The bibliometric analyses for the PFI are carried out centrally and are made publicly available via the website of the German Federal Ministry of Education and Research (for the 2016 report, see [18.19]). The report provides comparative information with regard to the performance of Germany as well as for the large research organizations and the universities. The analysis of performance is presented at an aggregate level. For universities, this means that the whole university sector is analyzed, rather than individual institutions, as the aim is to avoid constructing a league table. The same applies to the non-university organizations.

While the monitoring, which is carried out regularly, does not have direct and immediate consequences on the funding of the organizations, it is a way of reviewing whether the additional funding provided via the PFI yields any effects on the sector level.

18.5 Comparing What is Assessed in Each System

18.5.1 The United Kingdom

In the 2014 REF, and in the RAEs that preceded it, universities submitted units of assessment (UoA), which may, but need not, comprise staff who work within a single department or other organizational unit at the university. A submitted unit may comprise staff who work in multiple organizational units at the university [18.20]. It is, therefore, uncertain exactly what the REF assesses. It is not clear whether it is an organizational unit as defined within the university's structure, or all the output in a field as defined by the REF panel structure. Which of the two scenarios comes closest to describing an institution's submission will vary from university to university.

Universities submit only their *best four* outputs from the 6-year assessment period for each current research active member of staff, not their total output, and also select to which panel an academic's work is submitted. The effect of these two choices, looking specifically at our case study of chemistry, is:

1. Not all output in the chemical sciences is submitted for assessment.
2. Not all output in the chemical sciences is submitted to the chemical sciences panel (panel 8).
3. The output submitted to a panel does not necessarily (though it may) represent one academic department, school, or faculty.

In addition, the outputs submitted need not necessarily have been published while the staff member was employed by the university.

Given the above, to then interpret the results from panel 8 as showing the strength of chemical sciences, or schools of chemistry, in the different universities is problematic.

18.5.2 Australia

In the ERA exercise, the UoAs are fields of research as defined by the Australian and New Zealand Fields of Research Classification Scheme (FoR) [18.21]. Evaluation occurs at both the two-digit field (i. e., such as chemistry, physics, etc.) and the four-digit sub-field (i. e., such as organic chemistry, nuclear physics, etc.) FoR level for each institution that is considered research active. Universities must submit all publications for assessment for each FoR they are deemed active under ERA rules.

The ERA journal list forms an integral part of the ERA evaluation process. The list is used to define, with limited exceptions, the eligible FoR codes that research outputs may be assigned to during the submission phase. The journal lists also form the basis for the calculation of international and Australian benchmark figures.

In contrast to the United Kingdom REF exercise, Australian universities are assessed on all publications and have little freedom to choose the panel that assesses them. However, in one respect ERA and REF are the same—publications are not restricted to those based on research carried out at the university but can include publications authored before a staff member joined the institution.

18.5.3 Germany

The Research Rating of the WR is not comprehensive in the sense that all disciplines or fields of science are examined in a single exercise. By contrast, PFI monitoring covers all discipline areas but is a highly aggregated exercise focusing on the development of the organizations as a whole and does not cover the disciplinary level. Thus, while this exercise needs to be taken into account when discussing national research performance assessment systems, it does not provide assessment outcomes that allow us to make institutional comparisons with universities from Australia and the United Kingdom. For this reason, the discussion that follows will focus on the regional exercise implemented in Lower Saxony.

The evaluation in Lower Saxony is discipline focused and entails delimiting the field based on the organizational units active in the discipline. Like in the United Kingdom and Australia, these might also be located in different faculties. For the bibliometric analysis, which was carried out as part of the evaluation of chemistry, approximately 110 research groups in 24 institutes in 6 universities in Lower Saxony participated in the assessment. The overall assessment was carried out by an expert panel consisting of six members.

As has already been mentioned, each university had to provide a self-report including data on research output, third party funding, early career researchers, international visibility and networking, and prizes and awards. Information on research output included submitting publication lists per research group. In addition, the bibliometric analysis, which was carried out centrally, provided bibliometric indicators for each of the groups (Sect. 18.3.2).

18.6 Comparing the Role of Metrics in Each System

18.6.1 United Kingdom

While there has been much discussion over many years in the United Kingdom on the introduction of metrics into the assessment process, from Gareth Robert's review in 2003 to HEFCE's consultations in response to treasury requests from 2006 to 2009, and to the *Metrics Tide Report* in 2015 [18.1], ultimately they have had little impact on the process.

Citation data was introduced into panel deliberations for some of the sciences in the 2014 REF, but the only data provided were simple counts of citations for each publication. The way in which panels could use the data was very limited [18.22]:

> 62a. Where available and appropriate, citation data will form part of the process of assessment, in relation to the academic significance of outputs. It will be used as one element to inform peer-review judgements made about output quality, and will not be used as a primary tool in the assessment.

However, it was acknowledged in the Wilsdon et al. report that citation data did enter in the evaluation process where marginal judgments were concerned [18.20].

After the release of the *Metrics Tide Report* in 2015, it is unlikely that metrics will play any greater role in the 2018 exercise. There remains a strong belief in the United Kingdom that citation analysis (the main suite of metrics on which consultations took place) cannot be uniformly applied and is, therefore, inappropriate. The United Kingdom does not appear ready or willing to go down the path taken by Australia of developing a discipline-specific set of indicators.

18.6.2 Australia

In ERA, quantitative indicators played a pivotal role in the assessment of research in those fields where citation data were used. The information provided went well beyond the simple counts used in REF 2014 [18.9, 23]. Using data from Elsevier's Scopus database, three bibliometric profiles were provided to assessment panels:

1. Relative citation impact (RCI), calculated against Australian university and world benchmarks
2. Distribution of papers based on world centile thresholds and Australian university averages (centile analysis)
3. Distribution of papers against RCI classes.

The three indicators were designed to be considered as a complementary set and not used individually. Where citation data were deemed appropriate, no peer review of individual outputs was undertaken.

The disciplines that relied on citation analysis rather than peer review were: physical, chemical, mathematical (excluding pure mathematics), earth, biological, medical and health sciences, nanotechnology and biotechnology, and engineering.

18.6.3 Germany—The Example Lower Saxony

The chemistry evaluation referred to in this paper included an extensive bibliometric analysis. The universities were asked to submit publication lists for all research groups, which were subject to the evaluation. Clear guidelines were given as the data provided was used for matching and retrieving the publications from the Web of Science.

For the analysis, the in-house data infrastructure set up and run by the German Competence Center for Bibliometrics was used, with the Web of Science as the data source. Submitted publications were identified based on their DOI (digital object identifier) or, where no DOI was available, using a match key consisting of publication year, title, name of the first author, and source title. Around three-quarters of the publications submitted were identified by the matching procedure applied. The majority of non-identified publications were book chapters, proceedings papers, and German language publications. For the bibliometric analysis, only articles published in the period 2008–2013 were taken into consideration, and only if at least one author was a member of the unit of analysis within this period.

To inform the assessment of the performance of the institutions, a range of indicators were used:

- Publication data (number of publications, number of publications per research staff)
- Citation based impact indicators (average citation rate, field normalized citation rate, share of highly cited publications, and share of uncited papers)
- Co-authorship based indicators to assess extent and patterns of collaboration.

Benchmarks were provided for comparison with institutions in Lower Saxony and for Germany in total.

While the bibliometric data was taken into consideration to inform the panel, its representativeness was questioned by the expert panel due to the incomplete coverage. Overall, bibliometric data did not play a central role in the assessment, rather the assessment was reached based on bringing together qualitative information gathered from the institutional self-reports, the site-visits and data reflecting various performance dimensions as well as context information.

In summary (see Table 18.1), the three evaluation systems examined here show considerable differences with regard to the functions they fulfil and the methodologies applied. The question that arises from this is whether they also lead to different outcomes in terms of performance. Do we see differences and thus varying effects, which might be explained by the different approaches? Or, do different approaches to performance assessment result in similar outcomes? To address these questions we carried out a bibliometric analysis to find evidence that would allow us to draw conclusions on the effectiveness of the systems. Our primary focus is the institutional level, but we also present contextual data at the national level. We employ basic and widely used bibliometric indicators.

Table 18.1 Comparison of the assessment regimes of Australia (ERA), Germany (WKN), and the United Kingdom (REF)

	Australia	**Germany**	**United Kingdom**
Assessment system	ERA—National	WKN—regional (Länder) level-single discipline	REF
Format of assessment	For the sciences—metrics based assessment by expert panels; other disciplines—peer review by expert panels, also informed by a range of discipline-specific indicators	Assessment by expert panels informed by a range of discipline-specific indicators	Peer review with some contextual data
Role of bibliometrics	In the sciences, the central information used in the assessment of quality was drawn from a range of citation measures, supplemented by other indicators as set out in ERA's discipline-specific indicator matrix	For chemistry, extensive bibliometric data was provided including a range of citation measures and co-authorship information, but limited use of the data in the overall exercise	For the sciences, citation counts for each submitted journal article were provided. However, they were only to be regarded as contextual information. Some panels appear to have used them to resolve disputed assessments
Years conducted	2010, 2012, 2015. Next one is scheduled for 2018	Chemistry: 2000, 2005, 2015 (bibliometrics only used in the latest exercise)	1986, 1989, 1992, 1996, 2001, 2008, 2014. Next one scheduled for 2018
Funding implications	Only linked to a very small amount of funding	No direct link to funding decisions	65% of funding attached to the REF was tied to the assessment of outputs
Rating scale	5 well above world standard 4 above world standard 3 at world standard 2 below world standard 1 well below world standard n/a due to low volume	Descriptive rather than fixed scale	4* world leading 3* internationally excellent 2* recognized internationally 1* recognized nationally unclassified—below 1* standard or not classified as research
Unit of assessment	All outputs classified to a field. For chemistry, relevant outputs were determined by the journal in which they appeared. Universities had some discretion when it came to articles in multidisciplinary journals	All university based research groups active in the relevant discipline	Universities have freedom to decide which panel to submit researchers to—some submit whole departments/schools to one panel; others split staff across two or more panels
Publications assessed	Universities must submit all outputs from every research active staff member	All the publications of relevant research groups are submitted to the assessment panel	The *best four* publications for each research active staff member submitted
Institutional affiliation of work submitted	Publications of all current staff, irrespective of where research undertaken	Publications of all staff during their employment in units within the period of assessment submitted	Publications of all current staff, irrespective of where research undertaken
Identification of publications	Universities submit publication data	Universities submit publication data	Universities submit publication data

18.7 Data and Methods

For the analysis we used the in-house data infrastructure of the German Competence Centre for Bibliometrics, a consortium consisting of seven institutions funded by the German Federal Ministry of Education and Research. The data infrastructure consists of the Web of Science as well as Scopus and is hosted at the Leibniz Institute for Information Structure Karlsruhe (FIZ Karlsruhe). Our analysis used Scopus data and analyzed a subset that was restricted to:

- Publication years 1996 to 2013
- Article and review document types
- Publications from the United Kingdom, Australia, and Germany
- Publications appearing in a pre-defined chemistry journal set.

The chemistry journal set was constructed by combining chemistry journals from the 2015 ERA journal list and journals classified by Elsevier to either a chemistry discipline or the broad field of chemistry. We did not include journals classified to two or more broad fields of research by Scopus.

Within the data set we also identified all publications for nine universities, three from each country, for which to undertake lower level analysis. These were:

- *Australia*: The Australian National University (ERA rating 4), the University of Melbourne, (ERA rating 5), and Monash University (ERA rating 5)
- *United Kingdom*: The University of Birmingham (REF 4*—13.8%, 3*—81.6%), the University of Bristol (REF 4*—28%, 3*—69.5%), and the University of Edinburgh (REF 4*—17.4%, 3*—74.1%)
- *Germany*: The Technical University of Braunschweig, the University of Hannover, and the University of Göttingen; all three were rated *excellent* by the expert panel [18.24].

The project data set contains 4 065 823 articles.

The bibliometric indicators constructed for the analysis were:

- Number of publications, limited to articles and reviews, whole count.
- RCI based on 3 year windows, with calculations limited to articles and reviews and specific to year of publication and world averages calculated.
- Identification of highly cited publications (top 1% and top 10%) and those that received citations above the world median—again calculated by year on 3-year citation windows and limited to articles and reviews.

Methodological note: For the full set of research articles and reviews based on the project's journal list, citation count threshold values for the calculation of shares of highly cited papers were computed. Citations were counted for the year of publication and the two following years, forming sliding 3-year citation windows. The 99th (90th, 50th) percentile value of the citation count distribution of each publication year was used as the threshold for definition of the class of the 1% (10%, 50%) most highly cited chemistry papers of that year.

In contrast to the Australian REF and in the Lower Saxony research evaluations, where information on exhaustive publication lists were taken into account, the United Kingdom REF assessment used a selective set. As we were able to extract a full output in the chemical sciences journals for our three target universities, it is informative to compare the results obtained for each university as a whole, with those obtained using the smaller sub-set of publications submitted to REF 2014. How much of the United Kingdom's universities' output in these journals was actually assessed in the REF?

Data for REF 2014 publications were downloaded from the HEFCE website [18.25]. Universities submitted 4699 outputs to REF panel 8 (chemical sciences) for assessment, of which 4689 were journal articles, one was a chapter in book, two were conference publications, three were patents, and four were software.

The fields to which the journals that the articles appeared in could be broadly classified were:

Chemistry	3654 (78% of all journal articles)
Multidisciplinary	616
Other Natural Sciences	318
Biomedical Sciences	77
Unclassified	33.

Using DOIs, 3138 of chemistry journal articles matched articles in our project data set i. e., 85.9% of articles in chemistry journals, and 67% of all journal articles. There are a number of reasons for the missing chemistry articles—universities were able to submit the output of research staff published prior to their employment at the university, so many of the missing publications did not contain a United Kingdom address. Also, a number of submitted outputs did not fall into our two publication categories—articles and reviews—and so were excluded from our project data set.

18.8 Analysis of Bibliometric Data

As all three countries have different assessment regimes in place, we might expect to see the effects of this in the bibliometric analyses we undertook. With a nationwide system linked to significant levels of funding, the United Kingdom might be expected to have the strongest performance. Then Australia, with a system-wide assessment exercise, though in this case not linked to funding, might show a performance somewhat less than the United Kingdom, but ahead of Germany where no broad assessment regime currently exists.

We used the data we had extracted from Scopus to investigate whether this hypothesis could be supported. First, we estimated overall trends for total publication output in each country, then examined lower levels of aggregations using chemical sciences as a test case. We chose chemical sciences because this was a field in which we had data at an even lower level of aggregation—the university—on which to perform detailed analyses for all three countries.

18.8.1 National Level—All Fields

The anticipated diverging trends in the national level data did not emerge; rather, we observed similar trends of moderately increasing publication numbers for Germany and the United Kingdom, while for Australia the increase is much more pronounced. Figure 18.1 shows these trends, using a logarithmic scale to highlight the differences between Germany and the United Kingdom, on the one hand, and Australia, on the other.

This result leads us to conclude that at the national level, there is no unambiguous effect on simple publication counts from the different evaluation systems. Attaching resource allocations to the exercise (United Kingdom only) does not lead to significant increases in research output compared to those systems where funding is not tied to the assessment exercise (Australia) or where there is no country-wide assessment regime (Germany).

As expected, when we move from publication counts to examine trends in the countries' shares of world output (Fig. 18.2) the results are analogous, with similar trends for the United Kingdom and Germany (decreasing shares), but the reverse trend for Australia (increasing share). The decreasing share of publications from Germany and the United Kingdom is not surprising, as it may well reflect a displacement effect as new entrants such as China and India emerge. What then is driving Australia's increased share?

To further investigate, we used the field of chemistry to try and determine whether the findings were replicated at lower levels of aggregation—at the level of field in a country and for individual institutions. We also wished to examine whether the introduction of citation analyses could highlight any trends that are not apparent from a simple count of publication numbers.

18.8.2 National Level—Chemical Sciences

In chemistry, the trends mirror those found for the overall national publication output for the three countries: very moderate increases for Germany and the United Kingdom with at the same time decreasing publication shares, while for Australia we find a more pronounced increase and increasing publication share (Figs. 18.3 and 18.4).

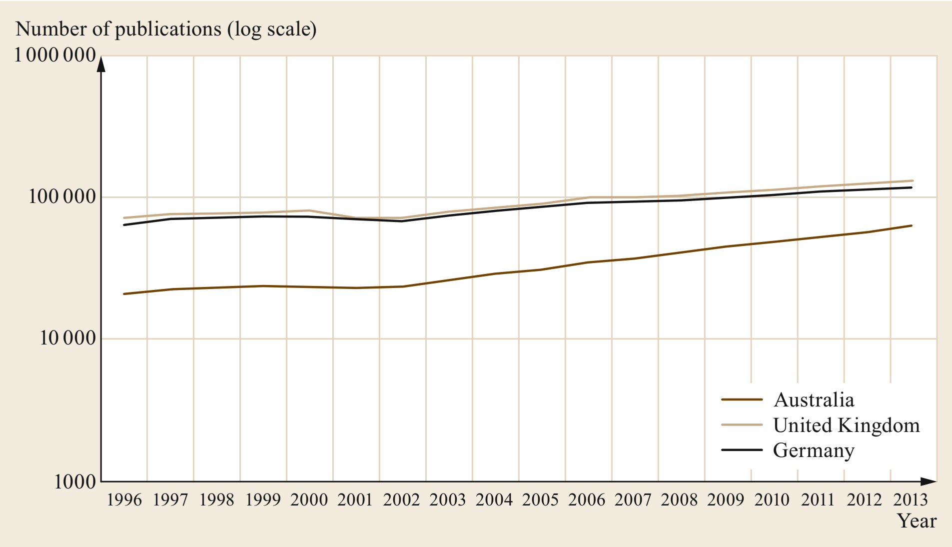

Fig. 18.1 Number of publications in all fields for the selected countries, 1996–2013. Data source: Scopus, authors' calculations

Part C | 18.8

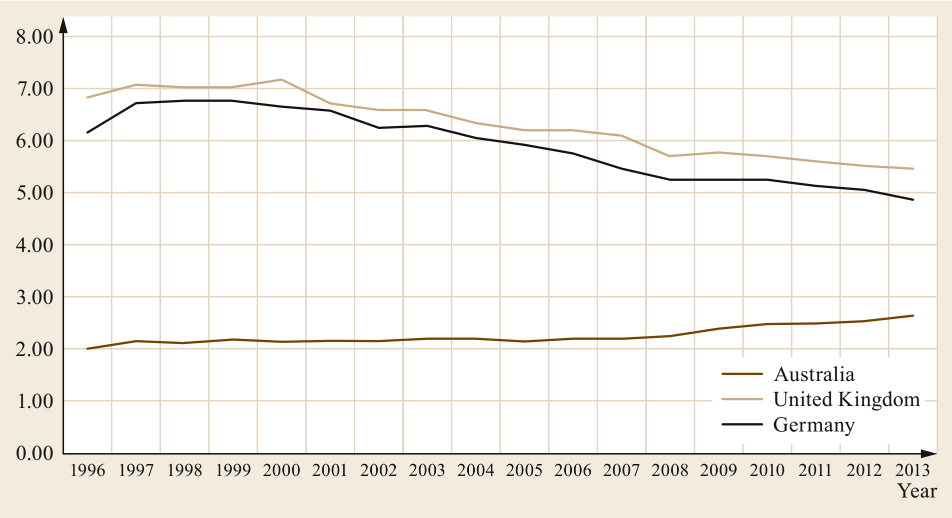

Fig. 18.2 Share of world publications in all fields for the selected countries, 1996–2013. Data source: Scopus, authors' calculations

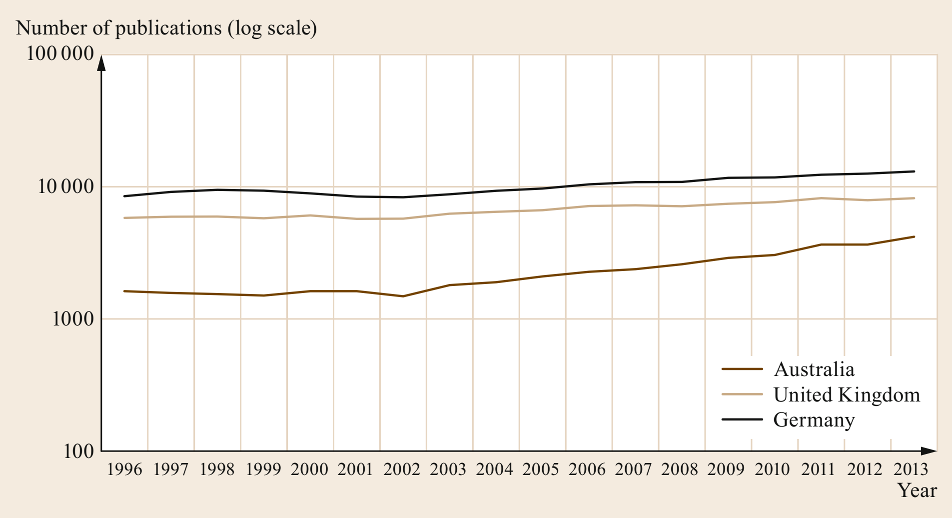

Fig. 18.3 Trends in number of publications in chemical sciences for the selected countries, 1996–2013. Data source: Scopus, authors' calculations

We examined trends in research performance for the three countries using two common citation measures—RCI (Fig. 18.5) and the proportion of output in the world's most highly cited publications (Fig. 18.6).

As with simple publication counts, the citation analysis highlights some counter-intuitive patterns, though all three countries remain at levels well above the world average. After some early volatility, the United Kingdom's RCI increased between 2002 and 2007 and has remained steady since. Allowing for yearly variances, Germany's RCI has remained unchanged across the 18 years of the analysis. In contrast, Australia's RCI increased significantly after 2002 and is now at a similar level to Germany, though at the start of the period it was well below Germany. Similarly, with their share of world publications in the top 10% most cited articles in the chemical sciences journals, Germany and the United Kingdom have been steadily declining since around 2000, while Australia's share has been rising. For all countries, the share of highly cited publications is above the share of total publications. This represents a strong performance.

Interestingly, the RCI for both the United Kingdom and Australia starts improving at the same time that policy discussions on the inclusion of citation measures in research assessment exercises begin to have currency. However, more analysis would need to be undertaken before any causal link between changes in policy and performance can be made, and the trends in shares of the top 10% of articles does not show the same consistency between countries.

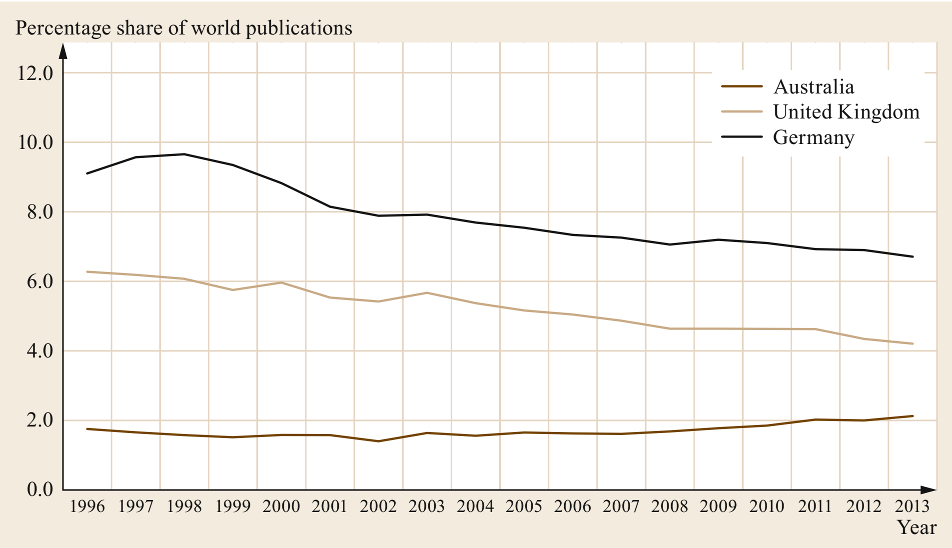

Fig. 18.4 Trends in share of world output in chemical sciences for the selected countries, 1996–2013. Data source: Scopus, authors' calculations

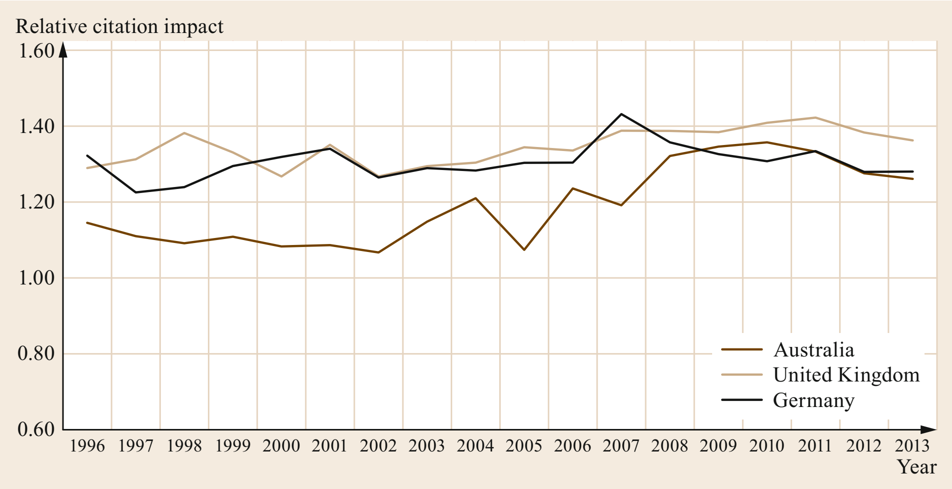

Fig. 18.5 Trends in relative citation impact for the selected countries in chemical sciences, 1996–2013. Data source: Scopus, authors' calculations

18.8.3 Institution Level—Chemical Sciences

While the overall developments found at the national level are mirrored by the selected institutions, varied performance among universities is also evident. As annual data at this lower level of aggregation is very volatile, the trends were analyzed using 3-year rolling windows.

For Germany, all three universities' publication numbers are increasing (Fig. 18.7), though for Braunschweig and Hannover, this was after a brief period of decline at the end of the 1990s. These three universities also increased the impact of their publications and, without assuming a strictly causal relationship, this improved performance occurred at the time of the initial evaluation in 2000 and in the period moving towards the follow-up exercise in 2005.

The steep increase in RCI for Göttingen at the end of the time frame is due to a small number of very highly cited articles from 2007, 2010, and 2011. The 2007 paper *A short history of SHELX* (Acta Crystallogr. A 64, 112–122; 2008) by G.M. Sheldrick drew 9236 citations in the first 3 years after publication, and thus is a very special case. It is often used to discuss potential distortions due to skewed citation distributions and outliers. The other two papers received just over 500 citations each in their first 3 years and, while they drew considerable impact, they do not have the same distorting effect as the Sheldrick paper. Consequently, the RCI peak shown for Göttingen needs to be interpreted with

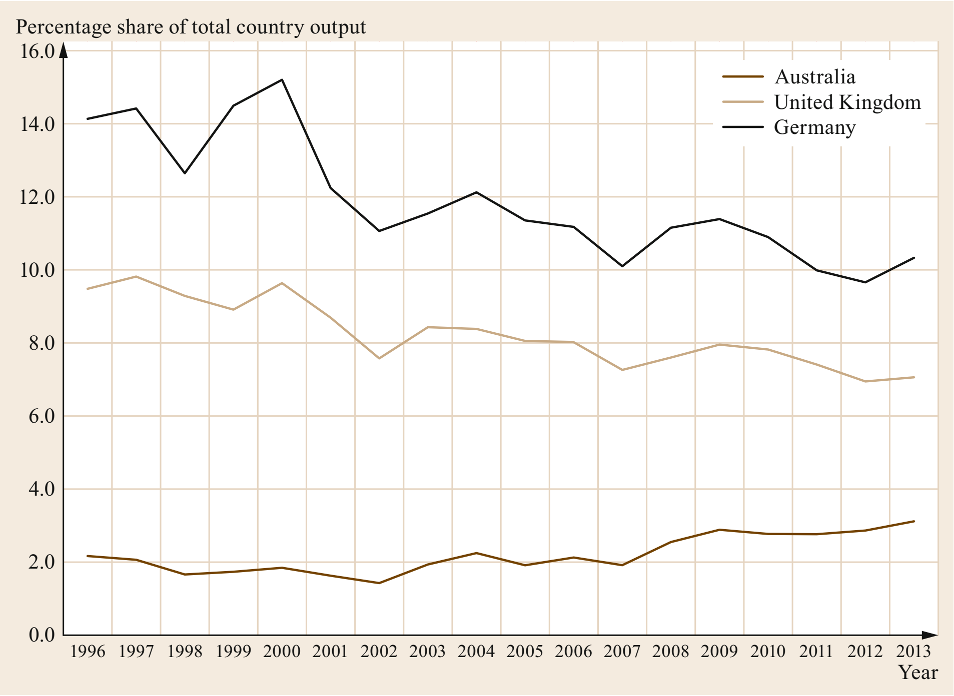

Fig. 18.6 Trends in the share of world publications in the top 10% most cited set for chemical sciences, selected countries, 1996–2013. Data source: Scopus, authors' calculations

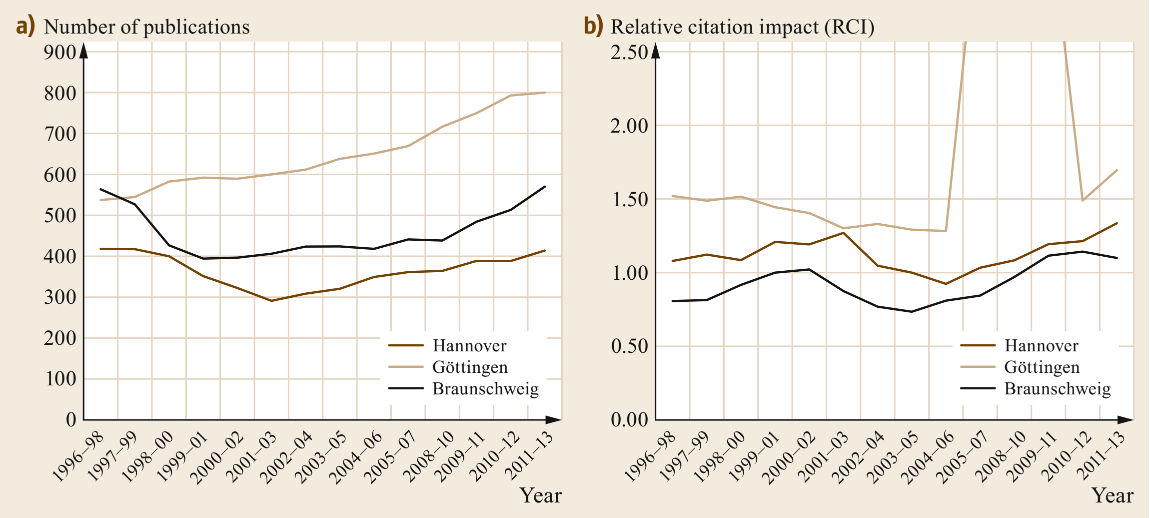

Fig. 18.7a,b Trends in publication output **(a)** and RCI **(b)** in the chemical sciences for selected German universities, 1996–2013. Data source: Scopus, authors' calculations

care. It does not reflect sustained performance change, but it does clearly demonstrate the rationale for using a suite of indicators rather than a single measure. In this case, complementary information based on size-independent or distribution-based indicators, as given in Table 18.2, are needed to correct for the distorting effects of outliers.

There is a very sharp increase in publication numbers for two of the three Australian universities we examined. While all three started from the same level of publication activity, Melbourne and, particularly, Monash show significant increases after 2000. However, the increase in numbers was not initially accompanied by similarly strong impact gains—a sustained

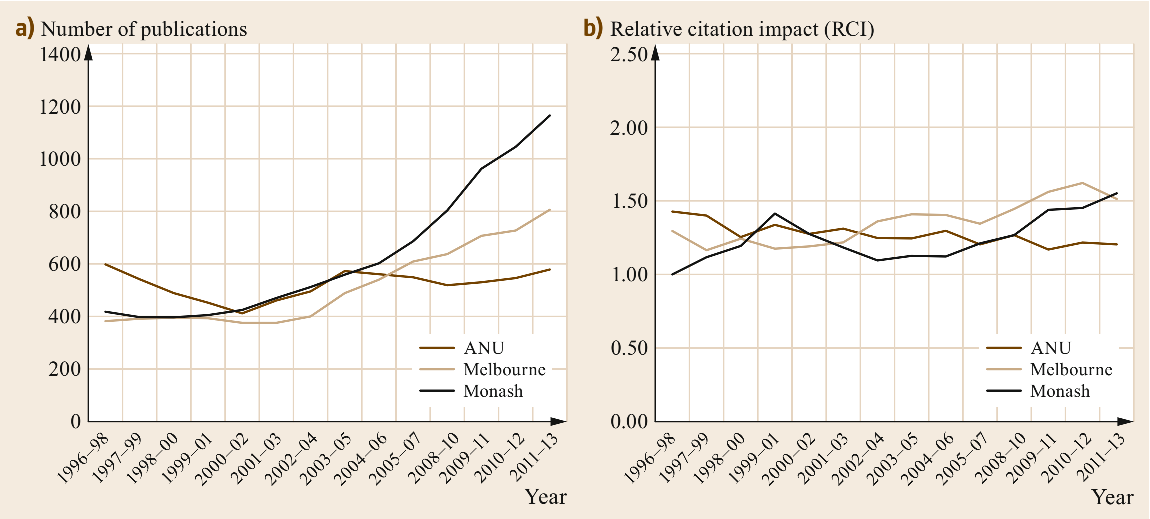

Fig. 18.8a,b Trends in publication output **(a)** and relative citation impact **(b)** in the chemical sciences for selected Australian universities, 1996–2013. Data source: Scopus, authors' calculations

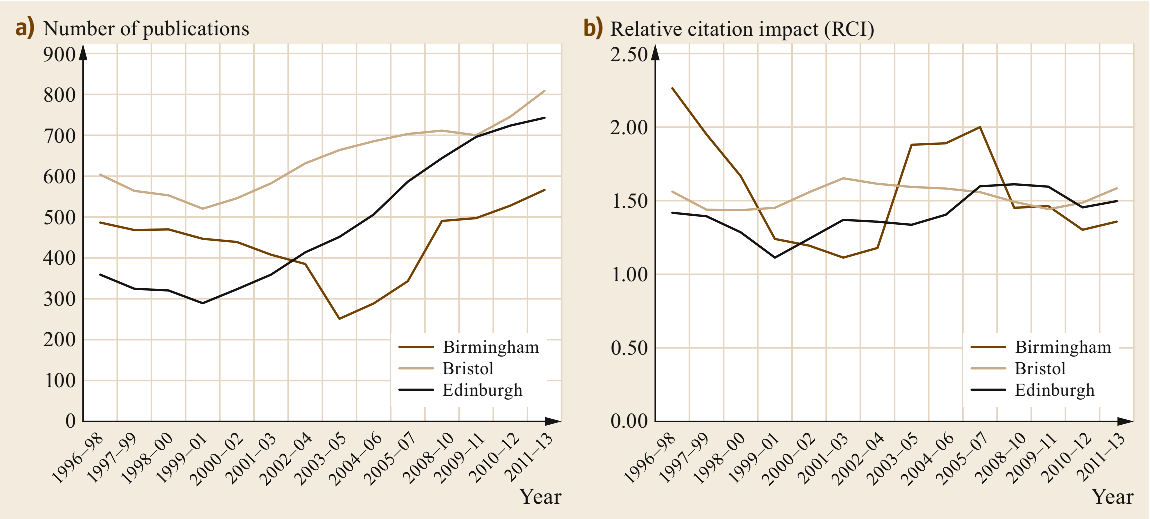

Fig. 18.9a,b Trends in publication output **(a)** and relative citation impact **(b)** in the chemical sciences for selected United Kingdom universities, 1996–2013. Data source: Scopus, authors' calculations

improvement in the average RCI did not occur for either institution until the second half of the period.

Whereas German universities maintained their relative standing in the RCI trends, this was not the case for the Australian universities (Fig. 18.8). The ANU had the strongest outcomes in terms of both quantity and impact at the beginning of the observation period but lost its leading position with regard to both performance dimensions by the end. Whatever external drivers of research performance existed, the internal drivers would appear to have more power, particularly in the case of the ANU.

Three different outcomes emerge for the three United Kingdom universities (Fig. 18.9). First, Edinburgh saw a huge increase in output in the period, and with a modest increase in the average RCI following an initial fall at the beginning. Second, Bristol also saw increasing publication numbers on a similar trajectory to Edinburgh, though not as steep, but their average RCI remained relatively stable across the period. Third, Birmingham's output has dropped below that of the other United Kingdom universities, and its average RCI dropped sharply at the start of the period; while it again overtook Edinburgh and Bristol, this was not a sustain-

Table 18.2 Assessment scores and bibliometric performance indicators for selected universities, 2008–2013

University	Assessment rating	Number of publications	Citations per publication	Relative citation impact	Percentage of output in top 1%	Percentage of output in top 10%
Hannover	Excellent	817	8.29	1.24	2.0	13.2
Göttingen	Excellent	1588	10.49	1.58	2.3	19.3
Braunschweig	Excellent	1072	7.56	1.14	1.0	12.2
ANU	3.7	1135	8.05	1.22	1.1	12.6
Melbourne	4.1	1649	9.58	1.46	1.8	15.9
Monash	4.7	2422	9.86	1.50	1.8	19.1
Birmingham	4.0	1151	9.38	1.41	2.1	16.2
Bristol	4.3	1538	10.46	1.56	1.8	19.0
Edinburgh	4.0	1434	9.83	1.48	1.7	18.9

Data source: Scopus, authors' calculations

able recovery, as it again lost ground at the end of the observation period.

We noted the variation in performance between universities that did not necessarily align with overall country trends, so we sought to investigate whether, within countries, they aligned with the outcomes of their relevant assessment exercises. For both the United Kingdom and Australia, we arrived at an overall score by either calculating a weighted average of the scores given for each discipline in the chemical sciences (Australia) or by weighting the distribution of scores given to outputs (United Kingdom). While the scores appear to be similar, they are not directly comparable (see Table 18.1 for a description of the different ratings). In Lower Saxony, the rating given was descriptive rather than numeric. The period analyzed in Table 18.2 closely aligns to the publication window used in all three assessments.

For Australia, the citation indicators appear to correlate well with the assessments given. This is not surprising given the central role that metrics played in the ERA process. In the United Kingdom, the results are not quite as clear cut. The university with the highest apparent rating (Bristol) outperforms the others on the two measures based on averages, but does not do so as convincingly on those based on the most highly cited publications in the field. For Germany, there is no differentiation in the assessment, though the data shows that Göttingen has a significantly stronger performance in all measures for this period (note: this period does not include the very highly cited paper by Sheldrick).

18.8.4 Institution Level—REF in Detail

We looked more closely at the output of United Kingdom universities (Table 18.3) as we were able to compare all output in the chemical sciences with that portion of the output that was submitted for assessment in REF2014 (i. e., the *best four* for each staff member).

Table 18.3 Bibliometric data for different sets of publications of the United Kingdom universities, 2008–2013

Business and Management Studies	C	0	0	1
Total		100	100	100

Data source: Scopus, authors' calculations

Not unexpectedly, the performance of the submitted articles exceeds that for the total output of each university. That is only of concern if the rhetoric of universities and analysts then extrapolates from this relatively small sub-set of output to make declarations about the overall performance of all publications from their university in that discipline.

We undertook a supplementary analysis, looking at how many publications in our chemistry journals were submitted to panels other than the panel directly tasked with assessing the chemical sciences for the three case-study universities. These results are shown in Table 18.4.

Most publications were submitted within main panel B, but the distribution across panels within that varied significantly between universities. Two-thirds of outputs in the chemistry journal set that the University of Bristol submitted for assessment found their way to panel 8, but only just over one-third of outputs from Birmingham in the same set of journals were submitted to the same panel. At Birmingham, one-quarter were submitted to the engineering panel that included chemical engineering. Edinburgh submitted one-quarter of their outputs in the same journal to the general engineering panel.

We also looked at what proportion of the total output of the universities in the journal set were submitted for assessment and what proportion of highly cited articles from the same journal set were submitted. The results are shown in Table 18.5.

Table 18.5 Proportion of output in chemistry journals submitted to REF 2014

	Birmingham	Bristol	Edinburgh

% of highly cited publications in chemistry journals (top 10%):			
Submitted to panel 8	13	20	17
Submitted to all panels	32	27	26

Data source: Scopus, authors' calculations

There are differences in the definition of a university output between our data set and the REF data set. To be classified to a university in our data set, the institution must be listed in the addresses given for the publication. In REF, academics may *bring* publications with them if they have recently moved to the university, though the institution's name will not appear in the addresses for that article. Similarly, if an academic has left the university for a new appointment in the REF census period, the publication will be submitted to REF by the new institution. However, we feel that these two factors will cancel out and the analysis should remain robust.

In total, less than 10% of the journal publications we identified for each university were submitted for assessment to panel 8. In contrast, we find that a far higher proportion of highly cited publications were submitted. Were universities anticipating that citations might play a greater role in panel deliberations and thus made a deliberate decision to select more highly cited items? Or is it the case that the *best outputs* tended to attract much higher citations? Whatever the reason, it is clear that the submitted output is not necessarily representative of the whole output of an institution.

18.9 Discussion and Conclusions

While the three evaluation systems—in Australia, Germany, and the United Kingdom—examined here differ considerably, we do not find the anticipated differences in changing performances, either at the country level or at the institutional level. For all three countries, we observe continuously increasing publication numbers since 2002. At the national level, the different trends in relative citation impact for the chemical sciences are more pronounced. All three countries, however, still remain well above the world average on this measure. Australia's improved performance was more pronounced than was the case for the United Kingdom, and Germany's performance even decreased slightly. This is also reflected in the increasing share of highly cited publications (top 10%) for Australia, while the German and United Kingdom shares remain stable. However, for all countries, the share of highly cited publications is still well above the world average.

When it comes to the institutional level, the picture is less clear. In each of the three countries, and also for most of our case study institutions, we see improved performance. This does not permit us to draw any general conclusions about the effectiveness of any of the systems in place. If we were to base our assessment on these systems using indicators alone, the data would not allow us to conclude that any of the systems has a beneficial or detrimental influence on performance.

Thus, it appears that it is not the specific system that makes a difference but, rather, the fact that performance becomes a central topic of conversation. Consequently, universities pay increasing attention to monitoring performance—be it based on quantitative, qualitative, or mixed information. Global developments such as international university rankings also play a role in heightening awareness of performance.

In order to better understand the mechanisms behind changing performance, restricting scrutiny to mere numbers is insufficient. Contextual information at various levels of aggregation—within and outside the institutions—is highly relevant. This is a requirement repeatedly formulated by bibliometricians when it comes to applying research metrics.

Ian McAllister is Distinguished Professor of Political Science at The Australian National University. He previously held chairs at ADFA and the University of Manchester. He has published several books. He has been Director of the Australian Election Study since 1987, a large national post-election survey of political attitudes and behaviour. His research covers Australian politics, comparative political behaviour and post-Communist politics. He is currently completing a book on Russian voting.

19. Scientific Collaboration Among BRICS: Trends and Priority Areas

Jacqueline Leta, Raymundo das Neves Machado, Roberto Mario Lovón Canchumani

The political and economic partnership known as BRIC (for Brazil, Russia, India and China) was formally established in 2008. Three years later, in a joint meeting in Cape Town, a new member, South Africa, was included in the group. In this meeting, BRICS delegates elaborated a list of priority areas for enhancing bi- or multilateral cooperation in the fields of science, technology and innovation. Considering the growing importance of BRICS in the global economy and other sectors, the present study investigates the performance of the group in the scientific arena before and after its formalization in 2008, looking closely at BRICS collaborative publications, in order to identify whether the priority areas established in the Cape Town declaration are being actually pursued. Data were collected during February and March 2017 from the Web of Science database, covering the period 2000–2015. To match scientific collaborations, specific searches were carried out by combining the names of two BRICS members and time periods. Various bibliometric techniques were used, including diachronic analysis, Bradford's law and journal co-citation analysis. Among the key findings highlighted here are a marked increase in BRICS participation during the period, widely varying levels of collaboration among members, and the presence of physics as a central field for most members. The chapter concludes with an in-depth discussion focusing on correlations between the fields with greater collaboration and the priority areas.

19.1 BRICS: From Origin to Priority Areas in ST&I

The beginning of the twenty-first century was marked by a severe economic crisis that affected the major world powers. This scenario has favored the formation of new geopolitical configurations, such as the BRIC, the acronym for the partnership between Brazil, Russia, India and China. The BRIC concept was introduced in 2001 by Jim O'Neill, who predicted that GDP growth among the BRIC would soon exceed that of the G7 countries [19.1].

At that time, the BRIC comprised the largest peripheral countries, including not only the two largest in population but also the two oldest. In addition, the group constituted almost half of the world's workforce, held a huge bulk of the global natural resources and sported booming economies. Other features that favored the establishment of the group as a new economic and political alliance included the expanded purchasing power of peripheral countries, especially China and South American countries such as Brazil, and the aggressive stance of Brazil and India towards the liberalization of world trade, especially of agricultural goods [19.2].

The BRIC emerged as an alternative to the traditional north–south model of cooperation, which at the time was "experiencing depletion" [19.3, p. 7]. Together, Brazil, Russia, India and China could have greater representation in global governance, and thus could broaden their participation in the power arena,

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_19

restricted at that time to the economic and political core countries known as the G7. *Cassiolato* and *Lastres* [19.4] highlighted various socioeconomic conditions that favored the creation of the BRIC alliance, such as their strategic geoposition, their diversity and rich territory with huge populations, and their economic performance, including growth in their export and import levels as well as in their foreign direct investments. The authors also highlighted that the 2007–2008 global economic crisis had "repositioned the role and importance of the BRIC" [19.4, p. 16]; in other words, the economic crisis propelled BRIC to occupy a more central position in the global economy.

The BRIC group was formally established during a meeting of the countries' foreign affairs ministers hosted in Yekaterinburg, Russia, in 2008. Since then, the group has organized annual meetings among the presidents or prime ministers of all the BRIC countries. The aim of these summits was both to strengthen cultural and political ties and to develop a common agenda of initiatives and actions to empower and consolidate the group. During the 2011 Sanya meeting in China, a new partner—South Africa—was included in the group, and an *S* was added to the acronym, officially establishing the BRICS group. In this meeting, the five countries discussed strategies to enhance their economies and to strengthen their ties in various sectors, including agriculture, energy, and science and technology, launching the first action plan [19.5].

In 2014, for the first time, BRICS delegates in science, technology and innovation (ST&I) met in Cape Town, South Africa, to discuss strategies to enhance their cooperation in this sector. The group established a list of priority areas in which the countries should initiate or increase bi- or multilateral cooperation. The list included [19.6]:

- Innovation and technology transfer
- Food security and sustainable agriculture
- Climate change and natural disaster preparedness and mitigation
- New and renewable energy, energy efficiency
- Nanotechnology
- High-performance computing
- Basic research
- Space research and exploration, aeronautics, astronomy and Earth observation
- Medicine and biotechnology
- Biomedicine and life sciences (biomedical engineering, bioinformatics, biomaterials)
- Water resources and pollution treatment
- High-tech zones/science parks and incubators
- Technology transfer
- Science popularization
- Information and communication technology
- Clean coal technologies
- Natural gas and nonconventional gases
- Ocean and polar sciences
- Geospatial technologies and their applications.

Many of these priority areas embrace a number of hot and emerging hot topics [19.7, 8], as they are also in accordance with the OECD 2016 report, which analyzes disruptive and promising trends in science, technology and innovation not only for OECD countries, but also for major nonmember OECD countries, including all BRICS countries [19.9].

Considering BRICS as a political-economic union of five large countries that have been capturing space in global governance, the present study aims to investigate how this group has performed in the scientific arena, before and after its formalization in 2008, looking closely at thematic trends among BRICS collaborative publications.

19.1.1 BRICS and Bibliometric Studies

The BRICS contribution to global science has been fairly well investigated, including studies with different approaches and/or the use of multiple indicators in science, technology and/or innovation [19.10–15].

In the following, we present a brief overview of bibliometric studies investigating trends in BRIC or BRICS scientific publications.

The bibliometric literature focusing on BRICS' scientific publications includes those with a more general approach, such as the study by *Wagner* and *Wong* [19.16], who investigated BRIC representation in the Science Citation Index Expanded (SCIE). Based on national and international sources, the authors compiled a list of 15 000 titles of BRIC national journals, of which 445 titles (almost 3%) were indexed in SCIE. According to the authors, this share is similar to that found in other sources. Considering such similarities, Wagner and Wong argued that the BRIC countries were not underrepresented in SCIE, but did note that many BRIC publications were less visible than those published in European or North American titles.

BRICS scientific excellence has also been examined based on their presence in the most frequently cited papers, that is, the top 1% and top 10% [19.17]. The authors found that China exhibited outstanding performance, but that, as with other BRICS countries, the share of Chinese publications (0.7 and 7.7%) among the 1 and 10% top-cited papers was below expectations. South Africa, Brazil, India and Russia, in descending order, were less represented among the set of top-cited papers. Focusing on citable documents reported by SCImago, *Guevara* and *Mendoza* [19.18] investigated the similarities and differences in publishing patterns among BRIC members. The authors used accurate statistics to measure the relative importance of thematic categories (based on journal classification) for each country. They found that BRIC members as a whole were more dissimilar, tending to be closer in terms of publishing patterns to their neighbors or to countries that shared the same language; India, however, was the exception.

The scientific collaboration involving BRICS countries is also a frequent theme in bibliometric literature. *Finardi* [19.19], for example, analyzed collaboration based on co-authorships of BRICS publications published during the period from 1980 to 2012. The results indicated that collaboration among the five BRICS has grown, especially after the 2000s. For the whole period, the strongest linkages were found between India and South Africa and between Brazil and South Africa. Engineering was the area with the highest share of collaboration in the former pair of countries, whereas medical sciences was highest in the latter. *Singh* and *Hasan* [19.20] investigated BRICS research output, including partners in publications, over three decades (1994–2013). According to the authors, around 26% of BRICS publications represented collaborations with another country, most frequently the USA, followed by Germany, England, Japan and France. Using probabilistic affinity indexes, *Finardi* and *Buratti* [19.21] also investigated key patterns in BRICS scientific publications, analyzing the group's linkage with 65 other countries. Geographical, cultural and historical proximity were found to be the major factors driving collaboration between BRICS and other countries.

Other studies have explored BRICS' contribution in specific scientific fields or areas. *Bai* et al. [19.22] analyzed the contribution of the group in literature on neglected diseases, using PubMed as the main informational source. The results revealed that Brazil, China and India were among the ten countries with the largest share of articles in this field. Using cluster analysis, the authors found eight groups of words, each associated with a neglected disease. Helminthiasis, human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS) and tuberculosis were the most frequent diseases among the BRICS. Other examples include the work on stem cells, led by Machado. The first studies focused on the performance of Brazilian scientists in this field [19.23, 24]. In later work, the authors turned their attention to mapping author productivity and main thematic categories for BRICS publications on stem cells [19.25]. Their results showed an increase in the number of authors with higher levels of productivity in this field across all BRICS countries. In recent years, BRICS' research on stem cells has reflected a strong emphasis not only in clinical medicine, especially hematology and oncology, but also in areas such as cell and molecular biology. According to the authors, this picture suggests a shift in the orientation of BRICS' publications on stem cells towards an understanding of stem cell mechanisms of division and differentiation.

Yang et al. [19.26] explored the disciplinary structure of G7 and BRIC publications during three separate years (1991, 2000 and 2009). The authors found a marked change in disciplinary structure among the BRIC, with a focus on basic research in physics, chemistry, mathematics and engineering. In contrast, the G7 publications were oriented more towards life sciences. Despite such differences, authors noted that the BRIC disciplinary structure has become more similar to that of G7 over time.

The above-mentioned studies represent a small fraction of the huge body of literature on BRICS' performance in science, including trends in journals, citation, collaboration, and specific fields and disciplines. The present study offers new insight into BRICS' performance in science, as it investigates the intellectual or disciplinary structure of BRICS' collaborative publications in order to identify whether the main themes addressed by BRICS in this set of publications is in accordance with the priority areas established in the Cape Town declaration.

19.2 Methodology

General data for the BRICS' scientific publications were collected directly from the *Web of Science* (WoS) core collection (Clarivate Analytics) database in March 2017 and analyzed using Microsoft Excel software. Descriptive analyses based on this data set are presented in an introductory section, including analysis of the compound annual growth rate (CAGR), which was calculated as follows

$$\mathrm{CAGR}\,(t_0, t_n) = \left(\frac{V(t_n)}{V(t_0)}\right)^{\frac{1}{t_n - t_0}} - 1\,,$$

where $V(t_0)$ = start value, $V(t_n)$ = finish value and $t_n - t_0$ = number of years.

BRICS collaborative publications were downloaded from the *WoS* (Clarivate Analytics) during February and March 2017 by combining the names of two of the BRICS countries (for instance, Brazil and Russia) in the *address* filter and the period 2000–2007 or 2008–2015 in the *year of publication* filter. Downloading was limited to 500 publications at a time, and each archive included complete information for all publications, including references, in a CSV (comma-separated values) format. These archives were then imported into Microsoft Excel software in order to identify inconsistencies and to exclude duplicates. Based on this set of publications, two main analyses were carried out, Bradford analysis and journal co-citation analysis, for each country in both periods.

Bradford's statistical model [19.27] was applied to identify core journals, that is, those in zone 1. Although fewer titles are included in Bradford's first zone, it comprises, in general, the largest number of articles, in this case, co-authored by two or more BRICS countries. Bradford statistics on BRICS' collaborative publications were calculated using Microsoft Excel.

The journal co-citation analysis as described by *McCain* [19.28] reveals the intellectual structure, or the main domains, of a set of publications. Considering the premise that the greater the frequency of co-cited pairs, the closer the relationship between the pairs, journal co-citation analysis allows one to identify clusters of journals with thematic similarities. Co-citation analysis on BRICS collaborative publications was carried out with the help of Gephi, an open-source software program for network analysis developed in 2009 [19.29]. Ten maps based on journal co-citation, one for each of the five BRICS countries during the periods 2000–2007 and 2008–20015, were then generated with Gephi. The analysis considered only journals that had been cited more than 100 times during a period. The identification of journal communities (or clusters) used the algorithm elaborated by *Blondel* et al. [19.30], in which nodes (journals) are grouped in neighborhoods with the greatest contribution to the positive variation in the modularity measure. Fruchterman-Reingold's classical spatial distribution algorithm, available in Gephi, was used to gain better visualization of the clusters; labels were also adjusted for better visualization of the nodes.

19.3 Results

The results are presented in three main sections: general trends in BRICS scientific output, trends in BRICS collaborative scientific publications, and scientific structure in BRICS collaborative scientific publications.

19.3.1 BRICS Scientific Production: General Trends

From 2000 to 2015, BRICS published 6 520 943 scientific publications. China was responsible for 61.03% of all publications, India for 16.47%, Russia for 10.08%, Brazil for 9.74% and South Africa for 0.68%. Among the total publications from BRICS during the period, the most frequent types were articles (74.06%) and conference papers (20.47%). Reviews and other types of publications summed to less than 6%.

The annual number of scientific publications for each of the BRICS member countries is shown in Fig. 19.1. A strong exponential growth trend ($r^2 > 0.90$, p-value < 0.05) can be observed. During the period, China exhibited the smallest rate of duplication time (2.5 years), while Russia had the largest (4.1 years); in other words, China had the fastest growth and Russia the slowest.

The inset in Fig. 19.1 shows the increase in the number of publications for each country over two periods, 2000–2007 and 2008–2015, representing the 8 year periods before and after the formal establishment of BRICS.

A better view of this increase can be seen in Table 19.1, which presents the total number of publications for each period and the compound annual growth rate (CAGR). The number of BRICS scientific publications demonstrates impressive growth from 2000–2007 to 2008–2015, with a CAGR of 15.70. Among the BRICS countries, China exhibits the highest CAGR, whereas Russia shows the lowest. This result is in accordance with the rates of duplication times indicated previously for China and Russia.

Table 19.1 The growth in BRICS publications indexed in the WoS database

Country	2000–2007	2008–2015	CAGR[a] 2000–2015
Brazil	186 061	449 372	13.42
Russia	283 151	374 307	4.07
India	284 302	789 418	15.71
China	919 956	3 059 658	18.73
South Africa	53 919	120 799	12.21
BRICS	1 727 389	4 793 554	15.70

[a] CAGR = compound annual growth rate

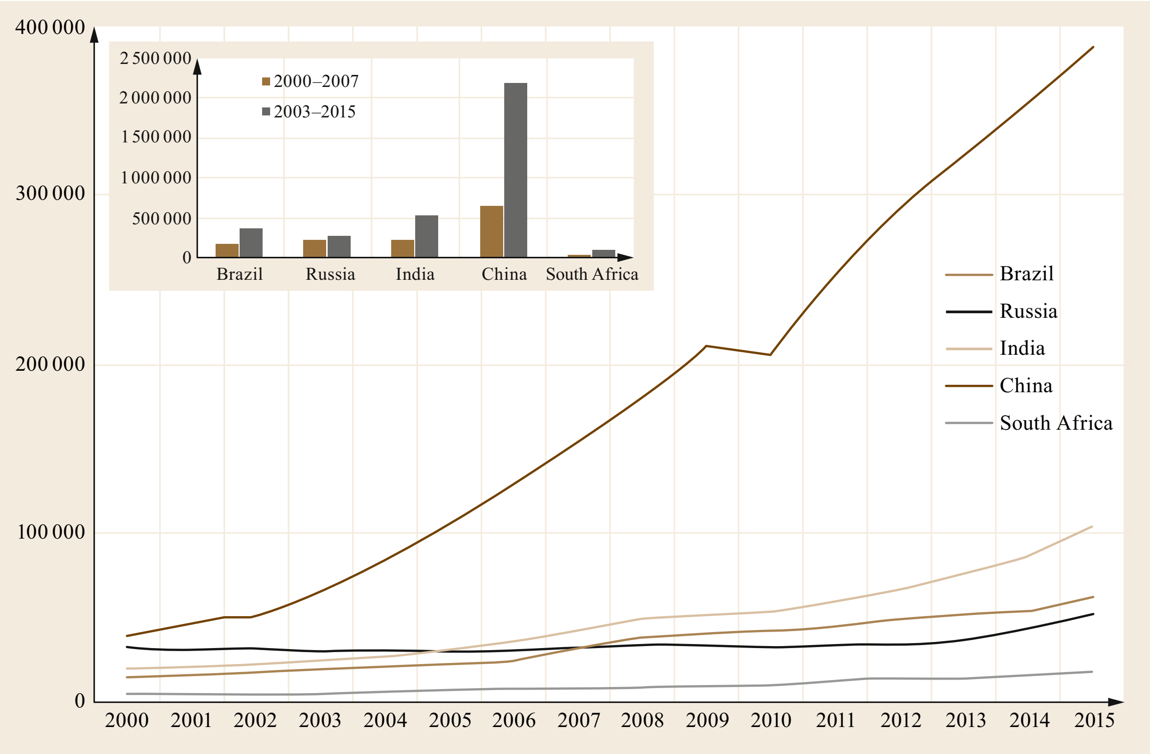

Fig. 19.1 BRICS' annual number of scientific publications in WoS database from 2000 to 2015

Wong and *Wang* [19.14] studied the growth trajectory of BRICS publications and observed three growth phases: slow growth in the initial years, fast exponential growth in the middle years, and no growth (or steady state) in later years. The authors note that China is experiencing the highest rate of growth, in the middle of the second growth phase. Russia, on the other hand, is already in the third phase, and thus entering a period of maturity, with little or no growth. Based on a logistic growth function analysis, the authors predicted that China will enter the mature phase when the country reaches around 3.3 million publications, whereas the other BRIC members will reach maturity at numbers below one million.

