamics of scientific communication.

Today, it is difficult to imagine a world without science policy. Ever since *Vannevar Bush* published and pushed his seminal insights [17.3] on the role of science in society, science policy has become deeply ingrained in government functions and functioning. Alongside the advent of science policy, the discipline of scientometrics developed and evolved. It started from library and information needs, helping the ever-growing scientific community as described by *Derek de Solla Price* [17.1] to access, retrieve and disseminate its ever-increasing output. However, as the library and information needs developed, scientometrics developed into a powerful set of scientifically validated data, indicators, methods and tools. Scientometrics thus became the cornerstone of the field of library and information science [17.4]. In addition, scientometrics diffused across many disciplines in the social sciences, such as the sociology of science, history of science and the economics of science. This diffusion is briefly summarized in Fig. 17.1.

Over time, this evolution drew the attention of policymakers. The wealth of data and indicators developed in the field of scientometrics (later extended to informetrics and webometrics) elicited interest in their policy use and usability. A symbiosis between scientometrics and science policy was born, as summarized in Fig. 17.2. This symbiosis has led to multiple uses of scientometrics in the policy scene [17.5, 6]. As a consequence, scientometrics has been shaping science policy, while science policy is shaping bibliometrics. This coevolution is significant and is further evidenced through the case of the Centre for Research & Development Monitoring (ECOOM) in Flanders.

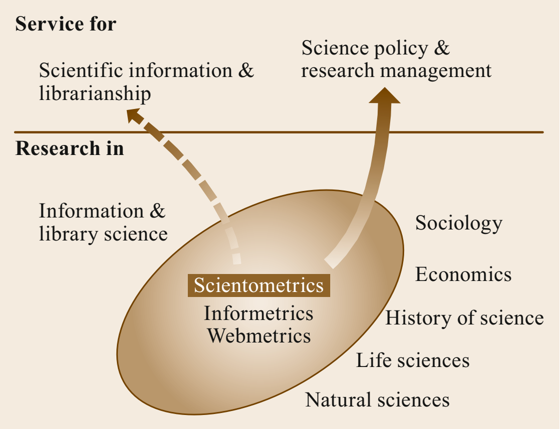

Fig. 17.1 The development and diffusion of scientometrics in the (social) sciences with application in research assessment becoming predominant (as shown by the thickness of the *arrows*)

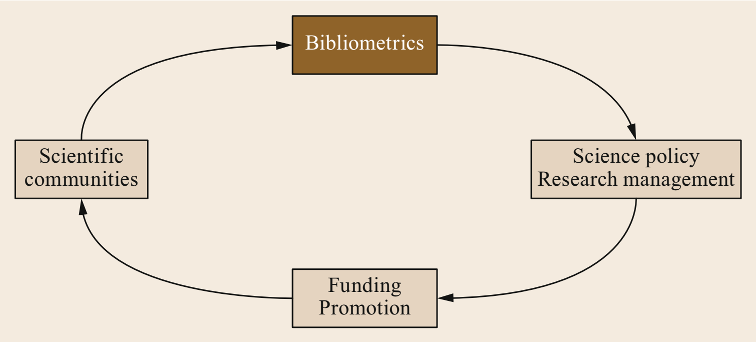

Fig. 17.2 The symbiosis of scientometrics and science policy (after [17.7]), *arrows* depicting the cycle of influence

17.2 ECOOM: An Instrument Linking Science Policy and Scientometrics in Flanders

In Flanders, the link between science policy and scientometrics is supported by and operationalized through the interuniversity consortium ECOOM, funded and monitored by the Flemish government. The precursor of ECOOM (i. e., Steunpunt O&O Statistieken or SOOS) was first created in 2001. In 2009 it was transformed into a permanent center of expertise of the Flemish government, called ECOOM (Expertise Centrum O&O Monitoring). The mission of ECOOM is to develop and maintain a performing system of science, technology and innovation indicators that provides the Flemish government with up-to-date and relevant statistical data on the science, technology and innovation performance of the Flemish region. Furthermore, ECOOM develops a portfolio of the relevant scientific research activities that support this mission. In order to fulfill this mission, ECOOM is expected to:

1. Conduct a series of targeted long-term, recurrent assignments and tasks that map, quantify and analyze the Flemish science, technology and innovation potential
2. Ascertain whether the Flemish government has the appropriate data and indicator management structure at its disposal on bibliometric, technometric, research and innovation data
3. Develop and maintain a qualified staff
4. Build, develop, extend and maintain the necessary original IT infrastructure
5. Deliver various ad hoc assignments and projects on demand for the Flemish government.

Bibliometrics is one ECOOM's core activity areas. The terms bibliometrics and scientometrics were introduced almost simultaneously by *Pritchard* [17.8] and by *Nalimov* and *Mulchenko* [17.9] in 1969. While *Pritchard* explained the term bibliometrics as "the application of mathematical and statistical methods to books and other media of communication" [17.8], *Nalimov* and *Mulchenko* defined scientometrics as "the application of those quantitative methods which are dealing with the analysis of science viewed as an information process." [17.9] According to these interpretations, scientometrics is restricted to the measurement of science communication, whereas bibliometrics is designed to deal with the more general information processes.

The sharp rise which bibliometrics has undergone since the late 1960s is reflected in remarkable academic activities. This rise is intimately connected with:

1. Advancements in information technology
2. Developments in computer science and technology
3. The worldwide availability of large bibliographic databases, serving as the groundwork for bibliometric research.

In particular, the (former) ISI databases should be mentioned in this context. The SCI, and more recently, the Web of Science, have become the generally accepted basic sources for bibliometric analysis. ECOOM has acquired access to the Thomson Reuters (now Clarivate Analytics) Web of Science (WoS) dataset, as well as to the conference proceedings data. The WoS data are available from 1980 and the conference proceedings data from 1991. In addition, ECOOM has access to an experimental version of Elsevier Scopus from 2008.

However, in the 1970s, when data collection was often still a matter of manual work, the bibliometric field was characterized by the personalities of enthusiastic researchers, whose work in the field was more of a *hobby*. Later, interdisciplinary approaches, mathematical and physical models, and sociological and psychological methods, as well as the long tradition of library science were integrated. Since the beginning of the 1980s, bibliometrics evolved into a distinct scientific discipline with a specific research profile, several subfields and the corresponding scientific communication structures. Imitating the transition from the *manufactural* form of *little science* to the *big science* of multinational research centers with enormous governmental and industrial support, scientometrics itself has claimed to have evolved from its *little* form to a *big* one with large computerized databases and with national and multinational research policy agencies as major customers.

In the 1990s, bibliometrics became a standard tool of science policy and research management. In particular, all significant compilations of science indicators heavily rely on publication and citation statistics and other more sophisticated bibliometric techniques. The IT revolution we have recently witnessed has further sped up scholarly communication. Electronic publication, open access, and the *World Wide Web* have essentially facilitated access to scientific information. ECOOM, like the Centre for Science and Technology Studies in Leiden (CWTS) or the Observatoire des Sciences et de Techniques in Paris (OST), has developed competencies in advanced bibliometric techniques and actively takes part in international, state-of-the-art research in the bibliometrics domain. But ECOOM does not limit its bibliometric activity to the large, international databases.

Given the limitations of those traditional databases to sufficiently capture and cover the bibliometric output of the social sciences and humanities, ECOOM has also developed the VABB-SHW, the Flemish Academic Bibliographic Database for the Social Sciences and Humanities (i. e., *Vlaams Academisch Bibliografisch Bestand voor de Sociale en Humane Wetenschappen*). This database captures the output of Flemish scientists from the social sciences and humanities that is not covered by WoS or Scopus. It not only includes peer-reviewed articles, but also books and monographs that have been subject to peer review. The list of journals and editors that are used for counting is determined and updated annually by the authoritative panel (*Gezaghebbende Panel*) on social sciences and humanities composed of 18 researchers in the fields of social sciences and humanities who have obtained international renown and recognition.

Since 2011, the outputs derived from the VABB-SHW, as stipulated in the Flemish university legislation on performance-based funding systems, are a parameter in the distribution of both the block grant and the dedicated research funds amongst the five Flemish universities. As such the VABB-SHW is an important addition to the Flemish performance-based research funding system. Apart from Norway [17.10], no other countries or regions have thus far succeeded in implementing a full coverage database of scholarly publications in the social sciences and humanities, making the VABB-SHW a prime international example of the innovative yet inclusive science policy pursued by the Flemish government.

We discuss the bibliometric activities of ECOOM. It should be mentioned, though, that ECOOM also contributes to the design and maintenance of technometric indicators (patent analyses), innovation indicators (based on the Frascati and Oslo manuals), indicators to measure outputs in the arts, and indicators on PhD activities in Flanders. Given this comprehensive scope, ECOOM explicitly supports the science, technology and innovation (STI) policy of the Flemish government. Not only do its various tasks and work packages support the Flemish government's recurrent needs for accurate and timely STI data and indicators, but they also provide the necessary input for dedicated policy objectives adopted by the Flemish government, i. e., the need for monitoring, benchmarking, and mapping the output of the Flemish STI system, as well as providing the necessary data and indicator support for the Flemish innovation cluster policies that have been adopted recently.

To this end, ECOOM operates as an interuniversity consortium, including the active participation of all Flemish universities: KU Leuven, UGent (Universiteit Gent), VUB (Vrije Universiteit Brussel), UA (Universiteit Antwerpen) and UHasselt (Universiteit Hasselt). It fulfills the following objectives:

- Develop and maintain a validated, robust, coherent and recurrent system of science, technology and innovation indicators
- Develop, grow and maintain the necessary and accessible IT infrastructure and cornerstone databases
- Conduct and deliver relevant and up-to-date research on the further development of STI indicator sets
- Deliver and provide the necessary indicators and statistics to the Flemish government to support its science, technology and innovation policy
- Execute a portfolio of policy-relevant studies and projects requested by the Flemish government
- Whenever necessary, reply to and advise on ad hoc questions of the Flemish government with respect to science, technology and innovation policy
- Coordinate and deliver the biennial editions of the *Flemish Indicator Book on Science, Technology and Innovation*.