The growth observed in the other BRICS countries may be influenced by different factors, including the well-known expansion of the WoS/Clarivate Analytics database. *Testa* [19.31] recently presented details regarding the increased number of journals indexed in WoS across ten countries, including Brazil, India, China and South Africa. The author posited that the motivation behind such an initiative was the desire to enhance visibility of regional journals and "their local importance" [19.31, p. 100]. Regarding database journal coverage, *Leta* [19.32] analyzed Brazilian growth in terms of the number of publications indexed in two international databases, including WoS. In the author's view, the increase was a result not only of internal factors such as an increase in science (S) and technology (T) resources and qualified human resources, but also of external factors, including the growth in the total number of Brazilian titles indexed in the databases.

There is no doubt that both internal and external factors have contributed to China's remarkable growth in terms of the number of scientific publications. Using data retrieved from the Ulrichsweb database, *Wang* et al. [19.33] presented a series of results revealing that China, which is among the top three publishing countries, experienced fluctuations in scholarly publishing over the period 1950–2013. According to the authors, such variation was related to the establishment of new internal rules, the Interim Regulations on the Administration of Periodical Publications, which to a certain extent prioritized quality over quantity of journals. Additional factors may also contribute, such as the search for new sources of publishing. *Yan* et al. [19.34], for instance, examined China's contributions in *PLOS One*, one of the largest and most successful open-access journals in the world, and observed exponential growth in the number of Chinese publications in this journal. In fact, in 2013, more than 6000 papers published in *PLOS One* had a Chinese author, accounting for almost 20% of its total volume that year.

Such a strong presence for China in a single open-access journal raises the possibility that this new paradigm in scientific communication also drove the growth in publications among the other BRICS countries. Hence, it seemed relevant to investigate how large a proportion of the BRICS articles were published in open-access journals. Table 19.2 shows the number of articles published in open- and restricted-access journals for each of the five BRICS countries. From 2000–2007 to 2008–2015, the five countries increased the number and share of articles in open-access journals. In both periods, China had the largest number of such publications, while South Africa had the lowest. Brazil displayed the highest share of articles in open-access journals in both periods (10.36 and 27.04%), while Russia exhibited the lowest (0.19 and 5.58%). Despite having the lowest share, however, Russia demonstrated the most impressive growth in this type of publication from one period to the other.

Comparing Tables 19.1 and 19.2, one can surmise that scientists in BRICS have invested in publishing in open-access journals as a strategy to gain visibility in the global science community. Despite the lack of familiarity and the criticism from scientists regarding this publishing model [19.35], there is considerable evidence to suggest that this type of publication does have quality and may contribute to increasing a paper's visibility and citation frequency [19.36, 37]. Such impact may be the reason behind BRICS' huge investment in developing research-oriented repositories as a strategy for disseminating scientific knowledge, as described by *Calderón-Martïnez* and *Ruiz-Conde* [19.11].

As a final analysis, Table 19.3 shows the fields in which BRICS publications most frequently appear. In 2000–2007, with the exception of South Africa, BRICS publications were strongly oriented towards the exact sciences and engineering fields. When Chinese publications are considered, nine of the most prolific fields fall into these categories. Brazilian publications were half dispersed in the exact sciences, while those for South African were spread among categories. The main fields for South African publications differed from the rest of BRICS, including fields in the biological sciences, such as environmental and plant science and zoology, which are closely aligned with the country's local issues, including its diverse ecosystems, flora and fauna. Brazil, which has one of the world's largest forests, exhibited a more international profile, while South African publications emphasized local issues that drove the country's mainstream research.

For the period 2008–2015, publications from China, Russia, India and Brazil, in descending order, again displayed a strong orientation towards exact sciences and engineering. This trend was still strongest in China.

For Brazilian publications, two new fields, pharmacology and environmental, science ecology, emerged in 2008–2015, replacing dentistry and neurosciences. This movement may signal a new orientation of Brazilian research towards local issues related to the country's fauna and flora, especially in Amazonia, which has the greatest biodiversity in the world.

Considering South African publications, it is clear that the country's mainstream research prioritizes local issues. In this period, a movement is also observed: infectious disease and environmental, science ecology replacing zoology and agriculture. Such growing interest in research on infectious disease in more recent years may be a response to a persistent scenario on the African continent, where hundreds of millions of people are victims of diseases such as malaria, yellow fever, dengue and HIV/AIDS. In recent years, various initiatives have been implemented, including the establishment of the South African Global Disease Detection (GDD) Center in 2010, to improve research in biomedicine and health sciences, including emerging infectious diseases [19.38].

19.3.2 BRICS Collaborative Articles: Main Journals

As shown previously, with the exception of South Africa, BRICS scientific publications are mainly oriented towards the fields of exact sciences and engineering. In order to delve more deeply into this information, we turn our attention to an analysis of the fields and main thematic content of BRICS' collaborative articles, that is, publications co-authored by two or more BRICS countries.

As an initial step, Bradford analysis was applied to the journals in which the collaborative articles were published. Table 19.4 shows the total number of journals and articles as well as the number of zones found for the collaborative articles of each country in both pe-

Table 19.4 Journal distribution of BRICS collaborative articles indexed in the WoS, according to Bradford's model

Country	Total		Number of zones	$r^{2\ a}$	Zone 1	
	Journals	Articles			Journals	Articles
2000–2017						
Brazil	943	2944	4	0.96	9	845
Russia	1155	5916	3	0.85	12	2338
India	832	2601	3	0.96	9	951
China	1400	4681	4	0.93	10	1410
South Africa	598	1053	3	0.85	5	79
2008–2015						
Brazil	1228	3470	4	0.93	8	758
Russia	1271	5196	4	0.97	10	1676
India	1329	3973	4	0.93	8	975
China	1993	6142	5	0.90	11	1206
South Africa	994	2137	6	0.87	6	181

[a] Coefficient of determination

riods, along with the coefficient of determination (r^2), which indicates that all data had a good fit to the Bradford distribution model ($r^2 > 0.80$).

As a first observation, the increase in BRICS' collaborative articles varied considerably, from negative growth observed for Russian articles to 103% growth for South Africa. China showed the largest number of co-authored papers, displaying a 31.2% increase during the period.

Bradford analysis for BRICS' collaborative articles in 2000–2007 showed that the number of journals varied from 598 (South Africa) to 1400 (China). This set of journals was distributed across three or four zones. As for the core journals, that is, journals found in zone 1, Russia had the largest nucleus, comprising 12 titles that jointly published 2338 articles, almost 40% of the country's total articles during this period. South Africa had the smallest number of core journals, with five titles, in which 79 (less than 8%) collaborative articles were published.

For the period 2008–2015, Bradford analysis revealed a different model for journal distribution, with the number of zones varying from four to six; Brazil was the only country in which the number of zones remained the same as in the previous period. With regard to the core journals in zone 1, South Africa again displayed the smallest nucleus, while China exhibited the largest, with 11 titles encompassing 1206 articles, almost 20% of all Chinese collaborative publications with a BRICS partner.

Table 19.5 lists journals included in zone 1 for each BRICS country in the period 2000–2007. Upon first observation, a high overlapping of journals can be seen, mainly related to the exact sciences, specifically in physics. Among the top-ranked core journals, six appeared in the Brazilian, Russian, Indian and Chinese lists, including *Physical Review Letters*, *Physics Letters B*, *Physical Review C*, *Physical Review D* and *European Physical Journal C*. It is important to highlight that with the exception of *Physical Review Letters*—a journal with a broader spectrum of subjects—the set of journals shared by BRICS included specific themes such as condensed matter and materials physics (*Physics Letters B*), nuclear physics (*Physical Review C*) and particle physics, gravitation and cosmology (*Physical Review D*).

A different trend, however, is observed for South Africa, encompassing a broader list of journals in different fields, including, for instance, *Monthly Notices of the Royal Astronomical Society* in physics, the *International Journal of Systematic and Evolutionary Microbiology* in biomedicine, and *The Lancet* in medicine.

Table 19.6 presents a list of journals from zone 1 for each BRICS country during the period 2008–2015. One general observation is that the number of journals was reduced compared to the previous period.

Table 19.5 List of core journals of BRICS collaborative articles, indexed in the WoS, 2000–2007

Full name	Abbreviation	Brazil	Russia	India	China	South Africa	Total

Again, the largest number of BRICS collaborative articles was published in journals classified in physics: three journals from this zone appeared in the lists for all BRICS countries: *Physical Review Letters*, *Physics Letters B* and *Physical Review C*. Although these journals appeared in the 2000–2007 list of core journals, this picture suggests a movement in BRICS, mainly in South Africa, towards an enlargement of the collaborative research among all members. Note that in the previous period, the five BRICS members published together in only one core journal, *Astronomy and Astrophysics*, published by the European Southern Observatory.

It is important to highlight that one of the most successful open-access journals appears in the list of core journals for three countries during this period—*PLOS One*, a journal classified in the field of multidisciplinary sciences. Similarly, *The Lancet*, one of the most prestigious journals in the medical sciences, appears in the list of core journals for three countries.

19.3.3 BRICS Collaborative Articles: Intellectual Structure

The data set presented in the previous section revealed that BRICS' collaborative articles tended to follow the general trends for BRICS' total publications (Table 19.3), with the field of physics in a central position. In order to better visualize the thematic trends, a journal co-citation analysis was performed for BRICS' collaborative papers. The co-citation analysis included only journals that were cited more than 100 times in each period. Figures 19.2 through 19.6 show each country's journal co-citation map.

For the Brazilian articles co-authored with other BRICS countries, the journal co-citation analysis generated a map with seven clusters for the period 2000–2007 (Fig. 19.2a). The largest cluster (violet) contains 15 (21.43%) of the 70 journals included in the analysis. The journals found in this cluster are predominantly related to biomedicine and general issues. *Nature* and *Science*, two major generalist journals included in cluster 1, have the highest degree of centrality. The second largest cluster (green) is strongly associated with physics and includes the journals with the largest numbers of citations: *Phys Rev Lett*, *Phys Rev D* and *Phys Lett B* (they can be identified on the map by the size of the nodes). The map presents five other communities, related to theoretical or applied physics (red, pink and dark red), astronomy/astrophysics (orange) and earth/-space sciences (light purple).

For the period 2008–2015, the Brazilian map exhibits eight clusters (Fig. 19.2b). Although the number of communities has increased compared to the previous period, the analysis shows a new arrangement for co-cited journals: the enlargement of the largest cluster (violet) and the reduction of some others, especially clusters 3 (light red) and 4 (pink). In this period, the largest cluster (violet) contains 48 (37.5%) of the 128 journals included in the analysis. The set of journals found in this cluster is mainly related to clinical medicine, and it does not include the journals with the highest degree of centrality, as was seen in the previous period. The profiles for clusters 4 (pink) and 7 (dark red) have also changed: cluster 4 is a multidisciplinary community, encompassing *Nature* and *Science*, which are again the journals with the highest degree of centrality, and cluster 7 is devoted to oral health. In ad-

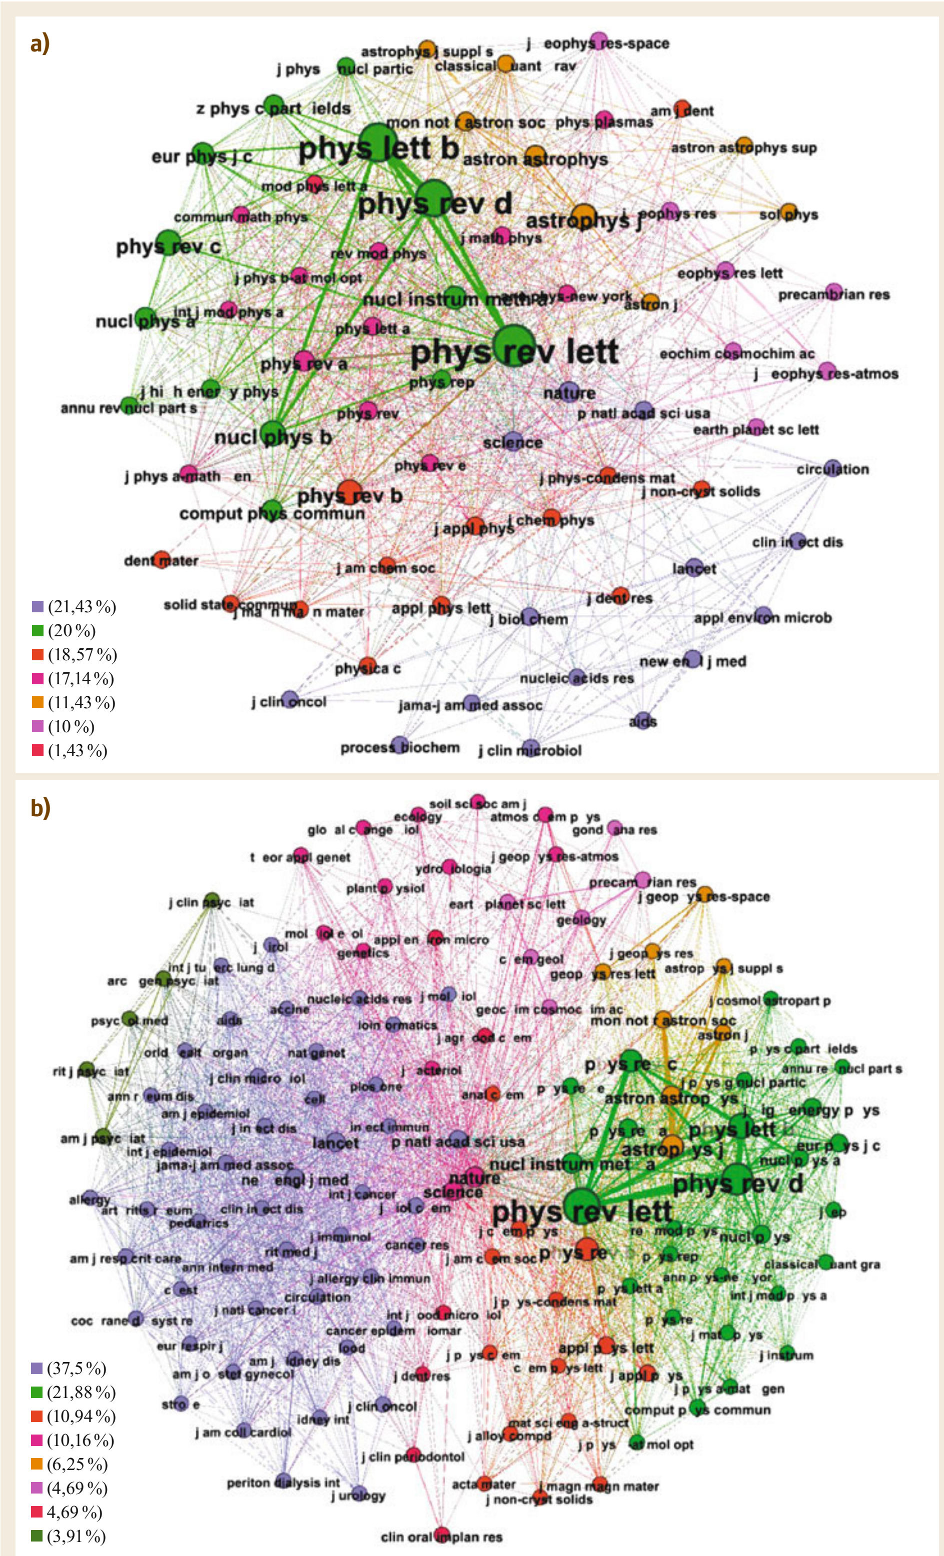

Fig. 19.2a,b Maps of co-cited journals of collaborative articles between Brazil and one or more other BRICS countries. Colors indicate different (thematic) clusters, while the size of the symbols represents the weight of the 70 **(a)** and 128 **(b)** journals in the analysis for 2000–2007 and 2008–2015, respectively. Gephi software (version 0.9.1)

dition, cluster 8 (dark green) has emerged in the field of psychiatry.

Despite these changes, some features remain unchanged from the previous period. Cluster 2 (light green), which is the largest, and cluster 3 (light red) are also related to physics. Cluster 2 still contains the journals with the largest number of citations, and they are the same as in the previous period: *Phys Rev Lett*, *Phys Rev D* and *Phys Lett B*. Clusters 5 (orange) and 6 (light purple) still comprise journals in astronomy/astrophysics and earth/space sciences, respectively.

Figure 19.3 displays the journal co-citation map based on Russian articles co-authored with one or more BRICS partners. The map for the period 2000–2007 presents nine clusters. The largest (violet) contains 45 (32.14%) of the 140 journals included in the map. Cluster 1 contains journals related to physics and chemistry. Cluster 2 (light green) is associated with physics, and it comprises one of the journals with the largest number of citations: *Phys Rev Lett*. Clusters 6 (light purple), 7 (dark red), 8 (dark green) and 9 (gray) are also associated with physics, while cluster 5 (orange) contains journals in astronomy and astrophysics (orange). Clusters 3 (light red) and 4 (pink) encompass journals in biomedicine and earth/space sciences, respectively. These clusters also include *Science* and *Nature*, journals with the highest degree of centrality.

With regard to the period 2008–2015, the map reveals only six clusters, indicating a compression of thematic communities. As observed for the previous period, cluster 1 (violet) remains associated with physics and chemistry. This is the largest cluster, with 64 (almost 35%) of the 183 journals included in this analysis. The other clusters display a new configuration compared to the previous period. Physics journals are found in clusters 3 (red) and 5 (orange), which include *Phys Rev Lett* and *Phys Rev Lett D*, the journals with the largest number of citations in this analysis. Clusters 4 (pink) and 6 (light purple) are now related to earth/space sciences and astronomy/astrophysics, respectively. Cluster 2 (green), the second largest community, encompasses journals related to biomedicine, including *Science* and *Nature*, which are again the journals with the highest degree of centrality in this map.

Considering Indian articles co-authored with other BRICS, the journal co-citation analysis generated a map with eight clusters for the period 2000–2007 (Fig. 19.4). Cluster 1 (violet) contains 15 (23.44%) of the 64 journals included in this map, which are mainly related to physics. Other small clusters are related to theoretical or nuclear physics: clusters 5 (orange), 6 (light purple) and 7 (dark red). These clusters contain the journals with the largest number of citations: *Phys Rev Lett*, *Phys Rev Lett B* and *Phys Rev Lett D*. Cluster 4 (pink) is related to astronomy/astrophysics, while cluster 8 (dark green) contains only one journal in mathematics (*J Math Anal Appl*). Finally, clusters 2 (light green) and 3 (light red) contain *Science* and *Nature*, the two journals with the highest degree of centrality in this analysis. Cluster 2 is strongly associated with the field of medicine, and cluster 3 with earth/space science.

For the period 2008–2015, the map based on journal co-citation analysis shows seven clusters, indicating a compression of thematic communities in India's collaborative papers. Cluster 1 (violet), which relates to physics and chemistry, contains 36 (23.68%) of the 152 journals included in this map. For this period, physics journals are observed in only one other community, cluster 4 (pink), which also contains journals with the largest number of citations: *Phys Rev Lett* and *Phys Rev Lett D*. Cluster 5 (orange) is related to earth and space sciences and contains *Science* and *Nature*, once again the journals with the highest degree of centrality in this analysis. Cluster 6 (light purple) comprises journals in astronomy and astrophysics, while clusters 2 (green) and 3 (light red) include journals in medicine and biomedicine, respectively. Cluster 7 (dark red) contains only one journal, *Ophthalmology*.

Figure 19.5 displays the map based on journal co-citation of Chinese articles co-authored with one or more BRICS partners in each periods. The analysis generates a map with eight clusters for the period 2000–2007. The largest cluster (violet) contains 33 journals (almost 28% of the total) related to biomedicine, with a strong emphasis in microbiology, virology, immunology and infectious diseases. Cluster 2 (light green) is mainly related to physics and chemistry, while clusters 3 (light red), 6 (light purple) and 7 (dark red) are related to nuclear and particle physics and theoretical physics. The journals with the largest number of citations are included in cluster 3 (*Phys Rev Lett* and *Phys Rev Lett B*) and cluster 6 (*Phys Rev D*). Cluster 4 (pink) comprises journals in earth and space science, including *Science* and *Nature*, which are the journals with the highest degree of centrality. Cluster 5 (orange) contains journals related to astronomy and astrophysics. The smallest community, cluster 8 (dark green), contains only one journal, related to veterinary science: *Small Ruminant Res*.

The map for the period 2008–2015 still holds eight clusters, but their profiles have changed substantially. Cluster 1 (violet) contains 72 journals (almost 28% of the total) and is related to physics and chemistry. Cluster 2 (light green) now contains multidisciplinary journals, including the fields of ecology, geophysics, genetics and biomedicine. This cluster also contains *Science* and *Nature*, again the journals with the highest

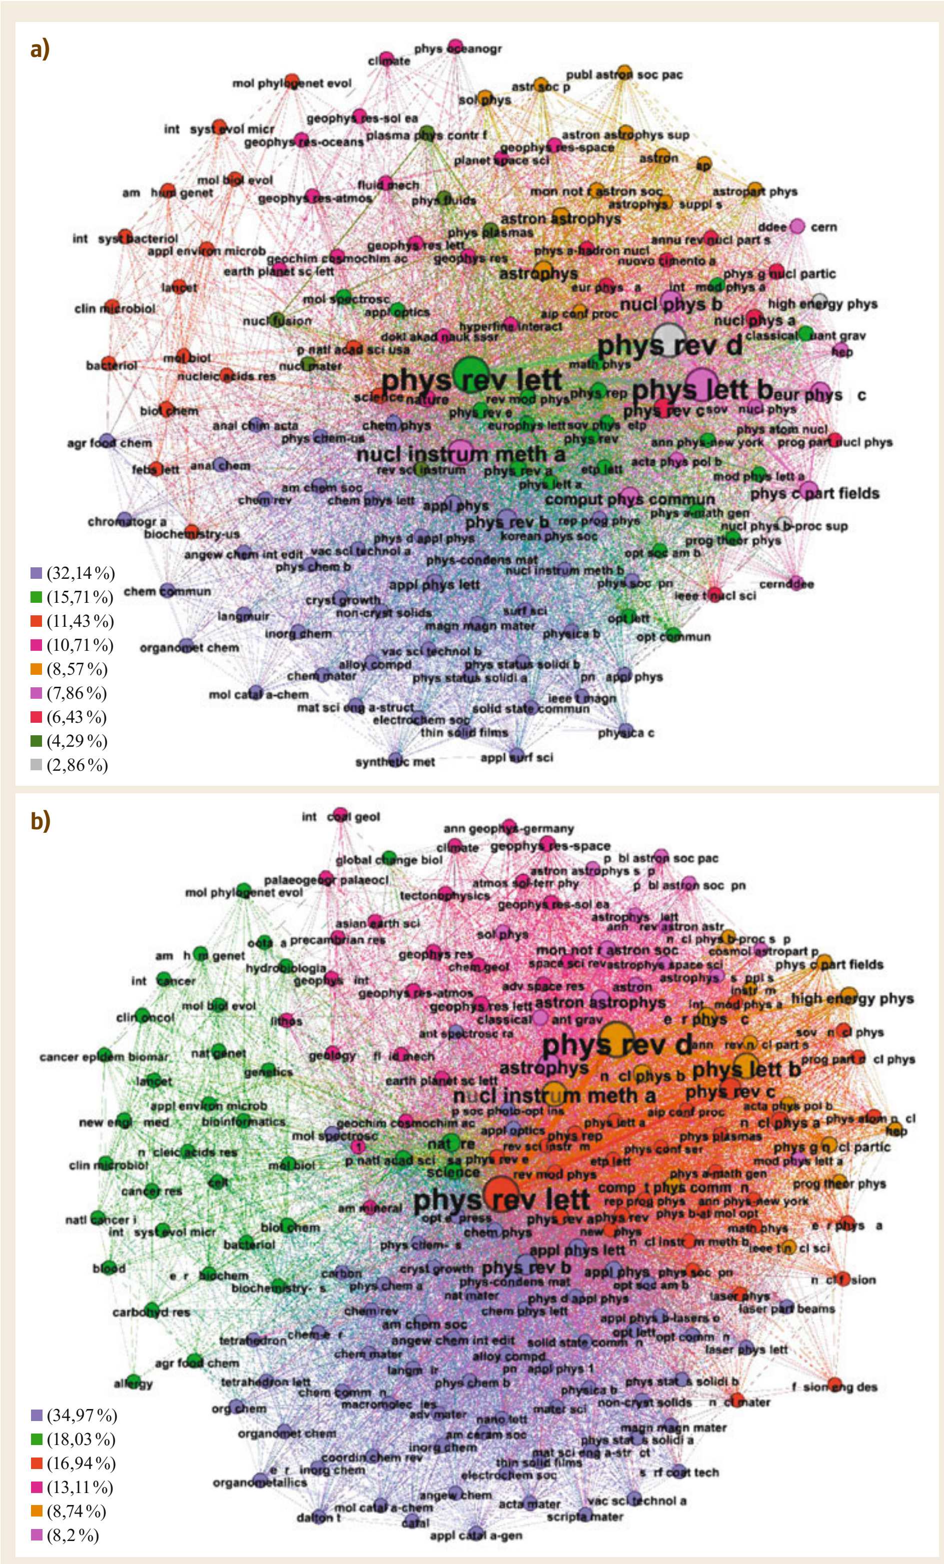

Fig. 19.3a,b Maps of co-cited journals of collaborative articles between Russia and one or more other BRICS countries. Colors indicate different (thematic) clusters, while the size of the symbols represents the weight of the 141 **(a)** and 183 **(b)** journals in the analysis for 2000–2007 and 2008–2015, respectively. Gephi software (version 0.9.1)

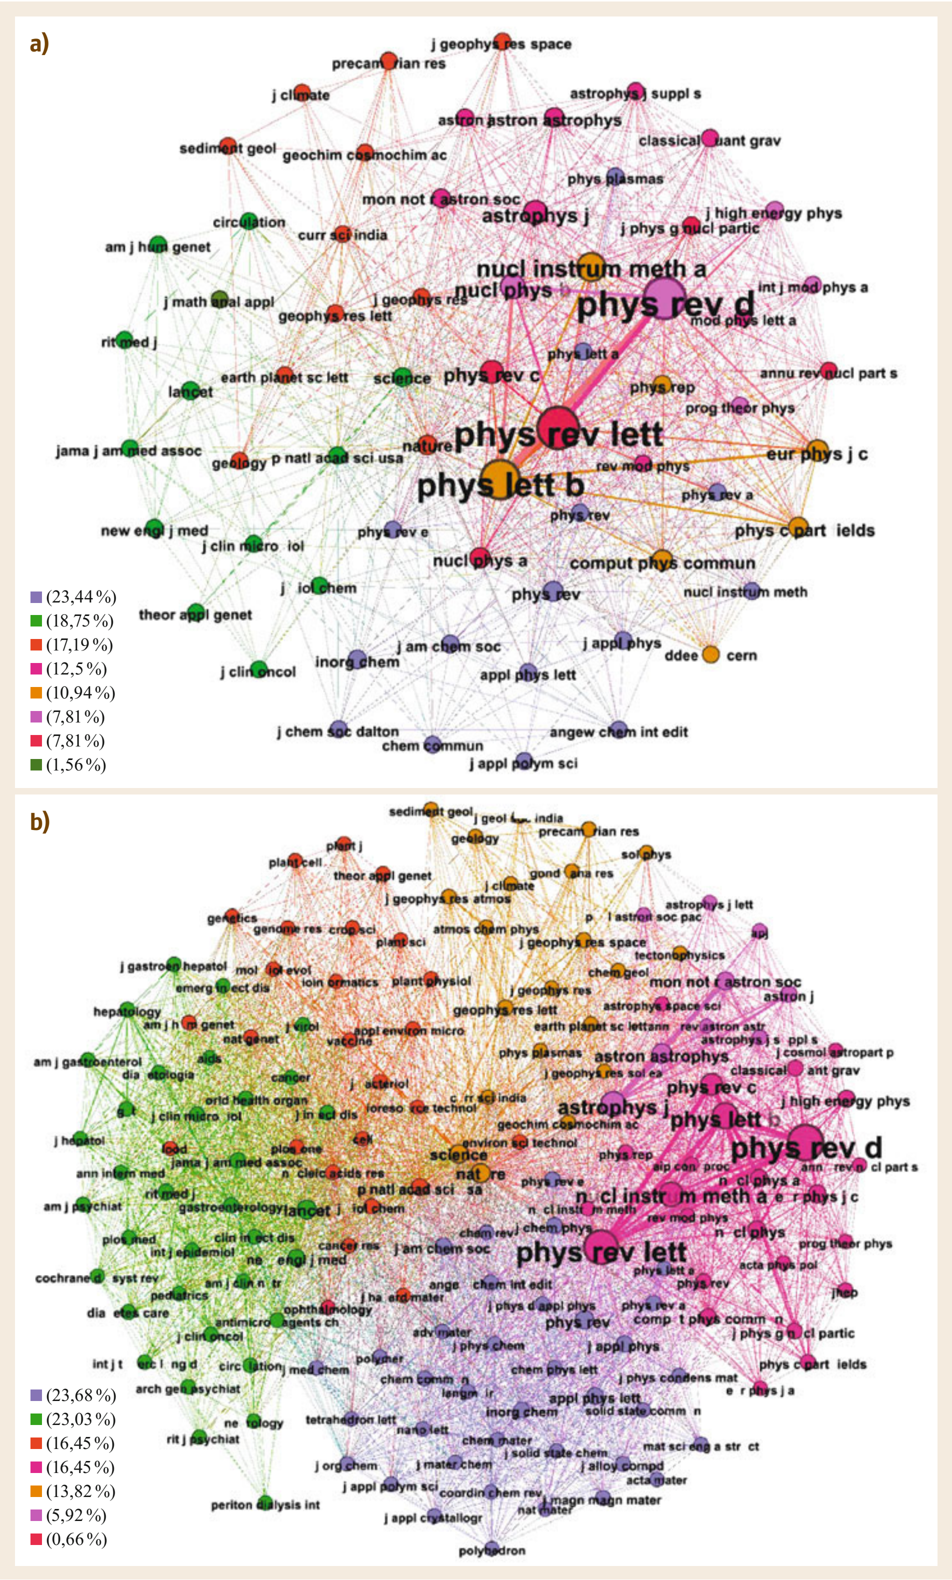

Fig. 19.4a,b Maps of co-cited journals of collaborative articles between India and one or more other BRICS countries. Colors indicate different (thematic) clusters, while the size of the symbols represents the weight of the 64 **(a)** and 152 **(b)** journals in the analysis for 2000–2007 and 2008–2015, respectively. Gephi software (version 0.9.1)

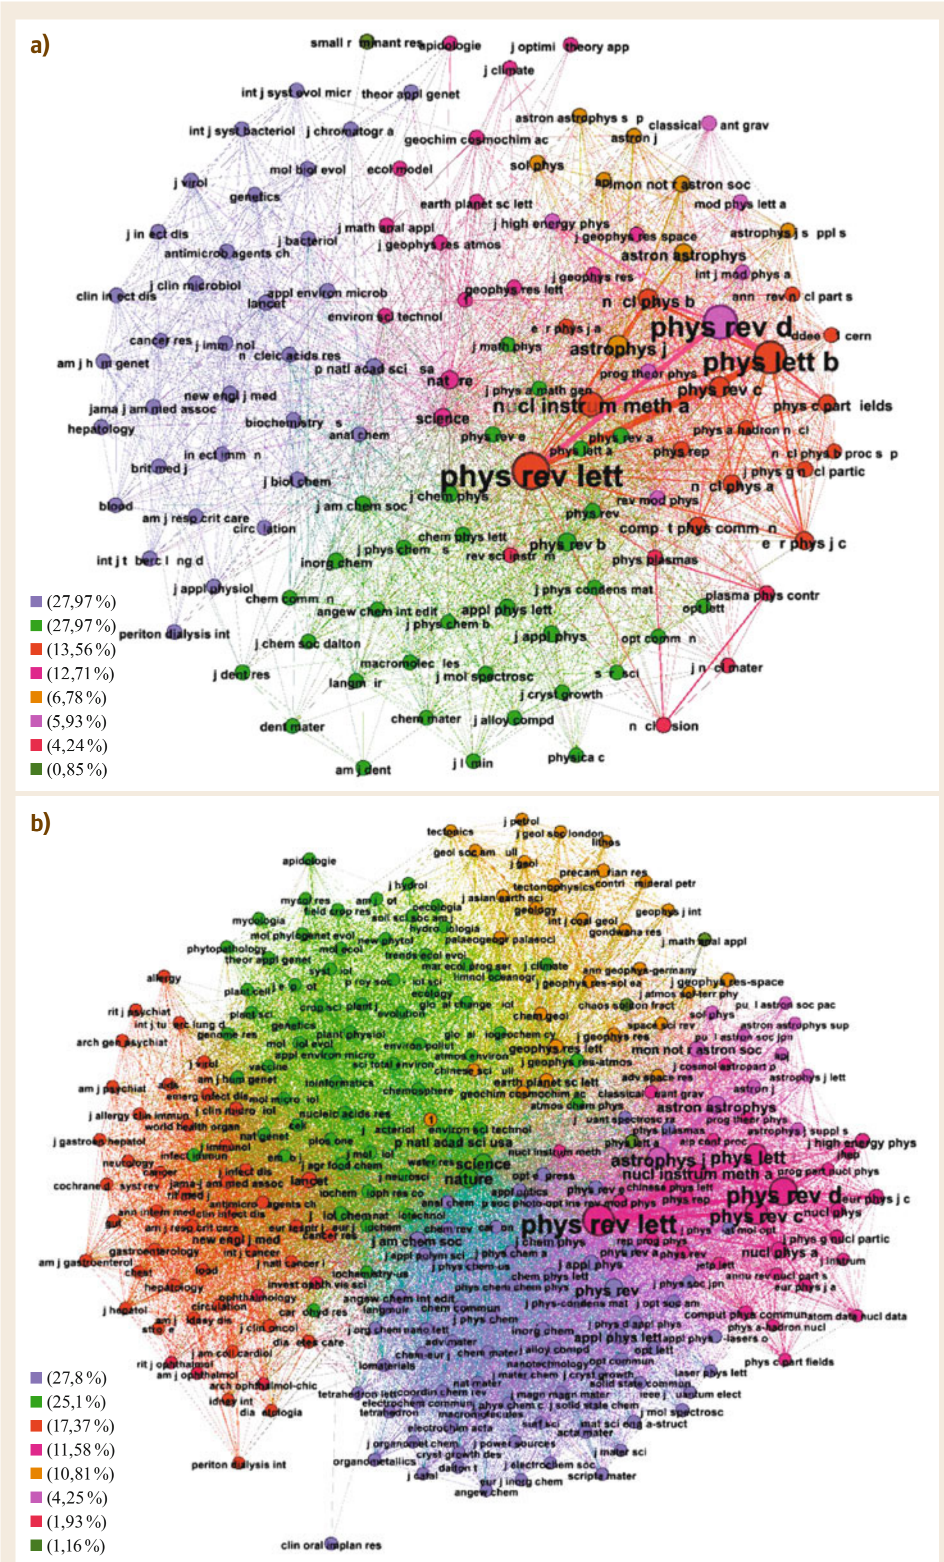

Fig. 19.5a,b Maps of co-cited journals of collaborative articles between China and one or more other BRICS countries. Colors indicate different (thematic) clusters, while the size of the symbols represents the weight of the 118 **(a)** and 259 **(b)** journals in the analysis for 2000–2007 and 2008–2015, respectively. Gephi software (version 0.9.1)

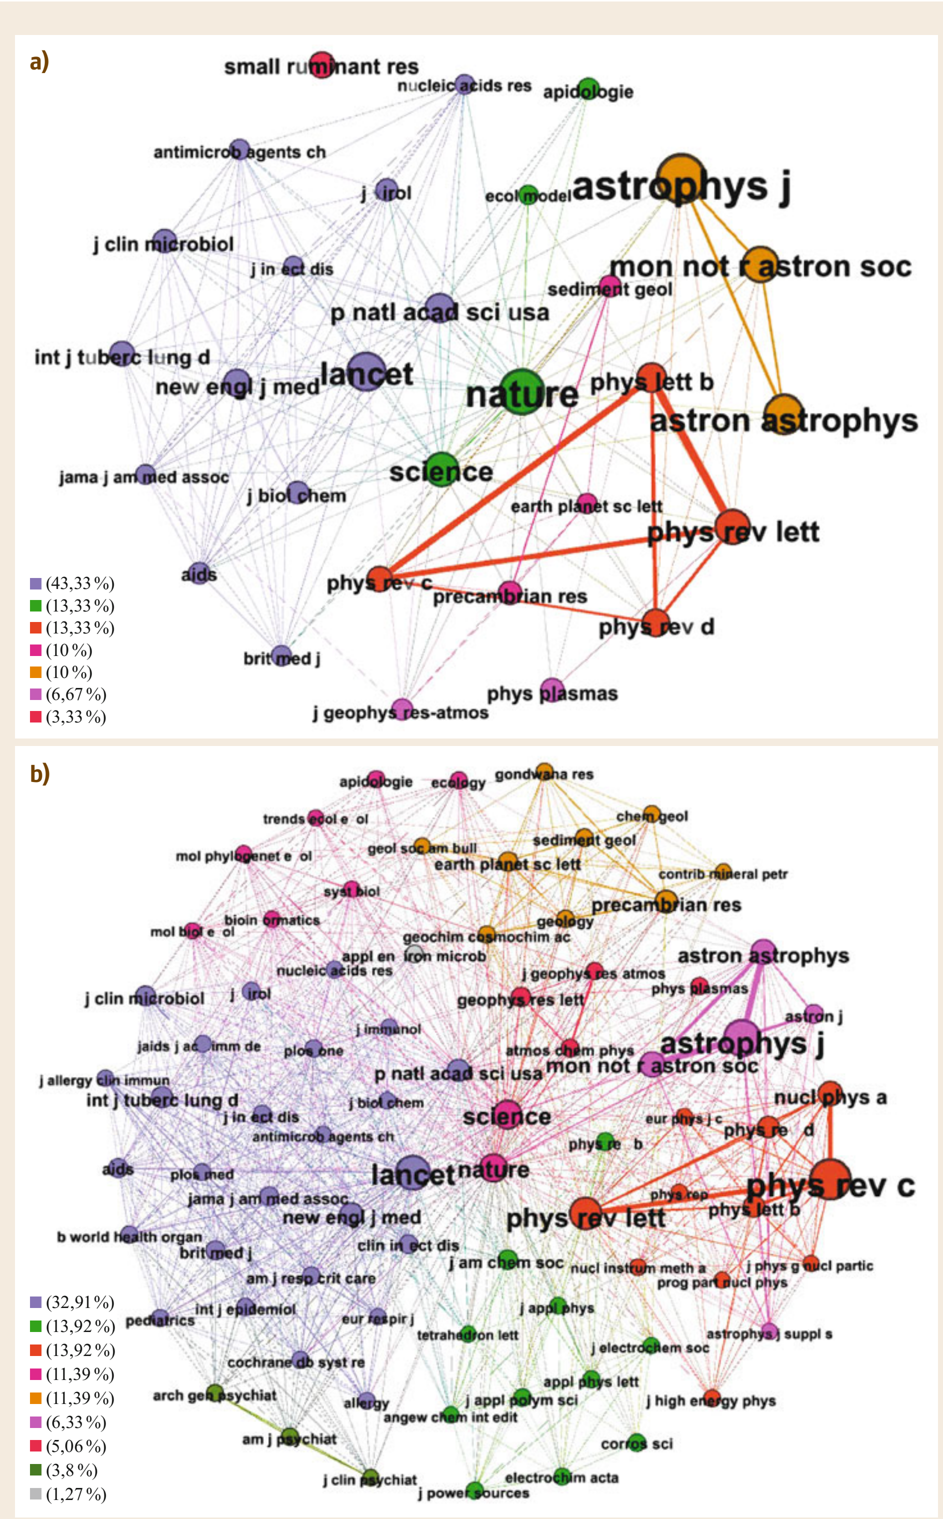

Fig. 19.6a,b Maps of co-cited journals of collaborative articles between South Africa and one or more other BRICS countries. Colors indicate different (thematic) clusters, while the size of the symbols represents the weight of the 30 **(a)** and 79 **(b)** journals in the analysis for 2000–2007 and 2008–2015, respectively. Gephi software (version 0.9.1)

degree of centrality. Clusters 3 (light red) and 7 (dark red) contain journals in clinical medicine and ophthalmology, respectively. Clusters 4 (pink), 6 (light purple) and 8 (dark green) comprise journals in physics (especially nuclear physics), astronomy and astrophysics, and mathematics and physics, respectively. The journals with the largest number of citations are included in cluster 4 (*Phys Rev Lett* and *Phys Rev Lett D*). Finally, cluster 5 (orange) comprises journals in earth and space sciences.

Finally, with regard to South African articles in collaboration with one or more BRICS countries, the analysis of journal co-citation generates a map with seven clusters for the period 2000–2007. As a first and general comment, South Africa's map is not as dense as those for the other BRICS countries, a result of the country's performance in terms of the total number of publications and number of collaborative publications (Tables 19.2 and 19.4). Cluster 1 (violet), the largest cluster, contains 13 journals in biomedicine. Other clusters have four or fewer journals, and thus are too sparse. Cluster 2 (green) contains *Nature* and *Science*, the journals with the highest degree of centrality. Clusters 3 (light red) and 6 (light purple) comprise journals in physics, and cluster 5 (orange) in astronomy and astrophysics. This cluster contains *Astrophys J*, the journal with the largest number of citations in this analysis. Cluster 4 (pink) encompasses journals in earth and space science; cluster 7 (dark red), with only one journal (*Small Ruminant Res*), is devoted to veterinary science.

For the period 2008–2015, the map displays nine clusters. The largest cluster (violet) contains 26 journals, still in the field of clinical medicine, with an emphasis in infectious diseases. Clusters 2 (light green), 3 (light red) and 7 (dark red) now contain journals in physics and chemistry, physics (mainly nuclear physics) and geophysics, respectively. Cluster 4 (pink) comprises journals in ecology and evolution, which are strongly linked to *Nature* and *Science*, those with the highest degree of centrality. Cluster 5 (orange) contains journals in earth sciences only, while cluster 6 (light purple) comprises journals in astronomy and astrophysics. Two small clusters, 8 (dark green) and 9 (gray), include three journals in psychiatry and one journal in applied microbiology, respectively. Unlike the maps for the other BRICS, here the journal with the largest number of citations includes not only those in physics, *Phys Rev C* and *Phys Rev Lett*, but also in astronomy and astrophysics (*Astrophys J*) and biomedicine (*Lancet*).

Table 19.7 summarizes various features found in the map analysis. The number of clusters per country varies from six to nine. Regarding changes in the number of clusters from one period to another, Brazil, China and South Africa show an increase, and Russia and India a reduction, indicating that as a whole, the thematic structure of BRICS collaborative papers did not increase after the group's formalization. Importantly, journals in the field of physics constitute those with the largest number of citations in both periods and across all countries. Also, *Nature* and *Science*, two prestigious multidisciplinary journals, appear with the highest degree of centrality in all countries for both periods. Although the main area of the largest cluster varied for some BRICS, the set of data presented in Table 19.7 indicates that there has been no relevant change at all.

Table 19.7 Map characteristics based on journal co-citation analysis of BRICS collaborative articles

Country	Clusters (n)	Centrality degree (mean)	Co-cited journals (n)	Largest cluster (area)	Journals with LNC[a]	Journals with HCD[b]
2000–2007						
Brazil	7	67	70	Biomedicine	*Phys Rev Lett*	*Nature*
Russia	9	139	140	Physics and chemistry	*Phys Rev Lett*	*Science*
India	8	63	64	Physics	*Phys Rev D*	*Nature*
China	8	111	118	Biomedicine	*Phys Rev Lett*	*Nature*
South Africa	7	28	30	Biomedicine	*Astrophys J*	*Nature*
2008–2015

19.4 Discussion and Final Remarks

The present study investigated BRICS collaborative articles in order to map thematic trends before and after the formal establishment of the group in 2008. The primary purpose was to investigate whether the main themes in BRICS publications covered the priority areas identified in the Cape Town declaration. To this end, three main analyses were carried out: diachronic analysis of total publications, Bradford analysis and journal co-citation analysis of collaborative publications.

The results of the diachronic analysis indicated that, with the exception of Russia, the BRICS are also power countries in science, exhibiting a high annual increase in publication rates (Table 19.1). Such growth may be explained, at least in part, by their adherence to publishing in open-access journals (Table 19.2), which seems to boost the rate of BRICS publications. *Bouabid* et al. [19.39] also observed a strong growth rate for BRICS' scientific publications when analyzing their performance in 1995–1997 and 2010–2012, where the authors found that BRICS's growth surpassed that of the G7 countries.

With regard to the areas of research, this first set of analyses revealed that BRICS publications as a whole were largely oriented towards physics, chemistry and engineering (Table 19.3). *Yang* et al. [19.26] presented similar findings in an analysis of BRICS' disciplinary structure based on publications in 1991, 2000, 2009. *Kumar* and *Asheulova* [19.40] also found contributions in physics to be the most prolific among the emerging fields in Brazil, China and India. *Aksnes* et al. [19.41], who investigated the relative specialization index (RSI) over time, found that China's RSI performance differed from the global average, including some of BRICS members; the authors highlight that Chinese research is heavily concentrated in engineering and physical sciences. *Bouabid* et al. [19.39] found higher growth rates in total BRICS scientific publications not only in engineering and technology, but also in medical sciences, for two distinct periods, 1995–1997 and 2010–2012.

The analysis of BRICS' collaborative publications revealed two relevant features: collaboration varied widely among countries, and physics appeared as a central field in most of the BRICS countries.

The Bradford analysis based on BRICS' collaborative articles indicated a strong and major presence of physics journals among the set of core journals (Tables 19.5 and 19.6), corroborating results observed for total BRICS publications. However, a few journals, mainly related to medicine, were also included in the core journals, a finding that was not observed in the previous period.

The maps based on journal co-citation analysis confirmed the central role of physics in BRICS' collaborative publications. The maps indicated that BRICS scientific structures gained in density but not in diversity, revealing no relevant changes for the group as a whole since its formal establishment.

Comparing the two periods, the maps showed specific features by country (Figs. 19.2–19.6). The Brazilian maps indicated an important shift in the main theme from physics to medicine, including oral health and psychiatry. The Russian map showed a reduction in the number of clusters over the period 2008–2015, which was accompanied by an increase in the weight of physics. The Indian map showed a similar reduction in clusters, but physics was reduced as well. As for the Chinese, the maps revealed an increase in physics as well as the flourishing of new clusters related to medicine and multidisciplinary fields. Finally, South Africa exhibited an increase in thematic clusters, but the primary emphasis remained in biomedicine.

Journals in the field of physics exhibited the largest number of citations in both periods and for all BRICS countries. Physics also appeared as the main field in most of the clusters, as well as representing the largest cluster for three countries in the period 2008–2015 (Table 19.7). It is important to highlight that the group also demonstrated a steady potential for cooperation in other fields, especially in astronomy/astrophysics and earth-/space sciences, which was found in all BRICS' maps in the period 2008–2015. These findings indicate that BRICS' collaborative articles do have the intellectual underpinnings needed for cooperative efforts in energy, nanotechnology, space research and exploration, aeronautics, earth observation, geospatial technologies and climate change, which are considered priority areas in the Cape Town declaration.

Although an extensive share of the BRICS collaborative structure is in the field of physics, one may reasonably assume that such a strong level of cooperation probably involves other countries, and is not solely a reflection of internal BRICS collaboration. In fact, as observed in Tables 19.5–19.7, BRICS members collaborate in some fields of physics, such as particle physics and astronomy, which are well known from having large research teams from multiple institutions sharing high-tech facilities.

The constant presence of *Science* and *Nature* as the journals with the highest degree of centrality revealed some specificity for each country. During the period 2008–2015, these two most highly connected journals appeared together in various thematic clusters: earth and space sciences (Indian map, cluster 5), biomedicine

(Russian map, cluster 2), and ecology and evolution (South African map, cluster 4). These periodicals were also found in multidisciplinary clusters, which included a miscellany of journals, and represented the largest communities in the Brazilian (cluster 1) and Chinese maps (cluster 2). The fact that *Science* and *Nature* were connected and giving support to journals in different fields suggests an internal diversity among BRICS competencies, which is fundamental to driving cooperative efforts among the group.

Looking closely at internal diversity during the period 2008–2015, Russia's scientific structure exhibited a robust emphasis in biomedicine, while Brazil, India, China and South Africa were strong in clinical medicine. Hence, BRICS' collaborative articles displayed the intellectual foundation needed to develop research in medicine, biomedicine and life sciences, also included in the Cape Town declaration as priority areas. These findings are in accordance with the study by *Bai* et al. [19.22], which found that BRICS members were among the ten countries with the largest share of articles on neglected diseases.

The map analysis did not allow the identification of groups of journals related to some of the priority areas listed in the Cape Town declaration, including food security, sustainable agriculture, computing, water resources, information and communication technology, and science popularization. Nevertheless, the lack of identification cannot be seen as a complete absence of these issues in BRICS' collaborative articles. Certain factors must be considered in this picture, including methodological limitations. One such limitation involves the journal coverage in the international data source used for collecting BRICS' scientific publications, including collaborative articles. When compared with Ulrich's extensive periodical directory (around 63 000 journals), *Mongeon* and *Paul-Hus* [19.42] found that the journals covered by WoS represented 33, 28 and around 15% of journals in natural sciences and engineering, biomedical research and social sciences, and arts and humanities, respectively. The authors also found a strong overrepresentation of English-language journals. These findings confirm that WoS is not a comprehensive data source, especially for peripheral countries in science, such as most of the BRICS. Hence, a considerable number of BRICS scientific publications in national journals, mostly in local languages and in fields where research is more oriented towards local issues, were not included in the analysis. If such invisible literature were included, it could paint a different picture of BRICS' scientific performance, both generally and in terms of collaborative contributions.

Another methodological limitation is related to the analysis period. The groundwork is still being laid for the economic and political alliance between the BRICS countries. BRICS was formally established only in 2008, which may be a short period in which to observe strong interactions in science, especially if they are measured by a single variable such as scientific articles.

Despite these limitations, however, this chapter reveals interesting aspects of BRICS collaboration in science based on co-authored articles. Although no significant change in collaboration has occurred since the formalization of the group, the analysis suggests that the BRICS countries are working to enhance their cooperation in their main scientific competencies.

As collaboration in science is a complex phenomenon, effectively focusing on priority areas as the basis for enhancing BRICS' cooperation in S and T will demand a large effort among the whole group, including the establishment of common policies and initiatives to effect greater collaboration on the part of institutions and scientists among different fields within the BRICS. One remarkable initiative towards this end was the establishment in 2013 of the BRICS Think Tanks Council, with the aim of enhancing cooperative research. Council members include the Institute for Applied Economic Research (Brazil), National Committee on BRICS Research (Russia), the Observer Research Foundation (India), the China Center for Contemporary World Studies (China) and the Human Sciences Research Council (South Africa).

Policies aimed at changing the culture around mobility, a non-technical factor that promotes cooperation among countries, is as important as those mentioned above. A recent report on international student mobility shows that students from Brazil, Russia, India and China are highly attracted to OECD universities for study abroad, with 89% of Brazilian, 65% of Russian, 90% of Indian and 85% of Chinese students enrolled in an OECD university [19.43]. Such preference for mainstream countries has implications for future research ties among scientists, and represents an obstacle to enhancing and strengthening BRICS cooperation in science. Hence, the BRICS countries must develop strategies to promote a change in the culture of overvaluing cooperation with partners such as the USA, Canada, Japan and Western Europe. Otherwise, a true, effective partnership within the scientific community among BRICS countries may represent a mere utopia.

Roberto Lovón is currently a Postdoctoral Fellow at the Graduate Program in Information Science at the Federal University of Rio the Janeiro (UFRJ), in association with the Brazilian Institute of Information in Science and Technology (IBICT). He received a PhD in Information Science from UFRJ-IBICT in 2015. Roberto holds a Masters in Production Engineering, with a focus on science and technology policies, and a Bachelor in Economics.

20. The Relevance of National Journals from a Chinese Perspective

Zheng Ma

The process of of journal evaluation began in the 1930s when the famous British scholar S.C. Bradford published his study of geophysics and lubrication, which presented the empirical law now known as Bradford's law of scattering, as well as the concept of core area journals. The citation indicator system and citation analysis theory system were founded in the middle of the twentieth century, and now have extensive influence. In the 1960s, Garfield carried out a large-scale statistical analysis of citations in journal literature. Generally speaking, the journal evaluation system has been gradually improved over time, producing an evaluation result that meets the development needs of science and technology. As one of the countries producing important science and technology outputs, China has ranked second according to the statistics of the number of scientific articles in recent years. At the same time, China has over 5000 scholarly journals, however, only 4% of them have been indexed in Web of Science and 10% of them in Scopus. A similar situation is found in Russia, Japan, Korea, and other non-English-speaking countries. Therefore, China has a lot of research and practice in the field of journal evaluation with which to explore more applicable and effective ways of assessing and improving national academic journal development. We will review the development situation of scientific, technical and medical (STM) journals in China to understand the demand for a national journal evaluation system. According to the comparative study on international and national evaluation systems and indicators of academic journals in China, we can find the characteristics of national journal evaluation under a framework of their respective evaluation purposes, evaluation methods, key features, and evaluation criteria. We introduce two cases of China's STM journal research and evaluation work: the development of the boom index and its monitoring function, and the definition and application of comprehensive performance scores (CPSs) for Chinese scientific and technical journals. English-language science and technology journals in China are more similar to international journals but are developing along a particular path. Therefore we also introduce three other cases: statistics and analysis of English-language science and technology journals in China, the communication value of Chinese-published English-language academic journals according to citation analysis, and the atomic structure model for evaluating English-language scientific journals published in non-English countries.

Part C | 20

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_20

Scientific and technological research activities in the field of natural science and scholarly communication and publication activities all show significant trends of globalization. The driver of this development comes from two sources. The first is the academic language, English, which plays an increasingly important role. Although Yuasa's idea on the shift of the global science center seems to predict that the world's science research center will leave the United States sometime in the future, the international research community seems to rely more and more on English as the sole de facto language of communication. Second, following large-scale trends, the massive volume of output from academic publishing continues to increase. Furthermore, mergers between science and technology publishing enterprises have become the norm. In this context, the *national belonging* of academic journals is itself a controversial and widely discussed topic.

In English-speaking countries, most academic journals are published in English. These English-language journals constitute the world's most extensive academic peer services, and generally they cannot be strictly defined as national or international journals. At the same time, the publishing of non-English-language journals seems to be walking in the shadow of English-language journals. Of the former, especially those from non-English-speaking developing countries, very few journals are included in international indicator systems. These journals can be viewed as *typical* of national academic journals.

In view of globalization trends, national academic journals could claim their value from four aspects. The first is at the academic resource level. In some research fields, including those with unique geographical and geological characteristics, such as traditional medicine among others, national academic journals tend to cover the most important academic research faster and more comprehensively and systematically. Second, at the methodology level, national journals might have unique and rational arrangements in terms of information organization and information architecture. For example, international journals usually provide research funding information in an acknowledgment section at the end the article. Most Chinese journals include funding information as a standalone annotation in the manuscript. Thus, the article funding ratio is a key indicator of a journal's quality. Inspired by this concept, the Science Citation Index (SCI) and other international search systems are beginning to include additional funding annotations. Third, regarding the efficiency of scholarly communication and behavior analysis, a huge number of national journals are an integral part of a country's scientific and technical output. China has over 5000 scholarly journals published in Chinese, 20 times that of English-language journals. A similar situation is found in Russia, Japan, Korea, and other non-English-speaking countries. Scientists, at the beginning of their careers, often publish important papers in national journals, which can be seen and confirmed by looking at the profiles of a number of Nobel Prize winners from China and Japan. Finally, in many countries governments provide substantial support for research and development activities, and therefore many achievements result from government-funded research and development. Thus, national researchers need to utilize this support as much as possible. Papers published in national journals are undoubtedly a rapid and effective way to achieve this. Furthermore, the readers and authors of national journals understand each other's scientific and social background, enabling the public supervision of academic ethics.

20.1 Journal Evaluation

20.1.1 The Origins of Journal Evaluation

Research on journal evaluation originates from philology [20.1]. Regarding the emergence of journal evaluation, scholars such as *Qian Ronggui*, *Qiu Junping*, and *Lai Maosheng* [20.2–4] noted that Western journal evaluation began in the 1930s. In 1934, the famous British scholar S.C. Bradford (b. 1878), in the study of geophysics and lubrication, presented the empirical law now known as Bradford's law of scattering. His research shows that

> if scientific journals in the size of the number of papers published in a certain subject, to reduce the order, then can be divided into a special subject for the core area of the discipline and the core of the same number of papers in several areas. At this time, the core area and successive districts of the number of journals into A1 A2 .... [20.5]

Based on this distribution, Bradford proposed the concept of *core area* journals, that is, many articles on a subject are published in the core area. The theory of foreign journal evaluation originates from this law.

Eugene Garfield was a famous American linguist. He helped to establish the Institute for Scientific Information and was one of the founders of scientometrics. The citation indicator system and citation analysis theory system were founded in the middle of the twentieth century, and have had extensive influence [20.6]. In the 1960s, *Garfield* carried out a large-scale statistical analysis of citations in journal literature, with the conclusion that many citations were concentrated in just a few journals and that a small number of citations were disseminated in many journals [20.7]. Subsequently, Garfield created the Institute for Scientific Information (ISI), and successively published the SCI, Social Science Citation Index (SSCI) and the Art and Humanities Citation Index databases.

Following the development of Western journal evaluation, efforts in journal evaluation are now emerging in China. In 1964, a number of Chinese scholars began to translate and use the SCI [20.8]. Gaining the attention of scholars, the theory of bibliometrics was soon introduced and disseminated in the 1970s. In the early 1980s, Chinese scholars translated and introduced several bibliometric laws. This included Bradford's law (1934) and Garfield's Law of Concentration (1955). These were followed by the literature aging index and citation peak theory in 1971 [20.2, 9]. These three laws are considered to be the theoretical basis for the quantitative evaluation of journals.

China's journal evaluation system was gradually established beginning with the introduction of foreign journal evaluation theory. In 1987, the Institute of Scientific and Technical Information of China (ISTIC) (commissioned by the Ministry of Science and Technology—formerly the National Scientific and Technological Commission) began to analyze the number of citations of Chinese scientific and technical researchers at home and abroad, and used statistical data to establish the Chinese Scientific and Technical Papers and Citations Database (CSTPCD) [20.10].

Based on research in the literature, this paper reviews the development of journal evaluation, the evolution of Chinese journal evaluation indexes from single indexes to composite indexes, and the change from object-oriented journal evaluation. The theory of journal evaluation has been developed over time, as has the establishment and development of various evaluation systems.

20.1.2 Development Trends Within the Evaluation System

An evaluation index typically involves two key methods of journal evaluation—a direct comparison according to the index of journal literature, and the evaluation of a composite evaluation index. The determination of core journals is ascertained from the initial single-index method to the production of a comprehensive composite index method. Furthermore, the journal evaluation system is gradually improved over time, producing an evaluation result that meets the development needs of science and technology.

When journal evaluation first began, a single index was used to determine core journals. With the development of evaluation work and the appearance of the composite index, evaluation work has become more scientific and reliable. According to the deviation of the function of each single index, the index can be divided into different categories such as evaluating the quality of journal papers or evaluating the performance of the journals [20.11].

The most common indicator for evaluating the quality of journal papers is Garfield's impact factor. Other indicators based on citation analysis include a journal's total citations, the rate of citation in other journals, and the percentage of deviations (as used by SCI and China's Citation Report for Chinese STM Journals) [20.12]. They also include the method of citation analysis of core journals proposed by *Garfield* [20.13], and the statistical method of the evaluation of core journals by means of important documents or indexes containing the number of journal papers [20.14]. In the evaluation of the volume of journals, this chapter proposes a method to determine Bradford's law of core journals. In general, these methods are used to measure the influence of academic journals as an alternative to the academic quality of academic journals. These methods include the annual index, the range of citations, citation rate, whether the full text of the article is reproduced in the journal, and the download rate. The index of the academic content in evaluating the ability of published journals includes the regional distribution of authors, the ratio of funded papers, and the number of citations [20.15].