17.3 ECOOM: Mapping and Benchmarking Science Activities in Flanders

Over the years, ECOOM has validated and benchmarked the bibliometric position of Flemish output in the WoS. The WoS data sources deployed by ECOOM include the Science Citation Index Expanded (SCIE), the Social Sciences Citation Index (SSCI), the Arts & Humanities Citation Index (A&HCI) and the conference proceeding citation indices. Multiple and diverse analyses are continuously executed in support of Flemish science policy.

By way of example, SCIE and the Conference Proceedings Citation Index – Science (CPCI-S) have allowed ECOOM to engage in longitudinal, citation-based analyses of Flemish scientific activity. To that end, the following indicator system was introduced in a systematic and recurrent manner. The analyses are usually based on the five so-called *relevant* or *citable* document types, namely *articles*, *letters*, *notes, proceedings* and *reviews*.

The *mean observed citation rate* (MOCR) (cf. *Braun* et al. [17.11]) provides the starting point for our analyses. MOCR is defined as the ratio of citation count (i. e., in a three-year citation window) to publication count. It reflects the factual citation impact of a country, region, institution, research group, etc. The MOCR indicator (as well as the following indicators) is used in two versions: the standard MOCR includes author self-citations, while MOCRX does not [17.12]. Normalized citation rates can then be calculated on the basis of the MOCR and the following two expected citation rates. These indicators allow us to assess the relationship between the factually achieved citation impact, the visibility/publication strategy and the subject standard:

- The journal-based mean expected citation rate (MECR)
- The subject-based field expected citation rate (FECR).

The *mean expected citation rate* (MECR) (cf. *Braun* et al. [17.11]) of a single paper is defined as the average citation rate of all citable papers (i. e., articles, letters, notes, reviews) published in the same journal in the same year. Instead of the one-year citation window to publications of the two preceding years as used in the journal citation report (JCR), a three-year citation window to one source year is used, as indicated above. For a set of papers assigned to a given country, region or institution in a given field or subfield, the indicator is the average of the individual expected citation rates over the whole set. Analogously to the previous indicator, the FECR of a single paper is defined as the average citation rate of all papers published in the same subject in the same year.

Those indicators form an indicator triplet that should best be considered and interpreted together. Their mathematical relation reveals details about publication strategy and factual impact with respect to what should be expected on the basis of the publications' subject. Several *configurations* are possible, for instance: MOCR > MECR > FECR, which reflects the most favorable situation, and means that the author under study publishes on average in journals with higher-than-discipline standard and receives even more citations (on an average) than the standard set by the journals in which the papers are published. MECR > MOCR > FECR means that the latter standard is not reached and, for instance, FECR > MOCR > MECR means that the researcher achieved a higher citation impact than expected on the basis of the journals in which he/she has published but these journals do not, on an average, belong to the top journals in their discipline. We just mention in passing that these relations can also be expressed numerically by forming the ratios MOCR/MECR, MOCR/FECR and MECR/FECR with the neutral value 1.0.

Braun and *Glänzel* [17.13] have introduced the foundations of the use of those indicators in the context of measuring national publication strategy, and they have been used in a multitude of quantitative studies of national, regional and institutional research assessment [17.6]. Versions of these indicators are used also at CWTS in Leiden [17.14].

In addition to these standard indicators we provide a more versatile, however also more complex, tool for measuring research performance as reflected by citation impact. The distribution of number and share of papers in so-called performance classes representing moderately and highly cited papers according to a four-class scheme of the self-adjusting method of characteristic scores and scales (CSS) is compared with the expectation based on the world standard. These scores and scales are obtained from iteratively truncating samples at their mean value and recalculating the mean of the truncated sample until the procedure is stopped or no new scores are generated. Usually three scores are sufficient, where the first one is identical to the mean value of the reference population. The resulting four classes are obtained by the intervals defined by adjoining scores (Chap. 13 by *Glänzel* et al. in this volume, [17.15, 16]). This method is a real alternative to the application of percentiles, but has two important advantages: 1) CSS is not biased by ties in the underlying citation ranking, and 2) CSS scores are self-adjusting and thus not defined on arbitrary preset values.

The four classes stand for:

1. Poorly cited papers
2. Fairly cited papers
3. Remarkably cited papers
4. Outstandingly cited papers.

Papers in classes 3 and 4 can be considered highly cited. CSS provides robust classes in terms of their insensitivity to publication year, citation windows and subject. Although CSS is not directly linked to percentiles, the standard distribution of papers over classes is about 70% (1), 21% (2), 6–7% (3) and 2–3% (4). The deviations of the institution's profile from the standard or from that of another institution provide a multifaceted picture of its citation impact. An institution's share in certain classes might be higher or lower than, or equal to, the corresponding standard and its profile might thus follow the above-mentioned reference standard or be more or less polarized than the standard or more skewed towards poorly or highly cited papers, respectively. An institution might have more highly cited papers than expected and at the same time less poorly cited papers than expected, but it might also be the other way around and thus have both more poorly and highly cited papers than the reference standard.

By way of example, an overview of some recent analyses is provided in the subsequent figures and tables. This overview gives a flavor of the richness and diversity of scientometric insight ECOOM provides to the Flemish government in support of its science policy. Figure 17.3 provides an overview of the Flemish output (SCIE + CPCI-S) per 10 000 inhabitants over the period 2002–2013 compared to 12 benchmark countries selected by the Flemish government given their relevance to Flemish science policy. Given the longitudinal perspective taken, it provides the Flemish government with a detailed overview of the evolution of Flemish scientific output. This output is further broken down into institutional categories (universities, strategic research centers, hospitals, companies) and into scientific disciplines and subdisciplines based on the Leuven–Budapest subject classification scheme as developed by *Glänzel* and *Schubert* [17.17] in 2003. Those recurrent analyses allow for a detailed and systemic understanding of Flemish research output and productivity. A standard set of 12 countries is used in those analyses. In addition to those 12 *standard* benchmark countries, comparisons with China, Japan and the US are also made on a regular basis.

Figure 17.4 provides an overview of the relative citation frequency of Flemish science and international

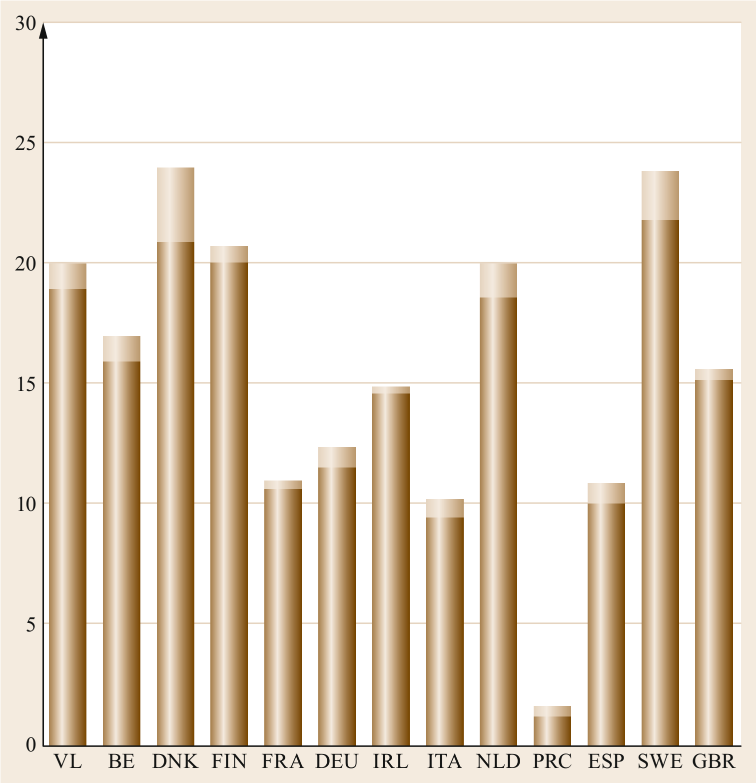

Fig. 17.3 Overview of the Flemish output (SCIE + CPCI-S) per 10 000 inhabitants over the period 2002–2007 (*dark bars*) and 2008–2013 (*light bars*), compared to 12 benchmark countries

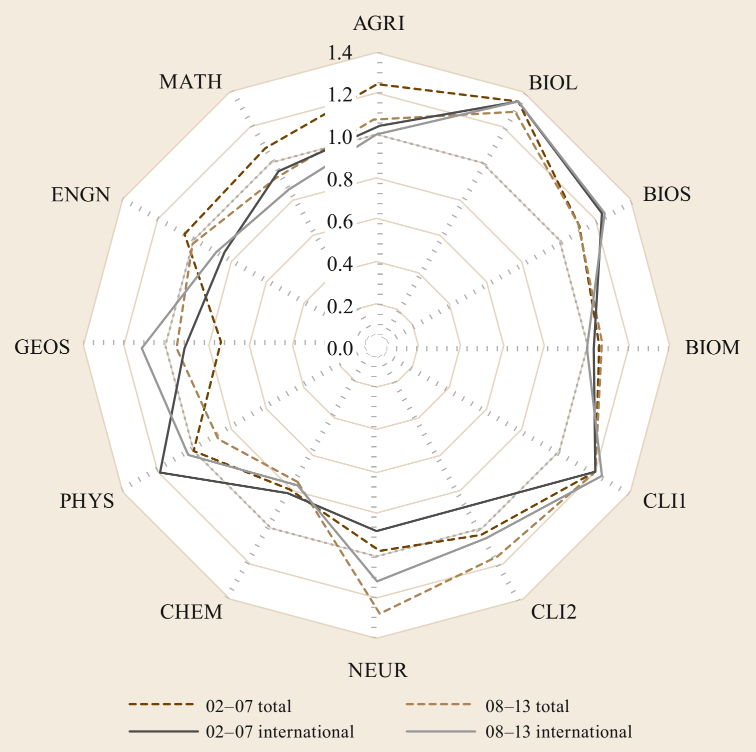

Fig. 17.4 Overview of relative citation frequency and international collaboration across 12 disciplines of the sciences in Flanders

collaboration across 12 disciplines of the sciences. Such citation analyses and collaboration analyses are another benchmark ECOOM computes for the Flemish government. This allows the Flemish government to assess the international visibility of Flemish science and its connectedness to the rest of the world.

Table 17.1 maps the bibliometric performance of a Flemish strategic research center using the *standard* ECOOM indicator set. This type of analysis is done regularly for all Flemish strategic research centers and allows the Flemish government to assess and benchmark their performance. Table 17.2 maps the bibliometric performance of a Flemish strategic research center using the ECOOM CSS approach, highlighting the citedness of the research output of the center under examination.

Those analyses are illustrative of the scientometric/bibliometric stance taken by ECOOM in its various tasks and activities to support Flemish science policy. Every two years, they are bundled into a new version of the Flemish STI indicator book. However, they do not only provide *factual*, quantitative input to the Flemish government as to the status of the Flemish science landscape and the performance of its actors. They are also used as one of the underpinning elements for expert assessments and informed peer reviews of the perfor-

Table 17.1 Bibliometric performance of a Flemish strategic research center using the *standard* ECOOM indicator set

Period	Publications	Citations	Self-citation	MOCR	RCR	NMCR	NMCR/RCR
2000–2004	1575	22 883	19.7%	14.53	1.25	1.98	1.58
2005–2009	2010	32 797	20.8%	16.32	1.22	2.10	1.73
2010–2012	1659	36 175	21.3%	21.81	1.40	2.80	2.00
2000–2012	5244	91 855	20.7%	17.52	1.29	2.29	1.77

Table 17.2 Bibliometric performance of a Flemish strategic research center using the ECOOM CSS approach

Period	Publications	Class 1	Class 2	Class 3	Class 4
2000–2004	1575	44.4%	32.6%	14.3%	8.6%
2005–2009	2010	41.6%	32.1%	18.3%	7.9%
2010–2012	1659	38.1%	32.2%	17.2%	12.5%
2000–2012	5244	41.4%	32.3%	16.8%	9.6%

mance of the various science organizations in Flanders. The main focus of those expert and peer-review exercises concerns the five-yearly reviews and regular monitoring of the strategic research centers (IMEC-iMinds (Interuniversitair Micro-Elektronica Centrum), VIB (Vlaams Instituut voor Biotechnologie), Flanders' Make and VITO (Vlaamse Instelling voor Technologisch Onderzoek)), supporting the composition of the scientific panels of the fund for scientific research Flanders (FWO), input to the multiannual expert evaluation of the extraordinary research fund (BOF) that provides lump-sum support for fundamental research at the five Flemish universities, input to the multiannual expert evaluation of FWO, input to the expert evaluation of various research institutes and initiatives supported by the Flemish government, etc. Hence, the ECOOM data sources and indicators are used extensively as an input to the research assessment endeavors that have become a central dimension of Flemish science policy.

In addition, ECOOM is asked regularly to engage in so-called domain studies. Those are forward-looking studies executed by the Flemish government to identify future areas or *domains* of science investment. Based on its bibliometric data sources and indicator base, ECOOM provides relevant bibliometric overviews and insights to such studies. In the past, domain studies were executed for such diverse fields as nanotechnology, translational medicine, plant biotechnology, stem cell research, bioinformatics, advanced materials, renewable energy, and the main Horizon 2020 key enabling technologies (KETs) as identified by the European Commission (https://ec.europa.eu/programmes/horizon2020/en/area/key-enabling-technologies).

More recently, ECOOM has been involved in providing input into such areas as industry 4.0, sustainable chemistry and circular economy. The bibliometric input to those domain studies provides the Flemish government with an in-depth insight into the structure and global evolution of the science base of the respective *domains*, into the main actors and their accomplishments, and into the relative position and accomplishment of Flemish research in the respective global contexts. In addition to the data and indicator sources described above, the use of advanced text mining techniques and search algorithm designs is high on the ECOOM research agenda as they allow for more detailed, fine grained and insightful analyses of the domain under study and the various cognitive streams of inquiry they consist of [17.18].

17.4 ECOOM: Input for Funding Formulas of Science Activities in Flanders

The publication and citation analyses of ECOOM are not only used for the mapping and assessment exercises as described previously. They are also an integral part of three major performance-based research funding systems deployed by the Flemish government. Bibliometric data are used as a significant component of three formulas that distribute lump-sum funding amongst the five Flemish universities. They are:

1. The block grant (approximately one billion Euro distributed annually amongst the five Flemish universities, aimed at capacity building in teaching and research)
2. The extraordinary research fund (BOF, approximately 160 million Euro distributed annually amongst the five Flemish universities to stimulate research excellence on the basis of peer-reviewed professorships and projects that are awarded by each university within the confines of the lump sum received)
3. The industrial research fund (IOF, approximately 30 million Euro distributed annually amongst the five Flemish universities to stimulate excellence in technology transfer on the basis of expert-reviewed innovation mandates and projects that are awarded by each university within the confines of the lump sum received).

Those funding formulas distribute the money as lump sums between the universities. The allocation within the universities is based on internal allocation rules (block grant), traditional scientific peer review (BOF) or expert review also involving representatives with industrial research and development and venture capital backgrounds (IOF). Each funding formula is built on a diversity of indicators, of which the bibliometric ones are only one set, albeit a significant one. The block grant formula further includes various educational indicators; the BOF formula also includes indicators on PhD activities as well as faculty mobility and diversity; while the IOF formula includes such parameters as patenting and spin-off activity, income from industrial collaborations and income from presence in the European framework programs. As the bibliometric component in the BOF formula is the basic one that is used across the three funding formulas, a brief overview of its design and evolution is provided here (for an overview of the origins of the BOF funding formula, reference is made to *Debackere* and *Glänzel* [17.5]).

The evolution of the BOF funding formula reads as follows:

- Phase I (prior to 2003):
  - Funding allocated on the basis of parameters based on the amount of block grant funding, student numbers and PhDs awarded. PhDs were the only research-related parameter in the allocation rule.
- Phase II (2003–2007):
  - Inclusion of bibliometric data, accounting for up to 30% of the allocation formula. Focus was on the WoS-SCIE data source. Data used: first-order publication counts (document types: article, letter, review, note) and citation counts over a ten-year time window (funding allocation in period t is based on publications appearing in period $[t-11, t-2]$ and on citations to those publications over the same time window). Both are weighted equally. The main effort consisted of cleaning and assigning publications to Flemish academic institutions, which were validated and corrected by the respective universities themselves.
- Phase III (2008–2011):
  - Extension of the bibliometric data, including publications originating from the WoS-SSCI and the WoS-A&HCI. This was a first step towards a full(er) inclusion of the research output in the social sciences and arts and humanities
  - Conference proceedings papers are also included (Conference Proceedings Citation Index – Science (CPCI-S) and Conference Proceedings Citation Index – Social Science & Humanities (CPCI-SSH)).
  - In addition, for those publications that appear in journals with an impact factor, the publications are weighted with the JCR impact factor
  - Evolution of the weight of the bibliometric component to 36% of the total funding formula by 2012
  - Segmentation into 16 major disciplines: 13 SCIE-based and three SSCI & AHCI-based (based on the scheme developed by *Glänzel* and *Schubert* [17.17])
  - Sophistication of the allocation rule increases considerably during this phase.

  During this third phase, the share of each university in the bibliometric part of the funding formula is computed as:

Definition of Variables 17.1

Formula deriving university shares of WoS outputs across discipline-based and impact-weighted publication counts and across citation counts over the period 2008–2011

$$
\begin{aligned}
B_\mathrm{u} = {} & \frac{gB_1}{gB}(g\mathrm{PSSI} \times \mathrm{BSSI_u}) \\
& + \frac{gB_1}{gB}(g\mathrm{PAH} \times \mathrm{BAH_u}) \\
& + \frac{gB_1}{gB}(g\mathrm{PR} \times \mathrm{BPR_u}) \\
& + \frac{gB_1}{gB}(g\mathrm{PSS} \times \mathrm{BSS_u}) + \frac{gB_2}{gB}\frac{C_\mathrm{u}}{\sum_i (C_i)}\,.
\end{aligned}
$$

B_u	share in bibliometric output B of each university u
gB_1	weight of the publication component in the funding formula
gB_2	weight of the citation component in the funding formula
gB	$gB_1 + gB_2$.

Publication counts:

- $P =$ sum of publications across universities, weighted 0.5 for proceedings and 1 for journal articles—$P = \mathrm{PSSI} + \mathrm{PAH} + 0.5\mathrm{PR} + \mathrm{PSS}$
- $\mathrm{PSSI_u} =$ total number of SCIE or SSCI publications with impact factor for university u
- $\mathrm{PSSI} = \sum_i(\mathrm{PSSI}_i)$, sum of SCIE and SSCI publications with impact factor across all universities
- $\mathrm{PAH_u} =$ total number of A&HCI publications for university u
- $\mathrm{PAH} = \sum_i(\mathrm{PAH}_i)$, sum of A&HCI publications across all universities
- $\mathrm{PR_u} =$ total number of proceedings papers for university u
- $\mathrm{PR} = \sum_i(\mathrm{PR}i)$, sum of proceedings papers across all universities
- $\mathrm{PSS_u} =$ total number of SCIE or SSCI publications without impact factor for university u
- $\mathrm{PSS} = \sum_i(\mathrm{PSS}_i)$, sum of SCIE and SSCI publications without impact factor across all universities
  - $g\mathrm{PSSI} = \mathrm{PSSI}/P$
  - $g\mathrm{PAH} = \mathrm{PAH}/P$
  - $g\mathrm{PR} = 0.5\mathrm{PR}/P$
  - $g\mathrm{PSS} = \mathrm{PSS}/P$
  - Sums i are across all universities.
- $\mathrm{BSSI_u}$, $\mathrm{BAH_u}$, $\mathrm{BPR_u}$, $\mathrm{BSS_u}$ then represent the (where possible, discipline-based, impact-weighted) publication shares of university u for each of the four WoS sources.