Using a composite index to evaluate STM journals avoids narrow perspectives and the limitations of single-index evaluation. Furthermore, a composite index can comprehensively and objectively reflect the quality level of journals and is more suitable for the full evaluation of journals. Thus, this method has been widely used. Based on the principle of structural equations, an analytic framework of journal influence was devised by *Yue* and *Wilson* [20.16]. Previous studies state that the evaluation of Chinese humanities and social sciences journals is typically achieved using the indicator system [20.17]. Furthermore, a three-dimensional hierarchical structure of the journal evaluation indicator system was proposed, and the grey relational method was used to evaluate that system [20.18]. Others have used an analytic hierarchy process (AHP) to evaluate journals [20.19]. In addition, some scholars combine two or more evaluation methods. For example, the composite method is used to evaluate weights according to the AHP, and the weighted technique for order of preference by similarity to ideal solution (TOPSIS) method is one such evaluation method. Although the composite evaluation method has only one evaluation result, it can still be regarded as a multiple index comprehensive evaluation method in essence. The multi-index comprehensive evaluation of academic journals is a complicated system that involves many aspects including evaluation principle, index selection, data standardization, and evaluation method selection. Data standardization is used as a basic method of statistics. It should be no surprise that there have been few in-depth studies on the matter. It is necessary to point out that different methods of data standardization have had a considerable influence on evaluation results, and this chapter proposes a new standardization method of reverse index data based on the features of several common data standardization methods. A number of methods have been developed: *Luo Shisheng* prosed the comprehensive appraisal method [20.20], Suk the weighted synthesis method and the fuzzy linear weighted transformation method, and *Qin Lifu* looked at journal cost [20.21]. This chapter puts forward an appropriate selection method for core journals. Furthermore, Ma Wei devised the fuzzy comprehensive determination method, which looks at journal information density, intelligence reliability, and intelligence reporting speed. Lastly, *Wang Genbin* prosed the principal component analysis method from a mathematical perspective [20.22].

Composite indexes have been applied in the current evaluation system, and the citation reports of Chinese STM journals published by the China Institute of Science and Technology Information have been adopted as comprehensive evaluation scores. That is, the comprehensive evaluation indicator system used for Chinese STM journals includes the following features: it calculates many scientific measurement indexes, uses AHP to determine key index weights, evaluates each journal, and calculates the total score of each journal. This current evaluation method is very effective.

China's current journal evaluation system includes the following indexes: ISTIC's *Statistical Source of Chinese Science and Technology Journal* (also known as *China's Science and Technology Core Journals*), which publishes the Chinese STM Citation Report (CJCR); the Chinese Science Citation Database (CSCD), a source journal list issued by Chinese Academy of Sciences (CAS); Peking University Library's *A Guide to the Core Journals of China*; Chinese Social Sciences Citation Index (CSSCI) from China Social Sciences Research Center of Nanjing University, which covering the core *Journals of China's Humanities and Social Sciences* [20.23].

Bradford's aim was to distribute research, and this could be achieved via core journals. Journal readers can find references in journal articles and this will help the reader to meet their own needs more efficiently. Advances in science and technology and the rapid growth of scientific research have meant a change in the evaluation of journals. Initially, such evaluations were reader-oriented, and later there was a greater focus on libraries and other organizations. Because of a shortage of library funding in China, foreign core journals were translated into Chinese and introduced to China to ensure a better use of available subsidies [20.24]. In 1992, Peking University Library created its first publication outlining China's core journals; it was intended for use by the staff of Peking University Library. The aim was also to reduce costs in establishing a wide choice of journals [20.25].

The standardization of the journal evaluation system seeks to reduce the gap between journals and core journals. Such efforts are made to aid the future development and quality of journals, and for guidance purposes. Authors can also better understand the requirements of different journals, so as to help them contribute to and improve the quality of their paper.

In addition, the publication and management of journals is also an important object of journal evaluation, and the evaluation of core journals is bound to have an important influence on the editorial direction of journal publications. To maintain the continuous development of academic journals, journal management staff carry out effective research on journal evaluation as well as supervision.

Through core journals, we can quickly understand the dynamics and development of each subject or field. The journal evaluation system is regarded as a reference foundation, enabling libraries to optimize their collections. Librarians offer reading-list guidance and provide reference services, and the journal evaluation system can be used in such a manner. The system can also provide reference for the evaluation of academic achievements. Furthermore, it can provide reference for authors who wish to submit contributions and for government departments to manage journals. Core journals also promote the study of bibliometrics to provide information for journal development and competition, and to promote the development of journals and improve their quality. Therefore, core journals are not only important for the end users but also for the development of journals and their quality.

Indexes of core journals provide empirical evaluation measures, such as access law, expert investigation methods, and the reader survey method. With the development of bibliometrics, more and more methods based on mathematics and statistics are being applied to the evaluation of core journals, gradually enriching evaluation methods. Three main laws, Bradford's law, Lotka's Law, and Zipf's law, provide the theoretical basis for evaluation. They use bibliometrics to measure core journals according to certain basic steps [20.26]. Citation analysis is the most commonly used evaluation measure of academic journal quality. The corresponding quantitative evaluation indexes are as follows: impact factor, citation frequency, reaction rate, average citation rate, journal citation rate, and journal citation half-life. The most intuitive evaluation index is the journal impact factor, which is synthesized by the statistical analysis of citations and the citation phenomenon.

Bradford's law is the theoretical basis of the core journals. Garfield and others looked at citation frequency to evaluate science and technology journals. The advent of this method in academia marked a milestone in the evaluation of the journal. However, there are some limitations in using the total citation frequency to evaluate a journal. Garfield revised his own research and proposed the impact factor index to evaluate journals. The impact factor is more reliable than the total number of citations, as it eliminates the influence of many uncertain factors. The impact factor has become a universal journal evaluation index, and the main measurement index to evaluate the academic influence of journals.

Total Citations: The total number of papers published by a journal since its inception and published in the year in which it was cited. The total citation frequency is a very objective and practical evaluation index, and can be used to measure the academic influence of journals. It can also be used to objectively explain the degree of use and attention of journals, and the position and function of journals in academic exchange. It does face the problem, however, where the impact factor will be low if there is an excessive volume of journals. The higher the frequency of citations, then the higher the value of the journal's utilization and academic level [20.27]. However, citation frequency is also subject to the publication of the journal, the number of papers published, and whether the publication is a professional journal or a comprehensive one [20.28].

Impact Factor: The number of citations received in that year by articles published in that journal during the two preceding years, divided by the total number of articles published in that journal during the two preceding years [20.29]. It reflects the overall academic level of the journal, generally in the same subject area: the larger the impact factor, the greater the impact of the journal [20.30].

Three basic factors are important when calculating an impact factor: the number of papers, time, and the number of citations. Furthermore, the peak period of a paper is dependent on the period of time. A scientific paper's peak citation period is claimed to be two years after publication, according to scientific metrology, so the current international practice is to set a period of two years.

Reverse Indicators: The index of reverse evaluation in journal evaluation concerns articles that received zero citations. This can be traced back to the 1960s, when Price, one of the fathers of scientific metrology, first looked at basic statistics regarding papers that received zero citations published in *Science*. He found that approximately 35% of the papers in any statistical time window had not received any citations [20.31]. Regarding zero citations, Chinese scholar Wu Yishan has proposed that we not forget the *Sleeping Beauty* phenomenon. A lack of citations may not necessarily mean poor quality research results, and zero citations may represent an excellent result from another perspective [20.32].

20.2 Development of STM Journals in China and Demand for Evaluation

20.2.1 The Status of STM Journals in China

In recent years, the number of published journals and the number of STM journals has remained stable. According to statistics from a *National Press and Publication Situation* report, China published 9867 journals in 2012, of which about half were natural science, with technical journals accounting for 4953. Since 2007, the annual growth rate of total journals and STM journals in China has been less than 1%.

The ISTIC has selected about 2000 high-quality and influential academic and technical journals as Chinese STM core journals. The institute uses quantitative indices to monitor the development level and trends of Chinese STM journals, and publishes the annual CHCR. China's core journals in science and technology published close to 500 000 papers in 2014, with an average of 260 papers published per journal each year.

Regarding journal evaluation, total citation frequency and impact factor are the indicators typically used to measure the absolute influence and relative influence level of journals. In 2012, the average citation frequency of Chinese STM journals reached 1023 citations per issue, 4.5 times that of the 2001 rate, and the average impact factor was 0.493, 1.7 times that of 2001. The article funding ratio index refers to the proportion of the results of provincial- and ministerial-funded projects published in a journal. This index reflects the ability of the journal to attract high-level research papers. The average value of the article funding ratio in China's journals was 52% in 2012, which means that more than half of the papers in the core journals were the research results of various nationally funded projects. The 2001 value of the fund thesis was 34%. The significant growth of the above indicators shows that China's STM journals play a significant role in the dissemination of knowledge and academic exchange.

The publishing cycle of China's STM journals has been gradually reduced. In 2007, the monthly ratio of China's STM core journals was 28.73%, rising to 35.79% in 2011. There was also a considerable shift from bimonthly publications to monthly, with a quarterly total of 13.22% in 2008 compared to 10.66% in 2011. The data show that China's STM journals are increasing in publication speed, reducing the journal publishing cycle and improving the timeliness of knowledge dissemination. At the same time, the total number of papers in Chinese STM core journals remains at around 500 000 a year.

Although the number of STM papers published in China ranks second in the world, the academic quality and influence of STM journals remains low. The SCI database is the world's most widely used science and technology literature retrieval system. Impact factors and other classical indicators are used to choose more than 8600 high-level scientific and technological journals worldwide (mainly English-language journals). According to the ranking of impact factors in corresponding disciplines, SCI journals are divided into four main categories: the impact factors determine whether a journal is classified as Q1, which indicates that the journal is a leading publication in that particular discipline, followed by Q2, Q3, and Q4. In 2015, 152 Chinese journals were covered in SCI, accounting for less than 2% of all journals published in China. Twenty journals were considered to be at the fore of their particular subject area, and were thus classified as Q1 journals, representing just 8% of Chinese STM journals. A total of 40 journals were classified as Q2, just 15% of all Chinese journals.

The world's largest scientific and technological publishing organization, the Elsevier Scopus database, is an important multilingual document retrieval database. It uses SCImago Journal Rank (SJR) and other indicators to assess and collect more than 12 000 major global scientific and technical journals. The SJR index also ranks journals from Q1–Q4: a journal considered a Q1 journal in the subject category ranking indicates that the journal is a leading journal in that particular subject area, followed by Q2, Q3 and Q4 journals. According to Scopus data, there are 554 journals from various areas in China, representing less than 5% of all Scopus journals. It is very difficult for Chinese journals to achieve a Q1 ranking, with just 27 journals considered Q1 journals, accounting for 5% of China's Scopus journals, with 152 (27%) ranked as Q2 journals. Thus, the majority of journals do not achieve such positive rankings.

20.2.2 The Main Evaluation Methods of National Science and Technology Organizations

China's Ministry of Science and Technology

Our government ministries have always attached great importance to the quality management of academic journals. Furthermore, it is common for third-party organizations to evaluate such journals. The journal evaluation system, which has had a considerable influence on the evaluation of STM journals, is a comprehensive evaluation indicator system of Chinese STM journals developed by the China Science and Technology Information Research Institute (CITIC Institute). The CITIC Institute has been developing evaluation indexes for Chinese STM journals since 1987, and publishes an annual citation report, looking at three key levels: academic quality, international competitiveness, and sustainable development potential. To comprehensively reflect the quality and influence of academic journals through more than 20 academic indexes of STM journals, the evaluation results are widely used by the General Administration of Press and Publication, the Ministry of Science and Technology, the Ministry of Education, the National Natural Science Foundation Committee, the CAS, and other industry departments and institutions of academic journal evaluation. This system has achieved good results. Since 2000, the CITIC Institute has been commissioned by the Ministry of Science and Technology to conduct pioneering work in the research of high-level STM journals. The institute has helped to outline a strategy of high-quality Chinese STM journals, develop an evaluation indicator system of such journals, and construct a service and guarantee system for these publications. Furthermore, every three years it publishes a list of China's high-quality STM journals (starting in 2008). The CITIC Institute is considered impartial and authoritative. Aside from these evaluation activities, it also plays a guidance role for STM journals. Under the promotion of the evaluation system of CITIC's STM journals, the overall level of our country's STM journals has improved. Journal cataloging has been standardized and internationalized, and the quality of journals has improved correspondingly.

In 2012, the CITIC Institute launched the *Leader of the 5000—China's top-level academic paper platform* (F5000). The F5000 project is the continuation of the high-quality STM journal project that annually selects 5000 outstanding articles from the top journals to further promote the brand image of *Chinese quality STM journals*. It is also important to promote the improvement of the overall academic level of Chinese STM journals and quality scientific research in China. Further aims include improvements to academic communication and the dissemination of knowledge, and the development of our academic influence and international competitiveness.

Ministry of Education

In 2006, the Ministry of Education published the results of the first *High-quality Chinese University STM Journals* report. STM journals from universities and colleges were classified according to the professional attributes of the organizers and journals, and in accordance with the needs of the development strategy for national quality STM journals. It established a model for university STM journals, and identified the desired characteristics of such journals.

China Association for Science and Technology

With the aim of promoting the innovation and development of Chinese STM journals and enhancing the core competitiveness of STM journals, the China Association for Science and Technology aims to continue to promote quality STM journals in China, under a project to cultivate quality STM journals, the international promotion of STM journals, and the development of science impfaction. In this way, English-language STM journals in China will be further developed. Additionally, a national service innovation system will be created. This will work to strengthen China's position in the international science and technology arena, and our cultural soft power. The China Association for Science and Technology, the Ministry of Finance, CAS, the Ministry of Education, and the China Institute of Engineering will work together to achieve *The Plan to Promote the International Influence of China's Scientific and Technological Journals*. The funding for the project is 100 million yuan, which represents the full support of China's ministries.

Chinese Academy of Sciences

CAS established the Science Publishing Fund of the Chinese Academy of Sciences in the early 1990s to support quality and important scientific and technical publications, advance scientific and technological publications, and promote the development of science and technology. The scope of the funding is to help key science and technology journals in various fields of natural science and technical sciences. The focus of funding on national key projects reflects the results of many papers, domestic and foreign high-frequency citations, impact, and the quality and efficiency of high-level science and technology journals.

20.2.3 The Demand for a Journal Evaluation System for Journal Development

Is it possible to evaluate a reasonable result under the same evaluation system in different stages of development? For the evaluation of academic journals based on different stages of development, such as the current evaluation system for the selection of *core journals* or *source journals*, the comprehensive journals of colleges and universities and CAS social sciences journals are classified as separate *comprehensive categories*, in parallel with the major journal categories. The evaluation of these two major journal types in the comprehensive category adopts the same method as the evaluation of professional journals. That is, the various disciplines of a comprehensive journal are regarded as a discipline, and the data of the whole journal is accumulated. This evaluation method has played an important role in improving the influence of university journals and comprehensive social science journals in the initial development stages. However, because of the emphasis on each subject, the difference between citation frequency and the impact factor of different subjects can sometimes be substantial, making the evaluation problematic [20.33]. For example, the following five categories are applied to China's STM journals: policy journal, academic journal, application journal, abstract journal, and popular science journal. These five categories of journal are all very different to each other, and so the assessment criteria system for each category of journal should be unique from all others [20.34]. In the evaluation of different types of journals, only one quantitative index or influence factor is used, and this practice has proved unsuitable.

SCI, founded in 1964 by the Institute for Technology Information, is one of the six largest retrieval systems in the world. In recent years, China has been attaching greater importance to SCI, which is often regarded as the main index to evaluate the level of scientific research of a unit and an individual. SCI includes journals with a high impact factor and a high level of scientific research. SCI can be used to evaluate the level of scientific research indicators, and can well reflect the scientific level of researchers. At the same time, low-level staff, if seeking the evaluation of scientific research, use SCI to evaluate the level of scientific research indicators. There will be a clear evaluation of what is inappropriate and not applicable.

Core journals are widely applied to the performance evaluation of scientific research. Although these have a certain evaluation function in scientific research work, their present function in research performance evaluation is exaggerated. It is not scientific to substitute the quality of a paper for the journal quality in the evaluation process. The aim of the core journals is to optimize the collections of library and information departments and to provide a reading service for readers. This has a certain objective reference effect on the performance evaluation of scientific research. When the scientific research management department carries on the scientific research performance evaluation, whether the scientific research results are published in the core journals, is often a key reference factor. However, other excellent scientific and comprehensive journals exist outside the core journals. Usually core journals are selected and other outstanding journals are ignored. Thus, the core journals should not be used to evaluate the performance of scientific research.

The existing evaluation criteria and evaluation indicator system (usually from journals, citations, and third-party evaluations of three dimensions to build an evaluation indicator system) along with people's understanding of the evaluation work has been deepened. The evaluation method has made great progress; each evaluation institution has adjusted the direction of their evaluation and has optimized its evaluation index. Evaluation in China has become even more refined. Furthermore, it has expanded from two or three initial indexes to nearly 20, although the evaluation indicator system adopted in each published evaluation report has changed or expanded from the original foundation. Some problems, however, have not been solved, including political quality, academic quality, editorial quality, and publication quality. These are important quality standards of journals, but the current evaluation of *core journals* based on impact does not directly embody political quality, and the evaluation indexes related to journal quality (e. g., editorial, institution, printing, and binding) are not considered [20.35]. As an important evaluation index in the evaluation system, impact factors (because of abnormal interactions among journals) suffer human interference, and the effect of download rate, click rate, and the academic ecological environment is destroyed. Therefore, the evaluation of academic journals faces great difficulties and problems. It is then necessary for the evaluation indicator system to be constantly adjusted and improved.

The evaluation of academic journals in China is currently facing a number of challenges such as the time lag in journal evaluation and the opacity of the evaluation process. When the evaluation results of core journals are applied to the evaluation of scientific research, many problems arise. The name-publication effect of the evaluation system has greatly tightened the environment of noncore journals and has essentially destroyed the academic environment. The premise of scientific evaluation results is the existence of a healthy academic environment. Once this environment is damaged, the good evaluation index also becomes flawed. Thus, China's system of journal evaluation has many problems including the situation concerning systematic evaluation results and the Matthew effect of core journals, which influences academic environment, and so on.

20.3 Comparative Study of International and National Evaluation Systems of Academic Journals in China

20.3.1 Overview of the Major International Journal Evaluation Systems

The international journal retrieval and evaluation system was developed and continues to be developed following the concept of Bradford's core journals and the development of bibliometrics. The process of journal evaluation is a standard measure of academic quality and the overall level of journals, with one aim being the reduction of disputes. At present, the widely recognized journal evaluation system comprises SCI and the Engineering index (Ei) published by Elsevier.

SCI, founded in the 1960s, is a citation database that was originally used for retrieval and was then developed to determine the international influence by journals. The Journal Citation Reports (JCR) established in 1975, are a tool for the quantitative evaluation of SCI-indexed academic journals. Because of the influence of SCI, the journals or papers included are generally considered to have higher academic level and greater influence.

Ei was established in 1884, and mainly contains engineering and technical journals, conference papers, and science and technology reports. As a widely recognized abstract retrieval tool, Ei has considerable authority in the field of engineering technology.

Scopus is the world's largest digest and citation database, developed by Elsevier. It concerns the fields of science and technology, medicine, and social sciences in peer-reviewed academic literature and high-quality network resources. Scopus also provides visual intelligence tools, aimed at providing tracking and analysis of research service results.

The MEDLINE database covers biomedical and life sciences topics vital to biomedical practitioners, educators, and researchers. This database covers publications from 1966. The literature represents the highest level of global medicine and provides the latest biomedical research results and trends.

J-STAGE is an academic journal network platform founded by Japan's Science and Technology Agency in the late twentieth century. It mainly includes Japanese science and technology journals in fields such as physics and computing.

SCI

SCI is a citation database launched in 1964 by the ISI. The SCI CD-ROM database was established in May 1988. Since 1975, ISI has published the annual worldwide JCR based on SCI. JCR is an effective tool for the quantitative evaluation of academic journals. SCI has a wide range of disciplines, academic influences, and extensive coverage. Thus, the journals and papers included in SCI reflect a high academic level and significant international influence. SCI is the most powerful tool in the evaluation of scientific research, science and technology, scientific research institutions, science publications, and science subjects themselves. SCI is the authoritative retrieval system of scientific and comprehensive engineering papers from all over the world. In addition to scientific evaluation, SCI's unique role has been widely recognized worldwide. Garfield stated: "A valid index must strictly limit the scope of its inclusion, only to collect information useful to the researcher." Therefore, we should look at and use the authoritative citation data of SCI.

Main Features. Looking at the external features, the main features of SCI are obvious, and include science and technology journals in the field of natural science as well as many journals from many countries. That is, it has a wide international scope, with an impressive and comprehensive number of journals covering many decades. Furthermore, it has a relatively short renewal cycle, resulting in excellent information timeliness.

Producer. ISI merged with Thomson Reuters in 1992. It is currently owned by Clarivate Analytics.

Target Journals. SCI covers all natural science disciplines, with a total of 273 categories. It is an improtant Journal Abstracts Index as it covers the most important journals in almost all science field specially in those subjects of basic theory of natural science. It can be used to retrieve journals in the following areas: mathematics, physics, chemistry, astronomy, biology, medicine, mechanics, optical engineering, science and technology, power engineering and thermal physics, electrical engineering, electronic science and technology, computer science and technology, civil engineering, aerospace science and technology, control science and engineering, environmental science and engineering, food science and engineering, management and education, materials science and engineering, and information and communication engineering. It has been providing important academic achievement information since 1945.

Purpose of Evaluation. It is convenient for researchers to conduct a comprehensive literature search to understand the historical evolution, the influence, and the development trends with the subject area. Furthermore, scientific research management departments can use SCI statistical analysis data as a quantitative basis for the performance evaluation of scientific research institutions and personnel.

Evaluation Method. Evaluation moves from qualitative evaluation to quantitative evaluation. Every year Chinese journals are audited, with approximately 200 selected. The selected journals will also be audited to ensure that they maintain their high level of quality. Each journal is subject to a broad evaluation process before being selected or eliminated. The editors responsible for the evaluation work have an appropriate educational background and professional experience and training in the relevant fields. Experts from various fields may be brought in where necessary.

Selection Criteria. From the perspective of requirements and procedure, SCI focuses on the quality of journal content editing, academic quality, and academic integrity. It also pays attention to the international and academic level of authors and editorial boards, and emphasizes sustainable development.

Evaluation Index. SCI mainly uses impact factor and citation frequency.

According to the upper introduction and study materials about SCI, we separat those raw materials into deconstruction items and re-organize them as reconstruction item as similar structure in order to comparative study different evaluation system. See Tables 20.1 and 20.2.

Ei

Ei (now Ei Compendex) was first published in 1884 by the United States Engineering Information Corporation, which publishes journals, conference papers, and scientific reports on engineering and technology disciplines. The literature contained in the database covers almost every field of applied engineering technology. Ei is a comprehensive and abstract retrieval tool in the field of engineering technology. It does not generally report on science literature focusing on pure theory, nor does it pursue a massive collection. Instead, attention is paid to the quality of the literature. Ei Compendex is the world's oldest database of engineering abstracts.

Main Features. Ei includes literature covering all engineering fields. The database contains 3639 of the world's leading engineering journals from more than 70 countries. It has been a respected provider since 1884, and 90% of the literature is in English. Ei retrieves weekly updates.

Producer. Elsevier.

Target Journals. Ei concerns engineering technology and covers more than 190 disciplines such as power, electrical, electronics, automatic control, mining and metallurgy, metal technology, machinery manufacturing, management, civil engineering, water conservancy, and education projects. The Ei retrieval system has a high level of comprehensiveness, a wide data source, extensive geographical coverage, wide coverage, high quality, and strong authority.

Purpose of Evaluation. To provide professional and practical online data and information services for scientific researchers and engineering technicians.

Selection Criteria. The Ei profile program consists of five main areas:

A. The primary criterion is journal subject, with Ei largely focusing on chemistry, computer engineering, and software. However, journals in the fields of agriculture, industry, textiles, applied chemistry, mathematics, and atmospheric science are included. More general fields may also be included if it is a very important publication; the value of the article determines whether it is included within the scope of Ei. Excluded journals are those in the areas of biology and astronomy.
B. Ei journal information generally includes journal name, ISSN, fax, e-mail, and similar information.

Table 20.1 SCI features and requirements

Raw materials	Deconstruction	Reconstruction
(1) SCI focuses on the field of natural science	(1) The field of natural science	(1) Subject characteristics
(2) SCI contains more than 80 countries	(2) Digest index database	(2) Database properties
(3) SCI contains more than 12 000 world-leading STM periodicals	(3) Basic theory	(3) World influence
(4) SCI covers more than 250 disciplines in the field of key academic results since 1900	(4) Involving national journals (5) Covering disciplines	(4) Efficiency and timeliness
(5) SCI database update frequency is once a week	(6) STM periodicals	(5) Journal attributes
	(7) Update frequency	
	(8) Academic achievements	
	(9) Areas of focus	
	(10) Time range	

Table 20.2 SCI requirements and process

Raw materials	Deconstruction	Reconstruction
(1) SCI believes that periodical publication is one of the most important indexes to measure periodicals, and it is very important to publish periodicals on time according to the publication cycle. Timely publication allows readers to obtain the latest information and reduces the collection of published early or outdated periodicals. Before completing the periodical evaluation, the editors usually follow three contiguous issues of the publication. (2) Sci-indexed periodicals require journal editors to conform to international editorial conventions, such as full number of addresses (3) English titles, abstracts, headings, keywords, etc. (4) SCI will peer review as an evaluation index, and to some extent it can be considered that through peer review, journal paper quality is also guaranteed (5) The periodicals included in SCI need to publish moral statements and practices that do not to accept falsehoods and academic misconduct (6) The periodical publication format printing or electronic format (XML) is qualified to participate in the evaluation (7) SCI will consider whether periodicals are the new research results published in new periodicals, and if they can enrich the contents of the database they can be considered included (8) SCI will examine the degree of internationalization of periodical authors, editorial boards and editorial boards, while at the same time, SCI will strive for the balanced collection of different disciplines and regions (9) Based on citation database, SCI analyzes the importance and influence of different periodicals to realize the dynamic management of the database (10) For the new periodicals, analyze the journals of the main authors and members of the editorial board before publication in other journal papers to see whether there is a reference record. For the existing periodicals, the calculation of the impact factors. New journals will be selected every year to eliminate the use of less old journals	(1) Timeliness (2) International editorial practice (3) Full-text English (4) Peer-review process (5) Publication of moral statements (6) Publication format (7) Edit content (8) International diversity (9) Discipline and regional balance (10) Dynamic management	(1) Publication cycle (2) Editorial standardization (3) Academic integrity (4) Academic quality (5) International influence (6) Editorial quality (7) Capacity for sustainable development

C. English-language journals are prioritized, followed by journals published by European countries and the major journals of other countries.
D. Further key Ei requirements include the timeliness of journal publication and the degree of internationalization. Journals need to show academic contribution and original research.
E. Dynamic management: Ei follows a dynamic management model where journals are reviewed annually. Low-quality journals are removed and replaced by higher-quality journals.

Scopus

Scopus is a relatively new index, but it has a wide application including more than 2000 universities and research institutes around the world. Those students and researchers using Scopus are typically engaged in study and research work. Nearly all of the world's top laboratories, research institutes, and ranking agencies use Scopus for evaluation. Scopus is also used by innovation leaders in various industrial sectors for research and development. The database is accredited by the British government, and England's top four universities use Scopus as the only bibliometric tool under the 2014 Research Excellence Framework (REF) to assess the quality of research in higher education institutions. The Australian Scientific Research Council (ARC) uses Scopus to provide assessment support for national research and evaluation work.

Main Features. The Scopus database contains data from more than 100 countries, 5000 international publishers of more than 20 000 peer-reviewed journals, and covers all fields of science and technology, medicine, social sciences, and the arts and humanities. It contains 32 million abstracts from 1996 to the present, and 21.3 million abstracts from 1823 to 1996. Approximately two million records are added each year by means of daily additions. It represents the comprehensive integration of STM web page resources: 545 million science and technology web pages from the five largest patent organizations in the world and 25.2 million pages of content with a wide geographical distribution. More than half of the content comes from Europe, Latin America, and Asian countries.

Producer. Elsevier.

Target Journals. Scopus covers 313 subjects in 27 subject areas including medicine, physics, and mathematics.

Purpose of Evaluation. Scopus provides a fast and accurate retrieval of the full text and referenced information in real-time tracking. It offers the latest results from related research fields, hot topics, and institutions. Scopus aims to enhance the academic impact of individuals and institutions to promote global academic exchange. It also provides customized services for the data and analysis needs of government and evaluation agencies.

Evaluation Method. The Scopus Content Selection and Advisory Committee (CSAB) is an international and independent committee operated by a group of experienced international peer-review journal editors. It also includes publishing, bibliometric, and library science experts; these members were invited based on their desire to improve Scopus. At the same time, a key objective of CSAB is to ensure the recording of high-quality journals.

Selection Criteria. Stage One: Preselection criteria:

a. Timeliness
b. International editorial practices
c. The process of peer review
d. Author declarations
e. Reference specifications.

Stage Two:

1. Standard characteristics:
   a. Journal policy, journal operation
   b. The level of the peer-review experts
   c. The internationalization and diversity of editors and editorial boards, the internationalization and diversity of authors
   d. Geographical diversity of journals.
2. Content quality of journals:
   a. Academic influence
   b. The text is readable
   c. Publication history of at least two years.
3. Online availability of journals.

Evaluation Indicators. Scopus indicators include SJR, SNP, IPP, etc.

MEDLINE

MEDLINE is the bibliographic database of the National Library of Medicine (NLM) in the United States. It covers biomedical and life sciences topics critical to biomedical practitioners, educators, and researchers, and abstracts databases based on biomedical science. It includes the Medical Index (Index Medicus), Dental Literature Indexing (Indexes to Dental Literature) and the International Nursing Index. MEDLINE includes articles from 1966 to the present day, and the collected documents represent the highest quality in the global medical field. They also reflect the latest development and research results in biomedicine.

Main Features. The MEDLINE collection includes articles from more than 70 countries and regions, and includes more than 3400 different subject areas. Since 1946, close to 21.6 million records have been added, and it includes weekly updates and has a high proportion of English-language articles.

Producer. National Library of Medicine.

Target Journals. Core biomedical topics.

Purpose. To meet the needs of the world's researchers, healthcare workers, educators, managers, and students.

Evaluation Method. A technical review committee for the selection of documents was set up in 1988 to evaluate the content of journals, to co-opt new journals, and to include journals that do not conform to usual standards and requirements.

Selection Criteria.

A. Biomedical-oriented
B. Focuses on the quality of journal content, editing, and publishing
   - The content quality of journals: the academic level of journals is the primary factor of MEDLINE journals. The scientific aspects, timeliness, originality, and contribution of the article content are the important aspects.
   - Editorial quality: selection, method, and process of manuscript review, ethical and moral declarations, proof of conflict of interest, chart of production, corrections, and comments.
   - Publication quality: publication layout, printing, illustrations, and binding quality are also important aspects of the evaluation of journals.
C. Readers
   The focus is on the study of health professionals, including general researchers, caregivers, educators, managers, students, and other readers interested in healthcare.
D. Non-English journals
   Non-English journals and English-language journals have a consistent standard of assessment. Non-English journals should include English-language abstracts, and subject, author, unit, and chart following acceptable English-language standards.
E. Other
   Good quality journals will be included wherever they are published. Special attention is given to epidemics and endemic diseases. The diversity and internationalization of journal authors and the aca-

demic status of editorial commissioners will affect the collection of journals.

J-STAGE

J-STAGE (Japan Science and Technology Information Aggregator) was created by the Japan Science and Technology Agency in October 1999. The aim was to provide a network platform for academic journals. As the core agency responsible for Japan's Science and Technology Basic Plan, J-Stage undertakes the electronic and international internationalization of Japanese science and technology papers. J-STAGE focuses on Japanese science and technology papers, from their submission to their online publication. It aims to create a smooth process, from electronic submission to the publication processes and electronic special issues. J-STAGE not only contains submitted papers, but also other articles linked to the citation data, including video and audio, and appendices. The development of the J-STAGE database has networked the publications of Japanese academic and journal circles, and exemplifies the advantages of data integration. It helps to disseminate the achievements of Japanese science and technology and STM journals worldwide via this network. Thus, it aids in their effective use.

Main Features. J-STAGE was founded at the end of the last century, and focuses on scientific and technical journals, conferences, and reports. There is open access to all documents, with full access to the full text of science and technology journals. The J-STAGE is now in its 1808th issue, and 19% of the content is Japanese-language papers, 40% are in English, and 41% a mixture of the two.

Producer. Japan Science and Technology Agency.

Target Journals. The J-STAGE database includes the detailed categorization of journals. According to their respective disciplines, these are divided into 18 topics, covering, for instance, the natural sciences, humanities, social sciences, medicine, and engineering. Life science journals account for approximately 70% of the total.

Purpose of Evaluation. J-STAGE aids the electronic and networked processes of Japanese STM journals. The speed of the database is convenient for the publication of related papers, and the network of papers helps to accelerate the circulation of Japanese scientific and technological success. It contributes to the worldwide spread of Japanese scientific and technological achievements.

Evaluation Method. National institutions and other professional academic groups have developed the main approach.

Selection Criteria. Generally, important academic journals are recommended for entry into the database. Regular adjustments are made (these are generally small). The abstracts and titles of most of the papers included in the journal are in English. J-STAGE's selection criteria for journal content include:

- Reflect innovative viewpoints from particular fields
- Logically rational scientific papers that accord with scientific culture and ethics
- Real and reliable research resources and data
- High-quality writing skills.

20.3.2 Major National Evaluation System of Academic Journals in China

China's current evaluation system of journal retrieval includes the following databases: CSTPCD, Journal of Chinese Core Periodicals, Chinese Humanities and Social Sciences Core Periodicals, Chinese SSCI, and CSCI.

The CSTPCD indexes the *China's Science and Technology Core Journals*. CSTPCD includes Chinese publications (but excludes those from Hong Kong, Macao, and Taiwan) and currently references 2312 Chinese and 71 English-language journals. It contains 2383 core Chinese STM journals (i. e., Chinese STM source journals), which are classified into two or three subjects according to 153 subjects in 10 fields (e. g., natural science synthesis and neo-Confucianism).

A total of six editions of CSTPCD were published between 1992 and 2014. Selected journals were assessed and qualitatively evaluated, and nearly 2000 core journals were selected from journals published in China. The database contains seven sections (excluding interdisciplinary repetition) and the 2014 edition contains 1983 journals. The database has a great influence on the society via its provision of a reference for the evaluation and ordering of journals for information departments and the management policy of administration departments.

The 2014 edition contains 733 journals concerned with humanities and social sciences. The journals are distributed in 23 categories and are divided into authoritative journals, core journals, and extended journals in different subjects.

The CSSCI was first established in 1998 and four editions have been published. The latest version (2014–2015 edition) concerns, for example, management, Marxism, and another 25 disciplines. It contains 533 journals, including the largest number of comprehensive journals. Furthermore, it includes comprehensive social sciences and 120 efficient comprehensive journals, accounting for 22.5% of the total number of journals.

Table 20.3 CSTPCD features and structure

Raw materials	Deconstruction	Reconstruction
(1) CSTPCD mainly includes national, provincial or regional outstanding periodicals in the field of natural science (2) The classification of 153 subjects and 10 subjects including natural science synthesis and CSTPCD (3) The citation report of Chinese STM periodicals started in 1988, with the latest edition in 2014, and a yearly report (4) CSTPCD includes Chinese publications (excluding Hong Kong, Macao): 2312 Chinese periodicals and 71 English periodicals, a total of 2383 ...	(1) The field of natural science (2) STM periodicals (3) Academic achievements (4) Involving national science (5) Interdisciplinary (6) Update frequency (7) Time range ...	(1) Major disciplines and interdisciplinary classifications (2) Domestic influence (3) Journal attributes (4) Update efficiency and timeliness

The CSCI 2015–2016 includes 1200 source journals, referencing Chinese (1006) and English-language (194) journals.

China Scientific and Technical Papers and Citations Database (CSTPCD)

Main Features. CSTPCD includes science and technology journals in the field of natural science, with a large number of journals and covering a wide time span. It includes interdisciplinary journals for multidisciplinary evaluation.

Producer. ISTIC was commissioned in 1987 by the Ministry of Science and Technology to undertake statistical work.

Target Journals. State-level academic journals, CAS journals, academic journals from key universities, and all natural and social sciences journals.

Purpose of Evaluation. CSTPCD was first published in 1998, with two versions: the core edition and the expanded edition. The latest edition was published in 2014. It is a journal evaluation tool for a vast number of scientific and technical personnel, journal editors, and scientific research managers, enabling them to quickly, accurately, and scientifically select and use journals.

Evaluation Method. Mainly uses a multiple index evaluation system, a combination of quantitative and qualitative methods, and quantitative methods (using a series of bibliometric indexes) to appraise journals.

Selection Criteria. The journals covered by CSTPCD should be peer-reviewed academic journals that have been published for more than 2 years, and whose indicators ranked in the forefront of the discipline. They should be in line with academic publishing norms and meet the publishing integrity and ethical requirements.

Evaluation Indicators. The CSTPCD uses two evaluation methods: single-index evaluation and comprehensive-index evaluation. Specific indexes include citation frequency, impact factor, important database collection, and comprehensive evaluation score.

According to the upper introduction and study materials about CSTPCD, we separat those raw materials into deconstruction items and re-organize them as reconstruction item as similar structure in order to comparative study different evaluation system (Tables 20.3 and 20.4).

A Guide to the Core Journals of China

Main Features. *A Guide to the Core Journals of China* (2014) contains 1982 core journals, published every four years from 1992 to 2011, and then again in 2014.

Producer. Developed by Peking University Library.

Target Journals. Covers a wide range of disciplines (Table 20.5).

Purpose of Evaluation. To provide reference for the library's journal purchases and Chinese journal collection, and to facilitate readers' access and authors' contributions.

Evaluation Method. Quantitative and qualitative comprehensive analysis and evaluation, based on bibliometrics, the use of evaluation indicators for the domestic publication of Chinese journals for statistical analysis, and the use of expert opinion.

Selection Criteria.

A. Indicator system: according to the law of Brinell, bibliometric statistics are used to screen the list of core journals from different disciplines.
B. Division of disciplines: overview using the medium-map method to divide the subject, based on subject size, number of journals, journal quality, and other factors that constantly modify the discipline.
C. Core journals are selected based on three aspects: the journal is considered a core journal, it is representative, and it is practical.

Table 20.4 CSTPCD description and structure

Raw materials	Deconstruction	Reconstruction
(1) CSTPCD includes mathematics, physics, medicine and other fields (2) CSTPCD includes STM and technical periodicals reflecting the development of scientific and industrial technologies (3) CSTPCD requires the periodical to conform to the description specification, such as the unified CN number, complete bibliographic information, etc. (4) The publication of CSTPCD from the peer-review process (5) Strict publication cycle of CSTPCD Source Journal (6) CSTPCD will consider whether the periodicals are indexed in SCI, SCIE, Ei, CA, and so on, as well as famous large-scale search systems (7) The social influence and academic status of the source periodicals. Academic reputation can attract high-quality papers at home and abroad. Excellent academic research journals at the local level (8) CSTPCD-included periodicals need to follow the international and domestic editing practices, and need to meet the normative requirements of the journal: complete bibliographic information and so on (9) Academic content should reflect the latest achievements in the field of science and research projects of major research funds. Should have the national authoritative expert composition of the editorial committee. Rigorous academic accreditation of periodicals (10) The evaluation principle must be a combination of qualitative and quantitative (11) To ensure the balanced collection of periodicals in different disciplines, especially new disciplines or high technology disciplines, and to take care of the new development area periodicals to ensure the integrity of the area	(1) Subject area (2) Domestic and international editorial practice (3) Editorial authority (4) Timeliness of publication (5) Domestic and foreign retrieval system included (6) Academic quality (7) Comprehensive assessment (8) Special consideration (9) Discipline and regional balance (10) Dynamic management	(1) Subject-biased (2) Editorial standardization (3) Editorial quality (4) Academic quality (5) International influence (6) Capacity for sustainable development

Table 20.5 The distribution of journals in *A Guide to the Core Journals of China*

Volume	Field	Number of periodicals
1	Philosophy, sociology, politics, law	274
2	Economics	155
3	Culture, education, history	311
4	Natural science	344
5	Medicine, health	250
6	Agricultural science	135
7	Industrial technology	514
	Total	1983

Evaluation Indicators. The seventh edition (2014) is based on 12 evaluation indicators such as the amount of article Full-Text requested in library system, the amount of article covered by important databases, the citation index of paper, the index of mutual citation etc.

Chinese Humanities and Social Sciences Core Journals Database (CHSSCD)

Main Features. The CHSSCD includes more than 700 journals on humanities and social sciences, and was established in 1996.

Producer. Chinese Academy of Social Sciences (CASS) Literature Information Center.

Target Journals. Humanities and social sciences journals (Table 20.6).

Purpose of Evaluation. To optimize the use of journals and literature resources for scientific research, to provide reference for journal evaluation, scientific research performance evaluation, scientific research management, and talent selection in scientific research.

Evaluation Method. Combination of quantitative evaluation and expert qualitative evaluation.

Selection Criteria. The 2014 report on the indicator system of journal evaluation creates three categories: attractions, management power, and influence. These are described below:

- *Attractions*: Academic reputation (award status, peer review), the inclusion of other domestic databases, the diversity of authors, and the quality of papers
- *Management power*: Journal orientation, academic ethics, editorial staff quality, editorial standardization, publishing norms, and networking.
- *Influence*: Academic quality of journals, internationalization of editorial board, social and international influence of journals, etc.

Table 20.6 Grade distribution for China's humanities and social sciences journals 2014

Rank	Field	Number of periodicals				
		Total	Top	Important	Core	Extend
1	Law	32	1	2	19	10
2	Management	25	1	2	12	10
3	Environmental science	5	0	1	3	1
4	Pedagogy	33	1	2	20	10
5	Economics	109	1	3	63	42
6	Archeology	18	1	2	9	6
7	History	32	1	2	21	8
8	Marxism	14	1	2	8	3
9	Ethnology and cultural studies	27	1	2	15	9
10	Human geography	12	0	1	7	4
11	Sociology	15	1	2	6	6
12	Physical education	14	0	1	7	6
13	Statistics	4	0	1	2	1
14	Library, information and archival science	31	1	2	16	12
15	Literature	24	1	2	14	7
16	Psychology	7	0	1	4	2
17	Journalism and communication science	11	1	1	5	4
18	Art	16	1	1	9	5
19	Linguistics	32	1	2	19	10
20	Philosophy	15	1	2	7	5
21	Politics	68	1	2	42	23
22	Religion	2	0	0	2	0
23	Comprehensive humanities and social sciences	187	1	4	120	62
Total		733	17	40	430	246

Evaluation Indicators. The 2014 edition uses citation frequency, the difference between the two-year and five-year impact factors, the article funding ratio, article downloads, and so on. This database is able to determine the current situation of journals in China.

Chinese Social Sciences Citation Index (CSSCI)

Main Features. The CSSCI (2014–2015) contains 533 humanities and social sciences journals; these have been selected four times since 1998.

Producer. Nanjing University.

Target Journals. Humanities and social sciences journals, divided into 25 fields (Table 20.7).

Purpose of Evaluation. It provides reference and help for academic evaluation, performance, management, and research on humanities and social sciences.

Evaluation Method. A combination of quantitative and qualitative methods.

Selection Criteria.

A. Principles of inclusion: the principle of prioritizing quality journals, the control of the total number of journals, and the use of quantitative and qualitative evaluation for regional and discipline balance, and dynamic high and low management.
B. Editorial specifications: full information provided with the academic norms of reference and literature notes.
C. Time and timeliness of the publication: Publishing frequency, deadlines met, published continuously for five years, the extension of more than two months of published journals belonging to the editors (journals that do not follow publishing norms are not selected).
D. Disciplines and sources of publications: a main focus on humanities and social sciences academic papers, academic reviews, and other original academic literature. The number of source journals is limited to 20% of the total academic journals of humanities and social sciences in China.
E. Citation factors, total citation frequency and other indicators, with different weights given to each for the quantitative evaluation of journals.

Evaluation Indicators. A Chinese Social Sciences Research Evaluation Center, Nanjing University, (2016–2017) publication outlines the quantitative evaluation of journals by citation quantity and other factors.

Table 20.7 The subject distribution of CSSCI

Field	Number of periodicals
Management	29
Marxism	16
Philosophy	12

Comprehensive Journal of Colleges and Universities	70
Total number of periodicals	533

China Science Citation Database (CSCD)

Main Features. The CSCD includes journals in the following areas: natural science, engineering technology, medicine, and other fields of science and technology. It includes thousands of journals, ranging from 1998 to the present day, and includes 300 000 articles, and nearly 17 million citations. Source journals are selected every two years.

Producer. Chinese Academy of Sciences Document Information Center (now known as the CAS National Library).

Target Journals. The CSCD focuses on basic scientific research in the field of natural science.

Purpose of Evaluation. It provides the basis for selecting source journals and evaluating STM journals for Chinese scientific citation databases.

Evaluation Method. Comprehensive evaluation method combining quantitative statistics and expert evaluation.

Selection Criteria.

A. Theoretical basis: based on literature concentration and the discrete law of Brinell.
B. Editing and publishing norms: has both an ISSN and CN, two standard publication numbers, and the journals must conform to standard journal descriptions.
C. Scope of disciplines: covering the fields of mathematics and physics, while paying attention to the collection of basic research, academic, theoretical, and leading-edge journals.

Evaluation Indicators. The index uses more than ten factors including impact factor, quality index, thesis utilization index, and mutual index.

20.3.3 Comparison of International and Chinese Journal Evaluation Systems

By summarizing the data of different journal evaluation systems, we can outline and refine the different attributes of various domestic journal evaluation systems (Table 20.8).

Main Features

The characteristics of the systems and the target journals can be divided into five categories: subject, country, the number of journals, the time span, and updating efficiency (Table 20.9). From the point of view of the distribution of disciplines, foreign journal evaluation systems contain major areas of difference. For example, SCI, the major areas of Ei, Scopus, MEDLINE, and J-STAGE concern natural sciences, social sciences, engineering technology, and biomedicine. Furthermore, foreign journal evaluation systems focus on those jour-

Table 20.8 Key characteristics of the main domestic and international journal evaluation databases

	Owner	Headquarters
SCI	Thomson Reuters	United States
Ei	Elsevier	United States
Scopus	Elsevier	Netherlands
MEDLINE	National Medical Library of America	United States
J-STAGE	Japan Science and Technology Revitalization Agency	Japan
CSTPCD	China Institute of Science and Technology Information	China
GSJC	The Library of Peking University	China
CHSSCD	Literature Information Center of Cass	China
CSSCI	South Social Science Research Center	China
CSCD	National Library of CAS	China

Table 20.9 Key features of international and national journal evaluation databases

	External features	Key disciplines	Number of periodicals	Operating since	Update time
Main international evaluation system	SCI	Natural science	>12 000	1900	Yearly
	Ei	Engineering technology	3639	1884	Weekly
	Scopus	Social	>20 000	1823	Daily
	MEDLINE	Medical	>3400	1946	Weekly
	J-STAGE	Natural science	>1000	1999	
Main evaluation system in China	CSTPCD	Natural science	2383	1987	Yearly
	GSJC	Wide range of disciplines	1982	1992	Three years
	CHSSCD	Human society	>700	1996	Yearly
	CSSCI	Human society	533	1998	Biennially
	CSCD	Natural science	>1200	1998	Biennially

nals that embody the characteristics of the subject and contribute to journal focus. For example, Ei focuses solely on engineering, and includes all journals with an engineering technology scope. From an evaluation perspective, the foreign evaluation system is discipline-oriented, which is helpful to find suitable data for analysis and research in different disciplines. Therefore, the distribution of journals reflects that the foreign journal evaluation system and databases pay attention to the subject matter and the specialty of the journals. The field of focus of the journal is an important aspect of foreign evaluation databases. China's journal evaluation systems include major areas of difference: CSTPCD and CSCI focus on natural science, CHSSCD (CASS) and CSSCI include humanities and social sciences, and GSJC (Peking University) journals are covered extensively. From the perspective of journal discipline, the foreign evaluation system places a greater emphasis on the subject characteristics of journals, and it focuses on the journals with academic contributions and clear characteristics.

Regarding the scope of coverage, SCI, Ei, MEDLINE, and Scopus cover more than 70 countries and regions, and significantly more than than J-STAGE's 3400 journals (mainly from Japan). Furthermore, SCI, Ei, and MEDLINE focus on Western countries. Scopus' content is more balanced in terms of geography, with more than half of the content coming from Europe, Latin America, and Asia. Thus, Scopus attracts more countries and regions to use and search the index. The journal evaluation system for different journals will consider the balance of the region and the subject. China's journal evaluation system only contains important journals from China. Because its geographical scope is narrow, the number of journals within China's journal evaluation systems is obviously less than that of the foreign journal evaluation systems. Therefore, it is worth considering whether it is necessary to enlarge the scope of China's journal evaluation system and to enhance its international influence.

Regarding the history of the various systems, international evaluation systems such as SCI and Ei have been operating for some time now. Ei has a long history of 130 years, while SCI was established 60 years ago. In contrast, China's index database and evaluation system were established just 30 years ago. The period of operation reflects the maturity degree of the journal evaluation system: the longer the history of the system, the greater the verification of the system's practices, and the greater the opportunities to improve and fine-tune the process. This can also occur via international influence and use. Therefore, China's journal evaluation system may be able to draw lessons from the development process of overseas journal evaluation systems, and provide a reference for the healthy development of its journal evaluation systems.

Regarding the frequency of updating, foreign journal evaluation systems are updated frequently. For example, SCI, Ei, and MEDLINE data are updated weekly, and Scopus data are updated daily. These updates are quick, ensuring the data remain relevant. Regarding the publication of citation reports or core journals in the journal evaluation system at home and abroad, JCR and CHCR publish once a year and *A Guide to the Core Journals of China* is now published once every three years. The CASS humanities and social sciences database is published annually. Thus, regular updates occur in both the domestic and foreign journal evaluation systems, as well as the dynamic management of the data and core journals, which reflects the continuous increase in user demand. The evaluation system continues to update the data, and reflects the sustainable development ability of the evaluation system. Therefore, China's journal evaluation system can also be combined with its own resources to provide users with more comprehensive search and data services to promote the sustainable development of journal evaluation.

Subject Characteristics

The main evaluation systems include ten domestic and international evaluation systems from three companies, three libraries, and four research institutions. Sixty percent of the foreign evaluation systems are owned by companies. In contrast, China's main journal evaluation systems include three scientific research institutions, and two universities or research institutions. Thus, China's journal evaluation systems are concentrated in research institutions and libraries.

As stated above, international journal evaluation systems are mainly owned by companies, while China's are mainly owned by scientific research institutions. Corporate enterprises are profit-oriented, so pay greater attention to user needs. Scientific research institutions generally have a clear direction and aim (i. e., academic research), and pay more attention to academic results and so on. Both ownership styles have their advantages and disadvantages.

Objective and Method of Evaluation

The index results are largely read by scientific research personnel, management departments, and librarians. For scientific researchers, the results of the journal evaluation provide a standard for evaluating the performance of scientific research. Furthermore, managers will use the evaluation results for performance appraisals and the development of management journals. Librarians will use the results of journal evaluation to determine which journals they will stock in their collections. Therefore, from the reader level, the use of the journal evaluation results regarding the extent and degree of accreditation can also reflect the results of the journal evaluation in terms of rationality, scientific merit, and influence.

The evaluation method of the journal appraisal system is based on quantitative evaluation and expert qualitative analysis, which is based on bibliometrics. That is, objectivity, the measurement and comparability of scientific research results from different perspectives are useful in the objective, fair, and reasonable evaluation of academic journals.

Selection Method

Based on the descriptions and standard main evaluation system at home and abroad, we continue to process the content of the various systems. Table 20.10 shows our results. Overall, the foreign evaluation systems pay more attention to, for example, journal content, edition, publication quality, and degree of internationalization. This can be seen in the fact that the foreign journal evaluation systems largely request the paper to have an English title, abstract, and so on. Similarly, other import factors include the journal's internationalization and diversification requirements, the nationality of the author, and the degree of internationalization of the editorial board and international evaluation experts. In China, the main evaluation systems pay attention to the categorization of the journal's subject range, the number of journals included in key domestic and foreign retrieval systems, editorial authority, and the influence of the journals. A further important point includes whether the journals conform to national standards (e. g., has a CN).

Based on the criteria and principles of the evaluation systems, we will identify the criteria and principles of the different evaluation systems, and summarize the evaluation systems of various journals in combination with their key characteristics (Table 20.11).

On the whole, foreign journal evaluation systems pay greater attention to the following aspects: journal influence, academic quality of journals, standardization of journal editors, timeliness of journal publication, author declarations, originality, dynamic management, editorial and author diversity and nationality, English-language content, discipline and regional balance, and peer reviews. In contrast, Chinese journal evaluation systems focus on: journal influence, academic quality of journals, the standardization of journal editors, timeliness of journal publication, and dynamic management. It can be seen that the domestic and foreign journal evaluation systems attach great importance to journal

Table 20.10 Purpose of evaluation of domestic and foreign journal evaluation databases

	Purpose of evaluation (object-oriented)	Evaluation method
SCI	Research personnel, management, etc.	Qualitative and quantitative combination
Ei	Scientific researchers, engineers and technicians	Qualitative and quantitative combination
Scopus	Academics, researchers, government administrations, etc.	Content Selection & Advisory Committee (CSAB)
MEDLINE	Nursing staff, healthcare providers, educators, researchers, academics and administration	Technical Review Committee on Document Selection (LSTRC)
J-STAGE	Researchers, academics, etc.	National Society and other professional academic groups recommend
CSTPCD	Technicians, editors and managers	Qualitative and quantitative combination
GSJC	Librarians, readers, research workers	Qualitative and quantitative combination
CHSSCD	Journal reviewers, researchers and management	Qualitative and quantitative combination
CSSCI	Provide reference for evaluation, performance appraisal, management and research	Qualitative and quantitative combination
CSCD	Provide basis for periodical evaluation	Qualitative and quantitative combination

Table 20.11 Selection criteria standards and principles included in domestic and international journal evaluation systems

	Standards and principles
SCI	Timeliness, editorial specification (English abstract, etc.), full text English, peer review, publishing moral statement, author and editorial board international diversity, discipline and regional balance, dynamic management, etc.
Ei	Editorial standards (English abstracts, etc.), priority of English-speaking countries, timeliness, internationalization, originality, academic contributions, dynamic management, etc.
Scopus	Timeliness, editorial standardization (English abstracts, etc.), peer review, moral statement, journal policy, academic level of the accreditation committee, international diversity of editorial board and authors, regional and discipline balance, journal influence and quality, etc.
MEDLINE	Academic level, timeliness, originality and contribution degree of the periodical, moral statement, editorial norm, editorial board and author's international diversity, regional and discipline balance
J-STAGE	Take recommendations as the main basis
CSTPCD	Editorial norms, authoritative editorial board, timeliness, the collection of important retrieval systems at home and abroad, the social and academic influence of periodicals, the balance of regions and disciplines, etc.
GSJC	Based on the quantitative selection of the core list, the use of middle-map method to divide the size of the subject; periodicals are representative and practical
CHSSCD	Academic quality of periodicals, collection of other domestic databases, diversity of authors, academic ethics, editorial norms, academic level of editorial board and international diversity, periodical influence, etc.
CSSCI	Journal quality, regional and discipline balance, editorial norms, timeliness, original innovative academic literature, etc.
CSCD	Editorial standardization, focus on basic research, academic and theoretical frontier periodicals, etc.

influence, academic quality, the standardization of journal editors, and the timeliness of publication. It can also be seen that dynamic management is key. It is only via dynamic management that an evaluation system will have the vigor to constantly develop, and to meet the increasing user demand.

There are also some differences in journal evaluation systems. For example, compared with China's journal evaluation systems, foreign systems pay more attention to author declarations and originality, the diversity and internationalization of the editorial board and author, English-language content, and peer-review processes. Regarding author declarations and originality, the governing principles of the journal evaluation systems in foreign countries concern the issue of academic ethics and ethical publishing. Thus, articles will be removed from the relevant database should they breach any ethical standards. That is, users can see an article has been revoked. Regarding ethics and conflicts of interest, in 2013 MEDLINE introduced stricter requirements for journals (in terms of application and after acceptance). Regarding the internationalization and diversification of the editorial board and authors, the foreign evaluation systems basically stipulate the international diversity of editorial board and the authors. The diversity of the authors is beneficial to the global influence of journals, and the international diversity of the editorial board is more advantageous when checking the quality of journal papers and improving academic quality. Concerning journal abstracts, it is generally required that the journals need to have English-language abstracts, which is not only beneficial to the unification of data form, but also to the use and dissemination of knowledge. With regard to expert review, foreign evaluation systems generally consider peer review to be an important guarantee to ensure journal quality. In addition, foreign systems have a high degree of network and computerization, and for MEDLINE, journal publication quality is an important selection factor. Generally speaking, foreign journal evaluation systems have a high quality guarantee in their journal selection, and fully embody internationalization. These systems pay close attention to information dissemination, and seek consistency.

Consistent with the key features outlined above, Ei and MEDLINE require that journals have the desired subject characteristics and the necessary academic requirements. At the same time, it can be seen from the standard of journals, both the subject and journal subject are prerequisites for Ei, and all the journals are engineering technology journals. Furthermore, the features of Ei and the selected journals are notable. For interdisciplinary journals, different journal evaluation systems have different ways of dealing with them, including SCI and CSTPCD (2015 edition). These databases calculate the journal index under different disciplines and highlight the subject characteristics of the journal.

In terms of selection criteria, the standards and principles can be divided into four categories: journals, editors, authors, and judges (Table 20.12). China's journal evaluation systems and those abroad attach great importance to the journal's core value, including the journal's influence, academic quality, editorial quality, and ethics. As journal editors and managers, the editorial board of foreign systems evaluates the internationalization and academic level of the editorial board.

Table 20.12 Summary of standard principles of journal evaluation systems

Standards and principles	SCI	Ei	Scopus	MEDLINE	J-STAGE	CSTPCD	GSJC	CHSSCD	CSSCI	CSCD
Journal influence	✓	✓	✓	✓		✓	✓	✓	✓	✓
Academic quality	✓	✓	✓	✓		✓	✓	✓	✓	✓

Additionally, the editorial board is an important factor in a journal's core value. The author is the main contributor to the content of the journal, but unlike the editorial board, the author is not fixed. To a certain extent, the author is also the factor that affects the journal's value, so foreign journal evaluation systems will also consider the diversity of the journal authors. The evaluation is more like foreign aid to the journal—it provides professional guidance and recommendations for the editorial board. Furthermore, it is advantageous to safeguard the journal quality. It can be seen both in the database descriptions in China and abroad that the journal, editorial board, and other actors are investigated and evaluated. Thus, it is worth considering whether these tasks could be performed by other *evaluators*.

Summary

From the above-mentioned domestic and foreign journal evaluation systems, we can see that any journal evaluation and screening system is based on bibliometrics. Through the deep discussion of Bradford's laws, we can see that the selection and evaluation of source journals is carried out under a framework of their respective evaluation purposes, evaluation methods, key features, and evaluation criteria, each with applicable scope and evaluation characteristics.

Foreign evaluation systems (e. g., SCI, Ei, and Scopus) are located all over the world, and include the key journals from many countries. Thus, the journals included in the evaluation systems of foreign major journals reflect the international influence of the journals to some extent. For Chinese journals, many of these journals with Chinese characteristics (e. g., differences in language and editing norms) have not been included in the key evaluation systems. To some extent, this can be explained by the fact that ranking of China's STM journals in the international arena still needs to be improved. Therefore, certain aspects of the foreign evaluation systems are not completely suitable for China. At the same time, the foreign systems offer considerable experience from which China can learn from in developing its own evaluation system.