Citation counts:

- C_u = total number of citations C to all publications of university u
- $\sum_i(C_i)$ = total number of citations C to all publications of all universities.

- Phase IV (post 2011):

  - The presence of arts and humanities and social sciences in the allocation rule is further developed and increased through the creation of a unique flemish academic bibliography (VABB-SHW), taking into account a broader (non-WoS-based) set of relevant publications from journals, books, monographs, proceedings, catalogues, ..., inspired by the Norwegian example
  - An authorative panel (*Gezaghebbende panel*) composed of 18 renowned scientists from the social sciences and humanities selects and approves the source materials included in the new database
  - Every 3 years, an evaluation panel consisting of minimum 5 researchers in the social sciences and humanities disciplines will assess the quality and validity of the VABB. These researchers should be familiar with the flemish research activity in the respective disciplines, while not being active in Belgium at the time of the evaluation.
  - Finally, the sophistication of the weighting formula further increases. The 16 major disciplines deployed in phase III are extended to 68 sub-disciplines, still according to the subject classification scheme developed by *Glänzel* and *Schubert* [17.17]. Instead of weighting the publications by their JCR impact factor (when available), journals are now classified into 20 5% intervals, ranking them from high to low based on their JCR impact factor (of course, for those disciplines where journal impact factors are available). The 20 intervals are then weighted equally across the 68 sub-disciplines, thus eliminating the cross-disciplinary distortions that originated from using the absolute impact factor values as weights (Table 17.3).

Although the Belgian Federal Science Policy Office (Belspo) regularly maps the aggregated Belgian publication output, no approach or setup equivalent to ECOOM exists in Wallonia at the moment.

To conclude, over the years, the bibliometric funding formula in Flanders has become more sophisticated. This sophistication originated as a result of a dialog between science policy and scientific community. Two major advances brought about by this dialog are:

1. The better recognition and more exhaustive inclusion of the social sciences and humanities in the funding formula
2. The adjustment of the publication weights taking into account the differences in citation patterns and subsequently impact factors across disciplines.

For sure, the formula thus became more complex, but at the same time it has gained in fairness across the various disciplines present at the five Flemish universities. In addition, weighting the publications this way is expected to reduce excessive publication behavior and hence to avoid large numbers of publications in low-impact journals. *Linda Butler* observed those excessive publication behavior effects in Australia [17.19].

The publication and citation components as computed for the BOF funding rule spill over into the publication and citation components of both the block grant and the industrial research fund (IOF) funding rules (although with different weights, given the different finality of those two other funding instruments).

Finally, it should be noted that data retrieval, validation and computation are done with absolute transparency. Each university has access to all data (also the ones of the other universities) and validates and corrects them before they are used in the funding formula, the computational outcome of which is also first verified by all institutions before it is applied to distribute the funding itself. As a consequence, fairness and transparency have been important drivers of the continuous development and adjustment of the funding formulas and their operationalization.

Table 17.3 Weights for the 20 Impact-Factor-based 5%-intervals ranked in descending order for the BOF formula

Interval	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
Weight	10	6	3	2	1	1	1	1	1	1	1	1	1	1	0.5	0.5	0.1	0.1	0.1	0.1

17.5 ECOOM: No Data and No Indicators Without a Solid IT Backbone

The key to—and one of the main pillars of—successfully delivering services to science policy stakeholders is the development, deployment and maintenance of a high-performing IT platform that satisfies the specific requirements of a research and service environment. Its main characteristics at ECOOM are:

- Ease of processing: The calculation of standard indicators on a set of publications must be a straightforward exercise. Also, research and services must not suffer from limitations in computational power. ECOOM therefore developed its own ASCII-based data format that proves to be very fast for processing and calculations for default, recurring tasks. For complex tasks with high computational demands, ECOOM has developed an extensive toolbox for using dedicated servers for parallel computing and hyper-threading or for using the shared memory cluster available in the universities' high performance computing centers or (when massive storage is needed) to access the Elastic MapReduce (EMR) service offered by Amazon web services.
- Large storage capacity: The data sources used for bibliometric research are to be stored locally. Given the size of these databases (several terabytes), an extensive storage capacity is needed. Storage alone is not sufficient, given the tremendous efforts put into preparing data, so a reliable backup policy is mandatory
- Fast retrieval: Getting the right data or information out of an archive or database is even more important than entering the data in the first place. Entering the data in the general Microsoft SQL Server database platform set up at ECOOM allows for fast retrieval of publications or counts of journals, countries, and fields. This is extended by NoSQL framework consisting of a Lucene text-index for text-based retrieval; a Neo4J graph database for authors and institutions; and finally an extensible markup language (XML)-based document store
- Accessible: All of ECOOM's partners need access to the bibliographic databases. This access is provided by the relational database. However, this accessibility comes with a security issue. Therefore, we have chosen to implement this on a dedicated Hyper-V virtualized environment with all necessary security precautions.
- Reliability: This is provided at different levels through the general ECOOM IT infrastructure, with a reliable backup policy implemented, hardware with all necessary redundancy built in, and mirror databases on virtual servers.
- Data quality: Indicators are only as valid as the quality of the underlying data permits. Therefore, the platform must enable us to ensure the highest possible quality of data for the tasks at hand. As research is done on different units of analysis and with different objectives, the procedures for data cleaning must be flexible and scalable.

The data on publications and citations—needed for the bibliometric services we provide—are gathered from two data providers: Clarivate Analytics (previously Thomson Reuters) and Elsevier. Currently, Clarivate provides us with the data available in the Web of Science, consisting of the following datasets: science citation index expanded, social science citation index, arts and humanities citation index, the two conference proceedings citation indexes, and the emerging sources citation index (ESCI). The journal citation report is also provided.

After ECOOM has explored the two editions, *Conference Proceedings Citation Index – Science (CPCI-S)*, and *Conference Proceedings Citation Index-Social Sciences and Humanities (CPCI-SSH)* of Thomson Reuters' (now Clarivate) proceedings database, a new, essential bibliographic source is now available. The Book Citation Index (BKCI) with a focus on technical sciences, social sciences, and humanities provides citations from journals, proceedings and other books. This new index is operational at the chapter level, as well as at the complete book level. Unlike the journal and proceedings citation indexes, several problems emerge in the context of subject classification and citation processes.

Establishing a categorical structure for books will become a new challenge, since this structure might considerably differ from the one used for journals and proceedings. A second issue refers to the aging of information. Aging, i. e., information use measured by citations, might be longer than in the case of periodicals. In this context, the issue of different editions might also emerge. The objective of ECOOM is to establish relevant and sensitive, but also robust baselines. Such baselines are indispensable for benchmarking and evaluative studies.

The exploitation of the opportunities offered by the second, large abstract and citation database—Elsevier's Scopus—forms an important task in the extension and validation of bibliometric studies. Although both WoS and Scopus have, in principle, similar features, their internal structure does essentially differ. Scopus subject classification based on journal assignment, as well as unification of author and institutions, considerably dif-