Based on the induction and refining process of the domestic and foreign journal evaluation systems, we find that the journal evaluation systems are largely concerned with the following issues:

1. The key characteristics of journals (professional characteristics or academic contributions)
2. Influence of journals
3. Dynamic management of journals (sustainable development)
4. Academic honesty and morality in publishing
5. Diversity and internationalization of editorial board
6. Diversity of authors
7. The balance of areas and disciplines
8. Standardization of editors
9. Readability (e. g., English-language abstract).

20.4 Comparative Study of International and National Evaluation Indicators of Academic Journals in China

20.4.1 Popular Evaluation Indicators of International Academic Journals: JCR

Comparatively speaking, foreign journal evaluation systems adopt a periodical journal evaluation index that is based on Garfield's citation analysis to statistically appraise citation data. Using bibliometrics and a combination of qualitative and quantitative methods to evaluate and select journals, JCR evaluations mainly include the annual number of published documents, citation frequency, and the calculation of impact factors. JCR has recently introduced evaluation indexes for feature factors and influence scores. Generally speaking, JCR is considered an authority on citation data.

The JCR index, providing a statistical and comparative analysis of Chinese journals and other major journals, includes country of origin data (Tables 20.13–20.15). The total number of journals included in the JCR (Science Edition) increased considerably between 2012 and 2014; so too has the number of Chinese journals. In contrast, there has been a decline in the number of journals from France, Russia, Japan, and India. The number of journals from the United States, Britain, and Germany is significantly higher than those from other countries. The number of Q1, Q2, and Q3 journals from China increased in the 2012–2014 period. Furthermore, China enjoys the highest growth rate for journal number, followed by South Korea, while France has largest decline.

A journal can focus on many subjects, and the impact factor may be different for different disciplines. If some journals have multiple subject areas, then the impact factor is calculated for each subject area. Thus, makes the number of journals in four sections of the table more likely than the total number of journals. The term *China (Exclude Duplicates)* means that if a journal focuses on multiple disciplines, only the best area is considered, at which time, the sum of the four areas equals the total number of journals.

Regarding the distribution of impact factors, the distribution of the number of journals in the four regions is more balanced, and the division of German journals represents the global situation. The distribution of U.S. and English journals differs from that in other countries, with the number of journals in the two countries decreasing with the increase in the number of partitions (e. g., Q1 and Q2 journals, Q3 journals, and Q4 journals). The opposite is true for the distribution of journals in other countries, including China. The proportion of Q1 journals in Britain, the United States, and Germany is much higher than that of other countries, and China's Q1 journals are second only to those three countries.

Regarding the number of English-language journals, the number of English-language journals from India remained stable, and the number of English-language journals from Japan decreased. The number of English-language journals from other countries increased. Furthermore, the number of English-language journals in the Q1, Q2 and Q3 divisions increased between 2012 and 2014. The three countries with the increase highest rate of English-language journals are South Korea, Brazil, and China; Japan shows the fastest decline.

Most of the journals entering the Q1 division in China are English-language journals. A total of 18, 19, and 21 Chinese STM journals were included in the JCR in the above three-year period, respectively, and the number of journals has increased gradually in recent years. Our analysis of these journals also shows that a number of Chinese STM journals have made it into the Q3 and Q4 divisions; 94.4% in 2012, 94.7% in 2013

Table 20.13 Number of journals included in JCR 2012

China (excluding duplicates)	179	23	38	57	61

and 90.5% in 2014. However, these rates show that the citation rates of Chinese STM journals are not considered influential. The reasons for this include the language of the journals, the fact that the main readers and citations of Chinese journals are concentrated in China (which results in a domestic rather than an international influence), and that it is difficult to get the attention of (and hence citations from) international academia.

20.4.2 National Journal Evaluation Systems in China

The comparison results of the evaluation methods of various systems show that the current journal evaluation systems generally use a comprehensive evaluation method that combines both qualitative and quantitative approaches. Regarding quantitative evaluation, each evaluation system has a set of indicators. This chapter focuses on the different indicators, highlighting similarities and differences. Looking at the different indicators, we will identify design principles, algorithm design, and the applicability and limitations of the indicators via comparative analysis. We have already identified the key characteristics, standard profiles, main principles, and evaluation indexes for the main evaluation systems in China and elsewhere. Thus, we have analyzed these systems based on various system-level indexes. We continue the analysis of these evaluation systems in Table 20.16.

The evaluation indicators used for the academic journals include impact factors and the total frequency of citation. These indicators directly reflect the academic quality of the journal papers cited and the level of influence. The article funding ratio, web downloads, and annual index are further evaluation indicators in many evaluation systems. At present, the journal evaluation systems basically select journals by looking at their overall reputation and long-term practices, as well as their level of authority and representation. Both qualitative and quantitative methods are used to conduct journal evaluations. Influenced by foreign journal evaluation systems, Chinese journal evaluation indexes have been revised to some extent from traditional evaluation indexes. That is, the impact factor index has produced further evaluation indexes for journal evaluation.

Table 20.16 Main evaluation indexes of Chinese journal evaluation systems

Evaluation system CSTPCD Evaluation indicators	GSJC	CHSSCD	CSSCI	CSCD
Overseas papers rate	Web downloads	Two-year and five-year impact factors	Citation amount	Article influence score
Number of institutions distributed	The amount of article Full-Text requested in library system	Cited frequency	Impact factor	Eigenfactor score
Funded papers rate	Cited quantity	Funded papers rate	Total cited frequency	Index of mutual indexing
Year indicator	Total quoted times	Year indicator		Diffusion factor
Source literature quantity	Quoted paper rate	Paper download		Paper use index
Average number of citations	Indexed by important retrieval systems	Subject expansion indicators		Other cited frequency
Average number of authors	Index of mutual indexing	Subject impact indicators		Other influencing factors
Other citation	Funded papers rate	Important databases		Excellent index
Rate of document selection	Paper cited index			
Quote half-life	Other cited			
Impact factor	Other influencing factors			
Important databases	Impact factor			
Total cited frequency				
Total score of comprehensive and evaluation				

The impact factor index includes a two- and five-year impact factor. The impact factor and the impact of its peak period are based on the impact factor in the computation process difference and different calculations.

The total score of the comprehensive evaluation of Chinese STM journals (hereinafter referred to as the *comprehensive evaluation score*) is based on the comprehensive evaluation indicator system of Chinese STM journals. The relative position score of each journal in the discipline is calculated according to the extreme value of each journal index in each subject category. The annual CHCR (core edition) of the *China Science and Technology Journal* published by CSTPCD regularly publishes the scientific measurement indexes of the statistical source journals of Chinese STM papers [20.6, 7]. Based on this index, a comprehensive evaluation indicator system for Chinese STM journals was implemented in 1996 and further developed. Each index in the evaluation indicator system is not given equal weight when calculating the total score; that is, different indexes are given different weights. The initial index weight distribution was determined by Delphi expert investigation and AHP. Subsequently, based on further research and feedback, new measurement indexes were continuously added. To ensure that feedback on the evaluation results can be properly given and received, ISTIC has held more than 20 expert seminars for scientific metrology experts, scientists, science and technology and journal management experts, and scholars to participate in evaluation, establish indicators, and to determine the weight of updates and adjustments. Thus, they contribute to the creation of the current set of scientific and technological journals to improve evaluation systems and methods.

The total score of comprehensive evaluation is based on the principle of scientific metrology, carefully considering the indexes of the evaluated journals. On the basis of widely solicited opinions, a comprehensive evaluation indicator system for Chinese STM journals is used to classify, divide, and assign different weights to journal indexes. The weighted scores of each index are collected to obtain the total score of the evaluated journals and the ranking within the scope of the subject and in the range of journals: the higher the value of the comprehensive evaluation index, the higher the comprehensive academic quality and impact level of the journal in its subject area.

Because the evaluation aim, scope, and perspective differ among journal evaluation systems, the index range and corresponding weight distribution are frequently adjusted. Taking the 2015 CHCR (core edition) as an example, the total score of the comprehensive evaluation, looking at the core of the main citation frequency (TC), the core impact factor (IF), the core six indexes of this index (OT), the article funding ratio (NT), citation rate (RE), and open factor (OP), is based on the relative position of the evaluated journal in its subject. These indexes are integrated according to certain weight coefficients.

20.4.3 Indicator Design Method for Academic Journals

Based on the statistics of the evaluation index distribution of the main evaluation systems at home and abroad, the indexes of three or more evaluation systems are summarized. Among them, indexes can be merged; for example, the citation index and mutual index are merged to create citation frequency, and the two-year and five-year impact factor become the impact factor index. The most commonly used indicators in the different evaluation systems are as follows: citation frequency, impact factor, the annual index, the thesis funding ratio, download volume, and the key retrieval system. Among them, the traditional evaluation indicators include citation frequency and impact factor. Citation frequency and impact factor are widely used, appearing in all evaluation indicator systems, and reflect the practice that traditional indicators are more reliable. However, this is also reflected in new emerging indicators. Overall, both domestic and foreign evaluation systems share similar evaluation indicators. A number of indexes—annual index, the ratio of funded papers, and key retrieval systems—are included in three or more of the evaluation indicator systems.

Based on the results of the evaluation indexes of domestic and foreign journals, we summarize and refine the design principle, algorithm design, and the applicability and limitation of citation frequency, impact factor, annual index, the article funding ratio, and key retrieval system (Table 20.17).

Design Principle

Among the main indexes used to evaluate journals, the majority relate to citation rate. This stems from Garfield's citation evaluation with citation frequency and impact factor. The main evaluation index of the domestic and foreign journal evaluation system is based on the relationship among citation frequency, influence factor, and annual index. The impact range, depth, and efficiency of the journal are measured separately. The article funding index originated from China, and ISTIC was the first to adopt this index in the selection of Chinese STM journals, thus promoting the extensive influence of the article funding ratio. The article funding ratio is based on whether an article has received government funding; it is generally believed that funding indicates research trends in the field of research. To

Table 20.17 Evaluation index attributes

Property	Total citation	Impact factor	Immediacy index	Funded papers rate	Information important for the retrieval system
Design principle	Journal citation relations	Based on the citation relationship, combined with the volume of postings and the cited batches	Journal citation relations	Is the paper funded?	The information of the retrieval system
Algorithm design	In a statistical source, the total number of papers published by a particular periodical since its inception has been cited in the journal of statistical sources	The average citation rate of journal papers, that is, the ratio of citation quantity and number of journal papers	Papers published in the year of the journal that were cited	The proportion of papers funded by national, provincial level and other important funds in periodicals	Statistics on the number of times a periodical is retrieved
Applicability	The total cited frequency is applicable to the evaluation of basic research results, showing the extent to which the journal has been used and valued, and the breadth of the measures affected	The influence factor is suitable for periodical comparison in the same subject, and the influence factor is helpful to measure the periodical's knowledge communication ability and academic influence	Immediate reaction rate of periodical measure in the period of annual index	The fund thesis is advantageous to highlight the output of the project	The recognition degree and influence of periodical evaluation system by domestic and foreign periodicals
Limitations	Without considering the subject area, publication time and so on, the difference of the citation opportunity is not considered; the importance of the paper in the citation network is not considered	It is easily influenced by human factors, and the influence factors can be increased by self-citation	The measure time span is small, and can be influenced by the discipline and so on.	It is easily influenced by human factors, and the proportion cannot reflect the difference of different funds; unreasonable evaluation of nonfunded papers	The evaluation angle is single; it is not easy to quantify; it is more suitable for reference index of evaluation results
Application	Widely used, domestic and foreign periodicals to evaluate the influence factors of SCI, CSTPCD, etc.	Widely used, domestic and foreign periodicals to evaluate SCI, CSTPCD, etc. are selected cited frequency	Widely used in the evaluation of domestic and foreign periodicals by SCI, CSTPCD, etc.	Mainly used in the evaluation of Chinese periodicals CSTPCD and GCHC	Widely used, by Ei, Scopus, CSTPCD, etc.
Data sources	JCR etc.	JCR etc.	JCR etc.	CJCR etc.	webpages

study the scope or focus of research, the article funding ratio can reflect the academic quality of journals. The inclusion of a key retrieval system concerns statistics on whether the journals are included in key domestic and foreign retrieval systems. For example, if a journal is included in an authoritative and respected system such as SCI, this reflects the high academic quality and international influence of the journal.

Algorithm Design

The total citation frequency is the cumulative sum of citations and impact factor refers to a certain time span, based on either two-, three-, or five-year impact factors. That is, the annual index is cited in CSTPCD, and the funded papers and the active papers mean all papers are accounted for. It can be seen here that there are differences in the perspectives of various index measures, which can be used to evaluate the journal by the accumulated degree of impact and different time periods.

Applicability and Limitations

Regarding applicability and limitations, total citation frequency is a cumulative approach that is more appropriate for basic research subjects regarding the impact of the measurement. The timeliness of the subject is not very applicable. However, the publication of the impact factor of journals with an early publication time provides a larger window for publication, and therefore a greater chance of citation. There is less evaluation of the total citation frequency compared with journals that were published later. Garfield, based on the optimization of the total citation frequency index, stated that the influencing factors are a combination of time, the volume of journals, and citation rate. Impact factors have their limitation in that they are only applicable to the comparison and evaluation of the influence and communication ability of journals under the same subject. The annual index reflects a journal's annual efficiency, and the effect factor is only applicable to the comparison of journals within the same subject area. In view of the above index only applying to the same discipline under journal evaluation, the journal evaluation system has continued with its unceasing optimization and consummation of subject classification. Interdisciplinary journals can include a range of disciplines under the index evaluation.

Application and Data Sources

Citation frequency, impact factor, and the annual index are evaluation indexes used by JCR. These are widely used in most evaluation systems, with the continuous improvement and optimization of traditional indexes. In this chapter, we propose derivative indexes and composite indexes for evaluation, which provide a new perspective for the rational and scientific evaluation of journals. The article funding index was first used in the selection of STM journals in China. The 2001 citation report and the 2008 core journal index have increased the number of indexes they use; journals are usually included in the systems' official websites, which is mainly used in the journal evaluation system, and is an important reference index for evaluating journals.

The main indicators of Chinese and foreign evaluation systems are citation frequency, impact factor, annual index, article funding ratio, and key retrieval system. These measure the impact of the scope of the journal, depth of influence, the rate of reflection and influence, the measure of the journal, the time frame of different measures, and the difference of measurement content, and are widely applied to the main journal evaluation systems at home and abroad. Therefore, the index of citation frequency influences the journal and academic quality in the rational and scientific assessment of different dimensions.

20.5 China's STM Journals: The Development of the Boom Index and its Monitoring Function

20.5.1 Introduction to Chinese STM Journals

In 2013, a total of 9877 periodicals were published in China; that is, the average quantity of printing for each issue is 164.53 million copies, and the quantitiy of printing for total issues is 3.272 billion copies. Total quantity of impression is 19.47 billion pieces, costing 25.335 billion RMB Yuan. Compared with 2012 rate, this represents an increase of 0.1% in new titles, and the average quantity of printing for each issue droped by 1.87%. Furthermore, the quantitiy of printing for total issues showed a 2.26% reduction, the total quantity of impression was down 0.67%. However, the costs increased by 0.26%.

During the period 2009–2013, the number of Chinese journals increased slightly in 2011. However, there was a decline in the total number of journals for 2012–2013, and the average period of Chinese journals declined continuously. Regarding total prints and total sales, these showed a decrease in 2013, while the cost of journals increased.

Compared with the publication numbers of other Chinese journals, STM journals in 2009–2013 have shown periods of growth and decline (Table 20.18).

Table 20.18 Publication of Chinese journals in 2009–2013

Indicator of China's periodicals	2009	2010	2011	2012	2013
Number of natural science and technology periodicals (A)	4926	4936	4920	4953	4944
Number of periodicals (B)	9851	9884	9849	9867	9877
A/B (%)	50.01	49.94	49.95	50.20	50.06

The number of journals decreased in 2012 and 2013, whereas previously the number had increased by 0.18%. The total number of STM journals in China has accounted for about 50% of the total of journals for many years. The values for STM journals in 2013 are as follows: the total of 463.44 million copies printed with total 3.7941 billion units of printing paper. Compared with the previous year, the number of total copies printed was down 4.58%, and the number of total units of printing paper decreased by 0.01%. Thus, in 2013, while the content of Chinese STM journals remained basically unchanged, there was a decrease in the printing volume of journals and the price increased.

20.5.2 Core Chinese STM Journals

The ISTIC was set up by the Ministry of Science and Technology, and since 1987 it has engaged in the statistical analysis of Chinese STM papers. This then led to the development of the CSTPCD. The data from the database is used to annually classify and analyze the status of Chinese scientific research output. The statistical analysis results are regularly published in the public arena in the form of annual research reports and press releases. A series of research reports have been published to provide decision-making support for government departments, universities, and research institutions.

Journals of Chinese STM papers and citation databases are called Chinese STM journals. Selected Chinese STM core journals (the statistical source journals of Chinese STM papers), after rigorous peer review and quantitative evaluation, represent quality research in the field of Chinese science and technology, and they reflect the level of development in that subject area. Furthermore, it has established a dynamic exit mechanism for the selection of Chinese STM core journals. To study the scientific indexes of Chinese STM core journals, we can determine the development of Chinese STM journals, and outline the research power of various disciplines in China. The data source of this chapter's journal index is core Chinese STM journals. The 2013 CSTPCD includes the core Chinese STM journals. There were 1989 core STM journals, five less than in 2012. The number of core Chinese STM journals has declined for the second consecutive year (Table 20.19).

The distribution of the subject area of the 1989 Chinese STM journals in 2013 is as follows: industrial technology (37.31%), medical and health (33.32%), basic science category III (15.03%), agriculture, forestry, and fishery (7.83%), and other categories (6.52%). Compared with the past five years, the total number of journals has declined slightly, and the proportion of the total number of journals in the five major categories has changed little. However, compared with 2012, the proportion of basic science and agriculture, forestry and fishery has increased, the proportion of medical and health journals has declined, and the proportion of industrial technical journals has increased.

In the selection of core Chinese STM journals, the proportion of industrial technical journals and agriculture, forestry, and fishery journals is smaller than that of other journals. This indicates that the overall level of industrial technology and agriculture, forestry, and fishery journals requires some improvement, and we should pay more attention these journals in the future.

According to the statistical analysis of the 2009 Urich's International Journal Guide, the world's STM journals make up 30% of all journals, and comprehensive STM journals account for just 3%. Compared with the number of Chinese STM journals, the proportion of comprehensive journals in China is larger than that worldwide, and the proportion of medical and health journals is consistent with the world trend.

20.5.3 Citation Reports of Chinese STM Journals

In 1997, the China Scientific and Technical Papers Statistics and Analysis project group published the first *China Science and Technology Journal Citation Report*. The research group has published a new edition of the scientific and technological journal indicators. The data used in the citation reports of Chinese STM journals (core editions) are taken from ISTIC's CSTPCD. The database includes the most important scientific and technological journals in China, thus journals become statistical sources, subject to annual dynamic adjustments. By 2014, there were 1989 statistical sources of scientific papers in China. This represents the statistical analysis of the overall situation of Chinese STM papers, as well as the development of tracking research in Chinese STM journals. This has formed an annual report on China's core STM journals outlining the measurement indicators of the system. In addition, it promotes the development of Chinese STM journals and provides an evaluation basis for journal and journal management.

Table 20.19 Core Chinese STM journals 2009–2013

Year	2009	2010	2011	2012	2013
Number of science and technology core periodicals (A)	1946	1998	1998	1994	1989
Number of natural science and technology periodicals (B)	4926	4936	4920	4953	4944
A/B	39.51%	40.48%	40.61%	40.25%	40.23%

To select the core Chinese STM journals, the institute also began publishing its *Citation Report of Chinese STM Journals* (full edition) in 1998. From 2007 onwards, an expanded version of the citation report has been jointly published by ISTIC and Wanfang Data–Digital Periodicals, covering more than 6000 Chinese STM journals.

Index Analysis of Chinese STM Journals

To ensure the comprehensive, accurate, impartial and objective evaluation and use of journals, the ISTIC's citation reports are consistent with the international evaluation system. Based on the actual situation affecting Chinese journals, the *2013 Citation Report of Chinese STM Journals' Citation Report* (core edition) selected 23 measurement indicators, and the 2014 report (core edition) added a further measurement index: core open factors. These indicators basically cover and describe the various aspects of the journal. Indicators include:

(1) The journal's citation-based indicator of measurement: the core total citation frequency, core impact factor, core annual index, core citation rate, core citation number, core diffusion factor, core open factor, core authority factor, and core citation half-life.
(2) Journal source measurement index: source literature, document selection rate, reference volume, average citation rate, average number of authors, region distribution, mechanism distribution, overseas thesis ratio, article funding ratio, and reference half-life.
(3) Index of journal measurement in subject classification: total score, subject diffusion index, subject impact index, deviation ratio of the core total citation frequency, and the deviation of the core impact factor.

Among these, the journal citation measurement index mainly shows the journal's degree of use and value by readers, as well as its position and function in scientific communication, which is an important basis and objective standard to evaluate the influence of journals.

Through the statistical analysis of source literature, this chapter comprehensively describes academic level, editorial status, and degree of scientific communication of the journal, which is also an important basis for evaluating journals.

The comprehensive evaluation score is a comprehensive description of the overall position of the journal.

Table 20.20 shows the changes in the main measurement indicators for STM journals from 2001 to 2013. Since 2001, the important indicators of Chinese STM journals (except those pertaining to foreign journals) have remained unchanged. Furthermore, the values of the remaining indexes are increasing. The total citation frequency and impact factors have improved every year, of which the average citation frequency of 2011 Chinese journals finally exceeded 1000, reaching 1022 citations. This rate was 1023 in 2012 and 1180 in 2013. The 2013 rate is 5.2 times greater than the 2001 rate, and the core impact factor rose to 0.523 in 2013, twice that of 2001. These two indicators are important indicators reflecting the impact of STM journals. The annual index, that is, the citation rate of the paper in the year since 2001, has gradually increased, reaching 0.072 in 2013. The article funding ratio shows the proportion of all papers in China's core STM journals that receive state/provincial-level funding or from other key funding areas. This is also an important index to measure the academic quality of journals. From 2001 to 2013, core Chinese STM journals with funded articles show an annual increase. This rate was 0.056 in 2013. That

[a] Paper with at least one author affiliated with an organization outside mainland China

is, of the 1989 core STM papers published, more than 50% of the papers are funded by the state. One of the indicators showing the international level of the journals, the rate of overseas papers, remained the same, staying between 0.01–0.02 (0.01 in 2007 and 2008). The average number of authors and citations have increased annually, from 3.26 and 7.36 in 2001 to 4.0 and 15.9 in 2013, respectively.

Regarding core citation rates, these show almost linear growth by 2011. The 2012 core average citation rate represents a significant slowdown, almost the same as the 2011 rate. However, in 2013, the core average citation rate increased to 1180. Table 20.20 shows the average core impact factor and the average core annual index for 2001–2013. The growth in the average core impact factor peaked in 2007, and after five years of decline, it increased again in 2012–2013, higher than the 2007 rates (0.493 and 0.523). The average core impact factor for 2001–2013 shows a steady upward trend, peaking in 2003. This was followed by a five-year decline, a three-year fine-tuning period, and then an increase in 2012–2013 to a high of 0.072. This shows that despite the fluctuations in the citations of the core Chinese STM journals, they now enjoy a steady increase.

At the same time, the average number of core Chinese STM journals has continued to increase, while the growth of average core influence factor in 2001–2013 has slowed. The core average of total citation frequency and the core average impact factor peaked in 2003, slowing from 2004 onwards. The growth of the average total citation frequency between 2004 and 2013 experienced three troughs, in 2004, 2008 and 2012. Interestingly, each trough is followed by three years of growth, but then falls again. The growth rate during the nadir period shows a gradual decrease. The 2012 growth rate is almost 0, while the growth rate of the core journals in 2013 increased again, reaching 0.153 for the first time in nearly four years. The average core impact factor experienced three troughs between 2004 and 2013 (i. e., in 2005, 2008 and 2011), and the growth rates of the average core factors in 2008 and 2011 were 0.05 and 0.02 respectively. The 2008 rate is the lowest for the period (−0.05), the average core impact factor did not increase, and the average core factor increased in 2012–2013, with a growth rate of 0.086 in 2012.

According to the index analysis of papers published by STM journals, the number of key funding grants and papers published in STM journals reflects the academic quality and the level of journals. For academic journals especially, this index appears to be very important. The publishing of foreign articles is an important index of a journal's level of internationalization. The article funding ratio increased from 0.34 in 2001 to 0.47 in 2006, and then experienced a slight decline for 2007–2008. It enjoyed an increasing trend during 2009–2011 reaching 0.56 in 2013. Thus, more than half of the papers published are supported by funding or grants from provincial and ministerial-level government departments.

In recent years, China has worked hard to increase its investment in scientific research. The success of the 11th Five-year Plan has meant that a large number of scientific research projects have produced many scientific papers. Overseas papers have remained at 2% since 2001–2006, falling to 1% in 2007–2008, and climbing to 2% in 2013. This shows that the international volume of Chinese STM core journals has been hovering at 1–2%, and therefore Chinese journals have a low level of internationalization.

The average citation index refers to the average reference quantity of each paper in a journal. It is a relative index to measure the degree of scientific communication of STM journals and the ability to absorb external information. Furthermore, the standardization of reference documents is also an important index that reflects the standardization degree of Chinese academic journals and the integration of international scientific research. The average citation number of core Chinese STM journals increased between 2001 and 2013, with a slight decrease in 2007 (however, 2007 also represented the first time the rate rose above 10, reaching 10.01). The average citation rate in 2013 was 15.9, 2.16 times that of the 2001 rate.

Over the past 20 years, there has been a noticeable development within the statistical and analytical research contained in Chinese STM papers. Furthermore, with the extensive publicity of the evaluation system of STM journals and with more and more Chinese and international researchers, researchers now pay greater attention to the completeness and standardization of articles. Aware of the importance of bibliographic references, a vast number of STM journal editors are acknowledging that the preservation of the objective of reference documents is an important channel for journals and academic exchanges. Therefore, the average number of citations has gradually improved. From 2001–2012, the average number of authors in Chinese STM journals hovered between 3.26 and 3.92. In 2013, the average number of authors reached 4.

The Status of Core Chinese STM Journals

In 2013, there were a total of 1989 core Chinese STM journals. They published 502 393 papers, a 1.49% decrease since 2012. On average, for each core journal, there are 252.59 source articles.

The quantity of source literature, that is, the quantity of the journals, refers to the amount of information contained in the journal, specifically the number of papers published in a journal year. It should be noted that Chinese STM papers and citation databases in the collection of papers refers to the choice of journal papers. We refer to the volume of papers that are in academic journals of scientific papers and research bulletins. These present research findings on new technologies, materials, processes and new products, and include research papers on basic medical theories in medical journals and important clinical practice summary reports as well as literature reviews.

In 2013, there were 623 journals that included more sources of literature than the average number of Chinese journals (in 2012 there were just eight). There were five journals with more than 2000 documents, with one including 2367 articles. There were journals with more than 1000 papers.

Between 2004 and 2013, the propotion of the journals whose number of publishing paper each year is no more than 50 showed a steady decline. Papers published in 100–200 journals accounted for the highest proportion. These show an overall slight downward trend. In ten years of core Chinese STM journals, 40% of all journals were included in 100–200 journals; the proportion of published articles in 50–100 journals has declined since 2004. The proportion of other journals is increasing, which shows that the information capacity of China's core STM journals is expanding and the volume of journals is increasing.

In this chapter, we also use statistics to determine the relation between subject classification and the region of article numbers of a journal. The percentage of basic subjects journals is 61.3% in regions where the volume of article is less than or equal to 50, which is much higher than that of the other four categories (engineering, agriculture, medicine, others). With an increasing volume of papers, the proportion of basic subject journals declined sharply, and the proportion of basic subject journals fell to 5.76% in regions with a volume of more than 500. Regarding the category of agriculture, forestry fishery, and husbandry compared with other three subject clusters (basic science categories, medical and health categories, industrial technology categories), the proportion of journals varies little in each region where the amount of papers is distributed. Journals in the medical and health categories show a decrease in volume and the proportion of journals obviously decreased. In regions where the volume is less than 300, the proportion of journals shows a near-linear decrease. Industrial technology journals in regions with a volume greater than 50 have a small distribution, between 36.55% and 39%, and the proportion of journals in regions less than 50 is sharply reduced to 18.75%. This shows that industrial technology and medical and health journals are distributed in larger areas, and basic science journals are distributed in more regions but in smaller volumes.

Subject Analysis of Core Chinese STM Journals

Compared with the previous version, the *2013 Citation Report of Chinese STM Journals* (core edition), shows considerable changes to the journal subject classification. The 2013 version is the latest implementation of the Discipline Classification and Code (national standard Gb 113745). We will use core Chinese STM journals to redefine the subject. The original 61 disciplines have been expanded to 113 disciplines. The 2014 edition of the citation report was further adjusted, adding two new subjects. Furthermore, the subject classification of journals was adjusted and divided, and interdisciplinary journals were classified as two or three subjects. The new subject classification system embodies the development and evolution of scientific research disciplines, which is more in line with the overall situation of the development of science and technology in China and the actual distribution of Chinese STM journals. In 2013, 1989 core Chinese STM journals covered various disciplines. *The Journal of Engineering Technology University*, the *University Journal* and the *Journal of Medical Universities* occupy the top three rankings, and the *Journal of Engineering and Technology University* is 108th. In all core journals, as the top proportion part, there are 13.68% of them are the academic transactions or journals of universities (including comprehensive universities, polytechnic universities and medical universities). For example there are 108 journals of polytechnic universites in all 1989 core journals. As a China characteristics, big number of journal of universities is a major force of Chinese STM journals.

The average impact factor and citation frequency of core Chinese STM journals in 2013 was 0.523 and 1180, respectively. A total of 58 subjects have impact factors higher than the average, representing 11 more than in 2012. Furthermore, there are 52 subjects with higher-than-average citation frequencies (ten fewer than in 2012). The top three impact factors were in grassland, atmospheric science, and geography, and the top three citation frequencies were ecology, nursing, and civil engineering. The influence factor has a strong correlation with the subject field, and the impact factors of different disciplines show clear differences. Because of the significant difference among subjects, we focus on the subjects' 2013 values.

For all 115 subjects in 2013, the midian value of total citations is more than 1000 times in 34 subjects. Among these, medical and health journals accounted for 50%, industrial technical journals accounted for 20.59%, basic science journals accounted for 17.65%, and agriculture, forestry, and fishery journals accounted for 8.82%. The top three subjects were ecology, nursing, and ecology. Geography, atmospheric science, and ecology are among the higher values of the 2013 discipline factors. Subjects with lower impact factors include comprehensive, metallurgical technology, and mathematics. Therefore, it is necessary to compare the impact factors of STM journals with the average level of the subject.

A Regional Analysis of Core Chinese STM Journals

The regional distribution number refers to the number of regions covered by the author of the source journal, which is calculated according to China's 31 provinces (municipalities).

Generally speaking, the geographical distribution of a journal can be used to determine whether the journal is a more widely covered journal, its influence in the whole country, and whether the regional distribution covers more than 20 provinces (cities). Journals meeting these criteria are considered national journals.

After 2004, the number of journals in China's core STM journals was more than or equal to the 30 provinces (cities), with 2011 having the largest number of journals, 106 in 2012, and an increase of 5% in 2013.

The regional distribution of more than 20 provinces continues to increase, with more than 64.23% of all journals. That is, in 2013, more than 64% of the journals are national STM journals. Moreover, the proportion of journals with a regional distribution of less than ten continues to decline.

Publishing Cycle of Core Chinese STM Journals

Because the speed of publication is an important basis of scientific discovery, the shorter the journal publication period, the stronger the ability to attract excellent manuscripts, and the higher the impact factor. Research shows that the publishing cycle of China's STM journals is reducing annually.

In 2013, the publishing cycle of China's core STM journals was further reduced, and monthly publications rose from 28.73% in 2007 to 37.45% in 2013. Additionally, bimonthly publications decreased from 52.49% in 2007 to 48.82% in 2013, as more bimonthly journals became monthly journals. Quarterly journals fell from 13.22% in 2008 to 9.6% in 2013. Compared with journal publication periods in 2012, the number of journals remains basically unchanged in all other periods. While the overall publication cycle of STM journals has been shortened, close to 50% of journals are published bimonthly.

From a classification perspective, basic science journals and those on agriculture, forestry, and fishery and comprehensive journals have relatively long publishing cycles, and quarterly and bimonthly ratios account for about 70%, which shows that in these three categories, journals are mainly published as quarterly or bimonthly journals. The publication cycle of basic science journals is:

- Quarterly: 22.54%
- Bimonthly: 49.21%
- Monthly: 26.98%
- Others: 1.27%.

For industrial and technical journals: 58.18% are published as either quarterly or bimonthly journals, up from 57.83% in 2012. In other words, more than 50% of the journals in industrial technical journals are quarterly and bimonthly, and this is 10% higher than the proportion of basic science, agroforestry, and other journals. The distribution for medical and health journals is: 46.63% of journals in this field are published as quarterly and bimonthly journals, and 53.37% are published monthly. Thus, more than 50% of the medical and health journals are monthly. 2012 data does not contain information on fortnightly and weekly publications, so no comparison can be made.

The world's largest journal directory guide, the Ulrich Journal Guide, surveyed 50 443 academic journals and found that quarterly journals accounted for nearly 30% of the total number of academic journals. Furthermore, quarterly, biannual, bimonthly, annual, and monthly publications accounted for 80.9% of the five publication cycles. Thus, for academic journals around the world, the quarterly journal is the most important publication cycle, accounting for 29.5% of all journals; this is followed by semiannual, bimonthly, and annual editions. Unlike in China, bimonthly publication is not the most common format.

In 2013, the JCR included a total of 8194 journals, with a diverse range of publication cycles. There were 37 types of publication cycle, with a maximum number is 60 issues per year and a minimum number is 1 issue per year. To facilitate our comparison with Chinese journals, we will include JCR journals according to the publication period, reducing the number of categories. We will merge weekly and more than weekly journals as a weekly comparison with Chinese journals. For example, 26 kinds of JCR journals are published weekly, whereas there is only one weekly journal in China. Sixty are published annually. The weekly journal and the 26 other more than weekly journals are merged into 27 weekly journals to aid in our comparison with Chinese journals.

It is clear that the 2013 JCR includes the largest proportion bimonthly journals (33.72%), followed by quarterly (28.08%), monthly (27.29%), and then triannual, semiannual, and annual (6.73%). Regarding China's

2013 core STM journals, the largest percentage are bimonthly publications. The JCR includes bimonthly, quarterly, triannual, and annual publications (68.53%). China's core STM journals published bimonthly and quarterly make up 58.43% of such journals (there are no triannual, semiannual, and annual journals). Therefore, the publication cycle of core Chinese STM journals is shorter than that of the journals in the JCR.

The 2013 content of SCI includes the distribution of 139 Chinese STM journals. The publication of journals has also diversified. In contrast to 2012, the proportion of monthly journals in 2013 (35.97%) exceeds bimonthly publications (34.53%). These two formats are followed by quarterly journals (26.62%), which has declined since 2012. Despite the increase in the monthly ratio, the ratio of bimonthly and quarterly journals is still high, at 61.15%, in line with the publication cycle of journals in the JCR.

20.5.4 An International Comparison of Chinese STM Journals

We now compare the average citation frequency, average impact factor, and average annual index of core Chinese STM journals and JCR journals for 2011–2012. The values for these three indicators have increased for JCR journals, which is consistent with the growth of China's core STM journals. However, our absolute value is not at a comparable level to international journals. International journals enjoy much higher scores than core Chinese STM journals. The average citation frequency and the average impact factor are four times higher than the annual index, which is six times higher.

In the issue of number of articles, China's core STM journals and journals covered by JCR are very different. In the region of volume of articles of more than 100, the percentage of core Chinese STM journals is obviously higher than JCR journals. The percentage of China's core STM journals are significantly lower than that of JCR journals when we look at the proportion of the journal in areas where number of papers is less than 100. Regarding areas where the paper number is less than 50, the gap is particularly obvious. China's core STM journals account for 1.61%, and JCR journals account for 33.35%, 31.96%, and 32.26%. China's core STM journals published more than 100 papers, accounting for more than 82% of the total number of journals. The total number of JCR journals publishing more than 100 papers is less than 44%. The number of journals with less than 100 papers accounts for more than 60% of the total number of journals. This shows that the number of papers published in Chinese STM core journals is higher than the number of papers published by JCR.

In 2013, the SCI database included 139 Chinese journals (Table 20.21). The main evaluation indexes of JCR include total citations, impact factor, immediacy index, current number of papers, and article half-life (citation life). One of the most important indicators is the ranking of the journal in this discipline according to its impact factor (journal rank in categories). The impact factor is used to determine whether a journal is considered a Q1 journal. A Q1 award shows that the journal is a top-ranked journal in that particular discipline and it can also be called the top academic journal in that subject area. Based on the impact factor, a journal will be either a Q1, Q2, Q3, or Q4 journal.

The influence factors of JCR-selected Chinese journals in 2013 concern various subjects. A total of eight journals gained a Q1 ranking (compared with seven in 2012), and 34 are Q2 journals (six in 2012). There were 42 Chinese STM journals in 2013 ranked in the middle of the subject (and only nine in 2012). According to data from 2009 and 2011–2013, we note a gradual increase in the number of Chinese journals entering their corresponding disciplines.

In 2013, the following retrieval systems included Chinese STM journals: SCI, 139 journals; Ei, 216; MEDLINE, 106; SSCI, 2, and Scopus, 776.

The quality of Chinese STM journals has also undergone a process of development and change. In 1987, SCI selected only 11 Chinese journals, accounting for 0.3% of journals worldwide, and Ei selected 20 Chinese journals. For more than 20 years, the ranking of Chinese STM journals has been improving, and their influence in the world retrieval system has become greater. The number of China's STM journals is slowly growing, and have now passed the stage of quality improvement. Our aim is for these journals to move towards a stage of comprehensive revitalization.

20.5.5 Development Survey of Chinese STM Journals

Development Policy of of STM Journals

The relevant policies of management departments at all levels regarding STM periodicals play an important role in the development of these journals. A question-

Table 20.21 The number of Chinese STM journals included in SCI and Ei 2002–2013

	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013
SCI	69	78	78	78	78	104	108	115	128	134	135	139
Ei	108	119	152	141	163	174	197	217	210	211	207	216

naire on impact factors and the development of Chinese STM journals has investigated concerns relating to the development policy of STM journals. Of the 541 questionnaires collected, 66.17% of respondents expressed great concern, 26.5% expressed concern, 5.5% said they were aware, and only 2.03% answered that they were not sure. The investigation shows that the relevant personnel of STM journals pay attention to "the relevant policies of the development of STM journals".

In the survey respondents were given the following statement: "The existing policy adapts to the development of your journals". A total of 348 (64.33%) respondents stated "basic adaptation" had occurred, indicating that the majority of respondents affirmed the policy of STM journals. In contrast, 193 respondents selected "further promotion required", accounting for 35.67%, indicating that the relevant policies for the development of STM journals still need to be improved and upgraded. Finally, 193 respondents answered that the existing policies have not adapted to the development of STM journals' specific performance. This mainly relates to evaluation system, management system, system reform, policy guidance, and support efforts. Additionally, 74 respondents mentioned the issue of scientific evaluation, accounting for 193 responses of "concrete performance" (38.34%). This largely refers to the establishment of the evaluation of STM journal targets, a STM journal evaluation body to address negative journal development, as well as scientific research personnel, organizations, research results, and so on. The contrary of direction between appraisal targets cause the disadvantageous influence for STM journal development. Forty-one respondents (21.24%) regarded the specific performance of STM journals as a "concrete performance". This includes the strengthening of funds, manpower, technology and other support issues. It also refers to the support for Chinese journals, English-language journals and others. Support also needs to come from the director, as well as sponsorship support. Thirty-three (17.09%) respondents answered "concrete performance" regarding reform efforts. This includes the specific issues of autonomy and marketization. Furthermore, 23 (11.91%) respondents answered "concrete performance" in the management of STM journals. This referred to the issue of examination and approval, academic journal identification, and other specific issues. Seventeen (8.9%) respondents also stated "concrete performance" regarding the unclear policy orientation of STM journals. A further five respondents mentioned the quality of science and technology journals, new media applications, digital issues, and other specific problems.

In recent years, the State Administration of Radio, Film, and Television (SARFT), the Ministry of Science and Technology, CAS, and other competent departments involved in STM journals have proposed a number of policies to promote STM journal development. In 2000, the Ministry of Science and Technology, through its *Strategic Study of China's Fine Science and Technology Journals* and *China through the Service and Guarantee System of Fine STM Journals*, proposed the concept of *Quality Chinese STM Journals* and sought to promote the construction of quality STM journals. In 2011, the Central Committee of the Communist Party of China and the State Council aimed to "deepen the reform of the nonpolitical publishing system", and implement the reform of the publishing system governing nonpolitical newspapers and journals. In 2013, the Chinese Association of Science and Technology, Ministry of Finance, Ministry of Education, the General Administration of Press and Publication, SARFT, CAS, and the China Institute of Engineering made efforts to implement the *Program to Promote the International Influence of China's Scientific and Technological Journals*. The aim was to promote the internationalization of STM journals. This is the largest and most far-reaching financial aid project in this area to date. On 14 April 2014, SARFT reported intentions to standardize the publishing order of academic journals to promote their healthy development. On 11 September 2014, plans were announced to carry out the accreditation of academic journal qualifications, and on 18 November, the first list of identified academic journals was publicized. On 15 May 2014, CAS and the Natural Science Foundation issued a policy statement: public funds would be made available for scientific research projects to promote open access to scientific research. On 18 August 18 2014, at the fourth meeting on the comprehensive and deepening reform, the Central Committee considered the adoption of guidance regarding the promotion of the integration of traditional media and emerging media, and the wave of convergence between traditional media and new media. This was an issue of general concern and received many responses from STM journals.

In the questionnaire survey on impact factors in the development of Chinese STM journals, 541 respondents responded to the statement about "the influence of the existing STM journal policy on the impact of your journal". Of the six listed responses, the respondents answered as follows: speeding up the integration of new media, 52.68%; the transformation of nonpolitical journals into enterprises, 29.94%; the examination and identification of academic journals, 41.96%; the promotion of international influence of journals, 54.71%; the construction of quality journals, 57.86%; and the proportion of open acquisition of scientific papers funded by public funds, 27.36%. In addition, 24 respondents suggested other specific policies, which relate to the evaluation of STM journals and their impact.

The questionnaire also investigated the role of the relevant policies and measures of management at all levels. According to the results for multiple selection, 409 (75.6%) respondents considered that the relevant policies and measures of the organization level had a great effect on the development of STM journals. Furthermore, 344 (63.59%) and 343 (63.4%) respondents selected "national and local press and publication management departments" and "the competent departments and units of journals", respectively, for the development of STM journals. A total of 172 respondents considered that the relevant policies of "social groups such as society" had a great effect on the development of STM journals.

The Competitive Environment of Chinese STM Journals

The questionnaire survey also investigated the competitive environment of Chinese STM journals. When replying to a question concerning "the number of similar journals in your subject", 60.44% of respondents considered that there was an "appropriate" number, indicating that the subject distribution of Chinese STM journals is largely reasonable. At the same time, it should be noted that 31.05% believe that the number of similar journals in the subject is too large, which indicates that the homogeneity of journals in some subjects is a serious problem, raising issues of strong fierce competition and an oversupply of resources. In addition, 8.5% of respondents thought that there were "too few" journals in the same subject area, indicating that there is only a small supply of resources in that discipline. Furthermore, in response to a question on the "competitive strength between your journal and the same subject", 112 (20.7%) replied "very strong", 253 (46.77%) answered "intense", and 166 (30.68%) answered "average". The results show that there is strong competition among Chinese STM journals.

The questionnaire also investigated the main aspects of competition among Chinese STM journals. According to the survey results, 95.19% of the respondents stated there was competition regarding "author and manuscript". At the same time, competition between Chinese STM journals and other journals was reflected in readership, funding, reporting speed, reviewers, and editors (34.38%, 29.57%, 24.77, and 20.33%, respectively).

When responding to a question about the "management policy of the same kind of journal", 416 (76.89%) respondents indicated that "guiding the construction of characteristic journals and reducing the degree of homogeneity" were important. A total of 348 (64.33%) respondents considered that "controlling quantity, supervising quality, and maintaining a healthy competitive environment" were effective policies. A total of 276 (51.02%) and 267 (49.35%) respondents selected "focus on helping the strong colleagues to eliminate low-level duplication of the journal" and "decentralization, encourage the innovation of scientific and technological journals", respectively. These results are very similar.

20.5.6 Development of the Chinese Science and Technology Boom Index

The Compilation of the Boom Index of STM Journals

The boom index of STM journals refers to the creation of a synthetic index (CI), the index of a comprehensive STM journal industry that includes demand, supply, policy, cost, and income. These features make up the boom index of STM journals. The boom index of STM journals is a dynamic and comprehensive industry index that can reflect the prosperity of the industry. It also monitors and predicts fluctuations in the STM journal market.

The index compilation method adopted by the industrial boom index is a synthetic index method used by the US Department of Commerce. The National Housing Boom Index is another method that can be used to calculate a synthetic index. The China Purchasing Manager index adopts the diffusion index method, and the development of the Yangtze River Industry index is a comprehensive use of the boom questionnaire and diffusion index.

In this chapter, using the above compiling method for the boom index, we use the synthesis index compiling method of the US Department of Commerce, which will reflect the health of the STM journal industry. The boom indicator system for STM journals includes a synthesis index, a consistent synthesis index, and a lag synthetic index. These will identify any recessions, recovery, expansions, and contractions within STM journals. Furthermore, the boom index has monitoring and forecasting functions.

The Classification of a Prosperity Index for STM Journals

Advance Index (Leading Indicators). The first index refers to the index of peaks or valleys before the macroeconomic fluctuation reaches the peak or trough. The general antecedent index should meet the following conditions: The peak (or valley) point of each special cycle of the sequence is at least three months prior to the reference cycle. This first relationship is stable; that is, there is not much difference between the super prophase and the sequence in the last two cycles. The peak (or valley) of the special cycle should remain ahead, and the lead time is more than three months. The economic nature of the index has a definite and clear antecedent. The first index has an antecedent character. There are are two reasons for this. First, some advance indicators act as forecast indicators of business trends, such as "predicting business conditions". Second, future economic activities will result in business changes; for example, such indicators include hiring new staff, new construction areas, and new residential areas. In many countries, the advance index is regarded as an important basis for short-term forecasts.

There are four leading indexes for STM journals: economic index, policy index, academic environment index, and technical progress index. Scientific research and experimental development funds can be used as an index to evaluate the input, scale, and intensity of science and technology in a country or region. These will reflect the future economic index of the STM journal industry. The policy index mainly determines which policy will be applied to the STM journal industry; for example, the journal quality project and the project for journals with international influence.

Consistent Indicator (Coincident Indicators). The consensus index (also known as the synchronous indicator) of STM journals measures the peaks and troughs and the date of the benchmark economic cycle fluctuations. Therefore, the consistent indicators reflect the current situation of the boom.

The consistent index of STM journals mainly includes:

(i) Sequence overall operation level: the publication scale of journals in the news publishing industry
(ii) Journal group level: based on the point of view of citation networks, the paper extracts the monitoring index of journal group level from the aspects of journal subject, publishing language, and adopting new media technology
(iii) Journal level: reflecting the operation index of STMjournal industry from individual journal level
(iv) Thesis level: to reflect the operating index of STM journal industry from a single thesis level.

Lagging Indicator (Lagging Indicators). The lagging indicator refers to the benchmark turning point, lagging behind the economic cycle fluctuations. The effect of the lag index is that its peak or valley appearance can confirm that the peaks or troughs of the economic fluctuations are indeed appearing.

A lagging index of STM journals includes the following features: qualitative index: a qualitative index that can be used to measure the development level of STM journals, including the status of major international retrieval systems; quantitative index: including the average citation number and reference number of journals; and the liquidity index: refers to the flow of the pyramid structure in the journal hierarchy. At the top of the journal pyramid is the journal sequence of TOP100, followed by quality STM journals, core STM core journals, and general journals.

A lagging index of STM journals includes the following features:

(i) Qualitative index: a qualitative index that can be used to measure the development level of STM journals, including the status of major international retrieval systems
(ii) Quantitative index: including the average citation number and reference number of journals
(iii) And the liquidity index: refers to the flow of the pyramid structure in the journal hierarchy.

The Intrinsic Mechanism of the Consistent Prosperity Index

The consistent prosperity index of STM journals is derived from the statistic index of the STM journal industry. This index of prosperity is compiled by the consistent index of prosperity. According to the selection principle of the boom index and the compilation methods of other boom indexes, the index of the industry prosperity of STM journals is composed of demand, supply, policy, labor, cost, and income.

(i) Production index of STM journals: publication quantity of STM journals; policy indicators of STM journals: quality journals, international influence, funded journals
(ii) Input index of STM journals: scientific research and experimental development outlay
(iii) And employment index of STM journals: number of editorial staff and number of journals. All indexes of STM journals are monthly or quarterly indicators, and the monthly indices are more timely and suitable for use in the boom index. However, statistical indexes are very difficult to obtain for STM journals, and the monthly data collection is very important. Therefore, the index of STM journals uses annual STM journals to meet the requirements.

Indicator System of Boom Index of STM Journals

Principles of Construction. The evaluation index concerns certain characteristic of the evaluation object and its quantitative performance, which not only identifies particular characteristics of the evaluation object (i. e., nature), but also the quantity of the evaluation object and the dual function of qualitative and quantitative cognition. According to the needs of the evaluation task and target, the evaluation indicator system, which comprehensively and systematically reflects a series of evaluation objects, has a relatively complete and structured relationship. The evaluation index and indicator system is a reflection of the whole or part of the subject, and the evaluation index and indicator system accurately reflect the true degree of certain matters. This is the basic guarantee of scientific and technological evaluation results.

The formation of an evaluation indicator system is a complex process because the indicator system itself is a complex system. Furthermore, it is an organic system composed of a series of interrelated evaluation indexes. Therefore, the design of a complete, scientific, and systematic indicator system is not a simple and random process, but a complex process of multiple interconnected features. The SMART (SMART) system is used by the World Bank and many national government departments and organizations as a guideline for the design of evaluation indicators. The SMART criteria essentially provides a description of the basic requirements for general evaluation index design.

It is a complicated task to comprehensively evaluate the prosperity index of STM journals. Therefore, the establishment of an indicator system of STM journals' prosperity index should follow the following principles.

Principle of Purpose. The selected index should be able to objectively describe the essential characteristics of the object and should serve the purpose of the evaluation. The construction of the boom index of STM journals should take any development trends and impact factors of STM journals into consideration.

Principles of Science. This is the basis to ensure that the evaluation structure is accurate and reasonable. That is, the meaning of the indicator system should be accurate and clear. The creation of an evaluation indicator system must be complete, so it can fully reflect the essential characteristics of the evaluation object. There must be a logical relationship between the indicators in the system, and the indexes should be adapted to the evaluation object and the evaluation target. In this way, the characteristics of the boom index of STM journals are reflected from different perspectives. Furthermore, the definition of the index should be clear and exact and the method needs to be scientific to ensure the credibility of the index.

Principles of Operability. All indicators should be able to reasonably quantify and have comparability and realistic feasibility.

The Principle of Completeness. The indexes in the evaluation indicator system must be fully understood and the ability of each cannot be evaluated in isolation. We need to focus on the characteristics of the boom index of STM journals and comprehensively evaluate the index of STM journals in different levels and to different degrees. To fully evaluate the prosperity index of STM journals, the indicator system should be comprehensive and objective, and able to reflect the overall situation of the evaluation object. The design of scientific and technical personnel evaluation indicators need to reflect the requirements of the introduction of scientific and technological journals. Furthermore, the evaluation indicator system should be able to comprehensively reflect the introduction of STM journals and evaluation objectives. The objective elements require comprehensive consideration to achieve the overall goal. Of course, the system should be kept as simple as possible, and this is conducive to the evaluation of the development and evaluation of the reliability of the improvement.

Construction Method. Generally speaking, the methods of scientific evaluation indicator system usually include the following processes:

A. *Evaluation indicator system-building methodology (primary method)*
   The construction of an evaluation indicator system is mainly based on questionnaire surveys, AHP, frequency statistical method, theoretical analysis method, and an expert investigation method (e.g., the Delphi method); thus, the primary indicator system is formed.
B. *Evaluation indicator system test method (preferred method)*
   The indicator system test mainly uses various qualitative and quantitative methods to detect the integrity, systematicness, accuracy, feasibility, reliability, scientificity, relevance, coordination, and redundancy of the indicator system. The method of expert judgment is generally based on quantitative testing.
C. *Evaluation indicator optimization methodology*
   The optimization of the evaluation indicator system structure mainly concerns the depth of the levels, the number of A levels, and the existence of a network structure. It can also be a combination of qualitative and quantitative analysis.
D. *Quantification and treatment of indicators of evaluation*
   Index quantification (i.e., the determination of the index attribute value) usually concerns the quantification of a quantitative index and a qualitative

index. Quantitative indicators are generally quantified and investigated. However, qualitative index quantification can be divided into two kinds: a direct quantification method and an indirect quantification method according to the features of the object. The direct quantification method gives a quantitative quantity (such as the direct scoring method) and a certain quality mark line. The indirect quantification law represents a set of all the possible values of the qualitative index. The value of each unit is converted to a quantity by registering the values of the variable and then quantifying the elements in the *qualitative index set* to that value.

Because the evaluation indicator system reflects the scale and level of the specific evaluation object from multiple perspectives and levels, the evaluation indicator system is an information system that reflects the subject of the evaluation. It also constructs an information system that reflects the whole picture or the important characteristics of the subject. The structure of the system generally includes the configuration of system elements and the arrangement of the system structure. In an evaluation indicator system, each index is the element of the system, and the interrelation of each index is the system structure. An important feature of the system is hierarchy; therefore, in the construction of a STM evaluation indicator system, AHP is generally used to establish the hierarchical structure model of the indicator system. Then, the index is used to filter and optimize the structure of the indicator system.

AHP is a practical multiattribute evaluation method developed by Professor Saaty in 1971. AHP is a combination of qualitative and quantitative analysis, and integrates qualitative and quantitative analysis. It is a simulation of human decision-making processes and can be used to solve complex multifactor systems, especially difficult-to-quantify social systems. Since 1982, the following processes have been applied in China: energy policy analysis, industrial structure research, STM achievement evaluation, development strategy planning, and personnel assessment.

Relying on qualitative analysis and decision-making based on experience, the results often lead to decision-making errors. A large number of mathematical methods rely solely on mathematical models to solve decision-making problems, which places an uneven emphasis on quantitative analysis. For many economic and social problems, it is difficult to rely solely on quantitative mathematical models. Although theoretically speaking a mathematical model seems appropriate, it is not always suitable for decision-making and the prediction of practical activities. Therefore, quantitative mathematical methods are not omnipresent. In addition, there are a number of factors that cannot be quantified in the decision-making process. It is necessary to rely on the experience and knowledge of the decision-maker to make a judgment even if the model is able to quantitatively describe the factors, in order to rationally use quantitative technology and establish the correct mathematical model. Furthermore, the analyst's personal experience and judgment cannot be completely removed and affect the whole process of decision-making. AHP is able to decompose the elements of decision-making into a target, criterion, scheme and so on, on the basis of which the author provides a quantitative description of human subjective judgment.

AHP decomposes a complex problem into several levels, and establishes an ordered hierarchy (i. e., a hierarchical structure model) in which the elements in each level have roughly equal status and have a certain connection with the previous level and the next level. In this way, people's experience and judgment can be expressed and dealt with as a quantity. That is, when comparing the importance of 22 factors, we use the results of 22 comparisons as the elements of the judgment matrix. To obtain each factor's relative importance in the sorting results, we construct the judgment matrix by solving the matrix of the largest feature roots and corresponding eigenvectors. A rigorous logical analysis and statistical test of the results of the comparisons and judgments ensure that the judgment elements and judgment matrices are consistent in the synthesis process.

The main steps of the AHP approach include the following aspects: structuring and systematizing the assessment of the problem, listing the related attributes, and establishing the target hierarchy. The goal-level architecture of AHP can make use of group decision-making or expert assistance, such as Delphi, brainstorming, or nominal group technology. The set of attributes within each level of the target hierarchy is based on the previous level of the target, and by repeatedly evaluating and correcting the selected attributes, the principles of integrity, deconstruction, scalability, repeatability, and minimization are ensured. The evaluation attribute and the paired comparison matrix of different schemes are established under each attribute. After constructing the target hierarchy, we will evaluate the relative importance of these two attributes to the upper level target, and then target any two of the attributes at a certain level. This method enables policymakers to focus on the judgments, and through the analysis of architecture and patterns, they will not lose control of the problem. The relative weights of each attribute and the relative evaluation values of each scheme are computed using eigenvectors. Consistency can be verified either by correcting the consistency requirement or by reopening the comparison matrix for the corresponding attribute.

Construction of the Boom Index of STM Journals

Investigation into the Influential Factors of the Development of Chinese STM Journals. To obtain more accurate and comprehensive indexes, we use surveys to investigate those factors that influence the development of Chinese STM journals. A total of 541 questionnaires were collected.

From the survey results, the existing policy of STM journals has a considerable influence on the construction of quality journals and the promotion of the plan to increase the international influence of Chinese journals. Another important factor is the acceleration of and integration with new media.

When questioned about the most important development aspect, 85% of respondents stated sufficient funding, while 80% responded stable staffing. Furthermore, 54.9% of the respondents thought that STM journals now enjoy a stable development pattern and that the development environment has little influence.

Constructing a Hierarchical Framework for the Boom Index of STM Journals. Based on the questionnaire analysis, this chapter identifies the boom index of STM journals and modifies and perfects the established evaluation indicator system using the expert consultation method. This mainly revolves around whether the evaluation index is reasonable, whether it can fully reflect the introduction of the boom index, and whether it is convincing enough to obtain the opinions of experts.

According to revised views to improve the evaluation framework and indicators system, the experts' feedback will be used to modify the index. After repeated discussions, the final formulation of a complete scientific and technological journals indicator system using a hierarchical structure model is described below.

Indicator description:

- III-1 Scientific research and experimental development funding: refers to the research and development funds provided by national science and technology funding into statistical journals.
- III-2 Chinese Journal Support Fund: selected by the Chinese Science and Technology Association led by the quality of scientific and technical journals to support the project.
- III-3 English Journal Support Fund: the selection of internationally influential journals funded by CAS.
- III-4 The number of new journals: the number of newly established journals approved by GapP each year.
- III-5 New financial support: refers to the increase of national financial science and technology allocations.
- III-6 Total number of journals published: the total number of STM journals published by the General Administration of Press and Publication.
- III-7 Average period in print: the average period of the annual publishing by the General Administration of Press and Publication.
- III-8 Citation frequency: the total average citation frequency of STM core journals.
- III-9 Impact factor: the average impact factor of STM core journals.
- III-10 Annual index: the average annual index of STM core journals.
- III-11 Literature sources: sources of literature.
- III-12 Size of editorial team: number of registered professional editors nationwide; national publishing industry practitioners.
- III-13 Citation average: the average number of citations per STM journal.
- III-14 Article funding ratio: the proportion of provincial and ministerial-funded papers in scientific journals.
- III-15 SCI journals: the number of Chinese journals included in the SCI database.
- III-16 Ei journals: the number of Chinese journals included in the Ei database.
- III-17 MEDLINE journals: the number of Chinese mainland journals included in the MEDLINE database.

The Determination of the Index Weight of the Boom Index of STM Journals. The basic principle of AHP is the principle of sequencing, which is the basis of decision-making. The goal and characteristics of the boom index of STM journals, and the comparison of each level of attributes, constructs a paired comparison matrix between the attributes of the targets. According to the construction of the judgment matrix, and the consistency of the test, the index weights can be determined.

An Empirical Study on the Boom Index of STM Journals

According to the indicator system and its weight of the boom index of STM journals, this section empirically studies the boom index by collecting the actual data from CTPCD.

The data sources used in the empirical study include the following:

- III-1 Scientific research and experimental development funds
- III-2 Chinese journal support
- III-3 English-language journal support: data source uses CAS to lead the Quality Science and Technology Journal Financing Project, the Outstanding

Table 20.22 Boom index of STM journals (1999–2013)

Year	1999	2000	2001	2002	2003	2004	2005	2006
CI	11.37	10.36	503.42	550.10	677.09	732.68	847.69	1000.00
Year	2007	2008	2009	2010	2011	2012	2013	
CI	1091.15	1215.36	1304.49	1227.66	1281.44	1270.49	1091.15	

International Journal Award, and the International Influence Journal Financing Project

- III-4 The number of new journals
- III-5 New financial support: data from the National Bureau of Statistics supporting the funding of research and development (1999–2013)
- III-6 Total number of journals
- III-7 Average period print
- III-8 Citation frequency
- III-9 Impact factor
- III-10 Annual index
- III-11 Source literature (quantity)
- III-12 Professional editors: data are from the General Administration of Press and Publication's annual statistical report (2005–2013)
- III-13 Average number of citations
- III-14 Article funding ratio
- III-15 Number of journals in SCI
- III-16 Number of journals in Ei
- III-17 Number of journals in MEDLINE: data sourced from ISTIC and Chinese Science and Technology Statistics and Analysis (2001–2013).

With 2006 as the benchmark, the remaining years of the boom index were multiplied by the weights of the index values of each level and the 2006 values. Thus, the 1999–2013 boom index of STM journals was calculated as shown in Table 20.22.

As can be seen, the boom index of Chinese STM journals showed a rising trend from 1999 to 2013 (Table 20.21). These results should be interpreted with care because there was a lack of data for 1999 and 2000, and because the index score itself is low, the calculation of the boom index is very small and can almost be considered an outlier.

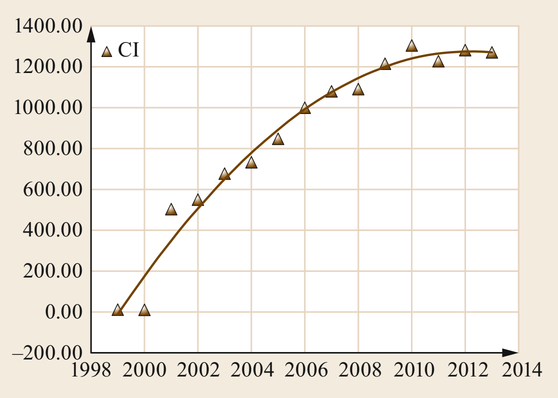

Fig. 20.1 Boom index of Chinese STM journals (1999–2013)

With the 2006 benchmark, the 2006 boom index was calculated at 1000. In the remaining years, the boom index was multiplied by the weights of the indices at all levels and by the 2006 benchmark.

As can be seen from Table 20.22, the 2001 boom index is 503.42, almost half the 2006 value. This result was obtained because prior to 2001, China's STM journals industry boom index was low. Between 2001 and 2006, the boom index maintained rapid growth, with the annual growth rate reaching 26.04%.

Since 2007, the Chinese STM journals industry has stepped up a level, with a boom index of more than 1200 points. Since 2009, the boom index has stabilized at 1200–1300 (Fig. 20.1). However, the pace of growth has slowed accordingly. The average annual growth rate in 2006–2013 was approximately 4.07%. From the above research, the boom index objectively reflects the development of China's STM journal industry.

20.6 The Definition and Application of Comprehensive Performance Scores (CPS) for Chinese Scientific and Technical Journals

STM journals play an irreplaceable role in scientific development and innovation activities, and the scientific progress and sustainable development of journals are the necessary guarantee and key link in the advancement of national science and technology. The research and evaluation results of STM journals are the basic guarantee of scientific decision-making in the management of STM journals and are effective tools to promote the development of STM journals themselves.

Because journal evaluation is a very complicated process that involves a wide range of fields, it is difficult to comprehensively and accurately evaluate the academic level and subject status of a single index. This needs to be evaluated by a comprehensive index, so as to make journal evaluation more objective, comprehensive, and accurate. In the past, the comprehensive evaluation of journals in a particular area was generally divided into two types. One type was experiments based on existing indicators, using mathematical statistical methods or mathematical models for numerical calculation. Methods include principal component analysis [20.36], normalization method [20.37], factor analysis method [20.38], and the rank-sum ratio [20.39]. The advantage of using these methods lies in the objective data that is based on the citation statistic or the literature measure method. The evaluation method is a mature mathematical statistical method. The evaluation process facilitates the public to accept supervision. There are also some limitations in the availability and sustainability of large-scale data. The second approach to the comprehensive evaluation of journals is to adopt AHP or other weighting methods and to summarize several indexes according to the method of normalized weighted calculation. This method has strong operability and applicability, and is often used in large-scale evaluation projects with a large evaluation range, longer time window, complex evaluation indexes, and many evaluation objects. It usually involves the design and creation of a comprehensive evaluation indicator system, using AHP, expert investigation, or other mathematical methods to determine the weights of each index. This is done to find the comprehensive index ranking value and finally to obtain the comprehensive ranking of journal indexes. In the practice of comprehensive evaluation of journals, it is a key technical point to realize interdisciplinary comparison, which is usually achieved by means of standardization [20.40].

20.6.1 Definitions

The comprehensive performance score (CPS) evaluation (hereafter, *comprehensive evaluation score*) of Chinese STM journals is based on the comprehensive evaluation indicator system of such journals. According to the value of periodical indicators in each subject category, the relative position score of each journal in its discipline is calculated, and the comprehensive evaluation score is made up by weighted value of all relative position scores of each indicator.

The annual Citation Report (Core Edition) of China Science and Technology Journals, published by the ISTIC (CSTPCD), regularly publishes measurement indexes of source journals of Chinese STM papers that are cited in other papers [20.41]. Based on that index, the comprehensive evaluation indicator system of Chinese STM journals was developed in 1999 [20.42]. Each index in the evaluation indicator system is not equal to the function of the journal when calculating the total score; thus, different indexes are given different weights. The initial index weight distribution was determined using a Delphi expert investigation method and AHP. Subsequently, with further research and the application of feedback in practice, the new measurement index is continuously supplemented. To assimilate feedback from all walks of life for the evaluation results in a timely manner, the CSTPCD has held more than 20 expert seminars. For those seminars, the institute invited scientific metrology experts, scientists, experts and scholars in science, technology, and journal management to participate. To improve the evaluation system and methods for the current set of scientific and technological journals, the CSTPCD established indicators and assessed weights and adjustments. CPS evaluation is based on the principle of scientific metrology; it comprehensively covers the indexes of evaluated journals. The comprehensive evaluation indicator system of Chinese STM journals is used to classify, divide, and assign different weights to journal indexes; the weighted scores of each index are collected to obtain the total score of the evaluated journals as well as the ranking within the scope of the subject area and within the whole range of journals. Generally speaking, the higher the value of the comprehensive evaluation index, the higher the comprehensive academic quality and influence level of the journal in its subject area.

20.6.2 Index Calculation

In line with the evaluation aims, scope, and angles of different journal evaluations, the index range and corresponding weight distribution are often adjusted when assessing STM journals. Taking the Citation Report of Chinese STM Journals in 2015 (core edition) as an example, the total score of the comprehensive evaluation is the score of the TC, the core impact factor (IF), and the score of six indexes (such as the index (OT), fund thesis ratio (NT), citation rate (RE), and open factor (OP)) according to the relative position of the evaluated journal in its discipline; these indexes are integrated according to certain weight coefficients. The specific algorithm is as follows,

$$\mathrm{CPS} = \sum_{i=1}^{n} \mu_i k_i \,,$$

where n is the index quantity (six indexes) and the weight coefficient of the index, k, is the relative position score of an index of the appraised journal in its discipline. k is calculated as follows,

$$k = \frac{x - x_{\min}}{x_{\max} - x_{\min}} \,,$$

Table 20.23 Calculation of total score of a chemistry journal

Indicator	Value x	Maximum value in chemical science x_{max}	Minimum value in chemical science x_{min}	Relative position score k	Weight μ	Weighted score $^{\mu}k$
TC	2541	4122	100	0.607	26	15.8
IF	1.057	1.954	0.177	0.495	26	12.9
OT	0.87	0.95	0.53	0.810	18	14.6
NT	0.91	0.93	0.24	0.971	10	9.7
RE	51.08	86.45	11.37	0.529	10	5.3
OP	29	60	2	0.466	10	4.7
CPS						62.9

where the value of an index of an evaluated journal is the maximum value of its subject, which is the minimum value of the index of the subject.

The total weight coefficient is designed to be 100; the total score of the comprehensive evaluation is from 0 to 100. The weight distribution of the six indicators adopted in the Citation Report (core edition) of China Science and Technology 2015 was determined using the Delphi expert investigation method. The specific weight distribution was as follows: TC, 26; IF, 26; OT, 18; NT, 10; RE, 10; and OP, 10.

An example appears in Tables 20.23 and 20.24. The index values of a particular chemistry journal in 2014 were compared with the extrema (maximum and minimum) of the corresponding indexes of all chemistry journals. The scores of relative positions of each index were obtained and the total score of the comprehensive evaluation of the journal was weighted.

The same method can be applied for all Chinese science and technology journals to calculate the total comprehensive evaluation score. For 2014, the total comprehensive evaluation score of 38 Chinese science and technology core journals was 62.9, which ranked them fourth in the world. By contrast for 1989, the ranking of all China's scientific and technological core journals was 231.

With respect to calculating the corresponding comprehensive evaluation score, some journals in Citation Report of Chinese STM Journals in 2015 (core edition) covered different disciplines.

Table 20.24 Top ten regions for producing English-language STM journals in China

Rank	Region	Number of English STM periodicals
1	Beijing	167
2	Shanghai	34
3	Hubei	13
4	Jiangsu	12
5	Sichuan	9
6	Zhejiang	8
7	Tianjin	7
7	Jilin	7
7	Guangdong	7
7	Heilongjiang	7

20.6.3 Application

The comprehensive evaluation score has been widely used. In 1999, the CSTPCD established the comprehensive evaluation indicator system of Chinese STM journals. This indicator system has been used to determine the total comprehensive evaluation score of Chinese STM core journals, and is a basis when selecting Chinese STM core journals. For Chinese science and technology core journals (statistical source journals), a dynamic adjustment mechanism—annual evaluation of journals—can be applied by combining quantitative and qualitative methods. Selecting more important or representative subjects can reflect the level of development of various journals. In that selection process, comprehensive journal evaluation is applied to assess new journals. The total score of a candidate journal can be entered into the final procedure by top-third subject ranking (which is exempt from expert inquiry). Alternatively, this approach may be used to eliminate existing core journals, where the elimination is based on the comprehensive score of the journal in its subject area.

The annual Citation Report (Core Edition) of China Science and Technology Journals features a chart, which covers various academic disciplines. The chart presents a comprehensive evaluation of the total number of journals and academic rankings in addition to their total citation frequency, impact factors, and distribution of comprehensive evaluation indicators. In a comprehensive evaluation within an overall ranking table, all journals are sorted according to total comprehensive evaluation score. The values of core influence factors and total citation frequency of each journal are listed. The ranking of all the journals can be used to determine their academic quality and relative position of influence in China. In 2014, the comprehensive evaluation index of science and technology core journals in China was 40.9; the number of comprehensive evaluation indexes amounted to 50 in 517.

In 2005, the National Science and Technology Department began promoting the quality of China's science and technology journals. One step it took was undertaking an overall evaluation and monitoring of those journals so as to stimulate scientific research in dominant disciplines. The department aimed to address problems in existing STM journals, take practical measures to enhance the overall quality and scientific level of STM journals, and promote independent innovation in science and technology in China. It also aimed to encourage the country's top academic journals to attain advanced world levels. The third session of China's top STM journals was published in 2014, and it included 315 publications. The evaluation of those quality journals involved classifying them according to subject area. Journals with higher total comprehensive evaluation scores were assessed more highly.

Since 2009, the CSTPCD has published the results that originally appeared in hundreds of outstanding academic journals in China. Those journals were selected as the most important in their various disciplines. In 2011, the comprehensive evaluation indicator system was used to assess changing trends and the current situation of academic journals in China; the indicator system for journals was modified and the index weights were approved. In 2014, 100 outstanding Chinese academic journals were identified from a total of 315 at the third session of China's top STM journals. With the classification system of Chinese STM core journals, there are 113 categories of disciplines in the natural sciences; thus, it is not possible for every discipline to produce hundreds of outstanding academic journals. During the selection process, the most important academic journals in each subject category are selected as outstanding, taking into account the nature of different disciplines and the size of the journals; an appropriate adjustment to the proportion is then made among the different disciplines.

In recent years, the China Science Association, CAS, Ministry of Health, national press, publications by the SARF, and other technical departments, as well as a number of top industrial associations and local science and technology management departments have made evaluations of academic journals using the comprehensive evaluation indicator system. In addition, journal publication departments and various research projects have made wide use of that indicator system. The total comprehensive evaluation score has emerged as an important indicator, including at the Citic Institute, for the development of scientific and technological journals in China.

In 2012, the CSTPCD and Istic-Elsevier Co., Ltd. established a research center for evaluating journals. One of the aims of that move was to promote China's outstanding STM journals to international data resources systems, such as Scopus and Ei. In selecting recommended journals for international data resources systems to evaluate those Chinese journals, the comprehensive evaluation score is regarded as one of the important objective evaluation bases [20.43].

20.6.4 Discussion

Quantitative indexes established using the citation analysis method can be employed to measure the attributes and distribution of papers published in STM journals. Such indexes can also be utilized to determine the influence and function of periodicals in scientific communication. The main purpose in evaluating and monitoring STM journals in the present study was to assess the evaluation indicator system of Chinese STM journals: it is important that the system accurately reflects the main characteristics of such publications from various angles. The indicator system has to reflect the overall development of STM journals and allow a comprehensive evaluation of each index to be accurately made. Journal editors and publishers may use the indicators to identify their own characteristics and deficiencies, which can assist them in developing the direction of their publications. Based on the quantitative index, the comprehensive evaluation score is an objective standard that reflects the influence level of journals. The score can be used to make an all-inclusive assessment of a journal's overall status with respect to various kinds of STM management.

Using the comprehensive evaluation indicator system of Chinese STM journals developed by the CSTPCD, the present study calculated a number of scientific measurement indexes. This study employed the AHP to determine the weights of important indexes; it evaluated each journal comprehensively and it calculated the total score for each publication. With the comprehensive evaluation indicator system, the total comprehensive evaluation score accommodates differences in the background value of the overall index among different subject areas; thus, it permits an appropriate comparison to be made.

If we assume the IF of physics journal A in 2014 to be 1.066 (average of the maximum (1.954) and minimum (0.177) values of the IF of the subject), the relative position of the journal in the IF index is 0.5. At the same time, the numerical value of the IF of mathematics journal B in 2014 is 0.341 (average of the maximum (0.602) and minimum (0.079) values of the IF of the subject), and the relative position score of the journal in the IF index is also 0.5. There is almost a three-fold difference in the IFs of journals A and B; however, their relative positions in their respective disciplines are the same.

Thus, based on the relative position score and index corresponding to weight, the scores of the two journals' IFs are the same. It is evident that regardless of the value of journal indicators, comprehensive evaluation of a journal permits an evaluation of its relative level within its own discipline; this allows an interdisciplinary comparison among different disciplines.

Some small journals that receive many citations often achieve the highest influence level: almost all the indicators of such journals are greater than those of their peers in the same subject area. The total comprehensive evaluation score signifies the relative level of a journal in its discipline. Accordingly, a single show journal will achieve a higher overall score. In the Citation Report (Core Edition) of China Science and Technology Journals 2015, 15 types of journals are listed, with a total score of over 90. However, with higher-ranked journals, a number of individual indicators (e. g., IFs, total cited frequency) often do not result in a high overall score. This is due to a number of other indicators being low, the degree of reference concentration in the subject being low, or the gap between performance indicators being small. For example, the first journal in a subject area receives a relative position of 1.0. If the second-ranked journal has a number of IFs that are close to those of the first, it will also receive a high score; however, if the difference in the IFs with the second-ranked journal is large, it may receive a relatively low position score despite its ranking.

With overall progress in science and technology and the development of academic publishing and research activities covered by STM journals in China, index selection and weight distribution with the total comprehensive evaluation score will undergo continuous improvement. The score system will be enhanced to meet the management needs of STM journals and various scientific and technological evaluation needs in the country. As part of that process, the CSTPCD will obtain valuable advice and suggestions from the editorial and management sections of scientific and technical journals. The aim of the CSTPCD is to develop a rational, objective operation-evaluation system and tools to provide effective support for the appropriate management of Chinese academic publishing activities and to guide the healthy development of Chinese STM journals.

20.7 Evaluation of English-Language Science and Technology Journals in China

20.7.1 Statistics and Analysis of English-Language Science and Technology Journals in China

The present study was based on a database survey of English-language science and technology (STM) journals in China; the database was created by the ISTIC. This study analyzed the impact indexes of 307 English-language STM journals that were formally published in China. We examined such factors as publication region, year, frequency, and subject area by analyzing the journals' impact in terms of impact indexes, such as impact factor and total number of citations. The number of English-language STM journals published in China has increased and their impact has grown. However, owing to operational resources being diverted elsewhere, English STM journals in China have not undergone large-scale development.

China produces a considerable number of papers in the area of science and technology papers, and the quality of those papers is increasing every year. As of September 2016, Chinese science and technology authors published 1.7429 million articles from 2006 to 2016. In 2015, China ranked second in the world in terms of the output of English-language STM papers; its output represented an increase of 10.2%. English-language STM papers produced in China during the period of 2006–2016 were cited 14.8985 million times—an increase of 15.7%. For that period, China ranked fourth in the world.

China is a major country in terms of producing STM journals; however, it has yet to become a powerful one [20.44]. According to the national press and publication statistics of the State Administration of Radio, Film, and Television (SARFT), China in 2014 published 9966 academic journals, of which 4974 were science and technology publications [20.45]. Compared with 2012, the number of STM journals in 2014 showed an increase of just 0.4%; thus, the number of STM journals in China appears to be reaching stable levels. Scientific and technological cooperation is an important part of research. Together with advances in science and technology and globalization trends, the internationalization of STM journals has become a major development in academic publishing. English-language STM journals have come to assume a very important role as the main platform for the exchange of science and technology information.

The area of China's English-language STM journals has not been extensively researched; when it has been studied, the focus has mainly been on editing, publishing, and distribution. One investigation conducted a statistical analysis of university English-language STM journals used in Chinese universities [20.46]. The study identified 73 journals, but it found that they were not fully representative of current China-produced English-language STM journals. Previous studies have determined that English-language journals published in China lack academic influence as international journals and have low academic indicators [20.47]. The number of English-language STM journals published in various subjects in China is not proportional to the output quantity of international papers covering various disciplines in that country [20.48]. It is imperative for China to publish STM journals in English, and it is necessary to make an accurate, comprehensive analysis of those journals.

In 2001, the ISTIC established a database for English-language STM journals published in China. That database is an important reference tool for management departments and it offers an international retrieval system for accessing the data in such journals. With the rapid development of science and technology and increasing globalization, China's English-language STM journals have likewise quickly evolved; in terms of global literature, the proportion of such journals is growing. As of June 2016, according to statistics of the ISTIC, its database covered 307 domestically published English-language STM journals (with uniform domestic issue numbers). Those journals accounted for 6% of the total number of national natural science and technical journals; that number showed a 1.1% increase over the previous year [20.49]. Compared with STM core journals in Chinese, the publishing frequency of those in English is longer. Among the 307 domestically published English-language STM journals, 123 (42.2%) were published quarterly; they were followed by bimonthly and monthly publications (33.2% and 21.3%, respectively). In 2014, 1989 Chinese-language STM core journals (natural sciences) were published in China; quarterly, bimonthly, and monthly publications accounted for 8.4%, 47.4% and 40.0%, respectively. Compared with Chinese-language STM journals, the number of those in English is low, the operating costs are high, and the publication frequency is low. However, the ISTIC and institutes of higher learning are a major force in establishing domestically published English-language STM journals. In all, 140 such journals are sponsored by the ISTIC, accounting for 45.6% of the total; 201 STM journals in English were supported by two or more organizations (65.5% of the total).

Regional Distribution

This section presents details regarding the regional distribution of English-language STM journals in terms of China's 31 provinces (cities and autonomous regions, excluding Hong Kong and Macao). In 2016, the 307 journals were distributed in 23 regions. Table 20.24 lists the top ten. The greatest concentration of such journals was in Beijing, which accounted for 167 (54.4%), followed by Shanghai, Hubei, and Jiangsu; those four regions accounted for 73.6% of STM journals in English. The number of such journals was related to regional academic exchange activity and also to the number and geographic distribution of scientific research institutions. Only six English-language journals were produced in provincial regions, reflecting the lack of science and technology development in such areas.

Publication History

Before 1949, only three English-language STM journals were published in China. Thereafter, just eight were added in the 30 years up to 1979. After China's economic reform, the number of domestically published STM journals in English developed rapidly. From 1980 to 1990, 79 such journals were established; since then, every decade a large number of those journals have come into being. As of 2011, there were 50 domestically produced English STM journals. The change in the number of journals reflects the progress in China's STM development and also the course of its economic reform.

To promote the international influence and core competence of domestically published STM journals in English, the Chinese Association of Science and Technology launched the International Influence Promotion Program in 2012. The plan called for the investment of almost a billion yuan to establish domestically published English-language STM journals over a three-year period. To further promote the internationalization of China's STM journals, the Chinese Association of Science and Technology, Ministry of Finance, Ministry of Education, SAPPRFT, CAS, and the CAE decided to continue to jointly implement the Chinese Science and Technology International Influence Promotion Program [20.50]. With the second phase of the International Influence Promotion Program (2016–2018), which continues to support new English-language journals in China, it is anticipated that the number of such journals will continue to grow over the next few years.

Interdisciplinary Distribution

With the development of science and technology, academic disciplines are in a state of flux—constantly converging, deriving, and changing. A number of journals cover interdisciplinary fields of scientific research. The database for English-language STM journals published in China and the Citation Report (Core Edition) of China Science and Technology Journals (natural science volume) adopt the same method, which is as follows. According to the main distribution field of each journal, multiple subjects and the interdisciplinary content of journals are classified into two or three subjects. Depending on the discipline, the classification and code (national standard GB/T 13745-2009) and Chinese Book Data Classification (fourth edition) are used for the subject classification; this takes into account the publication history of Chinese STM journals. The source journals are then classified into 113 subject categories [20.51].

According to statistics for 2016, 16 journals were classified into more than one subject category; they accounted for 5.2% of all English-language STM journals produced in China. The 307 such journals were categorized into 96 subject areas (85% of all such categories). The most widely distributed subject area was mathematics, with 19 journals (6.2% of all English-language STM journals); that was followed by physics and engineering, which accounted for 14 and 11 journals, respectively. The three most widely distributed subjects among China's STM journals were engineering and technology, natural science, and medicine.

Statistical Indicators

The source and citation data of English-language STM journals published in China originate from Wanfang Data–Digital Periodicals. Table 20.25 presents the main source indicators for such journals. In that table, *author number of articles* refers to the average number of authors of each paper in the source journal; it is an index of the scientific production capacity of journals. As indicated in that table, the average number of authors for 2014 was 3.98. That figure showed little change from the previous three years. The average number of authors of statistical source journals of Chinese scientific papers (natural sciences) was 4.1 [20.52]. In 2014, the average number of citations of English-language STM journals published in China was 29.9; that is a five-fold increase over 2011. Also in 2014, the average number of citations of Chinese-language STM core periodicals (natural sciences) was 17.1; lower than the figure for English-language journals by 12.8. Compared with statistical source journals, the papers published in China's English-language STM journals have more reference to previous ideas or research results; they are more in line with international standards with regard to bibliographic standardization.

The proportion of papers published by overseas authors in domestic publications compared to the total number of papers in overseas journals is a measure of the degree of internationalization of domestic journals. In 2014, domestically published English-language STM journals showed a slight decline in the number of papers from overseas compared with the previous three years. However, the number of overseas papers showed an increase of more than 50%. In 2012, overseas papers were published in 24 journals, which was less than 50% of the 49 for 2014. In 2014, five overseas papers were published in the following English-language journals: *Frontiers of Biology*, *Current Zoology*, *International Journal of Disaster Risk Science*, *Bone Research* and *Forest Ecosystems*. Attracting more manuscripts from overseas is a problem facing most domestically published journals in English. The proportion of papers that receive funding is an important index of the academic quality of journals. In 2014, the proportion of such papers in English-language STM journals was 65%, which is higher than the average for Chinese-language STM journals (natural sciences) for the same year.

Table 20.26 presents the main citation indicators of English-language STM journals published in China. It is evident that from 2011 to 2014, the total number of citations, impact factors, and the immediacy index

Table 20.25 Main source indicators of English-language STM journals published in China

Indicators	Chinese Journal of English Science and Technology				China Science and Technology core
	2011	2012	2013	2014	CSTPCD 2014 (Natural science volume)
Author number of articles	3.9	3.9	3.8	4.0	4.1
Average number of citations	24.9	27.5	28.4	29.9	17.1
Overseas papers rate	0.23	0.25	0.22	0.16	0.02
Funded papers rate	0.71	0.64	0.44	0.65	0.54

Table 20.26 Main citation indicators of English-language STM journals published in China

Indicators	Chinese Journal of English Science and Technology				China Science and Technology core
	2011	2012	2013	2014	CSTPCD 2014 (Natural science volume)
Total citations	385	380	369	433	1265
Impact factor	0.391	0.370	0.371	0.467	0.560
Immediacy Index	0.092	0.115	0.107	0.132	0.070
Other citation rate	0.84	0.84	0.84	0.85	0.82

showed an increase. This indicates that the impact of such journals is rising. *Total citations* in Table 20.26 refers to the total number of papers of a journal that received citations since the journal's inception: it reflects the extent to which the journal has been used and valued as well as its influence in scientific communication. Owing to the language used in journals and other reasons, the total citation frequency of English-language STM journals is much lower than that of Chinese-language ones. In 2014, English-language journals were cited 433 times; that means a 64 times increase comparing with 369 times in 2013.

Impact factor (IF) refers to the number of citations that appeared in the two years prior to a journal's evaluation. It is a measure of the journal's academic impact. The change in the IF for 2011–2014 for English-language STM journals and the Chinese-language STM journals is indexed by CSTPCD. Noticeable is that the IF of Chinese-language STM papers displayed a gradual increase during that period, while the IF of English-language journals was relatively steady. In 2014, a major improvement occurred: the IF of English-language journals in that year was 0.467, which was 25.9% higher than the 0.371 in 2013.

The immediacy index refers to papers published the same year as a cited paper: it characterizes the rate of immediate response indicators. The annual index of English-language STM periodicals published in China in 2014 was 0.132. It is evident in Table 20.26 that the instant reaction rate of such journals was slightly higher than that of the *Journal of Statistical Sources* (natural sciences) among Chinese-language STM journals. The quoted rate refers to the total citation frequency divided by the number of other citations accounted for in the ratio. The Chinese English-language STM periodicals are relatively stable in this rate, maintained at about 0.85, slightly higher than China's scientific and Technological paper Statistical Source Journal (natural science part) of his cited rate.

International Impact

International cumulative citation data for English-language STM journals published in China were derived from the Web of Science (SCI) database of the Thomson Reuters Group for 1995–2016 (as of June 2016). As of June 2016, such journals published in 2013–2014 were cited more than five times in 19 different journals. In 2016, only seven of the indicators exceeded five times. The number of English-language journals has increased greatly since June 2016; this indicates that the international influence of such journals is rising. The number of journals cited more than 300 times in 2016 was 13; that figure was seven in 2014.

According to the 2015 Journal Citation Report (retrieved in June 2016), among the 307 English-language STM journals published in China, 133 (43.3%) were included in SCI. Nine of China's English-language journals appeared in the top 25% of SCI journals in 2015; that compares with six in 2012; among those, the *Asian Journal of Andrology* (medicine specific to men) ranked first. Among China's STM journals, 133 covered 86 subject areas; among those, three were classified into four categories, ten into three categories, and 37 into two categories.

Conclusion

With improvements in China's academic quality and international influence, domestically produced English-language STM journals have undergone rapid development. The number of such journals has achieved basic stability: it has shown an increase of 1.1% compared with the previous statistical year. As of June 2016, 307 English-language STM journals were being produced in China (with a uniform domestic issue number). Such journals are an important platform for demonstrating the level of China's science and technology development and also enhance international cooperation.

Producing English-language STM journals demands high resource costs. The production of half of such journals in China is concentrated in Beijing; the next highest areas of production are in Shanghai, Jiangsu, and Hubei. Some scientific papers originate in China's provincial regions; however, some economically developed regions do not produce an appropriate number of English-language STM journals.

The key to an English-language journal's success is that it should be an internationalized operation that is able to attract outstanding papers from overseas. In 2014, overseas contributions accounted for more than 50% of papers in the case of 49 journals published in China. Compared with the previous statistical year, that is an increase of 25 journals. However, the overall level did not improve, and there is considerable room for development.

Among the 307 English-language STM journals produced in China, 85% cover 96 subject areas. The most common subject area is mathematics. English-language journals need to develop a clear orientation. They need to expand their international audience, strengthen their international operations, shorten their publication cycles, and improve their quality. Currently, the publishing cycle of China's English-language STM journals is relatively long: 42.2% of such journals are quarterlies.

The total citation frequency and influence factor of English-language journals have improved compared with the previous statistical period. The international cumulative index of the journals has also improved. As of 2016, 133 English-language STM journals were included in SCI: nine featured among the SCI's top 25% of journals, which was an increase of three over the previous statistical period. That is an indication of the growing influence of English-language STM journals produced in China.

20.7.2 Communication Value of China-published English-Language Academic Journals According to Citation Analysis

Introduction

The Bible has been translated into more than 1800 languages, but there is no definitive figure as to the total number of languages in the world. People use thousands of different languages. The communication barriers posed by language differences clearly affect cultural exchange and information sharing among different countries and nationalities. For barrier-free exchange among nations, there would seem to be only two ways to design and create a world language for all to learn based on natural human language. In this regard, linguistics has created a specialized discipline, termed Esperanto linguistics (Interlingua). Many studies and attempts have been made towards that end, but it would appear to be a dead end. The second option is to make a natural language to fulfill the role of Esperanto and become the mother tongue or second language of all people [20.53]. In view of the current world situation with respect to language development, English is widely learned and clearly used as Esperanto was created to be used. Notably, in activities related to international STM research and exchange, English plays a central role.

Abram de Swaan describes the relationships of various languages in the world in terms of supercentral, central, and peripheral languages [20.54]. A supercentral language is analogous to a star surrounded by planets (central languages), and the planets have their own moons (peripheral languages). When native speakers of one language learn another language, they often choose a broader language within the system of languages. Each supercentral language is associated with a number of users of central languages. With time, a large number of central language groups become linked to an oversized language group among the supercentral languages as a result of multilingual users.

The importance and position of a language in the system of world languages can be quantitatively assessed by calculating the communicative Q value of a language by means of the popularity index and central index. One study found that 12 languages—Arabic, Chinese, English, French, German, Hindi, Japanese, Malay, Portuguese, Russian, Spanish, and Swahili—constituted the supercentral languages. With the possible exception of Swahili, the number of speakers of supercentral languages is over 100 million each.

Among the supercentral languages, English is at the very center of the entire linguistic galaxy. Accordingly, *de Swaan* refers to English as the world's only hypercentral language [20.54]. Globally today, English is the most common language in science and technology. Most STM journals—especially high-quality journals—are published in English [20.55]. With the broadening of the international vision of Chinese researchers and rapid development in linguistics research [20.56], a clearer, deeper understanding has emerged in China of the role of English in science and technology. From the growing number of English-language STM journals produced in China, it is evident that English is playing an increasingly important role in its publishing and exchange activities in STM.

According to the English-language STM journal database, developed by the ISTIC, 212 English-language STM journals were published in China in 2010. The number of such journals has increased annually; the subject areas covered by those journals has also grown. Table 20.27 presents the historical development of China's English-language STM journals. It is evident that the number of such journals was very small before 1980. Over the past 30 years, the number has surged and that growth trend has been maintained [20.57].

As a result of the increasing volume of English-language STM journals produced in China, overseas scholars have devoted greater attention to the development and study of such publications. Those authors have analyzed the role of those journals with respect to research and the exchange of information related to STM in China. However, the conclusions and opinions of those scholars are not wholly consistent. Some authors believe that only by producing quality English-language STM journals can China become truly internationalized in an academic sense. For example, some

Table 20.27 Historical trend of new English-language STM journals published in China

Period	Before 1949	1950–1960	1961–1970	1971–1980	1981–1990	1991–2000	2001–2009
Number of new Chinese and English STM periodicals	2	10	2	6	75	62	54

authorities view language as the greatest obstacle: they regard it as an impediment to the internationalization of Chinese STM and that in "the internationalization of STM periodicals, English periodicals should be first" [20.58].

Some scholars believe that the number of English-language STM journals published in China falls below the country's requirements. Those authors consider that China's journals need to compete with other STM publications produced around the world; they believe that China has the potential for vigorous development and that it has a great role to play [20.59].

A number of studies have suggested that although in China the circulation of English-language STM journals is often lower than that of their Chinese-language counterparts, the impact on the readership is quite similar [20.60]. One report identified 11 characteristics of a world-standard journal, the first of which was publication in English; the second was a fully internationalized peer-review system [20.61]. However, other studies have found that there appears to be no link between international journals that are successful in China and use of the English language. One investigation conducted a comparison of various indexes of Chinese- and English-language journals in the field of materials science using an international retrieval system. The study determined that such features as the impact factor of English-language journals did not offer any advantages; it identified weaknesses as small publication scale and narrow area of influence [20.62]. Some scholars believe that publishing in English is not necessary for an international journal. They consider that the use of English or Chinese in STM journals published in China constitutes a strategic choice; whether the use of English is expected to play a key role depends on whether the journal conforms to its anticipated development strategy [20.63].

The basis for China's STM journals and the main object of publication are the vast number of Chinese people engaged in STM; such workers blindly pursue the study of English and forget the original purpose of those journals [20.64]. Some scholars believe that Chinese-language journals have a strong regional characteristic: they come mainly from China. Thus, language alone does not determine the influence of Chinese STM journals or account for their weak international competitiveness [20.65].

From the above, it is evident that current research on the role of English-language STM journals produced in China has been based on qualitative analysis methods. No objective, unified quantitative evaluation system has been applied to the topic, and so different authors have arrived at different conclusions. To attain a more accurate judgment on the value of such journals and provide objective data support with regard to their future development, the present study applies the ideas of de Swaan. This study examines the Q value of language communication, and it defines a new evaluation index using the Q value of English-language STM journals published in China.

Calculation Method of Exchange Value of English-Language STM Journals

This study takes into account differences in the prevalence of English among different subject areas. It does so with respect to the level of academic influence of journals and their degree of internationalization. This investigation determines the exchange value of English-language STM journals using quantitative research methods; it demonstrates the function and position of such journals in their subject areas using those methods.

In determining the exchange value of these journals, this study makes use of two indexes related to popularity and centrality as defined by de Swaan with regard to the language communicative value index Q [20.66]. This investigation also takes into account factors related to the international influence of such journals. Studies have shown that the number and proportion of papers cited in Chinese journals are generally lower than in overseas journals; accordingly, the international academic influence of STM journals published in China is particularly important.

The exchange value of English-language STM journals produced in China consists of three parts: popularity of English in the subject area; center of academic influence; and degree of international diffusion. For journal j in subject area i, the exchange value indicator is defined as follows,

$$Q_{ij} = \sqrt{P_i^2 + C_{ij}^2 + D_j^2}\,, \tag{20.1}$$

where Q_{ij} signifies the exchange value of the journal, P_i the popularity of English in the journal's subject area, C_{ij} the academic influence center of the journal in its discipline, and D_j the degree of international diffusion with respect to the journal's academic influence.

With the aim of an index calculation with good feasibility and validity, the indicators adopted in the present study are defined and calculated using citation analysis in scientific metrology.

English Popularity of Subjects. A notable feature of language is that the more people who use it, the greater its exchange value [20.67]. As a result, we may conclude that the greater the popularity of English in a scientific research area or the wider the use of English as an academic communication tool, the greater the importance of English-language STM journals.

The prevalence of English in a discipline can be examined by measuring the extent to which papers in that field use English. In terms of research results, the higher the absolute number of papers in English and their relative proportion, the greater the need for the communicative language to be English—and the greater the role and exchange value of English journals in that field. For a subject i, the equation for the English prevalence index is as follows,

$$P_i = \frac{N_i(\text{Engl. Ref.})}{N_i(\text{Total Ref.})} , \quad (20.2)$$

where P_i denotes the English prevalence of subject i, N_i(Engl. Ref.) the number of references in papers published in the particular journal on subject i, and N_i(Total Ref.) the number of all references in all journals to subject i.

Academic Impact Center of a Journal in its Discipline. Irrespective of whether a journal is in Chinese or English, the more it is used in academic exchange, the more it will be regarded as authoritative and will assume a guiding position; this will be reflected in the number of citations in other journals. Thus, the academic influence of a journal signifies its authority and academic position among other journals in a particular subject area.

In a certain field, mutual citations among journals can be used to represent the relative position of each; mutual citations reflect the academic exchange relationship and status among journals [20.68]. To determine the authority and position of a journal, the present study calculated the number of citations of a journal by other journals in the same subject area as well as the proportion of the maximum number of citations in that subject area. For subject area i, the academic impact center of journal j is defined as follows,

$$C_{ij} = \frac{N_{ij}(\text{Citation from others})}{\max_{j=1\approx n} N_{ij}(\text{Citation from others})} , \quad (20.3)$$

where C_{ij} signifies the academic impact center of journal j within subject area i, n the number of journals in subject area i, and N_{ij}(Citation from others) the number of citations of journal j by other $n-1$ journals in subject area i.

With this index, when the academic influence of the journal is determined, the number of citations is not taken into account. A reasonable amount of self-citation by a journal is normal in academia; it also reflects a journal's influence. However, in the present study, the emphasis is on measuring a journal's exchange value: the journal's external influence. In addition, self-citation by a journal is often susceptible to human factors and it does not necessarily reflect the influence of a paper in an objective manner. As a result, self-citation is not included in the present statistical analysis.

International Diffusion Degree of Academic Influence of Journals. The present study conducted an analysis of the exchange value of English-language STM journals published in China. The analysis included the exchange value in domestic disciplines. This study also examined the international exchange value of those journals: it investigated the achievements of Chinese STM in international academic circles and the promotion of international academic exchanges. Therefore, in designing the index for exchange value Q, this study added a third part: the international diffusion degree of academic influence of periodicals, which is reflected in the number of citations in international journals and number of citations in domestic journals. The equation for determining the international diffusion degree of academic influence of a journal j is as follows,

$$D_j = \frac{N_j(\text{NIC})}{N_j\,(\text{NIC}) + N_j(\text{NDC})} , \quad (20.4)$$

where D_j signifies the international diffusion degree of academic influence of journal j, N_j (NIC) the number of citations of journal j in international retrieval systems (i. e., the number of citations in international journals), and N_j (NDC) the number of citations of journal j in domestic retrieval systems (i. e., the number of citations in domestic journals).

Calculation of Exchange Value of 45 English-Language STM Journals

The present study examined 45 English-language STM journals included in JCR 2010 and the Citation Report (Core Edition) of China Science and Technology Journals 2011. This study used the CSTPCD of the ISTIC and the Scientific Citation Index (SCI) database of Thomson Reuters in the United States, respectively for domestic and international citation statistics in calculating the exchange value Q of the sample periodicals [20.69, 70]. The classification of subjects was based on the classification of the Citation Report (Core Edition) of China Science and Technology Journals 2011. All the citation analyses and calculations were based on statistics for 2010. The results of the calculation appear in Table 20.28.

As shown in Table 20.28, the Q value of the 45 journals was 1.475; the minimum was 0.676, median 1.027,

Table 20.28 Exchange value Q for 45 English-language STM journals published in China in 2010

and average value 1.004. From the distribution of the Q value, it is evident that there were only four journals with a Q value of more than 1.2; 19 journals with a Q value between 1 and 1.2, accounting for 42% in 45 periodicals; 17 journals with a Q value between 0.8 and 1, accounting for 38% in 45 periodicals; and 5 journals with a Q value of no more than 0.8. It is clear from the distribution of the Q value of the 45 journals (Fig. 20.2) that the calculated results of the sample show approximately a normal distribution.

In terms of disciplines, the 45 journals cover basic research in life sciences and engineering technology. However, there is no obvious difference in the evaluation results among the various disciplines.

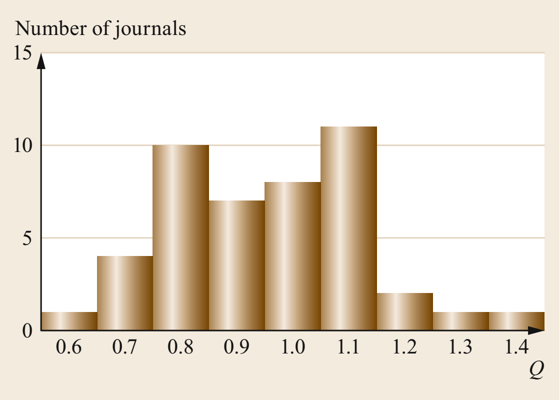

Fig. 20.2 Distribution of Q value of 45 English-language STM journals

It appears that journals in gastroenterology and cell research as well as other publications with distinctive characteristics and higher academic influence showed a good performance in terms of exchange value and Q value. At the same time, it is evident that the Q values of such journals as *Pedosphere* and *Chinese Journal of Aeronautics*, which have a clear regional bias and represent closed disciplines, are relatively low [20.71]. Therefore, it can be considered that the exchange value index Q of English-language STM journals published in China has a certain degree of accuracy; it may be used to characterize the actual role of such publications with respect to China's scientific research and publication exchange activities.

Conclusion and Discussion

Studies in linguistics have shown that English has become the only language in the world with the status of a hypercentral language. It is necessary to fully understand and use this communication tool in STM. The exchange value Q of English-language STM journals produced in China is a measure of the role of such publications in Chinese science and technology with respect to academic research and exchange activities. The exchange value Q can be used as an objective, practical quantitative analysis tool to track the development of such journals.

As evident in (20.1), the exchange value of a journal is expressed by the three coordinates of popularity (P), center (C), and international diffusion degree (D); the length of the vector formed by 0 points to the position of the journal. The relative differences in the results of those three coordinates can be likened to different angles produced by a journal in a three-dimensional coordinate space.

In subject areas where there is higher prevalence of English, Chinese STM journals are more likely to use that language for ease of communication. The prevalence of English (p) can be regarded as a measure of the international strength of a subject area. The prevalence of English can also be regarded as reflecting the demand for English-language journals as well as a reflection of the potential exchange value of such journals produced in China. The higher the proportion of Chinese researchers who access English-language literature, the greater the exchange value (potential exchange value) of English-language journals in China.

In designing the exchange value index, the difference between disciplines is considered a component. Thus, the data obtained using that index are not affected by differences in subject area. The exchange value Q of English-language STM journals can therefore be used for comparisons across disciplines.

The design of the exchange value index is based on the situation of English-language STM journals produced in China. It reflects the role played by Chinese scientific research activities. The domestic journal citation database of CSTPCD and international journal citation databases, such as SCI, are used to calculate Q. For other countries, especially non-English-speaking countries, it is impossible to use that index to calculate the exchange value of journals if they lack a complete domestic citation database like China's. Therefore, the exchange value index Q cannot be used in international comparisons. However, in a follow-up study, it will be possible to consider the value of Chinese-language STM journals and compare them with English-language journals produced in China.

The exchange value index reflects and evaluates the function of English-language STM journals produced in China from one aspect. The index cannot completely replace conventional measurement indexes of scientific journals, such as influence factor and total cited frequency. However, the exchange value index can be used as an extension to supplement the current comprehensive academic indicator system of English-language STM journals produced in China [20.47].

20.7.3 Atomic Structure Model for Evaluating English-Language Scientific Journals Published in Non-English Countries

Introduction

English-language scientific journals published in non-English-speaking countries account for only a small fraction of all scientific journals published in those countries. However, they play a particularly important role in connecting scientists whose native language is not English with their peers around the world and in improving international collaboration through scientific research. In China, for example, although over 5000 scientific journals are published (ranking it second after the United States in terms of number of journal titles published), its English-language journals amount to only about 4% of the whole [20.72]. As is well known, English is the most widely used language in almost all fields of science, technology, and current international economic and social affairs; there is a tendency to accept English as an official international language. Most scientific journals, especially the most outstanding ones, are published in English [20.73]. It is axiomatic therefore that international scientific communications and publications follow the existing trend. Accordingly, scientific journals published in English have become the major channel for international exchange and cooperation. Over 100 000 papers by Chinese scientists are indexed annually in Science Citation Index Expanded (SCIE); 14% of those papers appeared in English-language scientific journals published in China [20.74].

China aims to become a substantive member of the world scientific community. Thus, it has become important to make those few Chinese journals published in English better and more attractive to international scientists as places for publishing their academic findings. The same challenge is probably faced in other countries where English is not an official language.

In general, evaluating something is a good step towards improving it: the grades or marks accorded as part of a logical evaluation process and related to systematic indicators denote the advantages and disadvantages as well as the strengths and weaknesses of the matter under evaluation in a significant, precise, all-encompassing manner. Thus, evaluation is akin to the role of diagnosis, upon which prescription and amelioration are founded.

English-language scientific journals published in non-English-speaking countries have certain characteristics that make them different from most non-English journals. Those characteristics result in a lack of an accurate, suitable evaluation model and indicator system. Such English-language journals focus on international readers and authors; that is why their sponsors and editors made the decision to operate them in a country where English is not an official language. In China, it has been observed that international journals usually acquire more citations than domestic ones [20.75]. It is understandable why English-language journals in China do not attract many domestic authors and readers, who pay more attention to journals and articles in Chinese owing to the greater convenience of obtaining information and producing articles in their native language. Some scientific evaluation models or systems have been established for journals published in China, and English-language journals consistently obtain lower scores than most Chinese journals [20.76]. Most English-language journals deal with more peripheral fields, according to the mutual citation network, which groups journals by subject areas [20.77]; however, such evaluation results may not reflect the real academic level and impact of such English-language journals.

Most English-language scientific journals published in China are very new and limited in number and circulation; thus, they do not yet have sufficient strength to exert a wide influence and strong impact on the world scientific community. Established in 1887, China's first English-language scientific journal was entitled *China Medical Missionary Journal*. However, a recent survey conducted by W. Xu revealed that very few other English-language journals appeared in the almost 100 years that followed until the 1980s [20.78].

According to a comparison of the number of new English-language scientific journals published in China per decade, we can find that that the great majority have appeared in the last three decades; more than a quarter emerged after 2000. Those journals are so new that it would be inappropriate to evaluate them using the same standards that can be applied to other older Chinese-language journals.

More than half of China's English-language journals are not covered by SCIE. This means that most of them do not have an ISI impact factor or other indicators calculated by ISI JCR, the most popular international index of scientific journals [20.79]. Hence, neither the existing domestic evaluation system nor the normal international evaluation system is entirely appropriate for China's English-language journals.

It is possible that some of those journals may fall into a vicious cycle in the future if the current evaluation models continue to be adopted. That is because less influence leads to a lower evaluation score, a lower score leads to fewer submissions, and fewer submissions lead to less academic value and poorer impact of the journal. To address this problem, a new model, which resembles the structure of an atom, has been designed as described below to evaluate China's English-language scientific journals.

Atomic Structure Model

Characteristics of the Model. The most important achievement of John Dalton, a British chemist and physicist in the 1800s, was the atomic theory. Some scientists, including J.J. Thomson, Jean Baptiste Perrin, Hantaro Nagaoka, Niels Bohr, and Ernest Rutherford, conducted extremely fruitful research over a number of years in developing that theory and producing the universally acknowledged atomic model. As devised by Bohr and Rutherford, the atomic model is a structure

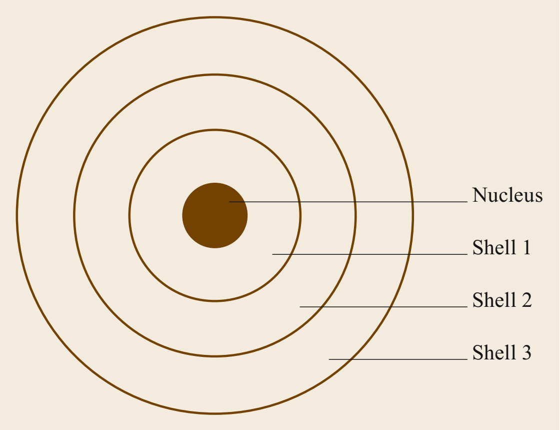

Fig. 20.3 Atomic structure model

that consists of various shells around the nucleus. In the present study, the atomic structure model (ASM) can be represented by the image shown in Fig. 20.3. There, three shells surround the nucleus, and the relationship (degree of interaction) between the shells and the nucleus gradually recedes with distance. The five characteristics of the ASM are as follows:

(1) There is only one nucleus in the system
(2) Three shells are located around the nucleus
(3) Each shell has a spherical surface
(4) Both shell–nucleus and shell–shell interactions occur
(5) The electrons on the three shells orbit around the nucleus.

Use of the ASM in Communication. Yongtao used the ASM in his study of an online communication model. According to his idea, the core of the model is human subjects, who actively push information [20.80]. All objects of information to be communicated by the subjects are distributed on the three shell layers; each shell corresponds to a different effect of communication or the environment of websites and human behavior. To maintain the balance of the whole system there are at the same time complex interactions among all elements in this model.

Scientific journals can be regarded as a branch of communication. Therefore, the ASM would appear to be useful in evaluating scientific journals.

Use of the ASM in Evaluating China's English-Language Scientific Journals. China's English-language scientific journals have some characteristics that match those of the ASM. The essential element determining a journal's academic quality is its core value. The core value is signified by the core (C). Around the core value, there are three classes of individuals located in order of decreasing relationship with the journal. They are somewhat similar to the electrons orbiting in three shells around the nucleus. As Fig. 20.4 shows, the three groups are the editors, authors, and readers. They appear, respectively, as Shell 1 (S1), Shell 2 (S2), and Shell 3 (S3) in that figure.

Editors, including chief editors, associate editors, and members of the editorial board, are those closest to the journal's core; thus, they are located in S1. In their work, they follow principles that are central to the production of a good journal, such as evaluating the quality of submissions and ensuring that the English is of an appropriate level. China's English-language journals are similar to those published overseas and are generally regarded as different from other journals produced in that

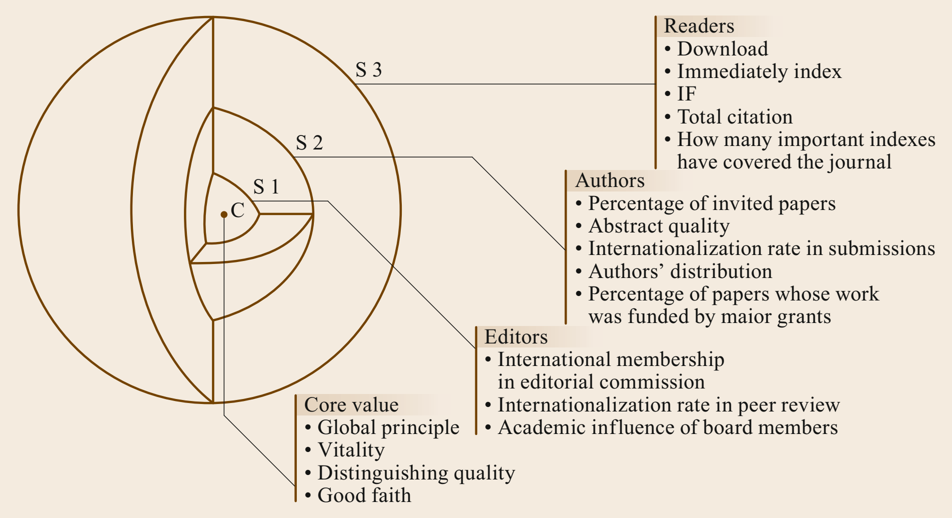

Fig. 20.4 Atomic structure model and indicators for evaluating China's English-language scientific journals

country. Therefore, to operate such English-language journals, it is a prerequisite that the editors have a global view and the capability for international exchange and collaboration. This point has to be examined in the evaluation.

S2 consists of authors whose articles are published in a journal. Clearly, a scientific journal's content mostly consists of academic articles from a large number of authors. Thus, the contact of each author with the journal may not be very frequent if they contribute only one or two submissions a year. The ability to claim a greater number of international authors is a positive attribute for international journals [20.81]. Therefore, it is necessary that the evaluation indicators reflect the quality of both authors and articles.

The most distant shell, S3, is that of the readers. Readers normally have a loose relationship with the journal's core, and direct communication between the two is ordinarily a one-way process. The evaluation of a given journal by readers offers an indirect way of observing the journal's quality by identifying and assessing its academic effect. Consequently, the following questions relating to citation analysis have to be answered to evaluate the response from readers to the journal in S3: how many readers have downloaded papers published in the journal, and what are the journal's citation indicators, such as impact factor and total number of citations?

Interaction between the shells and the nucleus occurs, just as it does among the various shells. A journal with a strong core value usually invests more resources in the journal, including human resources and financial support. In that way, the editorial team can be more effective in soliciting higher-quality submissions from good authors, and this in turn attracts more readers and more citations. This situation is similar to that of an electron's transition between shells in the ASM in that the status of all those involved with the journal changes according to the shell: a reader may become an author, and an author may become active as an editor of the journal. With a quality journal undergoing positive growth, there will be a good deal of transition from S3 to S2 and from S2 to S1: more readers will want to submit manuscripts and more editors will be required to deal with the increasing flow of manuscripts. Conversely, if a journal is not doing so well, some of its former authors will stop submitting new manuscripts, and the number of readers will also start to dwindle.

Based on the ASM for evaluating English-language scientific journals published in China, a series of tentative indicators was developed after dozens of information scientists and academic journal editors brainstormed the issue. Some of these tentative indicators were discarded owing to limited data availability or overlap with other indicators. Finally, 17 indicators were established for this evaluation model (Table 20.29).

Results

To test the usefulness of the ASM for evaluating China's English-language scientific journals, we selected 18 such journals as our sample (Table 20.30). First, we calculated the quantitative indicators for those journals, which are indicated by asterisks in Table 20.29; for the evaluation, we obtained print copies of the journals. Then, for each journal, a group of reviewers (consisting of three to five experts, including scientists in the journal's academic field and senior journal editors) were invited to make a conclusion according to the ASM indicator system. Each journal's core and three shells were rated as A (excellent), B (good), C (fair), or D (poor) through a combination of this quantitative and qualitative analysis. For example, *Journal of Computational Mathematics* was rated as A in S1, which means that editorially this journal is strong according to the three indicators listed in Table 20.29. Although the journal boasts an excellent performance, it scores only C in S2 and S3; this means that the journal's editors

are unable to attract top authors and expand their readership. The publisher or editor-in-chief of this journal should perhaps consider this situation and take appropriate steps. Another example is the journal *Chinese Physics C*, which scored D in S1 and S2; this means that the combined power of its editors and contributing authors is very weak in terms of the indicators defined above. Therefore, from this evaluation result, it would appear that the journal needs to make great efforts to bolster the capacity of its editors so as to attract better authors and improve the quality of its submissions.

Conclusion

The primary innovation in the present research was the use of the ASM to evaluate China's English-language scientific journals. Both indicators and layers of indicators in addition to the relationship and transitions between indicators and layers were considered by means of the ASM, a concept adapted from the field of communications.

Another original feature of the present study was considering the interaction among the shells in the ASM: these signify the individuals working for or related to a scientific journal. The changes in a journal's editors, authors, and readers could reflect its stage of development and possible future trends. However, the lack of data from the journals themselves meant that there was no possibility of evaluating such details in the present study.

Unlike the situation in some countries around the world, all Chinese journals are managed by public academic organizations, such as universities, research institutes, and academic societies. As the sponsor—more often than not the only sponsor—of scientific journals, those organizations have the competency and absolute responsibility to formulate a vision for a journal's development and carry it out. This aspect of the sponsor, or perhaps owner, is an important element with regard to the quality of a journal published in China; however, it was not considered in the present study.

With necessary adaptations, the indicators designed for China's English-language scientific journals could also be used to evaluate English-language journals published in other countries where English is not an official language. For example, English-language scientific journals published in Japan face many similar problems to those produced in China [20.82].

The ASM evaluation idea could also be applied in evaluating all scientific journals irrespective of language or country of publication: all journals share the same essential elements of core value, editors, authors, and readers. Further study is required to optimize the indicator system used with the ASM and verify it in a large sample.

Zheng Ma is Professor at the Institute of Scientific and Technical Information of China. He is Deputy Director of the Center for Science and Technology Metrics. He graduated from Tsinghua University in 1999 with a major in environmental engineering. He is an executive member of the councils of the China Editology Society of Science Periodicals and the China Periodicals Association.

21. Bibliometric Studies on Gender Disparities in Science

Gali Halevi

Understanding gender related disparities in science is an essential step in tackling these issues. Through the years, bibliometric studies have designed several methodologies to analyze scholarly output and demonstrate that there are significant gaps between men and women in the scientific arena. However, gender identification in itself is an enormous challenge, since bibliographic data does not reveal it. These bibliometric studies not only focused on publication output and impact, but also on cross-referencing output, promotions and tenure data, and other related curriculum vitae (CV) information. This chapter discusses the challenges of tracking gender disparities in science through bibliometrics and reviews the various approaches taken by bibliometricians to identify gender and analyze the bibliographic data in order to point to gender disparities in science.

21.1 Background

According to the 2015 report of the *National Science Foundation* (NSF) on Women, Minorities, and Persons with Disabilities in Science and Engineering [21.1], there appears to be an inherit disproportion in the number of women holding academic positions as full professors. Although the number of female scientists has more than doubled since 1993, women currently occupy only about one-fourth of senior faculty positions. The main reason for this disparity seems to be the fact that there are older cohorts in the current science, engineering, and health workforces who are predominantly male.

In the past decade there have been global efforts to promote women's participation in science, technology, engineering, and mathematics (STEM). These efforts include educational programming from K-12 through higher education. Examples include government sponsored North American programs such as *Educate to Innovate* [21.2], the hEr VOLUTION, the Society for Canadian Women in Science and Technology and the

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_21

Canadian Coalition of Women in Engineering, Science, Trades, and Technology (CCWESTT). In Asia, there are several programs sponsored by not-for-profit organizations such as Destination Imagination in Singapore, the National Association of Women Entrepreneurs of Malaysia, as well as the Girls Code program in India, which encourages girls to participate in computer sciences and mathematics. The European Union formed *The European Centre for Women and Technology*, a partnership of more than 130 organizations that support women in technology from all over Europe. In Australia, the government has made a significant push to get more women involved in STEM education and careers and has pledged to invest $13 million over the next 5 years to make it happen. Finally, in developing countries there are a few organizations that are dedicated to training young women in STEM fields. These include the Organization for Women in Science in the Developing World, which creates research training and networking opportunities for female scientists, and the Elsevier Foundation, an organization that provides grants to support scholars in the early stages of their careers, to name a few.

Tracking the participatory levels of young women in STEM fields at the early years of their education is relatively well documented. For example, using high school registrations and completion of advanced placement (AP) examinations in chemistry, statistics, and calculus, policy makers in the United States were able to determine the participation percentages of young girls in STEM related fields [21.3]. In a similar manner, the NSF report on Women, Minorities, and Persons with Disabilities in Science and Engineering uses college degrees received to track academic degrees earned by women through the different STEM fields.