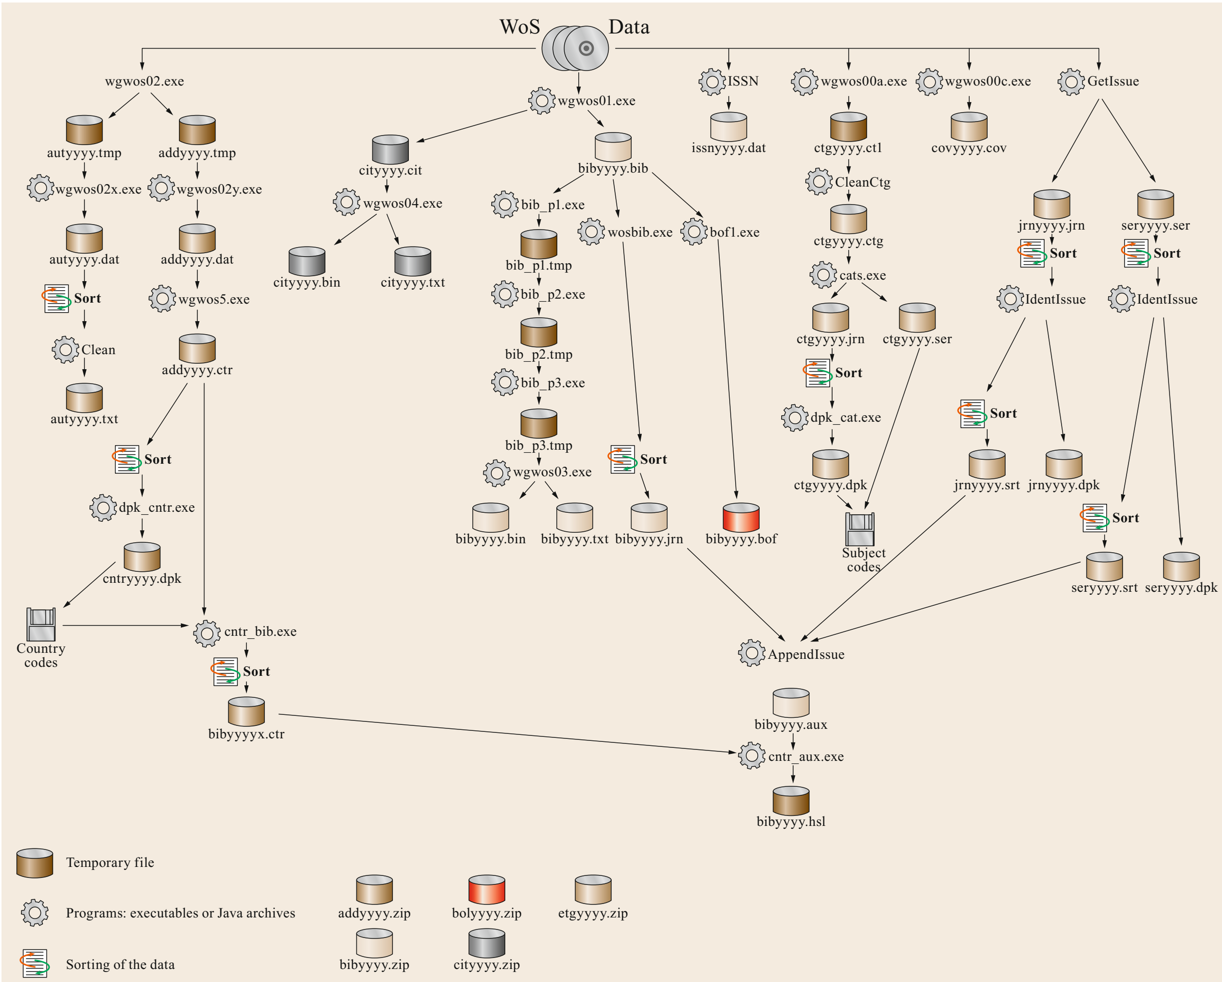

Fig. 17.5 The process of data cleaning and preprocessing for the relational database and the modular indicator-file system

fer from the classification and assignment provided by the Web of Science. The elaboration of a possible concordance between the two systems promises to become an important step in the improvement of the coverage and the reliability of bibliometric data sources.

The existing web interfaces to these databases do not meet the requirements ECOOM needs to perform its tasks. That is why, to be able to implement our own solutions, we receive the entire contents of these databases. Clarivate provides its yearly data volumes of flat text files in a tagged format and the complete custom-generated data including the book citation index in a XML format. Elsevier delivers the Scopus data as XML files.

These raw data are not in a format suitable for indicator calculations, so extensive processing needs to be done. For both datasets a three-step approach is taken. First, elaborate preprocessing is needed. Data files are checked for data integrity or file corruption, and corrections are made based on supplied information.

Next, effective processing is started. Procedures have been developed and improved over the years, using JAVA, Pascal, and AWK. As the provided data format changes, or new information becomes available, or new insights in the data are gained, adaptations need to be made to these procedures. Data are extracted from the source files, and are transformed and combined. Due to the huge amount of data to be processed (in the terabyte order of magnitude), many of the algorithms are adapted over time to allow parallel processing on our multicore servers by using the hyper-threading capabilities of the JAVA programming language or to distributed implementations on EMR.

For the deployment of the data, two paths are followed. For the recurring tasks, using the custom-built

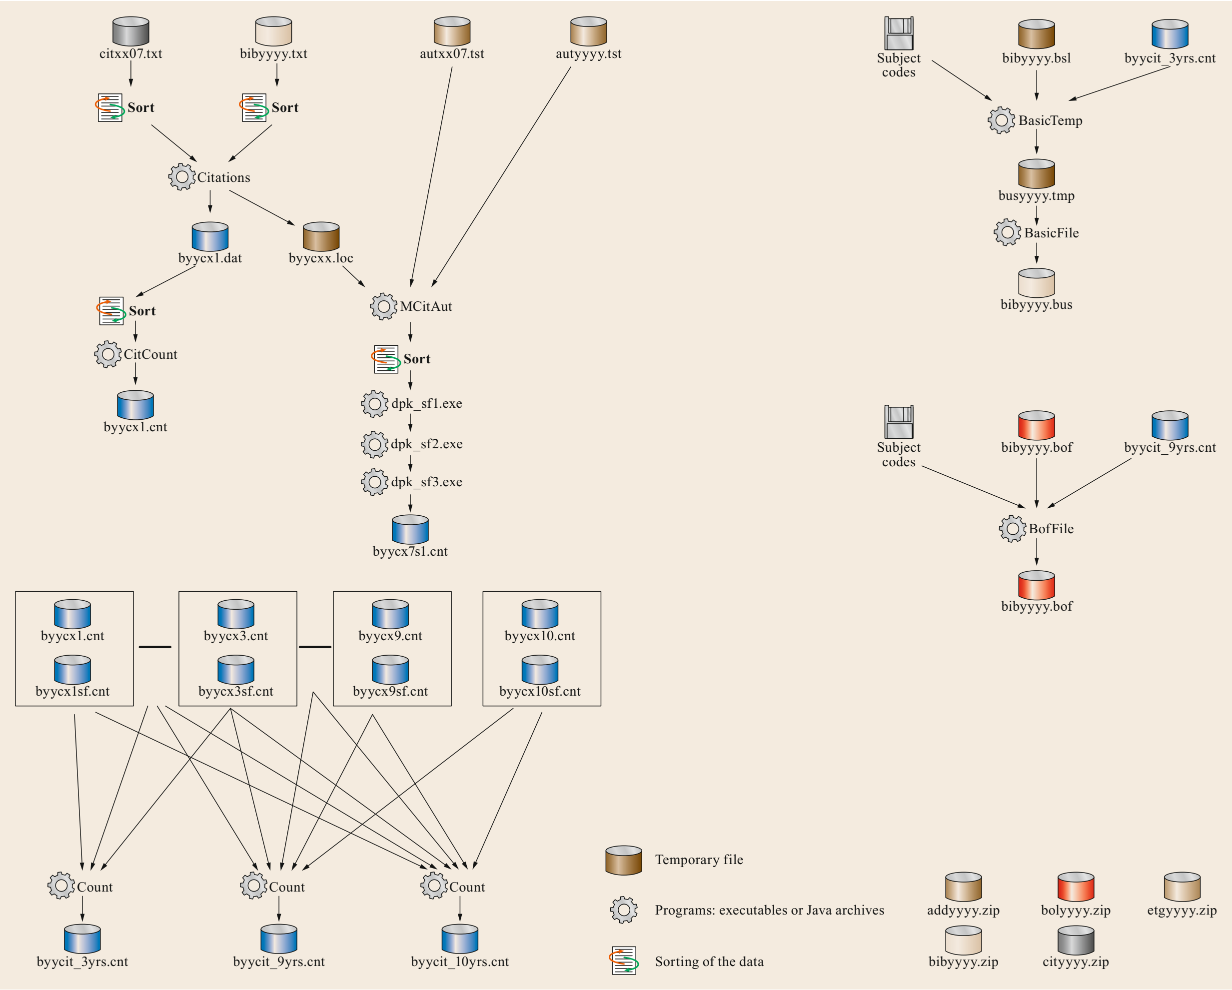

Fig. 17.5 (continued)

flat-file database is the optimal data structure. The procedures on the flat-file database are implemented in JAVA and Pascal. For other tasks, the data is uploaded into a Microsoft SQL Server relational database or the other data stores. For the XML data from WoS and Scopus databases additional steps are required using XQuery statements with FLOWR and XPath expressions to extract the required information.

Once the data are available in a relational database, materialized views and indexes are generated to meet the performance needs. Additionally, this step often requires changes to the database, the operating system, and sometimes even the hardware of the server the database runs on.

A copy of the relational database structure of the WoS data is moved to the dedicated server to ensure accessibility for all of ECOOM's consortium partners. All flat files and the database are backed up using the Tivoli TSM service provided by the central KU Leuven IT department. For the programming code, a SVN repository is deployed to ensure reliable storage and version control.

Processing and retrieval are further enhanced by the application of newly developed techniques based on hybrid combinations of text mining and citations. They also proved to be the most promising methods in the analysis of the epistemological structure of science [17.20–23]. Text mining can aid the summarization, categorization, and interpretation of large sets of documents and the analysis of their dynamics. It can provide powerful tools for the mapping of science. Citation links, in turn, provide a *natural* measure of the relatedness of documents. ECOOM has developed techniques for combining the advantages of both approaches and for compensating their shortcomings at the same time [17.24].

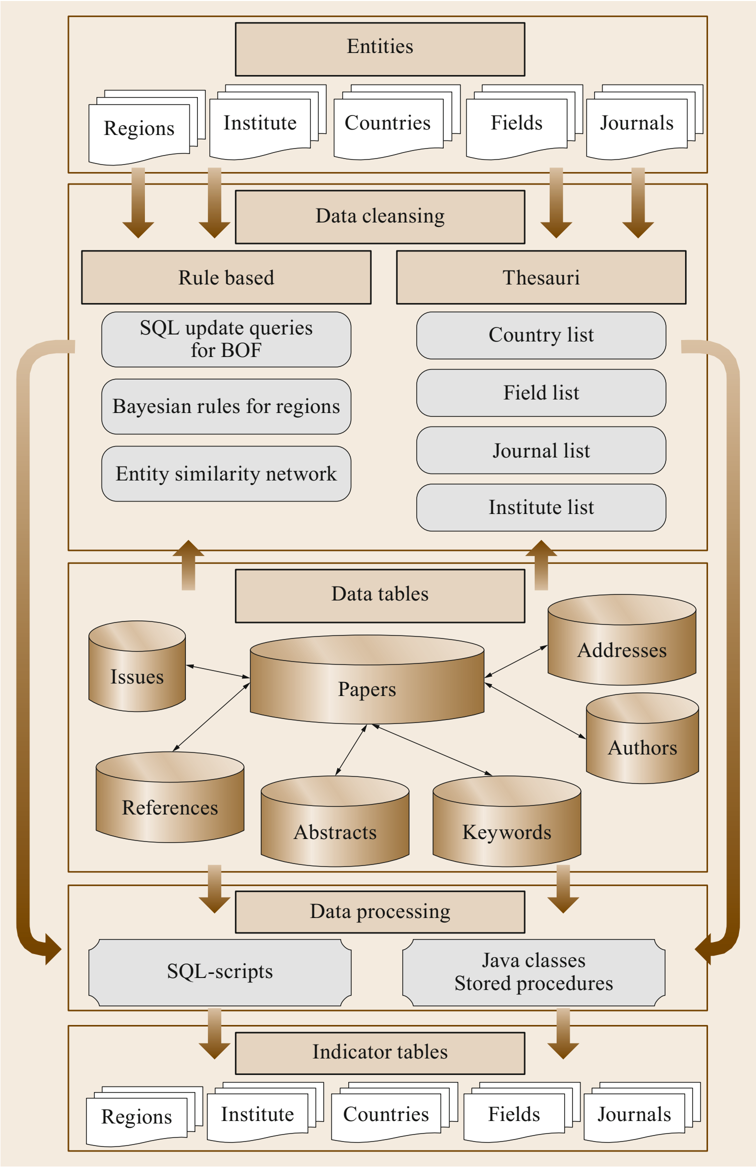

Fig. 17.6 Structure of the relational database created from the abstract and citation databases