In Europe, the annual *She Figures* indicators report uses Eurostat (the Statistical Office of the European Union (EU)), which provides sex-disaggregated data on education, research and development, professional earnings and scientific employment, as well as primary data (broken down by gender) on senior academic staff, university leaders, funding applicants, and beneficiaries, as well as membership on boards of national research organizations ([21.4], Google search, no date).

United Nations Educational, Scientific, and Cultural Organization's (UNESCO's) report Girls and Women in Science, Technology, Engineering, and Mathematics in Asia ([21.5], Google search, no date), uses national examination results, as well as educational achievements for countries participating in the Program for International Student Assessment (PISA). The Trends in International Mathematics and Science Study (TIMSS) uses existing structures and results of assessments in mathematics and science at the national level to determine girls' participation levels in STEM academics.

These types of data, made available by national educational systems, enable researchers to gain insights into the state of female participation in different STEM fields from early school years through higher education. In addition, there are several studies that address not only the statistical levels of participation of women in STEM, but also attempt to explain the reasons for their underrepresentation. These psychological, educational, and sociological studies [21.6–9] have identified several influencing factors that contribute to the underrepresentation of women in STEM. Some of the factors identified are negative ability stereotypes and perceived bias, lack of role models, insufficient early experience, lack of peer support, and negative attitudes.

Although these studies might explain some of the barriers to female participation in STEM from early schooling through higher education by reporting on employment rates in research and academic institutions [21.1], they are not able to draw a holistic picture of female participation in science and are geographically and politically dependent.

In attempting to create a more comprehensive picture of the underrepresentation of women in STEM, bibliometric studies become an essential tool for tracking not only research participation, but also its consequential impact on scientific discovery. One of the manners in which participation and impact in scientific disciplines is measured is the number of publications published and the number of citations these receive. There are numerous statistically generated scores such as the h-index, field-weighted citation impact (FWCI), CiteScore, scholarly and social activity online, media mentions, and others, that attempt to measure the scientific impact of a scientist.

With these challenges in mind, the bibliometric community developed a variety of methodologies to be able to identify female participation and impact in the scientific arena. This chapter will review the methodologies used by bibliometricians to estimate female scientific participation and impact. This review is organized based on the purpose of the research in order to identify best practices for each. In this arena, both traditional metrics and altmetrics are used to measure the participatory levels and impact of women in science. Traditional metrics typically include the number of publications and the impact factor of the journals in which they are published, while the number of citations measures the impact of these articles. Altmetrics measures the social impact of the articles by examining engagement via social networks such as Twitter, LinkedIn, Facebook, and others. In addition, altmetrics measure the level to which these articles are used. This includes downloads, views, shares, and others. The use of traditional metrics and altmetrics combined allows researchers to measure both the number of articles contributed by women and their impact on the scientific endeavor.

In addition to these counts, bibliometric methods have been used to delve deeper into the participatory and impact levels of women in science. As will be shown in this chapter, several studies examined impact by analyzing the placement of the author in the authors list. First and last authors are sometimes an indication of the level of leadership in the production of the publication [21.10, 11]. In the area of citation counting, research examined not only the mere number of citations as a measure of impact but also the gender of the citing author/s. These studies focus on the level of peer recognition of female authors. The literature shows that there is a link between gender and citation rates wherein females are cited less than their male peers [21.12, 13].

21.2 Gender Determination

Bibliometric measures use publication information such as title, author name/s and affiliation/s to identify the contributors and assign the number of citations, mentions, and activities around the publication to them. When it comes to the ability to track and measure the relative contribution of female versus male authors and their respective impact, the main challenge is that gender is difficult to determine, since the only indicator for gender is the author's name. Although there are some names that can be determined as female or male, such as `Barbara` or `John`, there are numerous names that are gender neutral. An example is `Andrea`, which is a typically a female name in north America but a male name in Italy. In addition, there are gender-neutral names such as `Robin` or `Leslie`, which make the process of gender identification by name almost impossible just by reading them. There are names that can be difficult to identify as female or male because of regional traits. Such names include, for example, Asian, Middle Eastern, and African names, which are challenging to identify without deep research into each one. Finally, there is an additional complexity relating to issues of gender self-identification. Some authors might have been born as males or females and carry names that express their birth gender but self-identify differently. This is a rather recent social development, which thus far has not been investigated in gender-related studies.

Therefore, before discussing the bibliometric approaches to gender analysis in science, it is vital to review the main techniques used to determine the gender of the authors:

21.2.1 Manual Assignment

Gender verification is processed through the examination of the author's first name and, in cases where the name is difficult to verify, the author engages in a manual internet search for that person. Manual analysis is difficult to scale up or apply to large datasets. The largest dataset to be decoded for gender manually used 1 059 939 articles [21.14]. This study analyzed the contribution of female Russian scientists to the overall Russian body of scientific literature. Although the gender decoding was performed manually, the authors were able to determine gender in a straightforward way because Russian names are gender driven, making them easier to identify. Similarly, gender specific names assisted in the identification of female authors in Poland [21.15]. Needless to say, such an approach would be difficult to apply to author names that do not adhere to traditional gender driven rules.

21.2.2 Institutional Rosters and National Databases

Studies focusing on institutional or national levels assume that larger amounts of articles produced by female authors can serve as an indication of their productivity and participatory levels. These studies decode gender by using existing databases that include gender information [21.16–19]. National databases can include data of federal or state agencies, which contain educational statistics and include the gender of the scientists. Examples are The Spanish Council for Scientific Research, The American Doctoral Dissertations Database, The Indian Directory of CSIR Scientists, and so forth. In these studies, the data collection includes the retrieval of articles assigned to an institution or a nation and cross-checking the names with national databases that hold the gender of the authors.

21.2.3 Questionnaires

A few studies included questionnaires in order to verify authors' gender and seniority, in addition to using institutional records. This was done mostly when the study spanned several universities across various locations or when a specific institution was examined [21.11–13, 20–22].

Table 21.1 Gender identifying software tools and databases

Chinese Name Gender Guesser	
Social Security US	https://www.ssa.gov/oact/babynames/
Gender API	https://www.gender-api.com/
First Name Sex	http://www.firstnamesex.com/

21.2.4 Software Tools

Finally, some studies on participation and productivity measures used specifically developed software and web tools that assist in identifying the gender of the author [21.23, 24]. These software tools rely on name data collected from sources such as name registries or national databases such as social security indexes to create matching algorithms that can identify whether a name is female or male (Table 21.1).

The accuracy of these approaches varies. Manual identification of gender by author names reports between 10 and 15% exclusion of articles due to the inability to identify the gender of the authors. Studies using software tools compliment the initial identification of the author names by manually searching for author names that the software was not able to identify. Studies using university rosters and national databases report the most accurate results with relatively large data samples [21.25–32]. However, it should be noted that no one methodology is superior. When the purpose of the study is to examine female participation in specific areas of science, the publication-level approach can serve as a good indicator. Choosing high impact journals or conferences and extracting their publications will ensure that the study focuses on a well-defined discipline or sub-discipline. However, in studies that span nations and institutions around the world, it is more efficient to obtain data from local rosters or national databases in a comprehensive manner. Studies in this arena could also benefit from using existing software tools for initial name screening and gender identification and compliment data gathering with manual searches on the internet. Although not very sophisticated, there are several name registries that are available freely on the web and provide gender identification of names in different regions of the world.

21.3 Definitions

The studies examining gender disparities in science while using bibliometric methodologies can be grouped into four main areas:

1. Productivity
2. Performance
3. Impact and visibility
4. Academic standing.

In the following sections of this chapter each of these areas of study will be discussed while covering the three major elements of the research investigation:

1. Unit of investigation
2. Data collection and dataset used
3. Research methodology.

21.3.1 Areas of Investigation

In order to better understand both the areas of investigation and the elements within the bibliometric approach there is a need to define them so that they can be further applied for future studies.

Productivity

In gender studies, the number of publications one produces mostly defines productivity. These include journal articles, conference papers, books, and book chapters. These publications are peer reviewed and indexed in either a controlled database such as the Web of Science or Scopus or in a non-controlled database such as Google Scholar. The main premise is that the more publications one can attribute to an author, the more productive the author is. Therefore, productivity studies rely on publication count per author.

Performance

The manner by which bibliometrics defines performance is mostly through applying analytical calculations to the number of publications and the number of citations they receive. The assumption is that the more citations an author's publications receive, the higher his/her performance. The impact factor (IF) of the journal in which they are published plays a major role. The higher the IF score of the journal in which the author publishes, the higher his/her performance is considered to be. Measures such as h-index scores, which use the number of citations and number of publications, are used in this context. Bibliometrics also developed several citations-driven analytics to publication data that aim to capture performance within the context of each scientific field and drive a more accurate capture of an author's performance. The field weighted citation impact (FWCI) measure, for example, aims to measure the impact of publications and citations within each field and is used to capture performance.

Impact

Impact is defined as both the number of times a publication is cited and the overall engagement an author's publications receive. Engagement is usually measured by altmetrics, which count the number of downloads, views, shares, and mentions of publications in academic and social networks. The underlying reason for such measurement is the assumption that publications have a wider range of impact, which goes beyond citations. Many publications might be read, shared, and discussed but not necessarily officially cited. Such engagement is considered impact and is attributed to the author/s whether or not their work is cited.

Career Track—Tenure and Promotions

In this arena, research is focused on examining the progression and development of authors' academic careers. Using bibliometric data and deep analytics of the authors' CVs for academic career progress, these studies aim to establish whether there is a link between productivity and impact and academic retention, promotion, and recruitment.

21.4 Research Approach

Units of investigation: Gender studies are seen to take two main approaches: (1) publication level or (2) department, institution, or country level. These require different data collection approaches and cross-analytics.

21.4.1 Publication Level Analysis

The journal/article level approach includes studies that collect data for a specific journal or proceedings over a span of time and analyze the number of female and male authors in each article or conference paper [21.25, 26, 28, 29, 31–33]. Interestingly, the vast majority of these studies are in the area of medicine, covering clinical practices such as surgery, emergency medicine, psychiatry, dermatology, and others [21.10, 23, 26, 31, 34–43]. There are very few publication-level studies that look at the output rates of females versus males that tackle specific areas of science [21.11, 23, 32]. The data collection described in these studies is straightforward. The procedures employed in these studies usually include the selection of 3–4 high-impact journals based on impact factor scores or the analysis of a specific journal over a few years.

21.4.2 Institutional and/or National Level

In most cases, these studies are used to determine the productivity and participation level of females in science overall rather than specific disciplines. Large areas such as STEM are usually addressed on a national or institutional level while using large amounts of publications verified for gender by national databases [21.16, 44, 45]. Institutional level studies look at the productivity and participation rates of female scientists across scientific areas in a specific academic institution [21.17, 46]. These studies utilize the institutional roster as a way to identify the gender of the authors. In many cases, studies are conducted on current faculty members and compare publications rates over time based on the number of authored papers and an author's seniority.

21.5 Data Collection and Datasets Used

Number of publications: The data is collected by retrieving the publications of each author, institution, department, or state, depending on the purpose of the research. In institution, department, or state level studies, the investigators retrieve the publications from known databases such as the Web of Science, Scopus, or Microsoft Academic and use the affiliation name and address to identify them. In studies that examine a known group of scientists, investigators use the authors' names to retrieve their publications. It should be noted here that each database could potentially retrieve different numbers of publications per author due to varying coverage policies. Unlike Google Scholar, controlled databases such as the Web of Science and Scopus have a selective approach to indexing coverage. Therefore, in many cases, the complete corpus of one's publications will not be retrieved. The data source in this case is crucial. Depending on the discipline, one should consider which database to use [21.47].

21.5.1 Number of Citations

Citations are counted per publication retrieved. Citation counts also depend on the database used. In some studies, citations are also calculated and normalized for a discipline, institution, or country [21.15, 17, 20, 48, 49]. The main purpose of calculating normalized citations is to achieve the outmost accuracy when comparing different disciplines, institutions, departments, etc. Normalization accounts for the size of the institution or department and the overall citations rates of a scientific field. In this manner, larger institutions or scientific fields are not compared to smaller ones without accounting for these differences. Some fields cite in higher rated publications than others, in the same way that some institutions have more faculty members than others [21.50–52]. When comparing citation rates, these should be taken into consideration as well.

21.5.2 Authors

Gender studies are focused on authors. The datasets selected cover different groups of authors. These datasets vary from one study to another and include the use of questionnaires distributed within an institution or department. The use of national databases include:

1. Spain: The Council for Scientific Research
2. Spain: CSIC database [21.29]
3. USA: American Doctoral Dissertations [21.53]
4. India: Bibliography of Doctoral Dissertations
5. India: Directory of CSIR scientists [21.19]
6. France: Centre National de la Recherche Scientifique (CNRS) [21.54]
7. Italy: Italian Observatory of Public Research [21.17]
8. USA: The US Social Security Database [21.55, 56]
9. USA: US AMA Fellowship and Residency Interactive Database [21.37, 57]
10. USA: US National Center for Education Statistics (NCES) [21.18]; use of institutional databases (rosters) [21.58]
11. South Africa: ten universities [21.59].

21.5.3 Publication Datasets

Publications are selected based mostly on their impact factor and within their disciplines in order to measure female participation in these fields [21.10, 23, 24, 31, 34, 35, 37, 40, 43, 60–62]. Interestingly, many of these studies focus on different medical fields while using a collection of leading journals to retrieve publications by female authors. There are some, although not many, that focus on other fields of science such as neuroscience, astronomy, library and information science, international relations, materials science, and computer science [21.21, 25, 26, 28, 29, 32, 63–65].

21.6 Methodology

21.6.1 Counting

This method uses simple counts to compare the number of female authors to the number of male authors [21.10, 14, 29, 31, 33–35, 37, 39, 41, 43, 62, 65]. This method is frequently used when the study focuses on a selection of journals or conference proceedings and compares the number of female authors to male authors over time. Many of these studies focus on high impact journals or conference proceedings in different disciplines.

21.6.2 Normalizing

This method is frequently used in the area of performance comparisons between female and male authors across disciplines. Disciplinary examination of performance requires careful consideration of the publication rates of different disciplines, as well as their citations and even grant amounts. Therefore, these studies must normalize the results to account for differences in the number of publications, citations, and even grants [21.16, 17, 30, 48, 66–68].

21.6.3 Matching and Clustering

This method uses matching and clustering techniques to compare not only gender but also chronological age, academic age, experience, and other qualifying variables [21.68, 69]. Studies using this technique tend to look at a specific population in an institution or a geographic location and conduct analysis of sub-groups based on the above characteristics. Since there are a number of qualifiers that are considered per gender group, these studies tend to be small but accurate as far as the analysis is concerned. Many of the studies using these methods focus on analyzing output rates between smaller sub-groups of the population studied [21.70–74]. A good example of using a variety of matching techniques is a study researching Danish health sciences graduates [21.75]. In this study, the authors studied 541 students enrolled at the Institute of Clinical Research at the University of Southern Denmark. The relatively small population studied allowed the authors to match the population studied based on their discipline and sub-discipline of study, their age, education, and time lapse from the enrolment date. This multimatching approach ensures that there is as little bias as possible in the analysis. However, as with other studies in this area, an approach like this requires that a relatively small population be studied and a reliable source of data, in this case, the university records.

21.6.4 Qualitative Measures via Surveys and Interviews

Qualitative methods are used especially in studies that look at career development differences between females and males. In order to track career paths and development, these studies use surveys and interviews to gain insights into the differences between males and females [21.69].

21.7 Productivity

Studies in the area of productivity mostly compare female and male scientific output in a variety of disciplines and regions of the world while sketching overall trends in female participation in science compared to that of males. These studies define *productivity* as the total number of publications produced by a scientist. This simple yet effective approach to such comparisons aims to demonstrate whether or not there is a gap between the numbers of publications produced by females as compared to those produced by males [21.26, 29, 37, 38, 42, 45, 55, 62, 76].

The majority of the studies examining productivity in the form of the number of article contributions by female scientists use the numbers as an indication of participation in a certain field. The main assumption is that an increase in female authors is an indication of an overall increase of female participation in the field. This could explain why many of these studies are in the area of medicine, a field that is still considered male dominated.

Despite the fact that this could be perceived as a simplistic approach to measure productivity, it is an effective way to examine male/female participation in specific areas of science. The main reason for choosing this approach is that it enables a straightforward selection of topics, body of literature, and time frames for analysis. For example, a study on the productivity rates of males and females in general medicine will require a selection of journals in the discipline, retrieval of publications in specific time frames, and an analysis of the number of publications produced by females as compared to those produced by males. In the same manner, a study can also examine whether females occupy the positions of first authors as opposed to second or third authors. By selecting a well-defined collection of journals, researchers can also examine the participation of females in science over time. This is especially true for well-established journals that have been publishing for decades, such as the *New England Journal of Medicine* or the *Journal of the American Medical Association*.

Interestingly, these type of studies are seen to be very popular in various clinical research areas [21.10, 23, 31, 32, 35, 37, 39, 41–43, 60, 61]. By selecting a few high impact journals and comparing female authorship to male authorship, researchers have been able to demonstrate an overall steady increase of female-authored papers in clinical research fields such as plastic surgery, pediatrics, ophthalmology, oncology, radiology, and others. In addition to clinical sciences, productivity in terms of number of publications has also been studied in the areas of library and information science (LIS), material sciences, computer science, nanoscience, and neuroscience [21.25, 26, 28, 29, 32, 33, 49, 65]. One of the few social sciences-related studies focused on the differences in productivity between female and male researchers in the areas of sociology and linguistics [21.67].

Productivity and output rates have also been used to measure the overall participation of females in science on a national level. In order to analyze the productivity rates of females and males on a national level, studies have been designed using two main approaches: (1) aggregating the literature to the institutional and national levels and (2) utilizing national databases and institutional rosters to identify female authors across departments and institutions and aggregating them to a national level [21.14, 15, 17, 18, 45, 46, 48, 56, 77–79].

Aggregation of the literature to a national level is often conducted when there is an interest in examining female participation in a specific area of science in a specific country. In these cases, the studies select a defined collection of publications in the discipline and limit it by year ranges. By using affiliations' names and locations, researchers retrieve the publications that list the country. A dataset containing publications, which lists the country, is then limited by year range and analyzed for female/male names. The results are usually able to show not only female–male participation rates in a scientific area, but also the quality of the journals in which they publish. In addition, these types of studies can usually serve as indicators of a country's level of publishing in high-quality publications.

There are several challenges with using this approach. First, the body of literature must be carefully selected. In order to measure national levels of female/-male authorships, one must include international and national publications in order to create a well-balanced dataset. This is especially true in disciplines such as arts and humanities and social sciences, which normally have areas of research that are unique to a country. These could include linguistics, social work, law, and others. Second, when retrieving publications based on names of affiliations, the dataset will not account for an author's publications published under an affiliation prior to the one they currently hold. For example, if a study is looking to examine the rates of Spanish female/male publication rates in pharmacology between 2000 and 2016, a list of publications that cover pharmacology will be defined. Once the list is defined, all publications that list Spain in the affiliation will be retrieved. Once the dataset is retrieved, the author names will be analyzed in order to find the number of females versus males. However, the names of the researchers in the dataset will probably not capture the entirety of the female or male scientist's body of work, as some could have moved outside of Spain in these years. This could be problematic when aggregating to a national level. Therefore, studies compare the results with current rosters or databases available via the institution or federal agencies or validate the author's affiliation through a CV.

Another approach is using national or institutional databases that contain names of scientists to identify their publications. In most cases, the names will be searched for in combination with affiliation name and countries in order to avoid including erroneous records. This approach works most effectively when the dataset is focused on specific areas of science. By using this approach, researchers are able to identify female–male participation ranges in specific areas of research. The challenge in this approach is the number of publications analyzed. Conducting large-scale studies over time and across disciplines requires high computational capabilities, which are not readily available at many research institutions.

Overall, studies found that despite of the steady increase of female-authored publications, there is still a gender gap when it comes to the number of publications produced by females and males in most areas of science and regardless of geography. In an attempt to explain this phenomenon, *Cole* and *Zuckerman* [21.53] listed four explanations of what they termed *the productivity puzzle*. These include:

1. Scientific ability
2. Self-selection
3. Social selection
4. Accumulated disadvantage.

Despite no previous findings pointing to the fact that gender is a factor of scientific ability, *Cole* and *Zuckerman* claim that various biological and psychological factors influence scientific output and put females at an inherent disadvantage. In addition, life events, which *Cole* and *Zuckerman* define as *self-selection* such as child bearing and family obligations, are seen to interrupt women's scientific careers and, therefore, their overall output rates. This was also found in other studies showing that the women begin their careers later than men due to life events and thus produce less publications in their early career [21.69, 80]. Late career mainly means that Ph.D. and Post doc training periods usually coincide with women's marriage and child bearing periods. This, in turn, creates a reality in which women are seen to produce less publications than men due to pregnancies and maternity leave, which put them at a disadvantage when returning to the workplace [21.81]. Trying to catch up with their male counterparts after periods of low productivity is very difficult.

The notion of *social-selection*, as explained by *Cole* and *Zuckerman*, pertains to how scientific productivity of female researchers is sometimes affected by social factors that could be discriminatory. Overall in society, men still dominate positions of power. This is also true in the scientific arena. Therefore, there are preexisting unfavorable conditions to the entry of females into research organizations, which drives lower productivity and participation in science [21.82–84].

There are several reasons identified in the literature that attempt to explain the gap in productivity between females and males, as show below.

21.7.1 Underrepresentation

Females are still underrepresented in many areas of science. Despite the growing numbers of females in academia, many scientific fields are still male dominated [21.39, 56, 85, 86]. There are certain disciplines that are considered more *female orientated*, which include nursing; midwifery; speech, language, and hearing; education; social work; and librarianship. Areas such as military sciences, engineering, robotics, aeronautics, physics, computer science, life sciences, and medicine are still dominated by men. Therefore, it is understandable that the number of publications attributed to males in these disciplines will be greater than those attributed to females.

21.7.2 Career Development

Females begin their careers later than males do. The career timeline of men and women is different. During their Ph.D. and post-doctoral years, men and women are seen to embark on different career paths [21.87, 88]. While men are seen to produce publications at these times, women are diverted by marriage and starting a family. These life events are seen to affect women's productivity more than men's. Time taken for maternity leave and child care creates a gap in productivity that can be difficult to bridge. Once women return to full academic and research activity they are at a disadvantage and need to make up for the time dedicated to family, for instance. This sociological issue could potentially explain the productivity gap seen in early career stages. However, it does not provide a full explanation for the publication gap in later years [21.69, 89–93].

21.7.3 Specialization Versus Diversification

The publication gap seems to persist later in women's careers due to several academic and scientific tendencies that have been identified in the literature. Studies have found that specialization promotes productivity. This mainly applies to increasing proficiency, reputation, and expertise building. Women seem to specialize less, which affects their productivity. There is an interesting difference between men's and women's perception of specialization; while men are of the overall opinion that specialization promotes excellence, women think that diversification in research activities will broaden their professional networks and the breadth of their scholarly activity [21.67, 94, 95].

21.7.4 Collaboration and Professional Networks

Men and women differ in their approaches to professional collaboration and networking. Women tend to achieve better performance in domestic and/or small collaborative groups. Men tend to create wider collaborative networks that overlap with their own, while women focus on smaller and homogenous networks [21.66, 69, 96, 97]. Yet despite of their overall research diversification tendencies, women do not follow this pattern when it comes to research collaboration, which is seen to be smaller and more focused.

21.7.5 Research Versus Teaching

Women are seen to focus on teaching and service rather than research [21.18, 98, 99]. There is a still a debate as to whether the focus on research is a choice or a result of bias. However, this phenomenon is prevalent across institutions and disciplines, which again can explain the gap in productivity rates between men and women.

21.8 Research Performance

Studies in this area use bibliometric measures such as citation rates, h-index scores [21.100], and research collaboration network analysis [21.30, 58, 66, 72] to determine the level of performance of scientists and compare males to females.

Within the area of performance studies, researchers have looked at gender differences in citation rates. Analyzing the number of citations that female-authored publications receive and comparing those to male-authored publications is a predominant method used in these studies [21.12, 13, 21, 22, 64, 101]. There are no definitive conclusions when it comes to citations rates. Some studies find that there are no major differences between males and females with regards to citation rates [21.46, 53, 86, 102, 103], while others find that female-authored publications receive more citations than male-authored ones [21.81, 104], and still others find that female-authored publications receive fewer citations than male-authored ones [21.56, 105].

The inconclusiveness of the results is an indication of the complexity of the subject. On the one hand, the ability to track citations to female-authored papers is straightforward, yet the explanation as to why is more complex. In disciplines where there are fewer female-authored publications, the low number of citations of their work is easily explained. However, in disciplines where the female–male ratio is more balanced, an explanation is difficult. Therefore, these results must be put in the context of their disciplines and even within the specialities they examine [21.96, 106, 107]. There is some evidence that female authors tend to be more selective in their choice of publications, while males are seen to produce as many publications as possible, most of which do not receive any citations. Females, on the other hand, might publish less but their articles receive higher rates of citation [21.108].

Adding to the level of complexity are studies that examine the male to female citation rates. These studies reveal the phenomenon that males do not cite women at the same rate that they cite their male counterparts. The reasons behind this are not clear. Some explanations include, again, disciplinary differences, networking within the research community, visibility, and even the type of publication as factors influencing the male–female citations rates. In areas of research that are inherently male dominated, higher male–male citations are to be expected because the number of male authors is larger. In addition, research has shown that there is an unconscious bias in citation patterns, as well as closely tight networks that generate a high degree of male-to-male citations [21.109].

Studies have also examined whether there is an inherent bias in the peer-review process that could influence female citation performance [21.110] and found no evidence of this. This is also true with regards to funding. Research has shown that the success rate of women and men are virtually equivalent when it comes to National Institutions Of Health (NIH) grant funding (for example, [21.36]). The main reason for the performance gap is the overall lower percentages of women's participation in science overall. This study found that large numbers of women prefer to pursue more independent career paths that are not strongly tied to NIH funding and make this decision earlier in their careers when they are seen to focus on family and children. Otherwise, men and women are more likely to be equally funded throughout their careers.

21.9 Impact and Visibility

Unlike performance measures that can be tracked by productivity and citations, impact and visibility are becoming broader in scope. With the advent of technology, there are several new metrics that aim at capturing user interaction with scientific literature. A *user*, in this broader context, applies not only to the professional reader, but also to the general public. The assumption in measuring these interactions is that a scientific publication can have an impact beyond citations, especially when relevant to the general public. Measures, such as the number of downloads, clicks, reads, mentions in social media channels, journalistic articles, and others can be counted towards impact. Citations, on the other hand, are selective. While writing an article one might read more articles than one cites. These read articles should be counted towards an author's overall impact. The same applies to views of articles, tables and graphs, mentions and discussions on social media channels, and so forth. These metrics generally are referred to as *altmetrics*.

There is growing evidence that scholars are adopting social media as an instrument to communicate, network, and promote their research [21.111–116]. Participation of academics in social networking ranges from using LinkedIn, ResearchGate, and other professional networking channels, as well as Twitter, Facebook, YouTube, and others. Thus far, there is very little research to be found in the area of gender and altmetrics.

One study that measured altmetrics as a function of impact in gender studies uses http://altmetrics.com as a platform to track impact [21.117]. The findings reveal that social media is more gender-balanced than citations, explaining that 'the scientific community which constitute the citing audience is more male-dominated than the social media environment' [21.117, p. 42]. A study focusing on the number of papers and readership rates of women and men on Mendeley [21.118] also shows that readership is more gender balanced.

Although we cannot conclude that impact is more gender balanced when measured through altmetrics, there is initial evidence that supports this. Using social media channels to promote one's work and achievements could be a path for women to become more visible.

An interesting study looking at the impact of web presence on productivity and citations [21.65] used a combined methodological approach to analyze male and female scientists in nanoscience and nanotechnology. The initial objectives of the study were to examine whether or not having a web presence correlates with a higher or lower number of publications and citations. The manner in which the authors approached such an analysis was to select first authors in defined journals in nanoscience and nanotechnology within specific year ranges. Once the list of authors was extracted, the researchers manually searched for each of the authors using Google in order to determine their gender as well as their web presence outlets. *Web presence* was defined as any online channel featuring that author. This could have included official university profiles, blogs, personal web pages, and others. The authors searched for over 1000 names in Google in order to identify gender and web presence.

Interestingly, this study found that the number of publications does not have a direct correlation with web presence. This means that there is no significant difference between the number of publications produced by web-present scholars and web-absent ones. However, with regards to citations, web-present scholars are shown to receive more citations than web-absent ones. Males and females are equally represented online in these areas of research, and females are equally as recognized (e. g., cited) as their male counterparts. Although this study is focused on two disciplines, its methodology can be easily applied to others. Overall, it seems that women can use social networks and social media to their advantage. Whereas previous research showed that women tend to have rather small and closed networks, having a strong web presence on professional social networking platforms could serve women in expanding their networks and reaching a wider audience, thus driving attention to their work and achievements.

Networking has a direct impact on visibility as well as on impact [21.119]. Being visible and active in the research community drives impact as people read and are aware of one's research. This seems to hold true regardless of gender. Studies in the area of collaborative patterns are not restricted to bibliometric investigations and include business, economics, and social explorations of the networking patterns of men and women in different work environments [21.72, 115, 120–122]. Bibliometric studies in this area, however, focus on the examination of whether men and women differ in their collaboration and networking practices, which, in turn, can influence visibility, productivity, and impact [21.66, 69, 123, 124]. The overall conclusions of these studies indicate that men and women have different networking behaviors and motivations [21.120, 121, 125]. Women, for example, join networks in order to develop their skills and seek mentors, but mostly for reasons beyond career motivation, including support and informal interactions. Men, on the other hand, are motivated more by career development and enhancement. This is not surprising considering the fact that there are still networks that are not accessible to women, including senior level management groups that operate on the premise of the *old boys' network* of men who know each other and share similar hobbies or recreational preferences.

A study by *Lee* and *Bozeman* [21.124] used a survey of approximately 400 scientists affiliated with research centers in the USA in order to discover whether age, gender, rank, or marital status influence productivity and collaboration. The survey found that people mostly collaborate with others within their local or immediate settings and environments. This was found to be true regardless of gender or other social factors. Collaboration was also found to have a positive impact on the number of publications produced. The 2005 initial dataset in *Bozeman* and *Gaughan* [21.123] was based on a national database. This set contained the names of the individual researchers working in multidisciplinary work groups or research areas, especially in centers funded by the National Science Foundation (NSF) and by the Department of Energy (DoE). Once the gender of the individuals had been established, the study used a questionnaire that included questions about research collaboration, grants and contracts, job selection, work environment, and demographic information. Although the study initially hypothesized that females would have less collaborators due to social dynamics, the results showed that, in fact, the number of collaborators is more a function of tenure and grant size. Therefore, if the principal investigator (PI) is a female awarded a large grant, her collaborative network will be as cosmopolitan and as large as that of a male under the same circumstances. That said, the study did find that female scientists have a higher percentage of female collaborators compared to males, especially when it comes to non-tenured females. However, tenured female faculty members collaborate with females at the same rate as males. Therefore, one can conclude that non-tenured females will seek to collaborate more with females rather than males. This was somewhat explained by the mentorship role that females tend to take.

The methodologies used in these studies rely heavily on combined data, which include individual names, gender, and CVs. Therefore, they are limited in scope and tend to target specific groups. Despite of the accuracy of the results, and their ability to portray a given situation, they are very difficult if not impossible to scale, since they rely on surveys and interviews.

21.10 Careers: Recruitment and Promotions

One of the most essential areas in the study of the gender gap in academia is the topic of recruitment and promotions, as they pertain to women's careers. There are several studies that attempt to demonstrate female rank and career development by looking at different academic institutions and disciplines. Tracking an academic career is a challenging task, since it requires not only identifying the gender of the authors but also detailed time-dependent information on their professional ranks and career progression. Most journals do not include an author's academic rank, which makes it almost impossible to track career development via bibliographic information. This is the main reason why this topic has been examined in bibliometrics by harnessing samples of publications combined with either interviews, CVs, or data from national databases depicting recruitment and tenure procedures of state universities [21.58, 71, 74, 76, 126].

The most common methodology used in order to track women's academic careers uses a collection of journals in a defined discipline and year ranges. Once the articles from these journals have been identified and downloaded, the researchers identify the gender of the authors either manually or by combining name check software tools. The next step for tracking the development of careers, tenures, and promotions is to send a survey and conduct interviews with as many authors as possible. These surveys and interviews provide insight into issues of time lapses between degrees obtained, promotions, tenures, and academic roles.

Another methodology seen in this arena is the use of national and/or professional databases to identify female academics. For example, *Hancock* et al. [21.71] utilized data from membership in the International Studies Association (ISA), and *Abramo* et al. [21.126] used publicly available data on the 2008 Italian Competition for Associate Professors, which includes data on the winners as well as their gender. Once the population had been identified, a bibliographic search for publications and citations was conducted. Both these approaches resulted in datasets that are a combination of qualitative and quantitative measures.

When tracking careers, the most common areas researchers look into are comparisons of the careers of women and men, as they pertain to three major areas:

1. Probability of gaining promotions and/or tenure
2. Probability of holding major leadership roles within academic institutions
3. Salary equality wherein women's salaries are compared to those of their male counterparts in the same positions. This data is mostly collected via interviews and surveys.

In order to discover biases, most of the studies utilize bibliometric data, such as number of publications and citations. The main premise is that if a female author has similar amount of publications and citations to a male in the same discipline, their rank, salary, and roles should be equal.

Research results show that the geographic location and type of academic institution play a role in achieving equality. In Italy, for example, *Abramo* et al. [21.126] found that in certain disciplines where there is a high number of males compared to females, males are most likely to win an academic position even if they are less deserving of the position than a female counterpart. In addition, there seems to also be favoritism, as a male committee president is more likely to award an academic position to a male candidate whom he has known for several years, again, regardless of merit. In The Netherlands, *van den Besselaar* and *Sandström* [21.74] found that productivity differences between men and women play a role in career development. In early career years, men and women show similar levels of performance. This changes in later years, when women diverge into teaching positions, while men choose research-oriented positions, which in turn affects their respective ranks and roles. The authors hypothesize that gender bias could play a role in this self-selection process, as women are seen to choose less competitive positions due to a lack of support compared to their male counterparts. In Sweden, on the other hand, *Mählck* [21.58] found that females do not perceive gender to be a factor in their academic career development despite the differences in rank between them and their male counterparts. The authors in this case assume that the overall culture of equality in the country is a factor influencing this perception, even if gaps exist.

The gender gap in career development is, therefore, found to be dependent on geographic location, culture, and self-selection, as well as, in some cases, favoritism and discrimination. In some cultures, females are discouraged from pursuing scientific careers and are either self-diverted or encouraged to pursue teaching rather than research paths. Methodologically, data collection for studies on this topic is complex and involves manual procedures and qualitative applications of surveys, for example.

21.11 Summary

Gender studies are seen to focus on topics including productivity, impact, visibility, performance, and career development. Methodologies in these areas include, in most cases, more than one procedure, because of the complex data collection. Table 21.2 summarizes the major approaches to the different studies and is organized on the basis of the four main comparative objectives of gender studies:

1. Productivity
2. Performance
3. Impact and visibility
4. Career development.

Each topic, except career tracking, presents some similarities in data collection approaches that usually begin by identifying high impact factor journals in a discipline. In most cases, the article collection is limited by year range. This approach is one of the most popular ones seen in the literature; it allows for a close study of a specific discipline by targeting journals that are considered core journals. The proportions of female and male authors in these journal publications provide an indication of impact measures as well as of productivity over time. Publishing overall is an indication of productivity, while the IF of the journals indicates impact. Comparing datasets of articles from different years allows researchers to notice which gender group publishes more and in what types of journals, as well as to track female participation levels over time.

Once the dataset of articles has been downloaded, the gender of the authors needs to be identified. This portion of the data collection presents a challenge. Unlike other bibliographic metadata, gender is not provided in the articles. Therefore, gender identification relies on the first name of the author. As was seen above, there are a few techniques to do so. The use of national name databases is helpful. These databases are usually made available by governments and list the most common names and their gender. They are, of course, not exhaustive, but they do provide some basic information about the gender of names in a specific country. The second technique is to use automated software

Table 21.2 Summary of common data collection approaches

Comparative measure	Most common data collection approaches
General female/male comparisons using bibliometric analysis	Journal selection: High impact factor journals in specific discipline/s are selected. Year range selection: Dependent on the purpose of study. If comparing output overtime articles are retrieved in various years or year ranges. Article retrieval: Articles are retrieved using an indexing database. Bibliographic data must include first names of author/s. Identifying gender: Female/male gender identification is done either manually, using a software tool, utilizing national or institutional databases, and a combination of the above. When gender cannot be identified, some studies utilize questionnaires or direct communications with the authors
Productivity: Most commonly measures the number of publications output	The number of articles attributed to female authors versus male authors is compared
Performance: Mostly measures citations received and grants received.	For article citations: Data is collected as above. Citations per article are collected using a citation tracking database such as Scopus or the Web of Science. For grants: If the study focuses on a specific institution and/or country, grant information is collected either through an open state or federal database or through the institution's own records. In cases where the study examines a specific discipline in various geographical locations, data is collected through article retrieval, identification of leading authors, followed by grant information retrieval.
Impact and visibility: Mostly measures the overall awareness of publications and authors.	Web presence: Tracked by searching for authors online, mostly manually. Web presence is attributed when an author has a website, blog, or any professional network activity. Altmetrics: Article level metrics such as usage, social media mentions, media, and others are collected via different platforms such as http://altmetric.com, Mendeley, and others
Career: Tenure and promotion	Institutional or national databases containing promotions and/or tenured appointments are used to compare female and male career progression. Surveys: Individual surveys to designated populations are used to collect information about promotions and tenure. CV analysis: This is used in many cases when an institution or department is studied. There are cases where CVs are available via state or federal institutions, which allows for a larger population to be studied

that allows for name searches and identifies their gender. These software tools are helpful but do not always properly identify gender. A third technique is manual checking of each name using the internet and finding information such as pictures or websites to identify the gender of authors. Finally, departmental or institutional human resources records are also used. This approach is, of course, the most accurate but limits the study and does not allow conclusions to be made beyond the institution. In general, any of the above techniques will always present a challenge if there is an attempt to scale it up. Since there is still no fully automated way to identify the gender of the authors, manual work will always be required.

In order to measure performance, researchers use the number of publications and the number of citations per article. This is the most common indicator of high performance. While these measures are quite straightforward, impact and visibility are more complex measures to analyze. In this arena, researchers use altmetrics indicators such as usage, media mentions, and others to measure the overall impact of articles published by women versus those published by men. Visibility was seen to be measured by web presence such as participation in online professional networks and having a blog or other online website.

Career development is more complex to track. In order to be able to measure promotions, tenure, and career progression of men and women, most studies use CV analysis combined with national or institutional records that provide gender information as well as career progression over time.

Gali Halevi

Icahn School of Medicine at Mount Sinai
New York, NY, USA
gali.halevi@mssm.edu

Gali Halevi is the Associate Dean of Libraries and Information Sciences at the Icahn School of Medicine at Mount Sinai. Gali oversees several physical libraries and library services to all Mount Sinai affiliations. Prior to this she was part of a team at Elsevier developing research and evaluation metrics tools. Areas of interest include research evaluation and output, global scientific trends, and international research collaborations.

22. How Biomedical Research Can Inform Both Clinicians and the General Public

Elena Pallari, Grant Lewison

This study involved the collection of clinical practice guidelines (CPGs) on five noncommunicable disease (NCD) areas from 21 European countries, and extraction of their evidence base in the form of papers in journals processed on the Web of Science (WoS). We analyzed these cited papers to see how their geographical provenance compared with European research in the respective subjects and found that European research (and that from the USA, Australia, and New Zealand) was over-cited compared with that from East Asia. In cancer, surgery and radiotherapy research made important contributions to the CPGs.

We also collected medical research stories from 30 newspapers from 22 European countries and the WoS papers that they cited. There was a heavy emphasis on cancer, particularly breast cancer, and its epidemiology, genetics, and prognosis, but new treatment methods were seldomly reported, particularly surgery and radiotherapy. Some of the stories quoted commentators, with those from the two UK newspapers often mentioning medical research charities, which thereby gained much free publicity.

Both sets of cited research papers showed a marked tendency to be over-cited by documents from their countrymen; the ratio was higher the smaller the country's contribution to research in the subject area.

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,

22.1 Study Objectives

The main purpose of biomedical research is to improve healthcare [22.1], both by the better treatment of patients and by the prevention of illness [22.2]. The second of these goals is often given lower priority by national healthcare systems, because the immediate need to treat patients claims more attention [22.2]. This is, of course, a common problem in policy-making, summed up neatly in the phrase, *we were fighting off the alligators, but the real need was to drain the swamp*. In effect, longer-term problems that could provide great benefit at a modest cost are neglected in favor of short-term problems that are crying out for a solution [22.3]. The question of what treatment to provide should be answered with reference to the best available science [22.4–6], but instead it is often based on the personal experience of clinicians [22.7, 8], and the lobbying of special interests [22.9], particularly in healthcare by pharmaceutical companies [22.10, 11].

22.1.1 Importance of Study

We considered that it was important to examine two ways in which biomedical research could influence these two goals. The first is to examine the evidence underlying clinical practice guidelines (CPGs), which are increasingly being used to determine patient treatment [22.12]. The second is to look at the stories in the mass media, which are the main means whereby research is brought to the attention of the public [22.13]. The *public* includes a wide range of people, from politicians who decide healthcare policy, their expert advisers, clinicians and other healthcare personnel, other researchers, and of course the general public. Nowadays, we are being encouraged to take a more active role in the protection of our own health, assisted by public health legislation [22.14, 15]. The latter depends to a large extent on public consensus, and good timing, so that it will readily be put into practice [22.16]. Examples of evidence-based policy [22.17] are the mandatory use of car seat belts [22.18], and the prohibitions on smoking in enclosed spaces such as offices and restaurants [22.19]. Others currently being considered, but having difficulty making headway against determined industrial lobbying, are minimum prices for alcoholic beverages and restrictions on sugary soft drinks [22.20].

The work to be described formed part of a major European Union (EU)-funded project on the mapping of European research on five noncommunicable diseases over 12 years, 2002–2013. *Europe* or EUR31 was defined as the 28 member states of the EU, plus Iceland, Norway, and Switzerland. The five NCDs were cardiovascular disease including stroke (cerebrovascular disease), designated as CARDI; diabetes or DIABE; mental disorders or MENTH; cancer or ONCOL; and respiratory diseases or RESPI. This was undertaken in 2014–2015 by King's College London (KCL) in association with six partners: the London School of Economics (LSE, the coordinator); in Estonia, the Estonian Research Council, Tartu; in France, Université Paris Est Créteil, Paris; in Germany, Technische Universität Berlin; in Italy, Università Commerciale Luigi Bocconi, Milan; and in Spain, Escuela Andaluza de Salud Pública, Granada. These partners assisted us with the updating and calibration of the five NCD filters that were used to identify research papers in the Web of Science (WoS, © Clarivate Analytics, formerly part of Thomson Reuters) and with the work described in this chapter. We also recruited KCL graduate students from most of the other EU Member States with the necessary research and language skills to read European CPGs and newspaper stories citing research.

22.1.2 The Development of Clinical Practice Guidelines in Europe

Clinical practice guidelines started to be described in the literature in 1971 [22.21], and the first papers were all from the USA. There was rather little notice taken of them in the 1970s and 1980s, but interest really began in the 1990s. After something of a lull in the 2000s, interest picked up in the 2010s (Fig. 22.1). There was also a shift in the countries that were involved. In the 1970s it was only the USA, but the UK started publishing in the 1980s, and was gradually overtaken by the other EUR31 countries, and the rest of the world (Fig. 22.2).

Figure 22.2 makes clear that the European Union (plus the two European Economic Area (EEA) states and Switzerland) has been increasingly dominant. In parallel with the growing numbers of research papers, there has been a similar growth in the numbers of CPGs published in European countries, see Fig. 22.3 which shows the numbers that concern diabetes.

Although our search for these CPGs was not exhaustive, we did identify ones from 21 countries out of the 31. In the UK, there are two organizations that publish CPGs: the Scottish Intercollegiate Guidelines Network (SIGN), which began operations in 1993 [22.22], six years before the one for England and Wales, the National Institute for Clinical and Care Excellence (NICE) [22.23]. In France, Guides Parcours de Soins are published by the Haute Autorité de Santé [22.24].

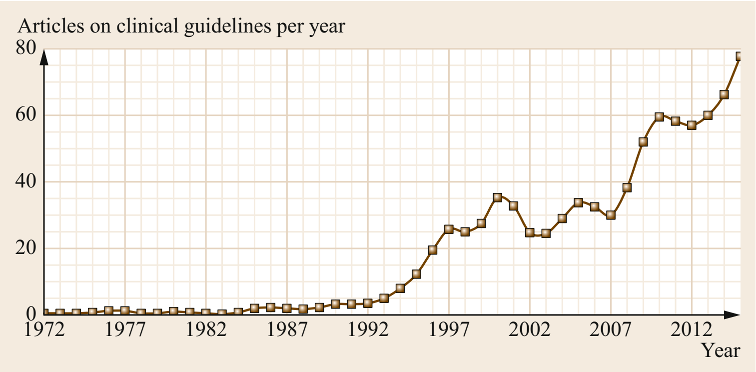

Fig. 22.1 Increase of numbers of articles in the Web of Science (WoS) with clinical guidelines in their title from 1971 to the present, 3-year running means

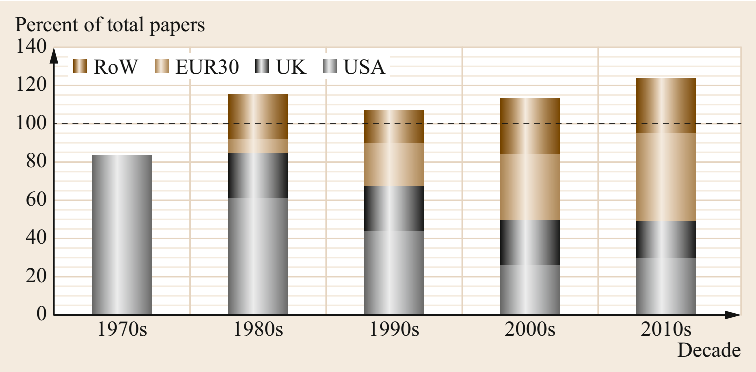

Fig. 22.2 Percentages of total set of clinical guidelines articles in the WoS in each of five decades from the USA, the UK, the rest of Europe (EUR30), and the rest of the world (RoW), integer counts. Note: percentages sum to more than 100% because of international collaboration. In the 1970s, some papers had no recorded addresses

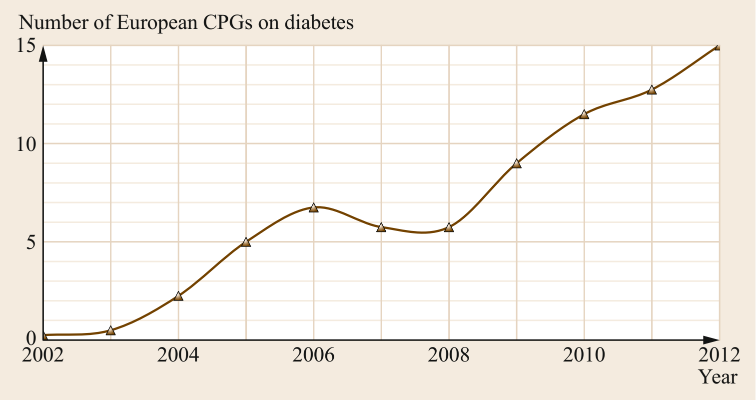

Fig. 22.3 Numbers of clinical practice guidelines in diabetes from EUR31 countries, 2002–2013, 3-year running means

In Germany, a large number of organizations, some federal and some private nonprofit, come together to prepare and publish CPGs, *Nationale VersorgungsLeitlinen* [22.25] as the collection of logos on a diabetes guideline shows (Fig. 22.4). In Italy, some CPGs are developed by the Istituto Superiore di Sanità in partnership with its parent department, the Ministero della Salute [22.26]; others are produced by nonprofit societies (Figs. 22.5 and 22.6). This is also common in Spain, where the societies form a group and the CPGs are published in an academic journal, but other guidelines are sponsored by national and regional ministries [22.27] (Figs. 22.7 and 22.8). So there is a wide variety of publishers of European CPGs, and both governments and nonprofit organizations are involved. A more comprehensive list of European CPG providers is provided in the Appendix, Table 22.17.

22.1.3 Previous Work on the References on Clinical Practice Guidelines

Although clinical practice guidelines started to be described in the literature in the 1970s, it was almost two decades before their impact on medical practice was

Fig. 22.4 The German organizations that were associated with a diabetes guideline

Fig. 22.5 The Italian organizations that were associated with a diabetes guideline

evaluated [22.28] or their evidence, in the form of the cited references, began to be considered as a means to evaluate biomedical research [22.29, 30]. Grant's conclusions are still valid, namely that the papers cited on CPGs published by the NICE are clinical rather than basic; that they are fairly recent; and that they tend to over-cite research by own-country authors. This last conclusion strictly only applied to British guidelines as there does not appear to be any comparable study based on those of other countries. Subsequently, the scope of these studies was extended to a wider selection of CPGs [22.31–33], including those from the SIGN and the British Medical Association's handbook, *Clinical Evidence*. Subsequently, *Kryl* et al. [22.34] showed that the references on two CPGs from the NICE, on dementia and chronic obstructive pulmonary disease (COPD), could provide a useful tool to evaluate medical research, particularly if the cited papers contained data on their funding sources—as papers in the WoS routinely do since late 2008.

Fig. 22.7 Sponsors of Spanish CPG in diabetes, including Catalonia

Fig. 22.8 Another example of Spanish diabetes CPG sponsors, including the Basque Country

A major part of the reason for the lack of further use of this tool is undoubtedly that it is difficult to extract the relevant information from the CPGs that would enable each reference to be tabulated with its salient information, such as the authors' addresses and the details of its funding. This is effectively a three-stage process. First, the relevant CPGs have to be found; usually (but not always) they are freely available on the Web. Their titles need to be translated, as those from most non-Anglophone countries will be in the local language. Second, their references have to be identified and collected from the CPG by means of a copying and pasting procedure to a spreadsheet, and then processed so as to give a series of standardized search statements that can be applied to the WoS. Third, they have to be sought in the WoS and their details have to be downloaded to file ready for analysis. This process is described in more detail in Sect. 22.2.1; it is inevitably rather labor-intensive because the different CPGs give references in different formats, and sometimes the references even within one CPG can differ in their format, although a certain degree of assistance can be provided with a visual basic application (VBA) macro. Moreover, some of the references will not be to papers in the serial literature; these cannot be processed in the same way and are usually ignored. A series of VBA programs (written by Philip Roe of Evaluametrics Ltd.) were developed to assist with the extraction of the bibliographic details of the research papers. These VBA macros were specifically formulated to work with the WoS and this was particularly useful as the WoS permits the retrieval of grey literature including conference proceedings not covered in other databases, as well as providing options for accessing address details, country of publication, citation impact metrics, and other parameters in an analyzable format.

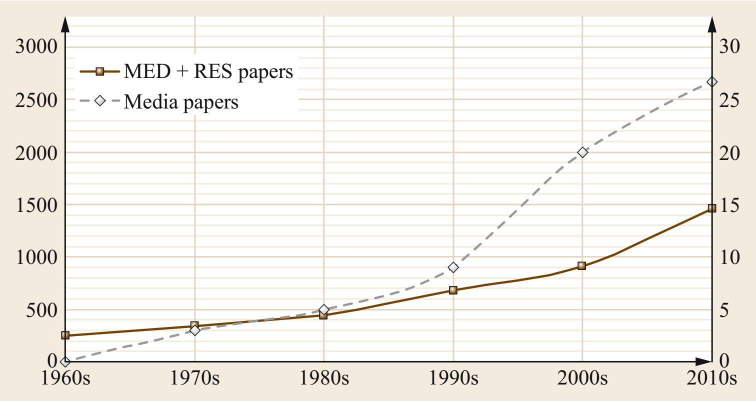

Fig. 22.9 Numbers of papers in the WoS in each decade since 1960 that have medical and research in their titles (*squares* and *solid line*, *left scale*), or concern how medical research is reported in the news media (*diamonds* and *dashed line*, *right scale*)

22.1.4 Newspaper Stories About Medical Research

In contrast to the paucity of papers about the use of the references on CPGs for research evaluation, there are over 50 papers in the WoS that concern how the mass media, particularly newspapers and magazines, report medical research, and their number has been increasing faster than the numbers with *medical* and *research* in their titles (Fig. 22.9).

Of these papers, the majority (31 out of the 52 with addresses) were from the USA, but this may reflect the bias in WoS coverage of social science journals, which accounted for half of the papers. Other countries that contributed papers were continental Europe (8), the UK (7), Canada (4), Japan (2), and China and Russia (1 each). A majority of the papers analyzed stories in newspapers (28) and/or magazines (12); only a handful were concerned with broadcast media, probably because archives of radio and television are less common and less easy to analyze. Many papers looked at how the general public, or sections within it, reacted to mass media coverage of a topic, and especially the effectiveness of public health campaigns [22.35]. Two papers showed that mass media coverage also led to more citations of the research publications as a result [22.36, 37]. The most popular disease area to be analyzed was cancer (25 papers), followed at some distance by mental health, including alcoholism (7), cardiovascular research (2), and arthritis and diabetes (1 each).

22.2 Methodology

A systematic approach was used to identify and download the CPGs, collect the cited evidence-base on these CPGs, download their bibliographical details, and conduct the analysis. Another search strategy was developed to identify the newspaper stories that reported medical research, enter their details to a spreadsheet, and then download the bibliographical details of those research studies for the analysis.

22.2.1 The References on Clinical Practice Guidelines

The first task, of course, was to find the CPGs in the various countries. Since most of them were in languages other than English, we called upon our European partners, other European collaborators, and the KCL graduate students to search for these on the Web, and to provide us with copies, normally in pdf format, with translations of their titles. Altogether we were able to obtain CPGs from 21 countries; some of the others did not appear to have any (e. g., Cyprus at the time, others may have had them, but lack of resources meant that we could not obtain them, e. g., Iceland and Norway). We compiled lists of all these guidelines, and it was immediately apparent that there were far too many for us to be able to process them all, since some had upwards of a thousand references, and many had several hundred, and they tended to be in different formats.

We therefore needed to make a selection, and decided to cover those CPGs that referred to diseases or disorders that were responsible for 1% or more of the disability-adjusted life years (DALYs) in EUR31 in 2010 as given by the Institute for Health Metrics and Evaluation at the University of Washington, USA [22.38]. These were as shown in Table 22.1, and included one or more disease areas from each of the five NCDs.

The next step was to find the references on each of these guidelines. Some CPGs had them neatly gathered

Table 22.1 List of 13 noncommunicable diseases or disorders selected for the analysis of their European clinical practice guidelines, with the estimated percentage European disease burden in DALYs in 2010

Disease area	(%)
Ischaemic heart disease	9.7
Cerebrovascular disease	5.3
Unipolar depressive disorders	4.3
Trachea, bronchus and lung cancers	3.5
Chronic obstructive pulmonary dis.	2.9
Diabetes mellitus	2.5
Colon and rectum cancers	2.0
Anxiety disorders	1.7
Alzheimer's dis. and other dementias	1.7
Breast cancer	1.5
Alcohol use disorders	1.3
Drug use disorders	1.3
Asthma	1.1

together at the end (for example, those from SIGN); others had them at the end of each chapter or section. Naturally, their format varied according to the source of the CPG, and sometimes even within the same document. The normal format included the names of several authors, the title, the year, and the source (journal, volume, pages). However, the Finnish CPGs only gave the name of the first author and did not give the title of the cited paper, and special arrangements were needed for these references (see below).

The reference section was copied and pasted into an Excel spreadsheet. For some CPGs, the references were numbered sequentially, which allowed a specially-written VBA program to identify where each reference ended and the next began (because many ran on to two or more rows in the spreadsheet). For those that did not, the reference section was copied and pasted into MS Word, so that the numbers could be manually inserted before being transferred back to a spreadsheet.

The VBA program then parsed each reference into a standard form of WoS search statement that included up to three authors, plus the three longest words from the reference title, plus the year, plus the initial letter of the journal. (We could not use the journal name because this was often abbreviated in a non-standard format.) An example is given below.

Original Form of Reference

Jensen DM, Damm P, Sorensen B, Molsted-Pedersen L, Westergaard JG, Korsholm L, et al. Proposed diagnostic thresholds for gestational diabetes mellitus according to a 75 g oral glucose tolerance test. Maternal and perinatal outcomes in 3260 Danish women. Diabet Med 2003 Jan;20(1):51–57.

Format when Search Statement Prepared

```
AU=(Jensen, D AND Damm, P AND
Sorensen, B) AND TI=(diagnostic
AND thresholds AND gestational)
AND PY=2003 AND SO=D*
```

These search statements were then grouped automatically into sets of a selected number, typically 20, that could be run against the WoS. References that did not appear to fit the format for journal papers were initially ignored by the program, but could be added later. Sometimes this was because the punctuation was not exact. (For example, the program expected journal references to have just three full stops: one after the list of authors, one after the title, and one at the end. In the example above, there are four because the title consists of two sentences, so this reference would initially have been rejected until the full stop after *test* was removed. Some other references were rejected because the title ended with a question mark.) It was also necessary to check that author names did not have accents, or other diacritical marks such as umlauts or Ø letters, as these are not used in the WoS.

For some sets of references where the numbers had been inserted manually in MS Word, they could each be separated by a paragraph mark, and then when they were transferred to Excel, each was on a single line. This enabled the different elements of the reference to be spread across to different columns, provided that the separators (usually a full stop) could be identified and they were correctly placed in the reference (see above). The `CONCATENATE` function could then be used to prepare search statements using the first author's name, the full title, and the year. The compound search statements were then run against the WoS for all years and all document types. However, sometimes these did not run if syntactic rules were inadvertently broken, such as the inclusion of terms such as *and/or* or the word *near* in the paper title.

Sometimes a compound search statement with, say, 20 individual statements yielded fewer than 20 papers; this was usually because one or more references were not in journals processed for the WoS in the given year. However, the reverse could also occur, with perhaps 22 or 23 papers identified. This was nearly always because the WoS had also recorded corrections or letters to the same journal about the original paper, together with the authors' reply, which would have had the same author(s), title and year, and so satisfied the search statement. We subsequently discarded items described by the WoS as *corrections* and *letters* as they would not have reported research results.

There was a particular problem with the Finnish CPG reference lists. The references were provided as a continuous list, such as this extract:

> 2014;23:39–46 80. Okin PM ym. Hypertension 2000;36:766–73 81. Koren MJ ym. Ann Intern Med 1991;114:45–52 82. Casale PN ym. Ann Intern Med 1986;105:173–8 83. Devereux RB ym. Hypertension 1994;23:802–9 84. Anavekar NS ym. N Engl J Med 2004;351:1285–95

The complete set of references on a CPG was first pasted into a Word document, and then paragraph marks were inserted before each reference number. They were then pasted into Excel, and the string *ym* (the Finnish form of et al.) removed from each where it occurred. The reference was then spread across columns containing the first author, the publication year, the journal name as given, and the volume number and pagination. The journal name had then to be converted into the full journal name with a journal name thesaurus. The resulting search strategies were then run against the WoS, and the papers downloaded to file, up to 500 at a time. These were converted into an Excel spreadsheet by means of another VBA program which put the downloaded data into a standard format for analysis. However, this file contained many additional records by the named author in the given journal and year, and those not conforming to the given page numbers were subsequently removed by hand.

The analysis of the downloaded files was carried out by a further set of VBA programs that carried out the following functions:

- Characterization of each paper as *clinical* or *basic* or *both* according to the presence of one or more words from two lists of selected words in its title [22.39]
- Provision of the fractional counts of each country listed in the addresses
- Identification of the disease area (e. g., cancer site, such as breast or colon, or mental disorder, such as Alzheimer's or depression)
- Identification of the research domain (e. g., genetics, surgery).

This classification enables an understanding of the type of research, whether it is applicable to patients in the clinic, at the laboratory stage, or a mix of both. Research level (RL) is designated by a decimal number between 1.0 = clinical and 4.0 = basic. Each paper cited within a guideline was classified as clinical (1) or basic (4) or both (2.5) and these values were averaged to yield the research level of the set of cited papers, shown as RL (*p*). The same process was repeated to get the average research level value based on the journals in which these papers were cited as described above, shown as RL (*j*)

Information was also available on the gap (in years) between the date of the citing CPG and that of the cited paper [22.33], and on its funding (if it was published in 2009 or later). The latter topic, which was discussed in a recent paper [22.40], will be explored in a later paper.

The references on the clinical practice guidelines for each of the five NCDs were collected together in five separate spreadsheets, and the results are presented separately. Overall comments on them are brought together in the Discussion section. Countries' tendency to cite their own papers on CPGs is examined for all five NCDs.

22.2.2 The Newspaper Stories and the Research That They Reported

Our original intention had been to select one, two, or three newspapers from each of the 31 European

for the papers to have an easily searchable archive, or for their full texts to be available on the Factiva © Dow Jones database. However, it proved difficult to find researchers with all the language skills needed (we were eventually able to cover 18 European languages but these did not include Icelandic, Latvian, Lithuanian, Maltese, Norwegian, Slovakian, and Slovene). The time necessary to process newspaper stories for the 12 years of the study period (2002–2013) also prevented us from covering as many newspapers as we would have wished, as it turned out that our search strategies for capturing relevant stories from newspaper archives yielded a large number of false positives, which had to be read individually in order for irrelevant stories to be discarded. (Stories were only retained if they cited research from one or more papers from journals covered in the WoS.) Another limitation was that some newspaper archives did not go back as far as 2002.

Table 22.2 shows a list of the newspapers that were processed. Each newspaper was given a code, consisting of its country ISO2 code (Table 22.3) and one letter, normally the initial letter of its name. Most newspapers had their own searchable databases, but for some the researchers used the Factiva full-text database © Dow Jones. The search strategies used included the names of the relevant NCD diseases or disorders, and a set of terms indicative of research, thus:

```
(cancer OR leukaemi* OR melanoma*
OR lymphoma*) AND (research* OR
study OR scientist* OR expert*)
```

This search strategy, and the four others like it, were all used to search for relevant stories. They were translated into the 17 languages needed to search the non-English language newspapers.

The researchers were all brought to KCL in groups for training. They were asked first to translate the search statements into their own languages, and then to check the selected newspapers' websites for their ability to be searched with the five search statements, and for how many years this could be done. Most of these archives were freely accessible, but for some we needed to subscribe to the newspaper for a short period in order to be granted access. The researchers were also taught about the use of short codes to connote the disease(s) or disorder(s) mentioned in the newspaper stories (three-character, or trigraphs) and the research domain (four-character, or tetragraphs). The NCD was to be connoted by its pentagraph code; some stories covered more than one of them.

The details of each selected newspaper story were then to be copied and pasted, or typed, into a spreadsheet containing 26 columns, as listed in Table 22.4.

The notes item (column W) was simply to assist the researcher to identify the cited paper in the WoS. This was the next task, and each paper that was identified was then downloaded with as identifier the index number of the story. (A few stories cited more than one research paper; these were given consecutive index numbers.) The full records were downloaded, and the details were converted into an Excel spreadsheet by means of the VBA macro used for the references on CPGs: they were then copied across to the spreadsheet of the stories with columns as in Table 22.5.

The cited papers were than analyzed by means of VBA programs in a similar way to that used for the references on CPGs, see the previous section. This added many extra columns to the spreadsheet.

22.3 Results: Clinical Practice Guidelines

In total, we selected 413 CPGs in 26 European countries across the five NCD areas with an evidence-base of 47 274 cited research papers. These were identified from the selected CPGs and their details identified and downloaded from the WoS for analysis.

22.3.1 Clinical Practice Guidelines—Cardiovascular Research and Stroke (CARDI)

We processed 74 CPGs in this disease area from 19 countries; 54 of the CPGs were for coronary heart disease (COR) and 20 were for stroke (STR). (These were the two disease areas that had been selected for study within CARDI, see Table 22.1). There were 11 762 references in total, of which 7447 were for heart disease and 4315 for stroke.

As is usual with the papers referenced on CPGs, the papers were very clinical, with mean RL (p) varying only slightly, from 1.12 for the papers cited by Austrian and Swedish CPGs to 1.03 for those cited by Spanish CPGs. However, the RL of the journals appeared less clinical, and the average RL (j) was 1.36. Some of the journals were more basic: 2110 papers (18%) had RL (j) > 1.5 and 220 of them (1.9%) had RL (j) > 2.5.

Some countries' research is much better cited on the European CPGs than others, and this is shown in Fig. 22.10. This figure shows that the spots for most European countries lie above the diagonal line, and those for East Asian countries lie below it. This is not surprising because the CPGs are all European and there is a tendency for research documents preferentially to cite papers by the countrymen of the document authors [22.33, 41, 42].

Nevertheless, some non-European countries' research is well cited by these CPGs, notably that of Canada, Australia, Israel, and the USA. It might be supposed that this is just because the English-language UK CPGs cite a substantial proportion of the references (2632 out of 11 762, or 22%) but this is not the case, as Fig. 22.11 demonstrates, where these four countries' papers appear to be at least as well cited by Austria + Germany, and by France + Poland.

The tendency of research documents to cite papers by their fellow countrymen is shown by Table 22.6, which shows the over-citation ratio (OCR) for eight European countries and also these countries' presence in CARDI research. The OCR is a measure of the tendency of authors preferentially to cite papers by their fellow countrymen [22.41]. It is greater for countries with smaller scientific outputs, and has also tended to decrease with time as international communication has become easier and cheaper.

Table 22.6 Over-citation ratio for own country papers cited in eight countries' CARDI CPGs

ISO	All	Own	% own	% WoS	OCR
SE	492	56	11.4	2.2	5.24
UK	2632	517	19.6	7.9	2.48
AT	610	18	3.0	1.2	2.39
FR	1437	148	10.3	4.6	2.23

PL	974	32	3.3	1.6	2.10
ES	433	19	4.4	3.0	1.45
DE	2048	206	10.1	8.5	1.18

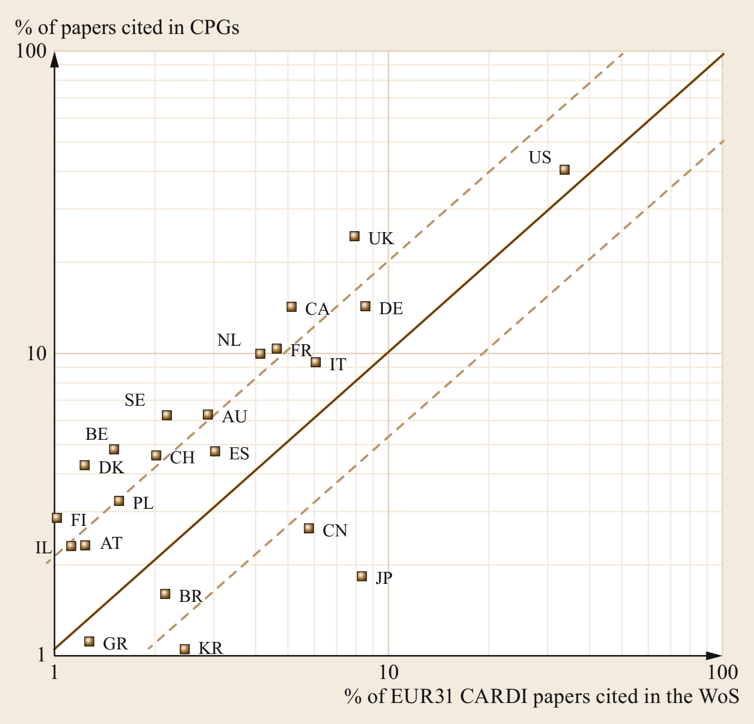

Fig. 22.10 Percentage presence of different countries in papers cited in European clinical practice guidelines for cardiovascular disease and stroke as a function of their percentage presence in CARDI papers in the Web of Science, 2002–2013, integer counts. For country codes, see Table 22.3. *Dashed lines* show percentage presence twice or half that expected on the basis of countries' presence in the WoS

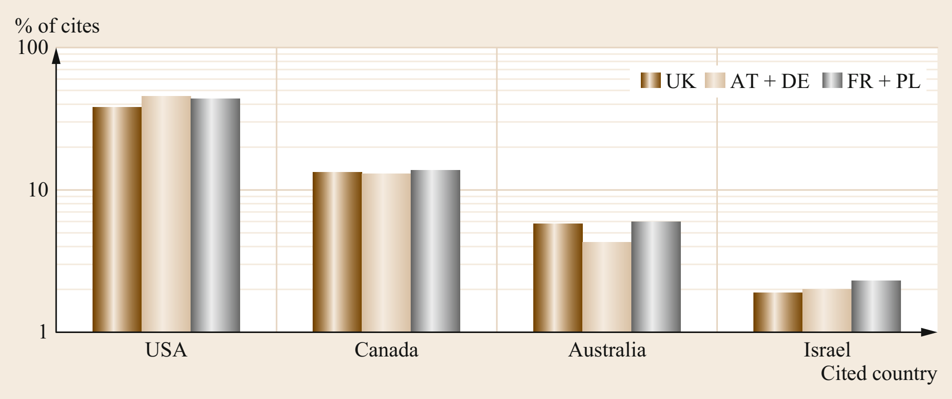

Fig. 22.11 Percentage presence of USA, Canada, Australia, and Israel among the papers cited by CARDI CPGs from the UK ($n = 2632$), from Austria and Germany ($n = 2658$), and from France and Poland ($n = 2411$), integer counts

Some over-citation ratios are somewhat smaller than expected, particularly from Spain and Portugal.

22.3.2 Clinical Practice Guidelines—Diabetes (DIABE)

These guidelines were not divided up by disease area, or by the *sequelae* that often result from diabetes, as the WHO and IHME data on disease burden do not distinguish between them. There was a total of 101 guidelines, see Fig. 22.3, from 25 countries, with a combined total of 5941 references. However, this total included many papers that were cited multiple times on these CPGs, with two papers being cited on as many as 17 of them. Figure 22.12 shows that the distribution of citations follows a logarithmic pattern.

The gap between publication of the CPGs and of the references that they cite is shown in Fig. 22.13 with, for comparison, the distribution by year of synchronous citations (references) on a sample of diabetes papers from 2013, both as percentages of citations over a 19-year

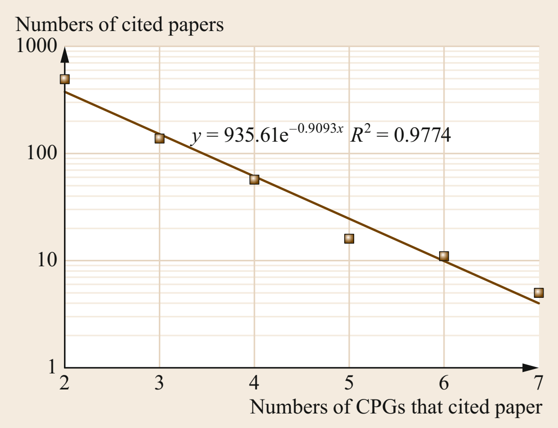

Fig. 22.12 Distribution of citation scores for diabetes papers on 101 European CPGs

period. This suggests that the references on the CPGs are relatively recent: half appeared no more than five years previously. However, the CPG countries varied in how recent their cited references were: this is shown in Fig. 22.14. Finland, Germany, and the UK cite relatively old papers, but Croatia and Portugal relatively recent ones.

The next analysis was of the subject areas of the cited references and a comparison with the subject areas of European diabetes research in 2002–2013. The subject areas were connoted by trigraph codes, listed in Table 22.7 and the comparison is in Fig. 22.15.

Table 22.7 List of diabetes research subject areas, with trigraph codes

Code	Subject area	Code	Complications
TY1	Type 1	FEE	Feet
TY2	Type 2	CAR	Cardiovascular
GES	Gestational diabetes	KID	Nephropathy
NEO	Neonatal diabetes	NEU	Neuropathy
MOD	Maturity onset diabetes of the young	LIV	Liver
ADA	Latent autoimmune diabetes of adults	HYP	Hypoglycaemia
RET	Complications: retinopathy	PSY	Psychosocial
		GEN	Genetics

It appears that there is a reasonable match between the subject areas in which European diabetes research is being undertaken and those that are important in the provision of the evidence base. This is not the case for cancer, as we shall see. The subject areas that are of less utility in the provision of this evidence are genetics and effects on the liver. The latter may be due to there being few CPGs covering this subject area. Conversely, there is a lack of research on the effects of diabetes on the feet, which appears important for clinical practice.

The tendency for countries to cite their own papers among the references on their clinical practice guidelines is examined in Table 22.8. The ratios are higher than they were for the CARDI CPGs, and Spain (with Portugal) and Germany are again citing their own papers less often than do the other countries.

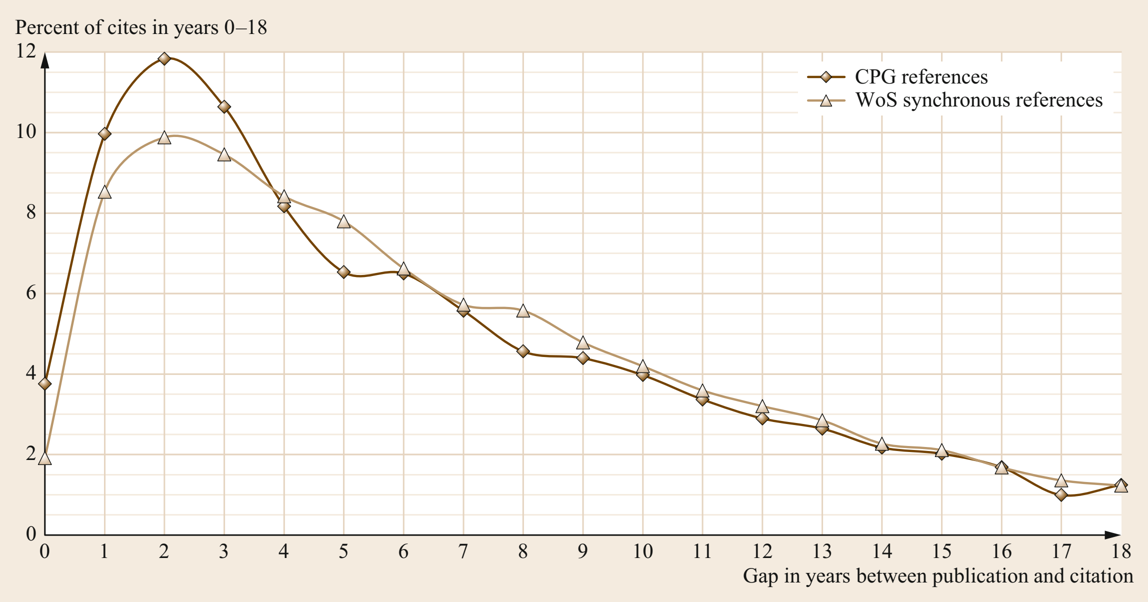

Fig. 22.13 Gap between dates of cited references on diabetes clinical practice guidelines and the guidelines (*light brown line*), and comparison with the time distribution of synchronous citations in 2013 from diabetes papers in the WoS (*dark brown line*)

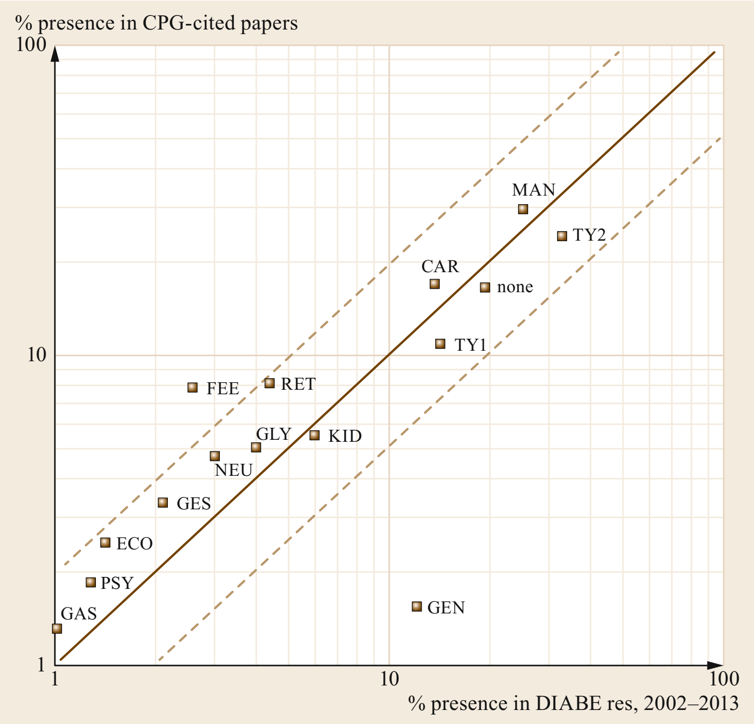

Fig. 22.15 Relationship between European diabetes research subjects, 2002–2013, and the evidence base of 101 European CPGs. For subject area codes, see Table 22.7

22.3.3 Clinical Practice Guidelines—Mental Disorders (MENTH)

This NCD differs from the others because the individual disorders are so different from each other. The CPGs selected for analysis covered five disorders: drug use disorders (addiction) (ADD); alcohol misuse disorders (ALC); Alzheimer's disease and other dementias (ALZ); anxiety disorders (ANX); and unipolar depressive disorders (DEP). Altogether, we analyzed 100 CPGs from 20 European countries citing 12 442 research papers and their division between the disorders, together with the numbers of references, the European disease burden, and the amount of European research,

Table 22.8 Over-citation ratio for own country papers cited in ten countries' DIABE CPGs

ISO	All	Own	% own	% WoS	OCR
AT	406	46	11.3	1.1	10.2

ES	1175	53	4.5	2.9	1.53
PT	262	1	0.4	0.4	1.04

is shown as a chart in Fig. 22.16. There appears to be a reasonable correspondence between the four parameters for each disorder: depression attracts the most research activity, and there are more references per CPG than for the other disorders.

The presence of the leading countries among the cited references on these CPGs is compared with their presence in mental disorders research in Table 22.9.

The UK, Sweden, Finland, and the Netherlands show to advantage here, and the non-European countries in Asia and South America are less cited, including Israel. Country self-citation ratios are rather higher than they were for CARDI (Table 22.10). It is striking that Germany and Spain cite their own papers less than do the other countries, as was the case for the CARDI and DIABE CPGs.

22.3.4 Clinical Practice Guidelines—Cancer (ONCOL)

The three most serious cancers—lung, breast, and colorectal—were the ones for which CPGs were selected. There were a total of 81 ONCOL CPGs: 31 for breast cancer (MAM, 3748 references), 30 for lung cancer (LUN, 4319 references), and 20 for colorectal cancer (COL, 1773 references). Figure 22.17 shows a log–log plot of 18 countries' presence among the cited references compared with their presence in cancer research in the WoS for 2002–2013.

The same pattern appears as with CARDI papers: most European countries' papers are relatively over-cited, and those from the three East Asian countries (China, Japan, Korea) are under-cited, here by a factor of about two. Belgian papers are the most cited relative to their presence in the WoS, followed by those of the Netherlands, Canada, and the UK. Each country's

CPGs over-cite their own countrymen's papers by factors shown in Table 22.11.

Although Germany has a low OCR value, as it does in the other NCDs, Spain and Portugal have much higher ones than usual, suggesting that their cancer research is of greater utility than their research on the other NCDs. Finland and Sweden are again quite reliant on their own research.

The next analysis was of the research domains of the papers that were cited on the CPGs, compared with those of European cancer research in 2002–2013. This is shown in Fig. 22.18, where the abscissa is the

percentage presence of each of 11 research domains and the ordinate is their presence in the 9840 CPG references.

The main conclusions are two-fold. Genetics research, which is by far the most popular research domain, is of little importance to the development of most CPGs. Conversely, surgery and radiotherapy, which are the main means of curing cancer (as opposed to its palliation), are of great importance for CPGs but are less popular with researchers, are not well funded, and are

not well cited in the literature [22.33, 43, 44]. Screening is also under-researched compared with its contribution to the evidence base of cancer CPGs.

22.3.5 Clinical Practice Guidelines—Respiratory Diseases (RESPI)

This was by far the smallest of the five NCDs that we investigated [22.45]. Most of the research was on just two diseases: asthma and chronic obstructive pulmonary disease (COPD). Asthma was covered by 27 CPGs with 3334 references; COPD by 30 CPGs (two covered both diseases) and 4014 references. One CPG covered pulmonary fibrosis, with 94 references. Altogether, 57 CPGs from 19 countries were processed, with a total of 7289 references.

The comparison between research output from the different countries and their presence on the cited references is shown in Table 22.12.

Once again, the Asian countries' outputs and ratios to their presence among the references on RESPI CPGs are all < 0.5 (and are shaded pink), and eight European countries have values > 1.41 (and are shaded bright or pale green).

The over-citation ratios for the countries whose CPGs have at least 100 references and at least one from their own country are shown in Table 22.13. The values for the larger countries are lower than for the other four NCDs, probably because European RESPI research has a bigger presence in the world (56%) than its output in the other NCDs, which averaged 40%.

22.4 Results: Newspaper Stories

From the 31 newspapers covered across 22 European countries, there were 8596 cited research studies featured in newspaper stories for the five NCDs. The details of the stories and of the cited research papers were entered into a single spreadsheet for analysis.

22.4.1 The Five Noncommunicable Diseases

The file of stories and cited papers contained 8596 entries, so it was comparable in size with the sets of references on each of the CPGs. Of these, 3498, or nearly 41%, concerned cancer, and the analysis of these stories and papers is treated in detail in the next section. Here we examine the distribution of the stories between the five NCDs, how it compares with the amount of research on each of them, and their relative disease burden in Europe. We also consider the geographical distribution of the cited papers and their research level.

The numbers of stories were very unequal between countries: the UK and Belgium, each with two newspapers, were much the most productive of data, and there were very few from Austria, Switzerland, and Cyprus (Fig. 22.19). It is not clear if these differences really reflect the amount of interest in medical research in the different countries, or are an artefact of the selection process.

As mentioned above, of the five NCDs cancer was the disease area most often mentioned. Figure 22.20 shows that this reflects the amount of research into the disease in the EUR31 countries, but exaggerates its burden. This is also the case for diabetes, although the burden from this NCD is increasing. Conversely, cardiovascular disease research is under-reported, as is respiratory disease, though the latter is clearly seriously under-researched [22.45]. Mental disorders appear to be getting a fair share of news space.

The research level of the papers cited by the newspaper stories was fairly similar to that of the European research in 2002–2013, except in CARDI and ONCOL where it is somewhat more clinical. This means that the newspapers are selecting research from the whole spectrum of RL for their stories, in contrast to the papers cited as references on CPGs which are almost entirely clinical (Fig. 22.21).

For all the newspaper stories, the over-citation ratios for the leading countries are shown in Table 22.14.

One of the features of the newspaper stories is that many of them included a comment on the significance of the results from an external expert. Altogether,

1520 stories mentioned a commentator (18%), but the percentages were much higher in the UK (900 with commentators, 32%), Denmark (60, 30%) and Sweden (92, 28%). There did not appear to be any in the German or Italian newspaper stories, but this may have been because the researchers simply did not record them. Table 22.15 lists the ones that were mentioned most often: the list is dominated by UK medical research charities, who are frequently invited to comment by the journalists on the *Daily Mail* and *The Guardian*. However, in other countries, most of the commentators are academics, many of them from the USA.

22.4.2 Mental Disorders Research Stories and Their Cited Papers

Within the subject area of mental disorders (MENTH), where there were 2175 stories and cited papers, the disorders of greatest interest to the journalists were Alzheimer's and other dementias, and depression. This accords with the volume of research, see Fig. 22.22, but it is not in accord with the burden (in DALYs in 2012).

The figure also reveals that alcohol misuse is a more serious problem than all the other disorders listed in the figure, but is relatively neglected both by researchers [22.46] and by the newspapers. There

is also a lack of attention to suicide and self-harm, which accounts for almost 10% of all mental health problems.

The countries authoring the papers cited in the news stories about mental disorders were, as expected, mostly from European countries and the USA (Table 22.16). The comparator is the countries' output of MENTH papers in 2002–2013.

It appears that the best-cited countries are the ones in Scandinavia, together with the UK, the Netherlands, and Belgium. (The value for Iceland is 11.6).

22.4.3 Cancer Research Stories and Their Cited Papers

We carried out a separate analysis of the cancer sites most often mentioned in the stories about cancer research, and also of the research domains. Figure 22.23 shows the leading sites mentioned in the stories, with, for comparison, the relative percentages of EUR31 cancer research and of the disease burden in Europe in 2012 in DALYs. There is clearly an imbalance in the selection of stories: breast and skin cancer (melanoma) get more coverage in the newspapers than they merit, but lung and pancreatic cancers get little coverage.

Figure 22.24 shows a similar comparison between the different research domains (here, based on the cited papers rather than the codes given by the researchers) and the amount of research by the EUR31 countries. Coverage is again unbalanced: the main topic of the stories is epidemiology and some distance behind come genetics and prognosis.

However, there is little coverage by the news stories of the three main methods of treatment—chemotherapy, and especially surgery and radiotherapy—suggesting that the main interest of the journalists is in the prevention of cancer rather than its treatment. Of the treatment methods, chemotherapy and targeted therapy combined are covered in 230 stories, but radiotherapy and surgery combined in only 166. This may well give the public the false impression that cancer is cured by drugs rather than the latter treatments [22.43, 44]. To their credit, the journalists do provide better coverage of screening than the researchers do.

22.5 Discussion

In this research work, we evaluated two indicators of research, specifically citations in the clinical practice guidelines and in newspaper stories. This is the first pan-European study to our knowledge that aimed to inform the research gap between research publications and impact on clinical practice through CPGs or public health awareness through newspapers. Furthermore, through a systematic search methodology, this study covered five noncommunicable disease areas, which again, make it perhaps the largest of its kind through an assessment of two research indicators (clinical practice guidelines, newspapers), multicountry comparison, and different disease and subdisease areas pattern examination. Further research on how best the research evidence base or reporting in newspapers can correspond to the disease pattern affecting each European country can perhaps influence clinical practice as well as inform more effective health-policy practices.

22.5.1 Limitations of This Study

The first limitation of this study concerns the inevitable selection of sources, of both CPGs and newspapers. This was constrained by the time and the resources available for the study. We were not unduly constrained by language, as King's College London has graduate students from nearly all continental European countries, and we were able to employ them for the short periods needed for their assignments. However, the training provided to the researchers who were responsible for identifying and processing the newspaper stories, and the papers that they cited, was inevitably rather brief. Some of them may not have fully understood all the complexities of the coding system, or the need for a cited paper to be found in the WoS for its citing story to be included, or indeed for the details of commentators to be recorded. We were able to clean some of the data and this task enabled the results from a few countries to be much better as a result. Some of the countries' newspaper stories did seem rather few in number but much of the analysis presented here is based on results from those countries that appeared to have good coverage of medical research, notably the UK and Belgium.

Many of the results presented were compared with other outputs, notably the amount of research carried out on the five NCDs in Europe, and in other countries. We had to select a time frame for these outputs. For most of the comparisons, we used the 12-year study period (2002–2013). This is probably fair for the newspaper stories, as nearly all of these are written about new research that has just been published, but is more problematic for the papers cited on the CPGs, where some references go back many years. There is no right answer for the appropriate time frame to be used, and the use of the last 12 years meant that the outputs of east Asian countries, most of which have increased rapidly (but not those of Japan), may have put them at a comparative disadvantage.

We found a similar difficulty with regard to the disease burden. There are two main sources of data: the World Health Organization (WHO), and the Institute for Health Metrics and Evaluation at the University of Washington. Both have changed their data from time to time as a result of (presumably) better methods of analysis. In particular, there is inevitably dispute about the weights that should be assigned to disabilities that provide the basis of DALYs. A particular disability may prove much more burdensome in some countries than in others, and the methods used make international comparisons difficult. For instance, the mental disorder DALYs depend critically on the severity of the particular condition (e. g., depression), and this is quite hard to determine.

22.5.2 Advantages of This Study

Despite the above reservations, this study is the first to have compared the references on CPGs and in newspaper stories on five major disease areas and in over 20 countries, with many different languages. It was brought about by the award of a contract by the European Commission, and led to a multinational research activity to find out about the outputs and impacts of European medical research using a standard methodology in these different countries. We are now bringing out a series of papers [22.40, 42, 45] on the individual disease areas and on the methods of analysis that we have developed that will for the first time show the strengths and weaknesses of European medical research, which is inevitably very fragmented and needs to be better coordinated if it is to be efficient. We have also developed a methodology for the measurement of impacts in the real world that can be compared with the traditional evaluation criteria of citation counts [22.47]. These appear rather one-dimensional in comparison and because they are used so much for the allocation of research grants may distort research priorities.

The methodology described here can, in principle, be used on a much wider scale to provide research funders and research performers with information on how their outputs have influenced medical care through CPGs and the public through the mass media. We are considering how best to develop these information sources commercially. The difficulty is that the varied nature of the source materials makes it hard to automate the process of collection of reliable information, and therefore the cost of data collection would need to be spread across many potential subscribers.

22.5.3 Main Conclusions of the Study

Perhaps the most important conclusion is that the papers cited on CPGs and in newspaper stories are not the same ones as receive many citations in the serial literature, and that some relatively neglected areas are unexpectedly important for the practice of medicine or for the provision of useful information to the public. In cancer, surgery and radiotherapy have emerged as important areas for the guidance of physicians and surgeons.

In mental health, the public perception of depression as a subject that used to be kept under wraps has changed, and there is now a willingness to accept it as an illness that can and should be treated. Similarly, the treatment of Alzheimer's and other dementias is getting increasingly more attention, and this is aided (in the UK) by the prominence of the two Alzheimer's medical research charities as commentators on mental health stories. This will help them in their mission to raise funds to support new research.

The solicitation of comments from collecting charities by the UK media, which was noted earlier [22.37], occurs in other disease areas, as witness the prominence of Cancer Research UK, the British Heart Foundation, and Diabetes UK among the leading commentators (Table 22.15). It would surely be helpful to the corresponding charities in other European countries if journalists could call on them regularly (and expeditiously) to comment on the news stories that they were planning to write. This seems to be happening on a small scale in Denmark and the Netherlands, but very little elsewhere.

We also noted the over-citation of the research papers by their authors' fellow countrymen. Some countries, particularly in Scandinavia, had high observed-to-expected ratios of citations. This was associated with a small percentage presence in the world literature of a subject area.

Acknowledgments. This study was supported by the European Commission through the award of a contract to the London School of Economics and Political Science (EC/FP7/602536). It was very materially assisted by the provision of several VBA programs for use with MS Excel for the collection and analysis of data; these were written by Philip Roe of Evaluametrics Ltd.

The CPGs and newspaper stories collection, and identification of the cited research studies from the newspapers, was done by the following individuals: for Austria, Germany, and Switzerland: Natalia Kelsch, Anne Spranger, Victor Stephani, and Tobias Schumacher from Technische Universität Berlin, Germany; for Belgium: Ann-Sophie de Mol and Gabrielle Emanuel from King's College London (KCL), UK; for Bulgaria: Eva Nacheva and Christina Tencheva from KCL; for Croatia: Ria Ivandic Emanuel from KCL; for Cyprus: Chryso T. Pallari from the University of Cyprus, Nicosia, Cyprus; for the Czech Republic and Poland: Kasia Zemanek from KCL; for Denmark: Maria Dahl and Maria Emilsson from KCL; for Estonia: Argo Soon from the Estonian Research Council, Tartu, Estonia; for Greece: Laura Mantovani from KCL; for Hungary: Csajbok Edit from Semmelweis University, Budapest, Hungary; for Italy: Ludovica Borsoi from Università Commerciale Luigi Bocconi, Milan, Italy; for Latvia: Ingrid Jaselskyte, Estonian Research Council, Tartu, Estonia; for Luxembourg and the Netherlands: Ann-Sophie de Mol from KCL; for Portugal: Diana Gosálvez-Prados, Elisabeth María Ilidio-Paulo, Camila Higueras-Callejón, and José Carlos Ruiz-Jiménez from Escuela Andaluza de Salud Publica, Granada, Spain; for Romania: Maria-Cristina Juverdeanu from KCL; for Spain: Diana Gosálvez-Prados and Elena Salamanca-Fernández from Escuela Andaluza de Salud Publica, Granada, Spain and Tahereh Dehdarirad from Universitat de Barcelona, Barcelona, Spain; for Sweden: Gustaf Nelhans from the University of Boras, Sweden; for the UK: Argo Soon, Marleen Saidla and Tiina Tasa (Estonia) and Eva Nacheva from KCL partly assisted EP on the data collection.

22.A Appendix

Table 22.17 Organizations that publish CPGs in Europe

Country	Coordination	Organization(s)	Website
Austria	Decentralized with various organizations involved	Scientific associations of medical specialists and collaboration with the AWMF (Association of the Scientific Medical Societies) in Germany and other European medical associations	n/a
Belgium	Decentralized with various organizations involved	EBMPracticeNet CEBAM (Belgian Center for Evidence-Based Medicine) KCE (Belgian Health Care Knowledge Center) College of Physicians	http://www.cebam.be/nl/Paginas/Home.aspx
Croatia	Centralized with various organizations involved and adapted locally	Ministry of Health of the Republic of Croatia (Ministarstvo Zdravlja Hrvatske) in collaboration with Croatian medical associations. Also, various hospitals and clinical centers adapting different guidelines to their standards	http://www.kbsd.hr/Klinicke-smjernice
Cyprus	Centralized but adapted locally	Health Insurance Organization (HIO) adopting clinical practice guidelines from the UK NICE and European medical associations	http://www.hio.org.cy/en/kko_intro.html
Czech Republic	Decentralized with various organizations involved	Czech Medical Association (CzMA) and other professional medical societies	http://www.cls.cz/english-info
Denmark	Centralized with various organizations involved	National Board of Health (Sundhedsstyrelsen) responsible for the development of national clinical guidelines (Nationale Kliniske Retningslinjer (NKR))	https://www.sst.dk/da/nkr
Estonia	Centralized with various organizations involved	Coordinated under the Estonian Health Insurance Fund (EHIF) in collaboration with the World Health Organization (WHO), the Medical Faculty at the University of Tartu (Ravijuhend)	http://www.ravijuhend.ee/juhendid/kasitlusjuhendid/
Finland	Centralized	National Institute for Health and Welfare (THL) Käypä hoito (Current Care) Unit Duodecim	http://www.kaypahoito.fi/web/english/guidelines/guideline?id=cCPG00004

King's College London
London, UK
elena.pallari@kcl.ac.uk

Elena Pallari is a Research Assistant at King's College London. She previously held positions on a wide range of multidisciplinary projects in the conduct, evaluation and evidence-synthesis of clinical studies at the University College London Medical School, the Brunel Institute of Bioengineering and Imperial College London Business School. Elena also works as a Life Sciences Consultant for various pharmaceutical clients, private firms and research groups.

Grant Lewison
Division of Cancer Studies
King's College London
London, UK
grantlewison@aol.co.uk

Grant Lewison is a Senior Research Fellow at King's College London. He has worked in bibliometrics for nearly 30 years and he is the Director of Evaluametrics Ltd., a bibliometric consultancy. His main interests are in alternative measures of biomedical research impact, such as citations on clinical guidelines and in the mass media. Previously, he worked at University College London, City University, and the Wellcome Trust.

23. Societal Impact Measurement of Research Papers

Lutz Bornmann, Robin Haunschild

What are the results of public investment in research from which society actually derives a benefit? The scope of research evaluations becomes broader when societal products (outputs), societal use (societal references), and societal benefits (changes in society) of research are considered. This chapter presents an overview of the literature in the area of societal impact measurement of scientific papers. It describes major research projects on societal impact measurements. Problems of societal impact assessments are discussed as well as proposals to measure societal impact. The chapter discusses the role of alternative metrics (altmetrics) in measuring societal impact. There is an ongoing debate in scientometrics as to whether altmetrics are able to measure this kind of impact.

In the second half of the twentieth century, it was initially assumed in the science policy of many countries that a society benefitted most from a science that was oriented to its own success criteria. *Godin* and *Dore* [23.1, p. 1] concluded:

> Although scientific policy has for a time been driven by the 'policy for science' philosophy or ideology, there has never been any doubt in the minds of policy-makers that the ultimate aim for funding science and technology was socio-economic goals such as national security, economic development, welfare and the environment.

Whereas scientific products and activities (such as manuscripts, research projects, or programs) were initially evaluated almost exclusively by means of the peer review procedure [23.2], later quantitative indicators were also used for research evaluation, mainly bibliometric indicators (based on publication output and impact) [23.3]. In this period, in which science was primarily judged by the benefit for itself, the societal and economic relevance of research was hardly doubted and taken as given [23.4]. An economically successful society needs research which—judged by the criteria inherent in science—operates at the highest level.

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_23

Since the 1980s, science policy has increasingly departed from this paradigm [23.5]. Just like other areas of society, science is increasingly influenced by the effects of an audit society [23.6] in which the use of public funds requires comprehensive accountability (keyword *new public management* [23.7]). However, it is no longer sufficient for accountability just to demonstrate the originality and excellence of research in self-regulated procedures [23.8], but the societal relevance of research, the practical real-world benefits from research, and the fulfilment of societal needs must also be shown [23.9–11]. According to *Godin* and *Dore* [23.1, p. 5]:

> What one expects today is measures of the impact of science on human lives and health, on organizational capacities of firms, institutional and group behavior, on the environment, etc.

There is a special focus on the production of direct societal and economic utility and impact [23.12].

This book chapter provides an overview of the literature on societal impact measurements of research. The chapter focuses on studies that analyze and discuss impact measurements on society—setting aside the literature dealing with forms of interaction between science and society other than impact. In the development of indicators for the measurement of societal impact, *Donovan* [23.13] distinguishes three phases, where it is particularly the last phase that is dealt with in this book chapter:

1. Technometrics (capture of data on investments from industry in science, commercialization of scientific products, and technology transfer)
2. Sociometrics (mapping of research outcomes onto existing government social statistics)
3. Case studies (demonstrating the societal impact of research).

However, the use of case studies for the measurement of societal impact forms only one section in this book chapter (Sect. 23.3.1). Prior to this, Sect. 23.1 outlines why it is increasingly regarded as necessary to measure the societal impact of research activities, how societal impact is defined, and which problems there are with societal impact measurement. Section 23.2 examines current practice in societal impact measurement in various areas (with funding bodies, in national evaluation exercises as well as with multidimensional frameworks and productive interactions). Starting from a critical discussion of the methods currently favored for societal impact measurement—the case studies—Sect. 23.3 discusses the use of quantitative indicators for societal impact measurement.

In classical scientometrics, scholarly communication predominantly formed the general framework of impact measurement. Impact mostly means perception by scientists as measured by citations, although some evaluation studies had already left this framework. For example, *Grant* [23.14] dealt with measures for the impact of medical research on clinical management and the general public. Leaving the scholarly communication framework along with a broadening of the notion of impact towards societal impact led to increased complexity in scientometrics. The field faced the more general questions of *impact on whom* [23.15] and *heterogeneity of users* regarding the so-called *alternative metrics* (altmetrics). Altmetrics count tweets, posts, and many other mentions of scholarly papers on the web. These questions not only affect the conceptual foundations of impact, but also the methodological implications, and the technical challenges of possible measurements of societal impact.

Thus, Sect. 23.4 in this book chapter covers the use of altmetrics for the measurement of societal impact. Altmetrics are regarded as a promising possibility for measuring the societal impact of research. The section outlines how societal impact measurement could be performed using altmetrics (chiefly with social media metrics, citations in patents, citations in clinical guidelines, and mentions in policy-related documents). Here, two key aspects are (1) the time- and field-normalization of altmetrics (with similar methods as for citations) and (2) the target-oriented measurement of impact. For example, the impact measurement of papers on policy-related documents may be a target-oriented impact measurement of research on the area of politics.

23.1 Definition of Societal Impact as Well as Reasons for and Problems with the Measurement

This section deals with three basic topics: reasons for societal impact measurements, definition of societal impact, and problems with societal impact measurement.

23.1.1 Reasons for Societal Impact Measurements

Until the 1980s, science could largely act autonomously in many countries, as long as it remained oriented towards its own excellence and originality criteria. Today, there "is a growing interest in methods of evaluation that focus on (or include) the societal relevance of research" [23.16, p. 20], which involves a weakening of the separation of fundamental categories, like private and public sectors, science and values, producers and users of knowledge [23.17]. In what follows, we would like to discuss the main reasons which have led to increased interest in the measurement of the societal impact of research in recent decades.

Accountability in an Audit Society

In an era in which governments are seeking to reduce spending by any means possible, even areas of society whose importance used to be (or is) unquestioned hung in the balance [23.3]. These areas—which include science—increasingly have to demonstrate that they provide a considerable contribution to society and the public investments are justified [23.18]. The audit society [23.19] would like to use societal impact measurement to obtain information on the way particular pieces of research (especially fundamental research) actually makes an important contribution [23.4, 8].

Societal Relevance of Research

The publication of research results (in high-impact journals) may be very important for scientists, but society does not benefit until the results are applied or used (e. g., via guidelines, medicaments, diagnostic tools, machines, and devices) [23.20–22]. *Ernø-Kjølhede* and *Hansson* [23.23, p. 132] concluded:

> Universities are to an increasing degree subject to a requirement to conduct research in close interaction with users and other stakeholders, implying that the research must cut across scientific disciplines and theories and focus on problem-solving and practical use-value.

In this connection, *Cohen* [23.24] describes an interesting conflict over more than $10 billion, which rich countries have poured into programs for malaria control. Researchers at the Center for Global Development (CGD) in Washington, D.C., have questioned the usefulness of this funding: did it really prevent malaria cases and save lives? These and similar questions illustrate a trend towards a search for reliable data about the benefits of research (e. g., in medicine the number of lives actually saved by the billions invested).

Strengthening the Economy of a Country

It is one of the most important objectives of the successful policy of a country to enhance international industrial and economic competitiveness [23.13]. According to *Toronto Region Research Alliance* [23.25, p. 3]:

> Modern economies increasingly view science and technology (ST) as a major competitive edge and are exploring strategies to use innovation and intellectual capital to drive economic development and growth.

Science policy therefore increasingly demands that contributions from science, particularly to strengthening the economy of a country, are demonstrated.

Proof of Various Kinds of Usefulness

In a perfect world of science, it should actually be the case that every research activity at a university is of high quality and at the same time produces societal benefits [23.26]. But in reality, universities have very diverse orientations and profiles which result in one case in a high quality of research for research (in particular subject categories) and in another case to great usefulness of the research for other areas of society. Thus, there is a broad spectrum of research and utility which "needs a holistic approach that examines the main channels that bind universities to the rest of society" [23.27, p. iv]. Whereas conventional impact measurement could (and can) chiefly demonstrate the usefulness of research for research, broad impact measurement should be in a position to demonstrate usefulness which was hardly possible with conventional impact measurement [23.18, 28]. An example of an obvious area for universities is the educational function provided for the society.

Focus on Relevant Research

For several years, a general trend has been evident in science policy to increase the application of research funds to tackle quite particular societal issues (such as climate change, social cohesion, and globalization) [23.12, 29] and a country's needs [23.30]. Societal impact measurement should on the one hand enable the universities to prove their engagement with the issues and needs. The use of particular indicators in the measurements should, on the other hand, create incentives for engagement with particular issues and needs [23.11].

23.1.2 Definition of Societal Impact

Before we present the definition of societal impact by *Wilsdon* et al. [23.31], we would first like to present some examples from the literature which show what can be understood concretely by the societal impact of research. We would like to begin with the paper by *Dance* [23.32], in which the following examples for broad impact of research are mentioned [23.32, p. 398]:

> For example, ... an engineer might chat to local industry figures about their environmental concerns, and work out how to use academic inventions to solve their problems. University knowledge—or technology—transfer offices may be able to help scientists to forge relationships with industry partners.

According to *Wilsdon* et al. [23.31] societal impact of research can look like this [23.31, pp. 44,45]:

> References to, citations of or discussion of an academic or their work; in a practitioner or commercial document; in media or specialist media outlets; in the records of meetings, conferences, seminars, working groups and other interchanges; in the speeches or statements of authoritative actors; or via inclusions or referencing or web links to research documents in an external organization's websites or intranets; in the funding, commissioning or contracting of research or research-based consultancy from university teams or academics; and in the direct involvement of academics in decision-making in government agencies, government or professional advisory committees, business corporations or interest groups, and trade unions, charities or other civil society organizations.

As the examples of *Dance* [23.32] and *Wilsdon* et al. [23.31] show, there is a broad spectrum of possible societal impact of research. An important reason for the variety could be that a range of social factors play an important role in the attribution of societal impact. According to the results of *Samuel* and *Derrick* [23.33], who conducted interviews with evaluators from the research excellence framework (REF) [23.33, p. 237]:

> The possibility of impact being realized [is]... more related to a range of social factors, than adequately reflecting the nature of the research, or the efforts of the researchers themselves. This concept is built from the observation that the societal impact of science is not value-free and neutral.

Correspondingly, there is also no uniform standard definition of societal impact. Whereas science generally uses impact to mean citation impact [23.34], there is no clear understanding for impact in society. "Impact is still a contested term, with a variety of definitions and understandings of its implications" [23.31, p. 44].

A very generally framed definition of societal impact is that of *Wilsdon* et al. [23.31, p. 6]:

> Research has a societal impact when auditable or recorded influence is achieved upon non-academic organization(s) or actor(s) in a sector outside the university sector itself—for instance, by being used by one or more business corporations, government bodies, civil society organizations, media or specialist/professional media organizations or in public debate. As is the case with academic impacts, societal impacts need to be demonstrated rather than assumed. Evidence of external impacts can take the form of references to, citations of or discussion of a person, their work or research results.

Societal impact measurement is therefore a matter of every measurable influence (effect) of research which can be demonstrated outside of research in a particular sector of society [23.35]. The *RQF Development Advisory Group* [23.36] (RQF is an abbreviation for research quality framework) and *Samuel* and *Derrick* [23.33] cite the following areas in which one could expect impact from research: informed public debate and improved policy-making (social benefit), adding to economic growth and wealth creation (economic benefit), improved management of natural resources (environmental benefit), supporting greater understanding of where we have come from, and who and what we are as a nation and society (cultural benefit).

Against the backdrop of the definition of *Wilsdon* et al. [23.31] it is astonishing to see that the majority of interviewees in the study by *Samuel* and *Derrick* [23.33] (see above) defined societal impact as an *outcome*, where this then led to a *change* or a *difference* in society. The results of the study could indicate that the interviewees often do not clearly distinguish output, outcome, impact, and effects. We would define these terms as follows: Whereas the outcome is a matter of a concrete research result (e. g., unemployment leads to psychosomatic ailments), output is a concrete product resulting from the research result (e. g., a publication or a lecture). Impact then describes those events, products or changes (e. g., in clinical guidelines), which are based on the outcome (in a sector of society). If this impact leads to broad, general societal changes (e. g., important political decisions), we can speak of effects [23.1, 18].

The measurement of outcome, output, impact, and effect can be further refined with respect to various parameters, e. g., temporal aspects. Thus, impact can be measured broadly, or it can be investigated whether particular research activities meet a particular social need [23.37]. According to *Lähteenmäki-Smith* et al. [23.18, p. 35]:

> It is useful to divide impacts as follows: anticipated and unanticipated; inside and outside the target area (or relevant or irrelevant); productive and detrimental (or neutral in impact).

Outcome, output, impact, and effect can additionally be differentiated on a temporal scale, as demonstrated in what follows taking the example of the outcome [23.9]:

> We can thus differentiate between immediate (e. g., publications, prototypes), intermediate (e. g., partnership-based cooperation, new/improved products) and ultimate (e. g., improved industry competitiveness) outcomes [23.18, p. 34]

According to *Ruegg* and *Feller* [23.38] it is the longer term outcomes which are of interest socially (e. g., improvements in the quality of life).

23.1.3 Problems with Societal Impact Measurement

As we can see from the difficulties with the definition of societal impact, the phenomenon of *societal impact* has a much more complex structure than the phenomenon of *academic impact*. For example, whereas the target group for academic impact is relatively clearly defined (the active scientists), with societal impact it is diffuse: it is a matter of all groups of people and areas which do not belong to science. The breadth alone that has to be taken into account in the measurement of societal impact raises many questions about the feasibility of the measurement and the interpretation of the results. The studies concerning the measurement of societal impact in recent years have mentioned numerous problems associated with this measurement. In what follows, we would like to outline a selection of the most important problems.

Various Exploitation Channels

We can generally assume that benefits of research for society arise through various "exploitation channels" [23.39]. There is the danger of concentrating on too few channels in the measurement of impact (in the worst case, on only one) and selecting indicators which use the channels that are the simplest to measure. This introduces a bias in the measurement of impact which raises questions about a reliable and valid impact measurement. We can additionally assume that the value of scientific research is assessed differently by stakeholders in society [23.40]:

> Scientific discoveries and inventions affect many different aspects of society. Different decision-makers will make different evaluations of the same outcomes. It is thus methodologically impossible to summarise the impact of scientific knowledge and inventions in any single indicator.

Attribution of Societal Impact

If research has effects in a societal sector, it is generally difficult to determine what portion of benefits should be attributed to a certain piece of research. This means that societal impact measurement has a causality or attribution problem [23.39]: which research caused a particular effect in society? For example, with societal impact like the improved state of public health, it is almost impossible to attribute this impact to particular pieces of research [23.5]. According to *Milat* et al. [23.11] "research impacts are complex, non-linear, and unpredictable in nature". The benefits of research are often "subtle, heterogeneous, difficult to track or measure, and mostly indirect" [23.41, p. 528]. They are derived "from serendipitous findings, good fortune, and complex networks interacting and translating knowledge and research" [23.35]. Thus, the paths from research to impact generally remain a black-box [23.1, 42].

There are often several scientists from various projects, research groups, funding schemes or funding sources or countries working on a research topic which makes it difficult to attribute the impact of the research to particular units [23.43, 44]. *Nightingale* and *Scott* [23.21, p. 543] concluded:

> The benefits of research are complex, contingent, often indirect, and typically involve the generation of intellectual infrastructure and the transfer of trained people, new instrumentation and methods, tacit skills, and networks.

Khazragui and *Hudson* [23.3] regard it as a fundamental problem with the impact measurement of research in the area of policy that the policy tends to be based upon a large body of research efforts which have constituted *the commons* [23.45].

Time Lag

The time lag between the outcome of the research and the later impact varies enormously: in one case the impact is quickly visible, in another case very late [23.43, 44]. This also involves the problem that the time of the impact measurement is hard to determine [23.27], and the result of the impact measurement is highly dependent on the selected time lag [23.46]. The length of the time lag should ultimately be oriented to the complexity of the object being researched. It should generally be borne in mind with societal impact measurement that one can only make positive and not negative statements about impact.

For *Milat* et al. [23.11] it is the long-term societal impact measurement of research which is most problematic, since this can involve periods of 15 years and more:

> It has been observed that, on average, it takes over 6 years for research evidence to reach reviews, papers, and textbooks, and a further 9 years for this evidence to be implemented into practice.

However, the literature also mentions shorter time frames for the measurement of the longer term impact: thus *Khazragui* and *Hudson* [23.3] for example mention a time frame of 6 years, related to the commercialization of research findings.

But research evaluations generally aim to measure (citation) impact over a shorter time window. Only up-to-date data forms a relevant basis for decision-making [23.43]. However, there is a risk that research bringing short-term benefits is over-emphasized [23.39].

Social Factors

University and nonuniversity research institutions have various profiles and missions which depend on internal and external institutional contexts and determine the particular research guidelines [23.44, 47]. According to *Molas-Gallart* et al. [23.27, p. 8] "there is no one model of the successful university." Therefore, only university and nonuniversity research institutions from the same context should be compared with one another. For this it is important that evaluations are performed as often as possible to provide space for various possibilities of impact measurement [23.48, p. 7]:

> The impact to be 'demonstrated' could be that of a project or research unit, of a program, of a funding body/strategy, of an area of research, or of the research system as a whole—each captured at different points in time, and relative to varying time horizons and to different types and methodologies of research.

These possibilities of impact measurement should also be utilized in practice to avoid leaving the impact of some research "under the radar" [23.49].

The results of the study of *Samuel* and *Derrick* [23.33] show that it is not only the social factors surrounding the production of research results which should be considered with impact measurement, but also social factors surrounding impact measurement [23.33, p. 237]:

> A number of interviewees ($n = 18$) recognized that impact was contingent on social processes. They perceived that the possibility of impact being realized was more related to a range of social factors, than adequately reflecting the nature of the research, or the efforts of the researchers themselves. This concept is built from the observation that the societal impact of science is not value-free and neutral and that science does not have an impact based solely on its particular capabilities. Rather, scientific research, its shaping and development, and its application to society, is related to multilayered social factors.

Serendipity

The results of research are generally hard to predict and serendipity plays a role in the research process which should not be underestimated [23.11, 50, 51]. This also makes the impact measurement difficult [23.27, 52]. Particularly in relation to the long-term impact of research the possibility of serendipity and unpredictable effects should always be considered [23.44, p. 69]:

> Is it possible that scientists who laid the groundwork for Google or wireless communication or their peers, or any metrics available today for that matter, could have predicted the multi-million dollar value of their original work? Is it possible to predict which projects undertaken today will lead to unfathomable transformations in the lives of future generations? Will metrics help protect seemingly obscure projects that could one day hold the key to these transformations, or will they encourage their dismissal?

The latter should be prevented if possible.

Societal Quality

Citations are often used as a proxy for quality in bibliometrics. This means that one actually wants to measure the quality of research and uses data for this which can measure the construct *quality*. According to *Martin* and *Irvine* [23.53] citations measure a specific part of quality, that is impact. Two other parts of quality can scarcely be measured by citations: importance and correctness of research. In discussions of the measurement of societal impact it is noticeable that the important connection to the quality of the research is lacking. Only occasionally do references to this occur in the literature: For *van der Meulen* and *Rip* [23.45] "it is not clear how to evaluate societal quality, especially for basic and strategic research" [23.25, p. 11]. According to *de Jong* et al. [23.4, p. 62]:

> Evaluating societal quality suffers from methodological problems, as it is difficult to attribute impact to specific inputs: The relation between knowledge and impact is complex and innovations are based on a variety of (knowledge) sources.

An impact measurement which has no relation to the quality of research should be avoided as far as possible in research evaluation. For example, we can assume an immense impact outside of science (such as in the media) especially for scientific activities which are ethically questionable (such as misconduct or fraud). In order to avoid giving scientists false incentives by the use of metrics (e. g., number of mentions on the news), the quality (correctness) of the research connected with impact measurement should always stand in the foreground. An impact measurement should therefore only be undertaken for publications which fulfil the scientific standards in their specialist area (for example, by including in the analysis only publications accepted for publication by a peer review procedure).

Research with Negative and Positive Effects

Research can have both positive as well as negative impact on society [23.44], as the following example makes clear [23.54, p. 6] clarifies:

> Environmental research that leads to the closure of a fishery might have an immediate negative economic impact, even though in the much longer term it will preserve a resource that might again become available for use. The fishing industry and conservationists might have very different views as to the nature of the initial impact—some of which may depend on their view about the excellence of the research and its disinterested nature.

In such cases, it is difficult to undertake a societal impact measurement which is oriented to the benefit for the society.

Subject-Specific Differences

There are clear subject-specific differences as to which societal impact one can expect and the possible extent of this societal impact [23.32, p. 398]:

> The type of broader-impact project can differ between disciplines. A mathematician could explain his or her research to scientists in other fields, who might find it useful for modelling their own systems, suggests John Hand, head of impact at the UK Engineering and Physical Sciences Research Council. Engineers, by contrast, might offer applied projects with more direct practical impact, such as ways to scale up production processes.

The specifics of the specialist areas lead—as with citation impact—to the societal impact from different specialist areas hardly being comparable with one another.

23.2 Societal Impact Considerations in Evaluative Practice

In this section, the following questions are addressed:

- How is societal impact assessed at funding bodies?
- How is societal impact measured in national evaluation systems?
- Which frameworks have been proposed for societal impact measurements?
- What is understood by *productive interactions* as an alternative to impact measurements?

23.2.1 Societal Impact Assessments at Funding Bodies

A number of funding bodies have in recent years begun to consider not only the expected scientific outcome of research in the allocation of research funding, but also the possible impact of the planned research beyond the area of science. There are numerous references in the literature to funding bodies which consider the expected broader impact in the selection process. Examples of these are the US National Science Foundation (NSF), the Research Councils of the UK (RCUK), the Research Council of Norway (RCN), and the EU Framework Program/Horizon 2020 (EU FP7/H2020) [23.43, 55]. According to *Dance* [23.32, p. 397]:

> The interest in broader impact is rising. In 2009, the seven government-funded granting agencies that make up Research Councils UK (RCUK) began requiring applicants to delineate their impact plans. The Swiss National Science Foundation (SNSF) added a section on broad impact to its application forms in 2011. The US National Science Foundation (NSF) has long required applicants to combine scientific value with impact outside the lab, and in 1997 made broader impact an explicit part of the grant review. The foundation started requiring a separate section on impacts in applications this year.

In the UK, measures to assess ex ante societal impact are commonly recognized as the "pathways to impact" statement [23.33].

The consideration of societal impact in the evaluation of research applications has a number of consequences for the peer review process:

1. In the peer review process, research is assessed by specialist colleagues [23.9]. Since the specialist colleagues generally cannot or do not wish to estimate the societal impact of a project [23.56], the question arises of involving other actors than scientists working in the same area [23.45]: Which other actors could be included in the assessment process in order to assess the possible societal impact of the applications? Should their opinion—if they are included—be considered equal to that of the academic actors [23.43]?
2. It is not only the effort for the assessment of the proposals that is increasing, but also the effort for the applicants. The applicants not only have to consider the possible scientific outcome of a project, but also the possible outcome beyond science [23.9, 22].
3. Since the assessment of the scientific quality of applications involves a number of criteria (such as the importance or methodological rigor of an application), attention must be paid to the relevant criteria for the assessment of societal impact [23.21].

23.2.2 National Evaluation Systems and the Measurement of Societal Impact

In recent years, several countries have established national research assessment exercises, with which a comparative evaluation of research institutions within a country is performed. In the framework of these exercises, the institutions are generally evaluated not only by criteria immanent in science, but also by the usefulness of their research for society, where the economic value of publicly funded research stands in the foreground [23.13]. According to *Ovseiko* et al. [23.55]:

> In 1989, the UK was the first country in the world to implement a performance-based research funding system, the research assessment exercise (RAE), now the research excellence framework (REF), and since then at least thirteen more countries, including Australia, New Zealand, Hong Kong (China), and several EU countries, have introduced such systems.

In the following, we would like to present three examples of these national research assessment exercises.

The best-known example of a national evaluation system, and which was the first to look at the impact beyond science, is the UK REF [23.23]. A detailed description of societal impact measurement in the REF can be found in *Samuel* and *Derrick* [23.33]. The aims of the REF are [23.55]:

> Primarily to provide a basis for resource allocation, accountability for public investment in research, and benchmarking information and reputational yardsticks for the higher education sector.

The term societal impact is very broadly defined in the framework of the REF: it is a matter of the effects/benefits of the research for the economy, society, culture, public policy or services, health, the environment, or quality of life [23.57]. The evaluation of the societal impact of an institution is directly linked to its funding allocation in the REF. The criterion makes up 20% of the overall assessment of an institution, on which basis the funding allocation is decided.