The research component in ECOOM's bibliometric service task aims at achieving two major objectives: 1) improving subject classification systems for bibliographic databases, such as the one developed by ECOOM [17.17] and, 2) the structural analysis of the document space. The latter approach has two important applications: the mapping and visualization of the structure of science and its dynamics, and the detection of emerging research topics. The application of the hybrid clustering of the document space will thus be done both globally (i. e., based on the complete database and/or major subject areas) and locally, that is, within narrower disciplines. While the first—the global approach—requires not only efficient dimensionality reduction algorithms, like latent semantic indexing (LSI) or singular value decomposition (SVD), but also improved feature creation based on noun phrases by the application of natural language processing and intelligent matching procedures like locality sensitive hashing. The structural topic analysis and the dynamic analysis—which is required for emergence detection at the local level—are faced with a different problem. Topic description cannot usually be based on the textual component alone, since the same vocabulary is commonly used within the often narrow discipline. In previous studies, ECOOM has shown that so-called *core documents*, i. e., frequently *and* strongly interlinked items, can readily be used for the description, characterization and labeling of topics at the local level [17.18], and also for dimensionality reduction on a large scale.

ECOOM continuously improves its data capabilities. The direct clustering of the document space, based on hybrid similarities, is now supplemented by what we will call second-order similarities. The idea is adopted from social network studies, where a strong correlation of mediate similarities is used to detect profile congruence of individual documents. In other words, instead of the similarities of direct links between documents, the correlation of their similarity profiles is used as the basis for clustering. This provides an additional viewpoint on what forms the basis of the cognitive environment of publications.

The issue of subject classification has already been mentioned; in addition, the combined text- and citation-based methods provide techniques for the delineation of (interdisciplinary) fields and topics, which the classification scheme does not immediately provide, such as stem-cell research or bioinformatics. Finally, the detection of emerging fields also provides the groundwork for the identification of the main players, and for evaluative and comparative bibliometric studies of these fields.

Data quality is related to the different services required by public agencies requesting ECOOM input at the national (OECD, Eurostat), regional (Flemish government, agencies like EWI, VLAIO and VARIO), institutional (BOF) or individual researcher (FWO) level. Unfortunately, author and institution names are not unique in the databases provided. Institutes or authors are recorded in the database as they appear on the publication. The use of multiple names, spelling variations, possible errors, or the use of different initials, make it hard to gather all information surrounding a certain entity of analysis. To solve this, record linkage techniques have to be applied to the data. This encompasses data cleaning, unification, duplication, and enriching of the data. Since a 0% fault-tolerance is applicable to some of the tasks (e. g., BOF and FWO), large portions of this work have to be done manually. We are therefore continuously looking into technologies to speed up this process.

The direct result of speeding up the rate at which data can be cleaned is a faster response rate to various policy requests. Yet more influential is the use of the time that becomes available. This time needs to be spent on increasing data quality.

Finally, the web-based data sources are also analyzed for their possible use in evaluative bibliometrics. Opportunities and limitations of these sources will be compared with those of traditional abstract and citation databases. Repositories like ResearchGate or Google Scholar and its various derivatives thus offer a main subject of analysis. The major IT backbones for the bibliometric activity are briefly summarized in Figs. 17.5 and 17.6.

17.6 Insights Obtained

Taking into account the rich indicator- and case-based evidence stemming from 16 years of ECOOM bibliometric experience in Flanders, the symbiotic role of scientometrics in shaping science policy and of science policy in setting the scientometric research and activity agenda has been illustrated. Two important dimensions of the *scientometrics–science policy* symbiosis can be recognized. One is its ex ante role. The other one its ex post role.

The ex ante role of scientometrics has become clear in various ECOOM cases and activities, such as:

- Informing the genesis of novel science policy instruments and areas of attention, e. g., the contribution to various domain studies on emerging fields of science that provide informed input to policymakers and create new supportive arrangements for such areas
- Supporting the design and evolution of performance-based research funding formulas like the BOF funding formula.

Informing and supporting science policy in turn generates new demands on the quality of scientometric data and indicators as, for instance, in the case of understanding the nature of scientific excellence. To this end, advanced research into the development of a state-of-the-art indicator base is absolutely necessary. However, this is not sufficient. In order to be productive and responsive, a well-performing and accessible IT system supporting the scientometric research and service tasks is required as well.

The ex post role of scientometrics also became clear in various ECOOM cases and activities, such as:

- Mapping cognitive structures, actor connectivity and institutional performance in the Flemish academic system
- Assessing the multilevel scientific performance of institutional actors in the Flemish science system
- Monitoring multiannual strategic plans and accompanying funding schemes for various actors in the

Flemish science system, based on the productivity and visibility of their most recent research activities.

This combination of ex ante and ex post roles leads to an intense symbiosis between developments in scientometrics and the design of science policy trajectories and instruments. The evolution, optimization and rejuvenation of science policy instruments are enabled and facilitated as a result. This evolution, optimization and rejuvenation of science policy instruments continuously necessitates the field of scientometrics to come up with novel, better, more relevant, more valid, more robust methods and indicators. The widespread advent and development of performance-based funding models for research organizations further underpins the above considerations [17.25, 26].

Although well entrenched in the Flemish science policy scene, the use of quantitative methods and metrics-based funding models and policy instruments will never be uncontested. Both policy makers and scientometricians therefore need to carefully understand their limitations as well as potential abuses. One of the basic principles adhered to in the ECOOM context is the complete openness of data and indicators amongst the actors involved, as described. Also, the design and use of the funding formulas and other policy instruments never is a top-down government decision, but always involves the participation of the actors involved and an intensive, exhaustive dialog between the science policy scene and the scientific community. Not without reason has ECOOM been constructed, deployed and funded as an interuniversity consortium and not as a government agency. This approach highlights the basic trust and dialog that should prevail in developing and growing a symbiotic relationship between science policy and scientometrics. And even with this zero-order principle in place, all stakeholders have to be aware of distorted behaviors that may result from the policy use and misuse of bibliometric data.

One issue concerns the changes in the publication, citation and collaboration behavior of scientists (both positive and negative) that the consistent policy use of bibliometric indicators might potentially induce. Studies on the problem choice behavior of academic scientists have revealed that both cognitive and social influences determine the manner in which scientists go about choosing the problems they work on [17.27]. Hence, the issue always has to be raised as to what extent the policy use of bibliometrics may or may not affect this behavior.

The problem of the inappropriate use of scientometrics or bibliometrics ranges from uninformed use, through selecting and collecting *most advantageous* indicators, to the obvious and deliberate misuse of data. Uninformed use and misuse are not always beyond the responsibility of bibliometricians. Unfortunately, bibliometricians do not always resist the temptation to follow popular, even populist trends in order to meet the expectations of the customers. Clearly, any kind of uninformed use or misuse of bibliometric results involves the danger of bringing bibliometric research itself into disrepute [17.28].

Uniformed use consists of:

- Incorrect presentation or interpretation of bibliometric indicators or their use in an inappropriate context caused by insufficient knowledge of methodology, background and data sources
- Generalization (*induction*) of special cases or of results obtained at lower levels of aggregation.

Misuse consists of:

- Intentionally incorrect presentation or interpretation of bibliometric indicators or their deliberate use in inappropriate contexts
- Tendentious application of biases
- Tendentious choice of (incompatible) indicators.

But even correct use might have undesired consequences. For instance, reinterpreting underlying contexts such as the notion of *citation* can show author self-citations in an unfavorable light. Authors might thus be urged to avoid self-citations—a clear intervention into the mechanism of scientific communication, which is not desirable if deployed in an uninformed, linear way. Less obvious repercussions may be observed when bibliometric tools are used in decision-making in science policy and research management and the scientific community recognizes the feedback in terms of their funding. This is one of the criticisms of performance-based funding formulas that we also encounter in Flanders. Hence the need to revisit and to adjust the funding formula regularly, as new and deeper insights on its positive, but also negative, effects emerge. *Butler* [17.19], for instance, has shown, based on the example of Australia, what may happen when funding is linked to publication counts. She found that the publications component of the composite index used at that time in Australia has stimulated an increased publication activity in the lower-impact journals. It is worth mentioning here that, in Australia, journal rankings were designed, published, used for evaluation purposes, and then retracted. See for instance the Australian ERA that was dismissed for being ill conceived and for compelling researchers to publish in selected venues rather than in venues suitable to their research. A revisit of Fig. 17.2 brings us back to the possible feedback loops of the policy use of bibliometrics on the scientific community. This feedback may, as we know in the meantime, both have positive and negative effects.

Possible positive effects are:

- Scientists might recognize that scientific collaboration and publishing in high-impact or even top journals pays
- Their publication activity might be stimulated.

Possible negative effects are:

- Exaggerated collaboration and even trends towards hyperauthorship, inflating publication output by splitting up publications into sequences (or *salami slicing*), inflating citation impact by self-citations and forming citation cliques, etc.
- Trends towards replacing quality and recognition by visibility at any price or towards preferring journals as publication channels in social sciences and humanities.

Fortunately, the increasing sophistication of bibliometric research provides us with the insights and the tools required to cope with such use, abuse, and positive and negative effects. Normalization and standardization are the mathematical avenues that can be pursued to explore and to remedy them. The dialog and transparency between the scientific community and the science policy scene as it is operated in Flanders through the creation of ECOOM is yet another, organizational mechanism to cope with the aforementioned effects. And, finally, we should never forget to fully use the rich complementarity that exists between peer review and the metrics toolboxes that have been developed [17.29]. Hence, a rich and varied array of approaches can be mastered and deployed to monitor the symbiosis between scientometrics and science policy. ECOOM hopefully provides an inspiring and interesting case in this respect.

Bart Thijs is Senior Researcher in bibliometrics at KU Leuven – ECOOM. His main research focuses on the identification of global and local network structures within scientific communication and on the development and application of citation-based indicators. In his work, he combines a background in mathematical psychology (master's degree at KU Leuven) and social sciences (PhD at Leiden University) with professional experience as a statistical consultant.

18. Different Processes, Similar Results? A Comparison of Performance Assessment in Three Countries

Sybille Hinze, Linda Butler, Paul Donner, Ian McAllister

Monitoring the scientific performance of a country, region, or organization has become a high priority for research managers and government agencies. Research assessments have been implemented to provide evidence and facilitate their decisions. They differ in the methodologies applied, the disciplinary and regional breadth, and the consequences that follow. We sought to examine the extent to which quantitative, indicator-based analysis can contribute to identifying and better understanding the effects and effectiveness of the different assessment regimes. To this end, we analyzed the publications from three countries (Australia, the United Kingdom, and Germany) with contrasting systems in place, seeking to demonstrate the possibilities and limitations of using an indicator-based methodology for determining the outcomes from different approaches to assessment.

We intentionally selected three countries with different assessment regimes, expecting to see the effects of this in the bibliometric analyses we undertook. However, we found that the data alone do not allow us to conclude that any one system has a beneficial or detrimental influence on performance. Rather, the data suggest that it is not the specific system that makes a difference but the fact that performance becomes a central topic of conversation.

In order to better understand the mechanisms behind changing performance, restricting scrutiny to mere numbers is insufficient. Contextual information at various levels of aggregation—within and outside the institutions—is highly relevant.

https://doi.org/10.1007/978-3-030-02511-3_18

18.1 Background

With changed governance mechanisms in science, the evaluation of university research performance is now widely used and accepted as an essential management tool. Evaluation and performance monitoring systems have been developed and put in place in a number of countries. While these systems differ in the methodologies they employ to evaluate performance, bibliometric analyses are increasingly being used, either as a central building block or as a component to inform peer review. Although one of the most well-known performance-based funding systems, the Research Assessment Exercise (RAE) in the United Kingdom, only uses bibliometrics as a minor element to inform the peer review process, other countries or regions have developed systems to allocate research funding that are more explicitly based on these quantitative indicators, such as Norway, Denmark, Finland, and Flanders.

In Australia the Excellence in Research for Australia (ERA) framework is based on reviews by experts where, for science disciplines, information is provided in the form of a range of indicators, including bibliometric measures, and no additional peer review of individual outputs is undertaken. However, while university research performance is assessed by ERA, little funding is reallocated as a consequence of the outcomes of these reviews.

While both the British RAE and the Australian ERA systems use subject-based panels of experts, they differ significantly with regard to what publications are assessed. In the United Kingdom only the self-selected *best four* publications are submitted, while in Australia the total academic output is taken into account.

In Germany, performance assessment systems for universities, using different methodologies, have been implemented at Länder level rather than the federal level. An exception is the Research Rating developed and implemented by the German Council of Science and Humanities (Wissenschaftsrat), though only a very limited number of exercises have been carried out. The Research Rating has not progressed beyond the pilot exercise phase and it has yet to be employed on a systematic basis. However, research-performing sectors in Germany are monitored at the federal level via the Pact for Research and Innovation (PFI). Bibliometric performance indicators are regularly constructed and form one part of the overall monitoring of research institutions. In addition, the Research Core Data Set (RCD) was recently developed with the intention of enabling decentralized data collection, including publication data. The RCD, despite the fact that its implementation is voluntary, could enable monitoring research performance at institutional level.

The highly aggregated PFI bibliometric analysis in Germany has, to this point, relied on extracting institutional data directly from one of the well-known commercial suppliers. In contrast, the exercises directed at the institutional level in the United Kingdom and Australia, as well as Länder-level exercises in Germany, draw on data submitted by the institutions themselves.

In this chapter we explore, compare, and assess the outcomes of different approaches. At the national level, we briefly examine two countries where performance monitoring systems are already in operation, namely the British RAE and the Australian ERA; we also examine Germany, where such a system was pilot-tested but has not yet been implemented on a national basis.

Using these countries for comparison enables us to assess outcomes based on three different systems:

- One where data collection is highly selective and is linked to funding (United Kingdom)
- One based on comprehensive data sets provided by institutions but not linked to funding (Australia)
- One without a broad national assessment system where, when used, publication data is primarily extracted centrally from the commercially available data bases (Germany).

We also look at a selective exercise at the Länder-level in Germany, where data sets are provided by institutions, but the outcomes are not linked to funding.

We examine the operation of these three national systems at the institutional level, using chemistry as a case study. For this discipline, we have information available in Germany from a Länder-level assessment in Lower Saxony, and for all three countries we can select institutions that have been the subject of performance assessment.

In the next section, we provide a brief introduction to the systems that are in place to monitor research performance in the three countries. As much has been written on the United Kingdom RAE, as well as on the Australian ERA, we will provide more detail on the exercises implemented in Germany, as these are less well known internationally.

18.2 Research Assessment in the United Kingdom

18.2.1 A Brief History

The United Kingdom has a long history of assessing the research performance of its universities, with the first steps towards establishing a national assessment system dating back to 1985. The United Kingdom University Grants Committee (UGC) announced that the first explicit and formalized assessment process of the quality of research would take place in 1986. Nearly a decade followed before other countries followed the United Kingdom's lead.

In the first *research selectivity exercise*, universities submitted five outputs (publications and/or patents) in 37 cost centers, along with a four-page context statement highlighting the unit's strengths. The assessments were undertaken by the UGC's subject sub-committees. A second selectivity exercise was undertaken in 1992, with universities submitting up to two publications for every member of staff covering 152 subject areas. These were assessed by 70 peer review panels, which were external to the Universities Funding Council, which had taken over the role from the now defunct UGC.

The United Kingdom's national assessment exercise was first known as the Research Assessment Exercise (RAE) in 1992; in this round, universities were able to submit up to four outputs per *research active* staff member, and a rating scale was used to evaluate units. Variations to the rating scale were introduced in the next two exercises (1996, 2001).

Concerns over the large cost of the RAE were raised, particularly by the United Kingdom Treasury Department. As a result, after the 2001 exercise, there were moves to have it replaced by a system that relied more heavily on metrics such as citations, research income, and postgraduate numbers, rather than peer review. From the beginning, there was scepticism among relevant actors in the system, including the Higher Education Funding Council for England (HEFCE) and individual institutions, which led to the rejection of a metrics-based system. This scepticism remains, as detailed in the recently carried out review of the *Role of Metrics in Research Assessment* [18.1]. Another concern of the existing methodology was that large universities could hide a long tail of lesser work and still obtain a 5* (top) rating and have all of their academics funded at this level. The 2008 RAE saw the introduction of quality profiles for each unit of assessment, rather than a single grade.

The last RAE was conducted in 2008. The national assessment exercise was re-branded, becoming the Research Excellence Framework (REF), with the first of the new assessments undertaken in 2014. It was broadened to include an assessment of the impact of research, and the environment in which it was undertaken, in addition to the quality of research outputs.

18.2.2 The Assessment Process

Since 1996, the research output of universities has been assessed by between 36 and 69 panels of experts. Institutions submitted up to four outputs per research active staff member across a 6 year period. *Outputs* included many forms of publication, such as journal articles, monographs, and chapters in books, as well as outputs disseminated in other ways such as patents, designs, performances, and exhibitions.

While the unit of assessment generally aligns with a department, school, or faculty within a university, it is not always a precise alignment—submitted staff (and, therefore, their outputs) may come from a range of organizational units drawn from across the organization. It is the university's choice to determine the panel that best fits their staff members' research.

The panels then assessed the quality of outputs against the criteria of originality, significance, and rigor. For all exercises, the assessment was based on peer review of the submitted outputs. In the 2014 REF, some panels were provided with basic citation information on the number of times a journal article was cited, as well as contextual information to support peer review.

Until the 2008 RAE, units of assessment were given a single star rating for the overall quality of their submission. The rating scale varied over time—four points (1986), five points (1992, 2008), and seven points (1996, 2001). In RAE 2008, quality profiles were introduced and panels determined the proportion of a unit's submission that fell into each of the five categories. Quality profiles across a five-point scale were retained for REF 2014 [18.2].

While the assessment of research output remained the central element of the process, from 2014 universities were also assessed on the impact their work had on *the economy, society, culture, public policy or services, health, the environment, or quality of life, beyond academia*. They were also assessed on the research environment, that is, the strategy, resources, and infrastructure that support research [18.3]. Each element contributing to the overall assessment would attract a discrete proportion of the funding—65% for outputs, 20% for impact, and 15% for the environment.

18.3 Research Assessment in Australia

18.3.1 A Brief History

There was a major overhaul of the Australian university sector in 1988 when the binary divide between universities, on the one hand, and colleges of advanced education and institutes of technology, on the other, was removed. Many institutions were merged, and all the organizations that were created by the reform were classified as universities. The original research quantum (RQ) was introduced in 1990 in order "... to provide a more equitable funding" to universities in the new national system [18.4]. However, from its inception, changes to the RQ were mooted as it was based solely on data for Commonwealth Competitive Research Grants, which favored the pre-reform universities; indeed, from 1990 to 1994, RQ allocations continued to go only to those universities.

The broadening of the index that underpinned the RQ was the subject of extensive consultations. In 1991, the government commissioned Russell Linke to undertake a review of performance indicators in higher education, in part to feed into changes that were anticipated to the RQ [18.5]. In late 1993, a working party was set up to develop a new index [18.4]. This new index consisted of three components—success in competitive grants, graduate student numbers, and publication output.

Australian higher education funding and assessment policies continued to be modified throughout the 1990s and into the first decade of the new millennium. The *Kemp* review at the end of the 1990s made it clear that while the RQ might, for better or worse, be acceptable for its purpose—the distribution of the block research grant among universities—but that it was a very poor instrument for assessing the performance of universities [18.6]. A close watch was being kept on developments in the United Kingdom, and Sir Gareth Roberts was asked to chair a committee to draw up a framework for assessing universities' research performance drawing on his review of the United Kingdom's research assessment exercise. The government's attention turned to research assessment, as distinct from mere funding distribution. The Research Quality Framework (RQF), later to be superseded by the ERA initiative, was developed. ERA is now a well-entrenched national research assessment exercise. The first pilot test of ERA, overseen by the Australian Research Council (ARC), was undertaken in 2009, followed by full-scale exercises in 2010, 2012, 2015, and 2018.

While ERA has little direct impact on government funding allocations (though its predecessor the RQF did intend to use it to distribute RQ money), Australian universities are heavily reliant on international students to generate income [18.7]. These students take considerable notice of both the international rankings and the detailed data published on ERA outcomes, so while they have no direct government funding implications, they do have significant financial implications.

18.3.2 The Assessment Process

The ERA assessment process was developed after extensive consultations between the ARC and the higher education sector. This involved setting up working groups in a range of disciplines and establishing an over-arching metrics working group drawing on local and international experts. Minor refinements to various aspects of the submission and assessment process have been made, but the suite of indicators prescribed in the discipline matrix of the framework remains largely unchanged.

Evaluation of data submitted by the universities for ERA 2015 was undertaken by eight Research Evaluation Committees (RECs), broadly representative of eight discipline clusters. The ERA 2015 RECs were comprised of 155 distinguished researchers from Australia and overseas, with expertise in their fields and in research evaluation. Their task was to assess the overall performance of universities for fields and sub-fields of research in which they were active. The decision to focus the ERA assessments on fields rather than departments or groups was taken after extensive consultations within the higher education sector and a detailed examination of the strengths and weaknesses of other systems, particularly the United Kingdom's RAE. ERA is based on the principle of expert review informed by indicators. Evaluations were performed by four broad categories of indicators covering quality, activity, application, and recognition.

Research quality was considered on the basis of a publishing profile, citation analysis, ERA peer review, and peer-reviewed Australian and international research income. ERA did not attempt to develop a uniform method of assessment, but rather developed a suite of indicators that varied across disciplines (known as the *discipline matrix*) [18.8]. For example, citation indicators were only used for relevant fields (i. e., those where at least 50% of the total output in the discipline was indexed by the selected citation data supplier), predominantly the sciences, while peer review of submitted outputs was undertaken for most disciplines in the social sciences, the humanities, and the arts.

Universities reported all the outputs of staff with appointments classified as research only or research and teaching. Where used, citation analysis was undertaken on the university's full publication set in the relevant field. Where peer review was used, the assessment was undertaken on 30% of the submitted publications from the university, which the institution itself nominated [18.9].

Universities were given an overall grade between 1 (low) and 5 (high) for each field and sub-field in which they were active, but individual ratings were not given for the four separate elements of the assessment—quality, activity, application, and recognition.

18.4 Research Assessment in Germany

18.4.1 National Level

The organization of research assessment in Germany is largely decentralized. It most commonly takes place either at the regional (Länder) level or at the institutional level, and hence comparative analyses are scarce. A few exceptions exist, such as the Research Rating, which was developed by the German Council of Science and Humanities (*Wissenschaftsrat*—WR), which undertook a critical analysis of national and international assessment methodologies [18.10]. While assessment of comparative research performance was seen as an "essential component of a reform process that reinforces the autonomy of academic institutions and involves a transformation from detailed state control to a global system comprising elements of competition" [18.10, p. 34], introducing a ranking based solely on quantitative data and indicators was not recommended in Germany.

Instead of quantitative indicators, an approach based on informed peer review that incorporated qualitative, quantitative, and contextual information was recommended. The process used by the Research Rating consisted of setting up a steering group and establishing assessment panels whose task it was to assess the performance of the institutions under review in the relevant field. It also outlined the assessment dimensions and criteria: research quality, impact and efficiency; promotion of young researchers—processes and success; and knowledge transfer—relevance, application in businesses, further education, and research-based consultancy. In order to take into account disciplinary differences, each assessment panel detailed the criteria to be applied and, in consultation with the steering group, defined the rating scale. This also included the decision as to which data, qualitative and quantitative, were to be applied to each criteria. It also included the decision on whether or not to consider bibliometric data. The exercise yielded a report reflecting a performance profile across the assessed dimensions for each institution.

The main objective of the Research Rating was not to distribute funds but to

> provide support for universities and non-university research institutions both in their missions and—in connection with other quality assurance and strategic planning procedures—in quality assurance measures in research, and to promote competition for quality. [18.10, p. 44]

Since its introduction, pilot studies have been carried out for chemistry (2007), sociology (2008), electrical engineering (2011), and English and American studies (2012), but the approach has not been introduced systemically. Besides criticism regarding continual evaluation and its unintended effects, the general appropriateness of the approach, the information and data used, data availability, and the efforts needed to make them available were all the subject of criticism.

Experiences gained from the pilot exercises were taken into consideration in the Council's recommendations about the future of the Research Rating [18.11] and consequently the recommendations towards developing a Research Core Data Set (RCD) [18.12]. The RCD aims to standardize data formats, making data sharing between all actors a much easier and more straightforward task. It is targeted at both research-performing institutions and report-requesting organizations and, by standardizing the reporting processes, should reduce the burden when it comes to responding to various internal and external information requests and, at the same time, ensure comparability of data.

The first version of the specification for the RCD was published in January 2016 [18.13] following discussions about its content (the data and research information to include) and its operationalization (the definition of the concepts). The RCD is not an actual data set as such, and no centralized data collection will be initiated. Rather, the RCD sets out rules and recommendations for data collection and processing in the research-performing institutions themselves. It covers input, output, and process data such as human resources, research projects and third-party funding, patents, spin-offs, and research infrastructures, as well as publications [18.14].

Universities and research organizations can decide upon the implementation of the RCD on a voluntary basis. As the RCD research is still in its infancy, it is too early to comment on the extent of its uptake, its use in the context of research assessments at various levels, or its potential effects.

18.4.2 Länder Level

Performance assessment at the Länder level varies widely. By 1999 the *Wissenschaftliche Kommission Niedersachsen* (WKN, English: Academic Advisory Council Lower Saxony) had implemented a framework to systematically assess research performance at universities and in research organizations [18.15]. At the time, and still to this day, it remains a unique exercise at the Länder level.

The WKN is an independent expert committee which, based on its evaluations, provides advice to the state government as well as the state-financed universities and research organizations in regard to further development, monitoring, and assessment of the state's higher education and research system, including its structure and research profile [18.16]. Initially, between 2000 and 2008, all disciplines represented at universities in Lower Saxony were successively evaluated. Approximately 3 to 4 years after the initial evaluation, an assessment of the implementation of the evaluation recommendations was undertaken (for an overview of the evaluations undertaken see [18.17]). From 2015 onwards, the system has used a demand-driven approach rather than evaluating all disciplines regularly. In order to ensure high quality research, a monitoring system aimed at identifying relevant disciplines for which an evaluation should be initiated was introduced. In addition, complementing the disciplinary approach, topic-focused evaluations were introduced (for an overview, see [18.18]). In addition to these initiatives, the WKN also carries out institutional evaluations.

Evaluations are carried out as *informed peer review* by an independent expert group. Universities active in the discipline or topic under evaluation are included. Self-reports are prepared by the universities based on the guidelines provided, and there are site-visits by the expert group. The evaluation concept prescribes quality and relevance of research and effectiveness and efficiency as the two criteria to be met. In their self-reports, universities also submit data on research output, third party funding, early career researchers, international visibility and networking, and prizes and awards.

To ensure discipline-relevant evaluations, each expert group defines a set of discipline-specific criteria and their operationalization. Bibliometric data and analysis can be taken into account and were utilized in the recent evaluation in chemistry, which was carried out in 2015. The assessment provided by the expert group is the basis for the final evaluation report, which is written by the WKN office and agreed upon with the expert group. As at the federal level, the evaluation has no direct consequences for funding, but instead provides recommendations and initiates processes of organizational learning and change.

18.4.3 Pact for Research and Innovation

While bibliometric data plays only a marginal role in the Research Rating, it is used systematically in monitoring the PFI. The PFI, initiated in 2005, is one of the major instruments designed to strengthen the performance of the German science system. Providing additional funds for the four large non-university research organizations (Max Planck Society, Fraunhofer Society, Helmholtz Association, and Leibniz Association) as well as the German Research Foundation (DFG), it complements the Excellence Initiative and the Higher Education Pact, both of which are primarily focused on higher education institutions. A monitoring report is published annually, presenting a wide range of indicators, including an extensive bibliometric analysis.