Since the mid-1990s, the Standard Evaluation Protocol has been published in the Netherlands, with a description of the methods that should be used for the six-yearly evaluation of the Dutch research institutions. The protocol currently used refers to the period between 2015 and 2021 (https://www.knaw.nl/nl/actueel/publicaties/standard-evaluation-protocol-2015-2021). In evaluations in the Netherlands, not only the quality of the research is assessed, but also its social, economic, and cultural relevance for areas of society outside science. Here institutions should show how far their research affects specific stakeholders or specific procedures in society (such as laws or regulations). The methods that are used for the evaluation of the societal relevance of research were developed in the project Evaluating Research in Context (ERiC) [23.29].

In Australia, the Australian Research Council organizes the national research evaluation framework, called Excellence in Research for Australia (ERA). In this framework, research is evaluated with the help of the peer review procedure and selected indicators. The indicators used for the evaluation (for example bibliometric indicators), have been identified or developed in collaboration with the relevant specialist bodies. According to the information of *Wilsdon* et al. [23.31, p. 128]:

> In the Australian ERA, some quantitative measures of broader impact are assessed, namely patents, plant breeders' rights, registered designs and research commercialisation income. We heard evidence that there are concerns with this approach, related to the implied narrow definition of societal impact and the potential that focusing on a small number of metrics might significantly skew behaviour.

Particular attention is applied in the evaluation to the commercialization of research discoveries [23.58]. It is generally simpler to measure than other effects.

23.2.3 Frameworks for the Measurement of Societal Impact

In recent years, a number of more complex frameworks have been developed for measuring the quality of research and its societal impact. An overview of these frameworks can be found, for example, in *Bornmann* [23.59, 60] and *Milat* et al. [23.11]. Even if the frameworks differ in their terminology and approaches, the shared common features include [23.11]:

> Assessment of traditional research outputs, such as publication and research funding, but also a broader range of potential benefits, including capacity, building, policy and product development, and service development, as well as broader societal and economic impacts.

We would like to present two frameworks as examples in what follows:

1. In the framework of the Dutch evaluation of research with the standard evaluation protocol, for example, the research embedment and performance profile (REPP) approach was developed [23.16]. For this a number of social domains were defined, in which scientists operate:

   a) Science and certified knowledge
   b) Education and training
   c) Innovation and professionals
   d) Public policy and societal issues
   e) Collaboration and visibility.

   For each domain, a variety of criteria and indicators were developed (such as production of qualified researchers or migration of researchers to positions in business organizations), with which research can be evaluated. For the presentation of the results, a special graphical layout was developed, where the values for the individual indicators are represented in a radar graph. These radar graphs provide a comprehensive visual depiction of the research of a unit (e. g., of an institute).
2. One of the best-known frameworks with which the societal impact of research can also be measured, is the payback framework [23.61]. This framework was originally developed for the investigation of *impact* or *payback* of health services research [23.62]. The framework is a research tool, with which data on research impact of a research unit can be compiled, in order then to make a comparative cross-case analysis. For this purpose, the framework provides a multidimensional categorization of benefits from research which refers to the following five areas:

   a) Knowledge
   b) Benefits to future research and research use
   c) Political and administrative benefits
   d) Health sector benefits
   e) Broader economic benefits.

   The data for the five categories can be collected from surveys of decision-makers and analysis of documents [23.9]. In recent years, the framework has been used in a number of different contexts, which extend beyond the borders of the health services [23.63].

Not only in the frameworks presented here, but also in others, *Milat* et al. [23.11] see a significant problem in maintaining the right balance between comprehensiveness and feasibility. In order to represent quality of research multidimensionally, a manifold of indicators is necessary. But the more indicators a framework uses, the more difficult it is to install it in an institution and the more awkward it is for concrete application in research evaluation.

23.2.4 Productive Interactions

In Sect. 23.1.3 we described a number of problems that are connected to societal impact measurement. One example of these problems consists in the often late appearance of the societal impact of research. However, in the evaluation of research a prompt societal impact measurement is desirable. Against the backdrop of this and other problems with societal impact measurement, some authors have suggested dropping impact measurement and focusing instead on productive interactions of researchers with societal stakeholders [23.64]. The background for this change in perspective consists in the reasonable assumption that the productive interactions will later also lead to societal impact [23.65]. As has been shown by the results of two case studies in the area of law and architecture, productive interactions are an [23.4, p. 70]:

> Important way of circulating knowledge between science and society. The intensity of the collaboration informs us about the type and amount of knowledge that is circulated. On top of that, collaborations are an indication of societal quality.

With the change of societal impact measurement to the assessment of productive interactions, one takes a glance at the efforts undertaken by an institution to achieve societal impact [23.27]. According to *SIAMPI* (Social Impact Assessment Methods for research and funding instruments, see http://www.siampi.eu) [23.66, p. 2]:

> Interactions are determined to be 'productive' when they lead towards changes in behaviour on either side—that is with researchers (changes in research agenda) or with stakeholders (changes in behaviour).

The productive interactions can consist of personal interactions (e. g., through video-conferencing), through some kind of material *carrier* of the interaction (e. g., written means of communication, exhibitions, models, or films), or through economic exchange between researchers and potential stakeholders (financial interactions). The interactions can then take place when the research agenda is specified, during the research itself or after the end of the research project [23.29]. The intensity of the interaction can vary depending on the context between "very incidental and informal relations to highly organized and professionalized networks" [23.66, p. 5]. In general, an increased intensity of interactions allows the assumption of a higher probability of societal impact [23.67]. A good example of a productive network which is intended to accelerate the propagation of knowledge and technology from academia down to industry is the knowledge transfer networks (KTN, https://connect.innovateuk.org/knowledge-transfer-networks).

For the intensification of productive interactions, *Bornmann* and *Marx* [23.68] have suggested that scientists write what are known as assessment reports to summarize the research status in a particular research area or on a particular research topic (e. g., in climate change research). These reports should be written so as to be comprehensible for people outside of the specialist area or for people outside of science.

23.3 Case Studies and Quantitative Indicators

As shown in Sect. 23.2.3, some frameworks for societal impact measurement have already been developed. However, the design of the frameworks is generally very complex, which complicates their use. The measurement of productive interactions is a promising method for the estimation of societal impact; but ultimately the impact is not directly measured. Since for societal impact measurement no generally satisfactory method has yet been found, scientometrics is in search of indicators which are more or less simple to use. Before we present some promising possibilities in Sect. 23.4 for the reliable and valid measurement of societal impact, we would first like to discuss the currently preferred method for societal impact measurement in Sect. 23.3.1: case studies. Criticism of the use of case studies (Sect. 23.3.1) led to awareness of the necessity of the development (use) of quantitative indicators for societal impact measurement (Sect. 23.3.2) [23.1].

Currently, it is chiefly alternative metrics (altmetrics) which are seen as a possibility for measuring the societal impact of research quantitatively [23.69]. Since this area has been accorded ever greater importance in recent times and has developed into a research area of its own in scientometrics, this chapter deals with altmetrics in Sect. 23.4. There we will—besides the social media metrics (such as tweets or readers) in Sect. 23.4.1 and references to publications in policy-related documents in Sect. 23.4.4—chiefly discuss two metrics which according to *Wilsdon* et al. [23.31] appear particularly promising for societal impact measurement [23.70, p. 49]:

> In sum, while some alternative metrics seem to reflect types of impact that are different from that of traditional citations, only Google patent citations and clinical guideline citations can yet be shown to reflect wider societal impact.

23.3.1 Case Studies—Advantages and Disadvantages

Against the backdrop of the difficulty of measuring societal impact quantitatively or with indicators, the method of case studies is currently preferred for the demonstration of societal impact (with institutions). Especially in connection with the UK REF, case studies are repeatedly discussed in the scientometric literature; but they also appear in other evaluation contexts [23.71]. In research evaluations, case studies are used to demonstrate success stories or best practices in the achievement of societal impact through research which was performed in a particular institution [23.49]. These case studies are generally produced in the course of self-evaluation and examined by review panels in the external evaluation [23.43].

The UK REF stipulates to the institutions an impact template for the recording of the case studies, which should cover about four sides. According to *Salter* and *Martin* [23.41, p. 232]:

> Within these templates, institutions had to nominate pieces of underpinning research conducted at their institutions—for example, reports in the grey literature, or academic journal articles—and explain how this research had had an 'impact' on society.

The research selected for the case studies should have a quality level as high as possible—judged by scientific standards. A case study in the UK REF should have five sections [23.3, p. 56]:

1. A summary
2. A description of the underpinning research
3. The references
4. The impact
5. Corroborating evidence for this impact.

Some examples of case studies from the UK REF are listed in a table by *Khazragui* and *Hudson* [23.3]. The London School of Economics and Political Science (LSE) maintains a database for research into case studies which were created by the LSE (http://www.lse.ac.uk/reserachAndExpertise/researchImpact/Home.aspx). For example, in the area "society and culture impacts" the database includes case studies on the topics "influencing the cultural diversity of the UK history curriculum", "creating more liveable cities", and "quotas are wrong way to increase female representation on boards". A database with all case studies submitted in the framework of the REF 2014 resides at the following URL: http://impact.ref.ac.uk/CaseStudies/. For example, the area of pure mathematics provides the following case studies: "a benchmark tool for high-performance computing" and "applications of singularity theory and three-dimensional (3-D) modeling in arts and retail".

In a comprehensive study, around 7000 case studies were evaluated, which arose in the framework of the REF 2014 [23.72, 73]. On the one hand the data was submitted to a qualitative analysis, and on the other hand text-mining techniques were used to synthesize the corpus of case studies. The results are summarized as follows [23.72, p. 6]:

> The societal impact of research from UK Higher Education Institutions is considerable, diverse and fascinating. One of the most striking observations from the analysis of the REF case studies was the diverse range of contributions that UK HEIs have made to society ... The relationship between 149 fields of research, 36 UOAs [units of assessments] and 60 impact topics is visualized ... What is evident from this visualization is that multiple fields of research underpin the case studies, leading to multiple types of impact. Overall we identified 3709 unique pathways to impact.

What exactly are the benefits of demonstrating societal impact via case studies in research evaluation? One great advantage is certainly that case studies have no limitations in the representation of societal impact. That is, the method places no restrictions on including any particular kind of societal impact from the start [23.72]. In principle, an institution can report any kind of societal impact. Furthermore, the results of the survey of REF main panel evaluators by *Derrick* [23.74] shows that the "evaluators felt confident that the case studies would prove beneficial in facilitating the evaluation process" [23.74, p. 141]. Case studies offer the possibility of representing the long process of research up to the achievement of societal impact in its complexity [23.31]. This is certainly not possible with any other method. Even if the production of case studies is associated with considerable effort for an institution, the effort seems to be worth it: "It has been reported that a single case study could be worth as much as £720 000 to a university over a 5 year period" [23.3, p. 52].

The effort for the production of case studies may pay off for the institutions, but the large amount of effort is still seen as an important criticism of the method [23.73, p. 150]:

> College London alone wrote 300 case studies that took around 15 person-years of work, and hired four full-time staff members to help, says David Price, the university's vice-provost for research.

An additional criticism of case studies which are produced in the framework of self-evaluation refers to the fact that they generally consist of success stories, which can strictly speaking say almost nothing about the return on total research funding [23.3]. The possibility of writing case studies without a precise specification may lead to a greater variance in the presentation, but it also hinders the production of useful comparisons between the institutions [23.3]. However, only a comparison of institutions makes it clear, which institutions have a better or worse performance than the average (in a country).

Criticism of the case study approach has led in the past to a desire for "a more consistent toolkit of impact metrics that can be more easily compared across and between cases" [23.31, p. 49]. *Atkinson* [23.75] also refers to this point with a concrete example:

> It is arguably harder for the REF to judge and compare quality in this area. There is no guarantee, for example, that a spin-off company that generates 200 jobs and £20 million (US $31 million) in investments will be judged to have more impact than a spin-off that generates 20 jobs and £2 million in investments. Automation is not possible here, but there is room for greater standardization of the dimensions by which impact is assessed and the criteria against which quality is judged.

In the following Sect. 23.3.2, we will describe the need for indicators which we see in the area of societal impact measurement.

23.3.2 The Use of Quantitative Indicators

If we regard the societal impact literature in overview, we see that many studies express dissatisfaction with the currently preferred approach of demonstrating societal impact with case studies (despite the advantages that this approach also offers). Thus, for example, *Ovseiko* et al. [23.55] write:

> The advantage of using quantitative indicators is that they can be standardized and aggregated, allowing universities to use them on a continuous basis to track their impact, compare it with other universities, and recognize the contribution of every faculty member.

According to *Godin* and *Dore* [23.1]:

> We still have, forty years after the first demands for impact indicators, to rely on case studies to quantify, very imperfectly, dimensions other than the economic one [23.1, p. 1].

The National Research Council [23.44] and *Khazragui* and *Hudson* [23.3] feel there is a lack of high-quality metrics, with which the societal (also including the economic) impact of federally funded research can be measured on a national scale. Scientometrics should develop robust indicators:

1. To measure the nature and quality of real world impacts
2. To be able to estimate the longer term benefits of research better
3. To identify the *relevant* research for society [23.12, 23].

The indicators to be developed should be both less labor intensive than case studies, as well as allowing meaningful assessments of research [23.27].

In the development of societal impact indicators, one should take into account that the development of indicators is generally characterized by a laborious iterative process in every area. Indicators must be defined, tested, revised, and validated [23.27]. It must be ensured that these indicators can measure evidence of research impact across different cases in a standardized and consistent manner [23.55]. In the area of societal impact measurement, this standardization will be especially difficult, since the societal impact can vary considerably (Sect. 23.1) [23.47]. An additional difficulty in the development of indicators will be that variants of indicators will be developed, from which it will not initially be clear which of the variants should be favored. The development of the indicators should essentially take into account all disciplines equally [23.76], to avoid a situation which has arisen with academic impact measurement: With the established literature databases (Web of Science, WoS, Clarivate Analytics, and Scopus, Elsevier) an elaborated citation impact measurement is—strictly speaking—only possible in the natural sciences.

Some authors have suggested that a database should be developed for societal impact measurement, which is constructed analogously to the WoS [23.77, p. 604], or a societal impact factor be defined, which resembles the journal impact factor (JIF) in bibliometrics [23.78].

Both suggestions are probably unrealistic (and are also not expedient), since (1) the societal impact measurement is very broad, and it will hardly be possible to measure impact in all areas with only one data source, and (2) the use of the JIF in research evaluation has been sharply criticized (see e. g., the San Francisco declaration on research assessment, DORA, at http://www.ascb.org/dora/). An important reason for the criticism is, for example, that a unit for the determination of the impact of a complete journal should not be used for the impact measurement of the individual contributions published in it. The overall impact does not correspond to the impact of the individual contributions in most cases. Societal impact measurement should not repeat the mistake in academic impact measurement that an indicator is developed or used which is subject to sharp criticism.

In Sect. 23.4, we provide an overview of the data sources and metrics from the area of altmetrics, which could be attractive for societal impact measurement. Altmetrics is a new topic which has only been investigated for a few years in scientometrics. The proponents of altmetrics often produce the impression that the first credible measurement of societal impact began with altmetrics. But, as the literature shows, indicators for the measurement of societal benefits of research have been suggested and applied for many years. *Molas-Gallart* et al. [23.27] suggest specifying the measurement of the societal impact of an individual department or university by the number of joint publications (academic publications) between university and industrial firms. These joint publications can be understood as productive interactions which are expected to produce considerable impact. *van der Meulen* and *Rip* [23.45] further expand the measurement of collaborations via publications with the following areas in which there could be direct relations with societal actors: collaborative projects, contract research, membership of advisory boards and committees.

To enable a reliable, fair, and valid societal impact measurement, the following should be considered in indicator developments:

- The indicators should in fact only measure what they claim to measure [23.17]. Since societal impact measurement is often very broadly construed, a restriction to the relevant areas is desirable [23.55]:

  > The issue of validity relates to the degree of certainty that the proposed indicators measure what they claim to measure, i. e., research impact. Without applying precise measures of impact and criteria for the attribution of impact to specific research activities across all universities, any impact assessment will be inconsistent and, thus, unreliable.

- Societal impact measurement is significantly more complex than academic impact measurement, which is primarily a matter of quality. According to *Smith* [23.76, p. 22]:

  > When research has to deal with society, however, a wide range of issues from ethics and safety to economics, legal issues and politics also come into play.

- The results of societal impact measurement should preferably be compared with a control situation, e. g., without the evaluated research activity. This comparison should reveal the effect an individual research activity really has [23.11].
- The indicators should be *socially robust*. *Barré* [23.17] considers that they can be understood in different contexts by stakeholders. These stakeholders could include [23.76]:

  1. Policy-makers at the intermediary or government level
  2. Professional users in industry and societal organizations (developing products and services)
  3. End users (the public at large or individual target groups).

- The use of indicators in research evaluation can lead to an adjustment of the behavior of the evaluated scientists [23.15, 23, 79]. This adjustment may or may not be intentional. Thus, for example, there is the danger in the development of indicators for societal impact measurement that indicators are suggested that are easy to measure but which can say little about the societal impact of research. The use of these indicators could result in the adjustment of scientists to these indicators which leads to a worsening of the societal benefit of research [23.23].
- With societal impact measurement it should be taken into account that different disciplines can expect different levels of societal impact. This is mainly because some disciplines are more productive and make a far greater contribution to society than others [23.40]. The impact to be expected is therefore context-dependent and should be measured in a context-dependent way [23.45]. The impact model may work in some disciplines (e. g., medicine or engineering), but many disciplines have other forms of impact through practices. One can imagine, for example, semantic maps (based on coword analysis) to provide richer means for societal impact assessment in these cases.
- *Molas-Gallart* et al. [23.27] regard it as necessary that the indicators for societal impact measurement be normalized for the size of a research unit: “Normalising by staff numbers provides a uni-

form procedure for indicators and therefore reduces the complexity of the scoring system" [23.27, p. 53].

- The indicator set for societal impact measurement should not be too extensive [23.80]. Since societal impact measurement is a wider field than academic impact measurement, societal impact measurement will certainly require more indicators than academic impact measurement. However, the set should still remain manageable.

23.4 Altmetrics

With the measurement of citations in patents and in clinical guidelines, two promising altmetrics for societal impact measurement have already been suggested and applied [23.81]. Social media metrics could also have potential for societal impact measurement. Even if some social media data (e. g., Mendeley reader counts) carry similar information as citation counts [23.82] and are more associated with academic than with societal impact, most social media data other than online reference manager counts very likely measures other kinds of impact than academic impact [23.83]. Thus, references to scientific papers in policy-related documents may be applied to measure the impact of papers on policy-related areas [23.84, 85].

In the following sub-sections, we will discuss social media metrics, citations in patents, citations in clinical guidelines, and references to scientific papers in policy-related documents in more detail for their potential use for measurement of societal impact. These four possibilities for societal impact measurement are mainly interesting for research evaluation because there are parallels with the measurement of academic impact by means of citations. The similarity of the data allows established methods and procedures of evaluation to be transferred from bibliometrics to altmetrics.

23.4.1 Social Media Metrics

Social media metrics constitute the core of altmetrics. *Robinson-Garcia* et al. [23.86] found that Twitter and Mendeley are the most important social media metrics when judging by the coverage of scientific papers in various sources tracked by Altmetric. Altmetric is a digital science company based in London that tracks and analyzes the online activity around scholarly research outputs (https://www.altmetric.com). Some social media metrics (including Twitter and Facebook counts) have already been included in the *Snowball Metrics Recipe Book* [23.87]. In this book, some universities (in cooperation with Elsevier) try to standardize their way of measuring institutional output and impact.

Some promising empirical results have been published which reveal the potential of altmetrics for societal impact measurements. *Bornmann* and *Haunschild* [23.88] combined expert-based evaluations about published scientific papers (post publication peer review as performed by F1000Prime) with altmetrics data. They found that in the case of a well-written article that provides a good overview of a topic, it tends to be better received by people outside research—measured by altmetrics. Similarly, *Bornmann* [23.69] reports that papers tailored for a readership outside the area of research lead to measurable societal impact. *Bornmann* [23.89] has shown that counts of tweets and Facebook posts might be useful for the measurement of societal impact. A meta-analysis of studies correlating citations with different altmetrics by *Bornmann* [23.90, p. 1140] points out:

> That the more a social media community is dominated by people focusing on research, the higher the correlation between the corresponding altmetric and traditional citations is.

A low pooled correlation between traditional citations and microblogging was found which indicates potential use for societal impact measurement. This conclusion was substantiated in the meta-analysis by *Erdt* et al. [23.91].

As normalization of altmetrics data is important when said data is to be used for impact measurement, *Bornmann* and *Haunschild* [23.92] proposed a methodology to normalize Twitter counts based on percentiles and introduced the Twitter index. Other normalization procedures were introduced for Mendeley readership data [23.93–96]. These normalization methods are based on the calculation of the average number of reader counts per scientific field and publication year. The ratio of the raw number of reader counts and the average number of reader counts of the same scientific field and publication year yields a normalized reader score. However, normalization methods based on averages are problematic when sparse altmetrics data are considered [23.97]. Thus, *Thelwall* [23.98], *Haunschild* and *Bornmann* [23.99], and *Bornmann* and *Haunschild* [23.100] proposed metrics based on the proportion of mentioned papers. In contrast to average-based methods, the methods based on mentioned proportions might be able to handle sparse altmetrics data, such as mentions in Wikipedia pages.

As the part of society represented by many social media metrics (especially tweets and Facebook posts) could not yet be defined accurately, their use for societal impact measurement should be questioned [23.101]. Furthermore, adherence to scientific citation habits cannot be expected for most altmetrics sources. Gaming metrics is much easier for social media metrics than for citation-based metrics in scientific documents [23.102]. Also, social media metrics are easier to manipulate using automated accounts and bots than citation-based metrics. This problem has been studied by *Haustein* et al. [23.103] for Twitter. Their results show that automated Twitter accounts create a considerable amount of tweets mentioning scientific papers. They also conclude that automated Twitter accounts and bots have critical implications for the use of raw Twitter counts in research evaluation.

Overall, certain social media metrics seem to be suitable sources for societal impact measurement. A promising approach to societal impact measurement is broad (many different sources) but target-oriented (using a specific group of the society). For example, Mendeley users can be assigned to certain groups of society based on their (academic) status groups [23.94]. Thus, it is possible to measure the impact of research on certain target groups in society (e.g., students). These measurements can be made time- and field-normalized. However, more research is necessary to identify standard approaches based on social media metrics which may be useful for measurement of societal impact of research papers [23.81, 102, 104, 105].

23.4.2 Citations in Patents

Patents are official documents that describe inventions (e.g., solutions to a specific technological problem, a new product, or an innovative process). Patent counts themselves have already been investigated as an indicator of societal impact: "A classical 'proxy' for measuring the technological orientation of a public research institution or a university, is to build an indicator of its patenting activity" [23.17, p. 128].

Similar to publications, patents also contain references. As most nonpatent references in patents are journal references [23.106], societal (economic) benefit from research might be demonstrable by using methods from traditional bibliometrics (citations from journal publications to journal publications). Thus, citations from patents to scientific publications may be used as indicators for societal impact measurement. Specifically, citations in patents may be used to assess the contribution of publicly funded research to innovations in industry [23.55]. *Kousha* and *Thelwall* [23.107] compared citations from patents to scientific publications with citations from scientific publications to scientific publications for 16 different research fields and found a low but positive correlation. Apparently, patent citations provide a different perspective of impact measurement than citations from scientific publications.

In a classical study, *Narin* et al. [23.108] examined the front pages of 400 000 US patents issued in 1987/1988 and 1993/1994, and traced the 430 226 nonpatent references contained in these patents, of which 242 000 were judged to be scientific references and 175 000 were to papers published in the (back then) 4000 journals covered by the science citation index. They found that many of the scientific references were funded by research organizations. However, not only universities but also top industrial laboratories (IBM, General Electric, Motorola, Xerox, and Hewlett Packard) published papers that were referenced in a substantial proportion of the analyzed patents. They also noted three other interesting points:

1. The research papers cited in patents originate predominantly from prestigious universities and are published in prestigious journals.
2. Patents with applicants from a certain country cite publications with authors from the same country more often than from other countries (about two to four times more often). Thus, they found a significant nationality bias.
3. The number of citations to US authored papers has tripled within six years (1987/1988 citing 1975–1985 versus 1993/1994 citing 1981–1991).

In a sophisticated, more recent patent study, *Chang* and *Breitzman* [23.109] focus on patent to patent citations. They provide a methodology to distinguish between hot patents and next-generation patents. They apply a cocitation analysis to cluster patents and rank the resulting clusters by the likelihood of the clusters to contain emerging technologies. Such analyses make it possible to measure the socioeconomic impact of science target-oriented on emerging technologies by determination of references to scientific publications in specific patents of clusters with a high likelihood of emerging technologies.

Analysis of patents and patent citations are not without limitations: (1) not all inventions are patented and (2) patenting habits vary across technological fields [23.106, 109]. The latter limitation may be overcome by normalization procedures. As it has become standard in bibliometrics for journal to journal citations, also analysis of patent to journal citations (as well as patent to patent citations) can employ normalization methods to account for differences in scientific discipline (and/or patent class) and publication years [23.70, 110].

Patent counts and (normalized) citations from patents to scientific publications seem to offer a promising route for societal impact measurement into the economic sector of science. SciVal, a commercial research evaluation tool by Elsevier, uses patent-based metrics [23.111, p. 2]:

> SciVal looks at the citations of scholarly output in patents and provides links to both the citing patents and cited Scopus articles. This helps showcase connections between science and industry as well as the knowledge flows.

23.4.3 Citations in Clinical Guidelines

Clinical guidelines are documents which aim to guide decisions and criteria regarding diagnosis, management, and treatment in healthcare. These documents have been in use for the entire history of medicine in one form or another. However, in contrast to earlier forms, which were often based on tradition or authority, modern clinical guidelines are based on an examination of current evidence within the paradigm of evidence-based medicine. They usually include summarized consensus statements on best practices in healthcare. Their formulations bring pieces of important and influential research together. It is an indication for funders that research they have supported is likely to be influencing medical policy and clinical practice, if the funded research is referenced as part of the evidence supporting a national and/or international clinical guideline.

Grimshaw and *Russell* [23.112] have analyzed 59 studies that evaluated clinical guidelines. They concluded that clinical guidelines do improve medical practice. It has been recommended that medical experts come together periodically to review existing evidence and formulate official guidelines for preventive care, diagnosis, and treatment of diseases. Such practices not only help to identify and disseminate best practices for treating patients but also increase the potential value of clinical guidelines for societal impact measurements. Also existing clinical guidelines should be reviewed and if necessary updated on a regular basis [23.113].

Andersen [23.114] analyzed 80 clinical guidelines which were rated regarding their "rigor of development". He extracted 5970 scientific publications indexed in the WoS from the reference lists of the clinical guidelines. Computing two different kinds of normalized citation scores (one based on averages and one based on percentiles), he found a significantly positive correlation between both normalized citation scores and the expert ratings regarding the rigor of development of the clinical guidelines. This indicates that the quality of clinical guidelines correlates with the quality of the scientific publications they are based on. This is in agreement with *Thelwall* and *Maflahi* [23.115] who found that papers in clinical guidelines are much more likely to be cited more often than comparable papers not referenced in clinical guidelines.

In a pilot study on citations in clinical guidelines, *Grant* [23.14] analyzed clinical guidelines with regard to outcomes of biomedical research on healthcare. He found that out of a total of 284 publications, which were referenced in the reference lists of clinical guidelines, 273 (or 96%) were papers in research journals. 235 (or 86%) of these papers were found in library catalogues and 154 (or 65%) had a funding acknowledgement. Therefore, reference lists of clinical guidelines and the funding attributions in the referenced publications are potentially an attractive resource to support research evaluation regarding societal impact [23.116]. Usage of clinical guidelines means demonstrating an improvement in healthcare for biomedical agencies. However, there are potential problems as there exists a complex relationship between research and its incorporation into new treatment guidelines. The main conclusion from his pilot study is that it is possible to apply conventional bibliometric techniques to trace the transfer of knowledge from research funding into clinical practice.

Lewison and *Sullivan* [23.117] studied UK clinical guidelines relevant to cancer (43 documents) as well as 3217 references cited therein. These references were mainly published in high-impact journals, but this might be a circular effect [23.117, p. 1948]:

> It appears that if researchers want their work, particularly clinical trials, to be part of the evidence base for clinical guidelines, then it is desirable for them to publish in highly cited journals.

Lewison and *Sullivan* [23.117] used the cited reference data to investigate the contribution of countries to clinical guidelines relevant to cancer. They found that UK papers were referenced three times as frequently as one would expect from their occurrence in the world oncology literature. Thus, a similar effect as found by *Narin* et al. [23.108] for patents might have been observed by *Lewison* and *Sullivan* [23.117] for clinical guidelines.

Thelwall and *Maflahi* [23.115] found that scientific publications mentioned in clinical guidelines are also often highly cited in the academic literature, especially in the case of publications older than three years. They see a potential benefit from the use of clinical guideline citations especially for recent publications. According to *Jones* and *Hanney* [23.118], societal impact studies based on citations from clinical guidelines usually only focus "on the direct influence from the paper cited, and it is argued that impacts usually arise from one or more streams of research or from a variety of papers" [23.118, pp. 976/977]. They investigated the indirect societal impact of biomedical research by studying several citation generations from key research articles and clinical guidelines.

Assessing the value of medical funding is of increasing importance [23.115]. Besides analysis of citations from clinical guidelines, also mentions of healthcare funders are used in impact measurement. In the latter cases, the societal impact of research funded by healthcare organizations is measured: Funders of medical research have made efforts to enhance the understanding of the impact of their funded research and to provide evidence of the value of investments in particular areas of research. Research evaluation around impact on policy and practice of medical treatments represents one of the most challenging areas.

Medical research funders have already started to track clinical guidelines as potential indicators of societal impact. *Kryl* et al. [23.116] analyzed authorship and funding attribution of scientific publications which are part of the reference lists of two clinical guidelines from the National Institute of Health and Clinical Excellence (NICE). They found that about a third of the scientific publications are authored by at least one scientist in the UK and about half of these publications from the UK listed a diverse set of funders in their acknowledgment sections. They conclude that reference lists of clinical guidelines offer great potential for the quality assessment of scientific publications. In principle, a presence in clinical guideline reference lists could serve as evidence that a research funder's money has been useful for society in ways other than scientific knowledge building. They recognize tracking and harnessing the relevant information in a reliable way as one of the main challenges.

Bunn et al. [23.119] have studied societal and scientific impact of Cochrane Reviews. Cochrane Reviews contain scientific publications as well as clinical guidelines in their reference lists. Cochrane Review Groups (CRGs) gather and summarize medical evidence from research. The aim is to provide help to make informed choices about medical treatments. The findings of CRGs are available in the Cochrane Database of Systematic Reviews (http://www.cochranelibrary.com/). *Bunn* et al. [23.119] found that Cochrane Reviews are used to inform healthcare policy-makers and are helpful during development and improvement of clinical guidelines. Among the benefits that Cochrane Reviews appeared to have had, *Bunn* et al. [23.119] mentioned safer or more appropriate use of medication or other healthcare technologies, or the identification of new effective drugs or treatments. It is unclear, however, whether or not these changes were directly a result of the Cochrane Reviews and not the result of subsequent clinical guidelines. In any case, the reference lists of Cochrane Reviews seem to be another promising source for societal impact measurement.

Although references in clinical guidelines to scientific documents are useful in societal impact measurement, there are limitations, as clinical guidelines do not always contain references. Furthermore, the relevance and value of the listed references is not explicitly indicated [23.116]. However, this is not different to citations in scientific publications or mentions in various altmetrics sources. Still, the value of clinical guidelines for societal impact measurement could be increased if research funders and policy-makers would advocate for references to be systematically added to and labeled in clinical guidelines. Other limitations are likely to remain:

1. Citation of review articles rather than the original studies
2. Biases in the selection committees of clinical guidelines
3. Citing follow-up studies rather than the original research articles
4. Standardized procedures for updating clinical guidelines are not implemented [23.115]. Clinical guidelines may lose their clinical relevance as they age and newer research emerges. Outdated clinical guidelines should be retracted but often are not.
5. An analysis of scientific papers stating support from healthcare funders may be incomplete and papers might acknowledge funding although the funding did not provide any substantive contribution for the paper and subsequently for the improvement of healthcare.

Despite these limitations, clinical guidelines seem to be an attractive resource for societal impact measurement into the healthcare sector of science.

23.4.4 References in Policy-Related Documents

Ritter and *Lancaster* [23.120] argue that assessment of the extent to which "research influences and impacts policy decision making needs to go beyond bibliometric analysis of academic citations" [23.79, p. 30]. They recommend a systematic analysis of policy documents.

Policy-related documents (policy documents) are published by governmental agencies as well as by nongovernmental organizations (NGOs). The types of NGOs publishing policy documents varies from large international organizations (such as the World Health

Organization, see http://www.who.int) to small local organizations (such as the Economic Commission for Latin America and the Caribbean, see http://www.cepal.org/en) and special interest groups (such as think tanks and lobbying groups). Policy documents authored by NGOs are mainly directed to leaders and decision-makers in politics in order to shape political decisions, while policy documents published by governments are mainly directed to the general public to support and explain decision-making in politics. Modern governments exhibit scientific service facilities and NGOs employ (depending on their organization's size) scientific staff members to help draft policy documents. Irrespective of the author of a policy document, such documents contain three crucial sections:

1. A current problem is presented
2. A particular course of action is recommended
3. Supporting evidence for the recommendation is cited. As a variety of different people work on a single policy document, one should not expect scientific citation habits in policy documents.

Analysis of reference lists of policy documents on a large scale were made possible by aggregators of altmetrics. Altmetric started to provide mentions of scholarly papers in policy documents in 2014. *Liu* [23.121] writes:

> As you might have already learned from our June press release announcing the launch of Altmetric for institutions, we recently started tracking some highly impactful new sources of attention: policy and guidance documents.

Plum Analytics started to provide similar information in December 2016 [23.122]. *Haunschild* and *Bornmann* [23.85] analyzed how many and which proportion of papers are mentioned in policy documents tracked by Altmetric. They found that less than 0.5% of the papers published in different subject categories are mentioned at least once in policy documents using a large interdisciplinary database (WoS). *Bornmann* et al. [23.84] studied more specifically how many and which proportion of papers from climate change literature were mentioned in policy documents. As climate change research is a rather politicized and important topic, many mentions in policy documents could be expected. However, only 1.2% out of 191 276 papers on climate change were found to have at least one policy mention.

Although an indicator based on papers mentioned in policy documents seems to be a promising indicator for societal impact measurement, several problems exist currently:

1. Mainly, international, English documents are tracked by data providers. Thus, more non-English policy sources should be tracked.
2. Policy documents are often published in different languages as different documents but with the same content. Disambiguation of such duplicates is problematic.
3. It is unknown where a particular paper has been mentioned in a policy document or policy source website. For example, the mention could be in a publication list in a CV instead of a policy document.

More studies should investigate coverage of policy documents and their mentions of scholarly material and solutions to the aforementioned problems should be found before mentions in policy documents are used for societal impact measurement.

23.5 Discussion

As a part of society, science is also affected by the overall development towards an audit society. It is no longer taken for granted that science makes an important contribution to society; this contribution must be demonstrated or proven. Here, it is chiefly a matter of the production of direct societal and economic utility and impact. For science, this means that research evaluation must go beyond the established instruments of peer review and bibliometrics or that the established instruments must be adapted to the new conditions. One possible adaptation could be to include people from areas outside science in peer review panels. As the results of *Ballabeni* et al. [23.123] show, the societal relevance of research is nothing new for many scientists and plays an important role in the motivation for pursuing research. The authors surveyed more than 300 scientists at Harvard Medical School and affiliated institutes [23.123]:

> The majority of the scientists who participated in the survey indicated that the most important goal of publicly funded basic 'biomedical' research is the production of health benefits to society (86%) ... and that the desire to effectively benefit society

is an important or very important motivation for most of them (87%).

The measurement of societal impact can be regarded as a "Kuhnian revolution for research evaluation criteria" [23.74, p. 137] see also [23.124, 125]. Societal impact measurement is a matter of the measurable influence (effect) of research which can be detected outside of research in a particular sector of society. Besides the accountability in an audit society, this chapter mentions additional reasons for the desire for societal impact measurement: science should be more strongly oriented towards the application or use of its results. This is mainly in the hope of strengthening the economy of a country. Furthermore, research projects should be promoted when these research projects help to tackle specific societal problems.

However, research evaluation and funding decisions should always be carried out in a contextualized manner. Most fundamental research has no measurable societal impact during useful evaluation periods, but most fundamental research projects do have significant societal impact over the long run (e. g., climate change research and space sciences). Since research happens in very disparate areas and—besides fundamental research—there is also application-oriented research, societal impact measurement should take account of the breadth of the possible usefulness of research. However, societal impact measurement is afflicted with a number of problems which we discussed in Sect. 23.1.3. These include:

1. The difficulty with the attribution of societal impact to a particular piece of research
2. The possibility that the impact of research on society can be both positive and negative at the same time
3. The often long time lag between the performance of the research and its (measurable) effect on society. These problems should always be taken into account for societal impact measurement.

In Sect. 23.2 we have given an overview of societal impact measurement in various areas (with funding bodies, in national evaluation exercises as well as through multidimensional frameworks and productive interactions). As we have set out in Sect. 23.3, case studies are currently the method favored for societal impact measurement. Case studies offer a number of advantages, such as the possibility of acquainting an audience which does not consist of specialists with complex issues. In addition, case studies can be used in all disciplines—without restriction. Case studies, however, have some serious disadvantages: their results cannot be generalized nor are they suitable for the comparison of research units. They are also relatively expensive to perform. Therefore, it is desirable (in research evaluation) that quantitative indicators for societal impact measurement be developed, the results of which can both be generalized and permit a comparison between different research units. When these indicators are available, they should not replace the case studies approach completely, but complement it in a mixed-methods approach [23.64].

Section 23.4 therefore discusses which altmetrics have been suggested or are already used for the measurement of societal impact. Sections 23.4.2 and 23.4.3 describe studies which show that citations in patents and citations in clinical guidelines can already be used in certain areas for societal impact measurement. Clinical guidelines in particular extract information from research literature quickly [23.82]. A great advantage of citations in patents and citations in clinical guidelines is that they contain citation data which can be evaluated with the established methods of bibliometrics. Section 23.4.4 discusses the potential use of mentions of papers in policy-related documents for societal impact measurement. The documents also contain reference lists which can be analyzed with methods from bibliometrics. However, too few studies have been carried out thus far so that it is an open question as to whether policy-related documents will be useful in societal impact measurement although they look rather promising at this point.

Social media metrics—as presented in Sect. 23.4.1—are also seen as a possibility for measuring the societal impact of research. It is however not yet clear whether social media metrics can really satisfy this requirement. We assume that only a subset of social media metrics can actually be used for societal impact measurement. Which metrics these will be in practice, will be shown by scientometric research. In addition, we do not regard it as sensible to use raw counts for impact measurement or to combine the raw counts of various altmetrics sources into composite indicators, but rather to undertake a field- and time-normalized impact measurement, which is target-oriented (and focused on such groups in society as students or others).

Lutz Bornmann

Division for Science and Innovation Studies
Administrative Headquarters of the Max Planck Society
Munich, Germany
bornmann@gv.mpg.de

Lutz Bornmann works as a Sociologist of Science at the Division for Science and Innovation Studies of the Max Planck Society in Munich. His current research interests include research evaluation, peer review, bibliometrics, and altmetrics. He is a member of the editorial board of the *Journal of Informetrics* (Elsevier), *PLOS ONE*, and *Scientometrics* (Springer). Furthermore, he is a Senior Associate Editor at theInternational Journal of Biomedical Science Editing (Kowsar).

Robin Haunschild

Central Information Service
Max Planck Institute for Solid State Research
Stuttgart, Germany
r.haunschild@fkf.mpg.de

Robin Haunschild studied Chemistry in Hannover and Marburg. After two Postdoctoral positions (Rice University in Houston and Karlsruhe Institute of Technology) he joined the Central Information Service for the Institutes of the Chemical, Physical, and Technical Section of the Max Planck Society in 2014. His current research interests include the study of altmetrics and the application of bibliometrics to specific fields of natural sciences, e.g., climate change.

24. Econometric Approaches to the Measurement of Research Productivity

Cinzia Daraio

The measurement of research productivity is receiving more and more attention. Besides scholars that are interested in understanding how research works and evolves over time, there are supranational, national and local governments, and national evaluation agencies, as well as various stakeholders, including managers of academic and research institutions, scholars and more generally the wider public, who are interested in the accountability and transparency of the scholarly production process.

The main objective of this chapter is to analyze econometric approaches to research productivity and efficiency, highlighting what econometric approaches to research assessment can offer and what their benefit is, compared to traditional bibliometric or informetric approaches. We describe the nature of, and the ambiguities connected to, the measurement of research productivity, as well as the potential of econometric approaches for research measurement and assessment. Finally, we propose a checklist when developing econometric models of research assessment as a starting point for further research.

The main objective of this chapter is to describe what econometrics can offer to informetrics. It is a set of conceptual and methodological models with estimation tools to provide empirical estimates of research productivity and efficiency (towards effectiveness and impact) conceived as a multidimensional and complex related set of activities. The chapter relies on [24.1], which is its departure base, and on [24.2–4].

As we will see in the next sections, the evolution of research in economics and econometrics related to the measurement of productivity and efficiency in addition to the changes in research activity itself is challenging the traditional efficiency estimation methods.

We think that due to the complex nature of the research activity, *nonparametric methods* (which do not rely on strict hypotheses about the parameters of the re-

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_24

lationships among inputs and outputs) can offer a valid analysis tool, with a broader generality than *parametric methods* (which in turn are based on more restrictive hypotheses about the parameters). Nevertheless, the *validity* and *appropriateness* (quality in our framework) must be conceptualized, formalized and analyzed with reference to the specific problem (fitness for purpose). Within this context, *semiparametric* and parametric methods can also be useful, perhaps in combination with nonparametric methods used as preliminary exploratory methods.

We do not have a specific approach or technique that dominates all the others in every context of application, and there are a lot of methods that are proposed in the specialized literature each day. We have hence to choose the estimation tool according to the problem at hand. There are many tools and there are many problems and there are many different fields of research that study the problems through different perspectives. The selection of the most appropriate tool is not easy given also the rapid evolution, the technicalities and jargon of the different disciplines. This rapid evolution currently affects both the research activity and the productivity estimation. In order to be able to understand which may be the most suitable tool, to highlight pros and cons and the consequent caveats for the users of the estimation we propose a very rough checklist.

24.1 Assessing the Productivity of Research

The quantitative assessment of the productivity of the research activity is not only a fascinating and complex research problem, but it is also a relevant policy issue. This is because it may be connected to policies of evaluation, funding allocation, promotion and more generally to performance comparisons, which can be carried out at different level of analysis, such as at a macro (country), meso (regional), micro (institutional) and micro-micro (individual and group-based) level.

In fact, the measurement of productivity of research is receiving more and more attention by different policymakers. Beside scholars that are interested in understanding how research works and evolves over time, there are supranational, national and local governments, and national evaluation agencies, as well as various stakeholders, including managers of academic and research institutions, scholars and more generally the wider public, who are interested into the accountability and transparency of the scholarly production process.

The main objective of this chapter is to analyze econometric approaches to research productivity and efficiency, highlighting what econometric approaches to research assessment can offer and what their benefit is, compared to traditional bibliometric or informetric approaches. We will analyze the nature and potential of econometric approaches for research measurement and assessment. In particular we will show what the potential benefits of nonparametric techniques and more advanced econometric frontier models are.

Before entering into its purposes, the chapter describes the main concepts involved and illustrates the main ambiguities connected to the measurement of research productivity. In particular, we will show that the measurement of research productivity is a *component* of research assessment and its ambiguities are essential and should be taken into account. We will then introduce the need for a framework to accomplish this task and will show some examples of its usefulness in research assessment.

In recent decades, the rapid changes taking place in the production, communication and evaluation of research have been signs of an ongoing transformation. One could maintain that we are living a sort of middle age guided by the information and communication technologies (ICT) revolution, or the so-called *fourth revolution* as described by *Floridi* [24.5], which emphasizes the importance of information.

Largely, the current middle age of research evaluation might be understood as the transition from a traditional evaluation model, based on bibliometric indicators of publications and citations, to a modern evaluation, characterized by a multiplicity of distinct, complementary dimensions. This step is guided by the development and increasing availability of data and statistical and computerized techniques for their treatment, including among others the recent advancements in artificial intelligence and machine learning.

At the same time, the recent changes also have an impact on econometric techniques and therefore on the *ways* in which production is conceived (and represented) and productivity measured (estimated). It will therefore be necessary to present all these changes in a synthetic way before analyzing the potential of the econometric techniques for the evaluation of research. The main methodological challenges related to estimating productivity and efficiency will be made clear to the reader and analyzed in detail.

Finally, this chapter applies the notions of standardization and harmonization to the methodological dimension of the research assessment. We are well aware that this is a difficult and challenging task because, among other factors, it depends on the purposes of the assessment. Nevertheless, the proposed checklist when developing econometric models of research assessment, although very preliminary, might constitute a useful starting point for further research.

24.2 What Do We Measure?

24.2.1 Some Hints from a Recent Debate

The theme of the evaluation of research productivity may be subject to easy misunderstandings, as has been clearly shown by *Glänzel* et al. [24.6] in the debate on [24.7]. "Mean normalized citation scores (MNCSs) and like size-independent indicators". In this debate, different terms were used, such as *research performance*, *productivity*, *efficiency*, and *true evaluation of research productivity* [24.8] without an in-depth introduction and discussion of their meanings.

We do not enter here into the discussion about the MNCS, which relates to *output bibliometrics* [24.9]. Further information about MNCS can be found in Chap. 11 in this Handbook.

Nevertheless, we take into account some of the warnings provided within this debate for the development of this chapter. In particular, we refer to the contributions of *Zitt* [24.9] and *Glänzel* et al. [24.6]. *Zitt* has observed that [24.9, p. 675]:

> More generally, economics of science (as sociology of science) rightly claims science networks, the core of scientometrics, as important objects, with two implications: 1) Output bibliometricians should remain modest and prudent, and welcome strong concepts and the toolbox coming from economics. On the policy side, many bibliometricians have devoted much time to warn against the limitations of bibliometric measures, to emphasize their properties and their conditions of use, to stress the dangers of misusage, and to insist on the traps of one-figure descriptions. 2) Conversely, authors with another background should be cautious in the criticism of bibliometric measures considered independently from their historical context or the question of sources and data.

Glänzel et al. [24.6, pp. 658/659], on the other hand, have pointed out a series of important aspects to consider. They include the question of the *correct interpretation*, the fact that *productivity and performance* are distinct concepts; the *multidimensionality* of performance; and the distinction between the *efficiency* and the *effectiveness* and the observation that system performance relates to the effectiveness of a system, while productivity only hints at its efficiency. *Efficiency or productivity* also poses its specific challenges in terms of operationalization and quality of the underlying data; *comparability (and hence validity) of the underlying data themselves* constitutes *a problem*, and finally the authors addressed the *difficulty of quantification*.

24.2.2 The Measurement of the Productivity as a Component of a Research Assessment

Before turning to the definition of the basic concepts, a distinction is in order here. There are at least two main reasons for carrying out a measurement of the productivity of research. The first one (study purpose) is to understand how research is produced, how research works, and its evolution over time. The second (assessment purpose) is related to the use of the measurement of productivity carried out as an assessment measure in an evaluative framework of the research activity. We should always take into account why we are carrying out our measurement, because given the peculiarity of the research activity, in the case of an assessment purpose much more care should be taken. Generally, we cannot speak about *true measurement of research efficiency* in either cases, because, as will be shown in the continuation of this chapter, the assessment of productivity and efficiency is *tricky* and involves several conceptual, analytical, methodological and data-related *issues*. Being more specific, it is much more dangerous to speak about *true measurement of research efficiency* if the assessment is done in an evaluative framework in which some scholars are compared with each other for the allocation of research funds, than in a research paper that analyses the scientific developments of a set of countries. In our opinion, the analyst should be careful in both cases, and also in the second case should state clearly the underlying assumptions, and the simplistic notions that were made to handle a much more complex issue. Nevertheless, as far as the first case is concerned, it is important to warn the users of the productivity/efficiency measurement about all the hypotheses, simplifications and possible distortions, because in this case, the measurement may affect individual people and society at large much more than a wrong or a superficial paper. This is linked to the distinction between *research tools* and *management or assessment tools*, well known in the quantitative studies of science [24.10, p. 90].

Measuring is different from assessing, which in turn is different from evaluating. According to the Cambridge dictionary (https://dictionary.cambridge.org/), to measure means *to discover the exact size or amount of something*, to assess means *to judge or decide the amount, value, quality, or importance of something*, and to evaluate means *to judge or calculate the quality, importance, amount, or value of something*. Assess and evaluate are then considered as synonyms. Nevertheless, for the sake of clarity, we adopt the distinction made by *Moed* [24.10, p. 94] and will consider, in the following, assessment as "the total of activities in assessment or evaluation processes, or the act of evaluating or assessing in general". The research assessment, according to *Moed* [24.10, Table 6.3, p. 95], includes four domains, namely:

1. Policy or management
2. Evaluation
3. Analytics
4. Data collection.

The *policy or management* formulates the policy issue and the assessment objectives, it defines the organizational aspects and the budget and its outcome is to make a policy decision based on the outcomes from the evaluative domain. The *evaluation* defines and evaluates worth, it specifies the *evaluative framework* that is a set of evaluation criteria in agreement with the constituent policy issue and assessment objectives, and its outcome is making judgments on the basis of the evaluative framework and the empirical evidence collected.

This distinction is important here because it allows us to clearly understand that the measurement of the productivity of research is a *component* of a research assessment. For this reason, when research productivity measurements are carried out within a research assessment, we have to take into account the assessment context in its *entirety*.

24.2.3 What is Research?

To define the research, we propose to the readers the definitions of the Frascati manual developed by the Organisation for Economic Co-operation and Development (OECD), which are *definitions for measurement purposes* and represent a commonly shared standard in the literature.

In the *Frascati manual* last edition [24.11] the basic definitions of research and development (R&D) are slightly modified with respect to the previous edition of the manual. Some extensions of the current version of the manual refer to the description of the peculiarities of R&D in social science and humanities [24.11, pp. 55–57]. In addition, the 2015 edition of the Frascati manual introduces a set of five core criteria that explain what key features must be met for an activity to qualify as R&D. Table 24.1 reports the definition of R&D and its subcomponents together with the five criteria adopted by the last edition of the Frascati manual.

The definition of R&D subcomponents reported in Table 24.1 is consistent with the definition of R&D used in the previous 2002 edition of the Frascati manual and covers the same range of activities.

From the definitions reported in Table 24.1, it follows that the research productivity measured by means of any analytic method and/or empirical approach, even the most sophisticated one, should be considered as an *estimate* of the *true* research productivity, which is unknown and very difficult to assess.

24.2.4 What is Productivity?

Basic Notions

The topic of productivity has been at the core of the economic analysis since Adam Smith's *Wealth of Nations* pin factory, and even before. *Productivity* is commonly defined as a ratio between the output produced and the inputs used to produce it, in a given production process. The measurement of research productivity can then benefit from the application of methods developed in this field. The measurement of the productivity of an economic activity can be carried out in different ways and according to different approaches.

A handbook chapter by *Bonaccorsi* and *Daraio* [24.1], which is the starting base of this chapter, carried out a survey and discussed the potential and limitations of econometric methods for the evaluation of the productivity of scientific and technological systems. They compared the advantages and disadvantages of the main approaches proposed in the literature, namely the production function and the production frontier (or efficiency analysis) approach.

We provide here a short overview of the main methods, starting with a brief sketch of ratio measures and index numbers. This is taken from [24.1]. After that, we will analyze the two main approaches proposed in the literature, namely production functions and production frontiers (or efficiency analysis).

A very simple *measure of productivity* is given by the ratio between the output realized and the input used to produce it. This measure considers one category of input and relates it to one category of output, without considering the complementarity and substitution rela-

Table 24.1 Definition of R&D and its subcomponents according to the *Frascati manual* last edition [24.11]

Concept	Definition	Page in the Frascati manual (2015)
Important premise about R&D	The defining feature of R&D in this manual is that it is carried out in order to generate new knowledge as an output, irrespective of its purpose, which could be the generation of economic benefit, addressing societal challenges or simply having the knowledge in itself. This intentionality is used in this manual to distinguish between experimental development and basic and applied research. In the same manner, it is of interest to identify and, if possible, to measure the different types of outputs from R&D. However, it is difficult to identify and measure R&D outputs. This is due to a series of factors that affect both how knowledge is distributed and used in the economy and the complementary inputs necessary for results to occur. Any outputs and effects may take a long time to be realized and may occur at different places and for different actors than those carrying out the R&D. *Only very partial outputs can currently be directly identified and measured* as part of collecting information on R&D activities and funding.	*OECD* [24.11, p. 25]
R&D definition	Research and experimental development (R&D) comprises creative and systematic work undertaken in order to increase the stock of knowledge—including knowledge of humankind, culture and society—and to devise new applications of available knowledge.	*OECD* [24.11, p. 44]
Core criteria to identify R&D	For an activity to be an R&D activity, it must satisfy five core criteria. The activity must be: 1. Novel 2. Creative 3. Uncertain 4. Systematic 5. Transferable and/or reproducible.	*OECD* [24.11, p. 45, see also pp. 46–48]
Definition of subcomponents of R&D (basic research, applied research and experimental development)	The term R&D covers three types of activity: basic research, applied research and experimental development. *Basic research* is experimental or theoretical work undertaken primarily to acquire new knowledge of the underlying foundation of phenomena and observable facts, without any particular application or use in view. *Applied research* is original investigation undertaken in order to acquire new knowledge. It is, however, directed primarily towards a specific, practical aim or objective. *Experimental development* is systematic work, drawing on knowledge gained from research and practical experience and producing additional knowledge, which is directed to producing new products or processes or to improving existing products or processes.	*OECD* [24.11, p. 45], [24.12]
Product	The manual follows the system of national accounts (SNA) convention in which *product* refers to a good or a service.	*OECD* [24.11, p. 45]
Process	Refers to the transformation of inputs to outputs and to their delivery or to organizational structures or practices.	*OECD* [24.11, p. 45]

tions between inputs, and ignoring the effects of joint production in outputs. They may be used as a kind of first-order approximation.

These ratio-based measures of productivity (output–input) are defined also as *partial* productivity measures (see *Daraio* and *Simar* [24.13, p. 14], for their description within the efficiency analysis context). On the other hand, *total* factor productivity measures aim at the measurement of a value of the output–input ratio, which considers *all* outputs and inputs. The estimation of total factor productivity measures by combining all inputs and all outputs to obtain a single ratio aims to avoid imputing gains to one factor (or one output) that should be attributed to some other input (or output). However, total factor productivity measures present aggregation problems such as choosing the weights to be used in order to obtain a *single output to single input* ratio.

Another simple measure of productivity is given by *index numbers*. An index number is defined as a real number that measures changes in a set of variables. In particular, index numbers are applied to measure price and quantity changes over time, as well as to measure differences in the levels across firms, industries, regions, or countries. Panel data allow the measurement of productivity change as well as the estimation of technical progress or regress. Productivity change occurs when an index of outputs changes at a different rate from that at which an index of inputs does. Productivity change can be calculated using index number techniques such as Fischer or Tornqvist productivity indices. Both these indices require quantity and price information, as well as assumptions about the structure of the technology and the behavior of producers. Productivity change can also be calculated using a production frontier approach to construct a Malmquist productivity index. This approach does not require price information or technological and behavioral assumptions, and allows the identification of the sources of measured productivity change (i. e., technological progress/regress and efficiency changes). It requires the estimation of a representation of production technology that can be made using different frontier approaches (see *Daraio* and *Simar* [24.13, p. 14], for their description within the efficiency analysis context).

A distinction between productivity and efficiency is in order here. Although in the specialized productivity and efficiency analysis literature the terms productivity and efficiency are used often as synonyms, we think it is more appropriate to distinguish their meanings [24.13].

Productivity is the ratio of the outputs over the inputs, and we may consider it as an efficiency *in the narrow sense*. Efficiency, in the broad sense, is defined instead as the output–input with respect to an estimated reference frontier, or frontier of the best practices [24.13, p. 14]. Given that we have introduced the concept of frontier, we can analyze the differences between production functions and production frontiers in the next section.

Production Functions versus Production Frontiers

As recalled above, the two main approaches proposed in the literature to econometrically estimate productivity and efficiency are production functions and production frontiers (or efficiency analysis). In the production function approach, the measurement of productivity relies on an average relation or a relationship that intersects the input–output data, looking for the *representative* units (or expected behaviors). Most often, the estimation of production function is based on the specification of a functional form of the relationship between inputs and output, characterized by coefficients that relate the inputs to the output (which is typically univariate).

In any discipline, knowing the past is useful to understand the present and the current challenges. The knowledge and history of production functions may therefore be informative for the main purpose of this chapter. *Mishra* [24.14] has carried out a short description of the evolution of the concept and econometrics of production functions. He highlights the assumption of technical efficiency behind the production function, its main economic features and the subsequent controversies in economics about the use of aggregate production functions.

Thanks to the parameters of the production function, from which the name parametric comes from, it is possible to analyze the level of productivity, which is usually given by a coefficient that multiplies the function (this is the case of neutral technical progress); the marginal productivity of each factor (making the assumptions that the factors can be measured without ambiguity, the other inputs can be kept constant, and the availability of an infinite number of techniques such that the passage from one combination of factors to another could happen also for infinitesimal variations); the marginal rate of substitutions amongst factors; the factors' intensity, given by the ratio of the amount of two inputs, given the marginal rate of substitutions; the optimal choice of the combination of inputs, through the equality of the factors' marginal rate of substitutions and their prices ratio; simple measures of productivity by obtaining the ratio of the observed level of output over the production function optimal level; measures of technical change; returns to scale; inputs' elasticity of substitution, and the like.

One may also estimate more generally, without relying on parametric assumptions, i. e., nonparametrically, a production function, by applying methods from nonparametric statistics and econometrics (see basic definitions in Table 24.4, and *Hardle* [24.15], and *Henderson* and *Parmeter* [24.16]. This has not been done very often in the empirical literature. One reason is the economic interpretation of coefficients that facilitate the understanding of the data, and another reason is that up to recently there was not a lot of econometric software implementing nonparametric techniques.

In the *production frontier* approach, or efficiency analysis, the measurement of productivity is based on the estimation of a frontier that envelops the data, and in gaging the distance of *each unit* from the estimated *best performing* frontier.

The production frontier approach or efficiency analysis ([24.17, 18] and [24.13, p. 1]) challenges the basic implicit assumption of production function efficiency. Indeed, in standard microeconomic theory [24.19], a production function describes the maximum achievable output for given inputs. With respect to input–output characterization, production functions then implicitly assume a *maximizing* behavior of the units.

A rigorous analytical approach to productivity and efficiency originated with the works of *Koopmans* [24.20], *Debreu* [24.21] and *Shephard* [24.22], among others, and was empirically applied by *Farrell* [24.23], *Charnes* et al. [24.24] and others. These seminal works gave rise to a considerable amount of studies that challenged theoretical mainstream production analysis focused on production activity as an optimization process.

One may specify and estimate a production frontier by means of a *parametric* production frontier (in which the relationship between input–output relies on specific parameters of their functional form) or through a *nonparametric* production frontier, based for instance on linear programming techniques that envelop the data without assuming any functional relations between input–output. Data envelopment analysis (DEA) [24.23, 24] is a nonparametric approach based on linear programming techniques.

Mishra presents the nonparametric approach to efficiency analysis, based on DEA as a more realistic approach, as follows [24.14, p. 7]:

> It has been noted that although the notion of production function generally assumes that technical efficiency has been achieved, this is not true in reality. Some economists and operations research scholars [...] addressed this problem by what is known as the Data Envelopment Analysis (DEA). The advantages of DEA are: here one need not specify a mathematical form for the production function explicitly; it is capable of handling multiple inputs and outputs and being used with any input/output measurement; and efficiency at technical/managerial level is not presumed. It has been found useful for investigating the hidden relationships and causes of inefficiency.

On the other hand, most empirical production analysis has used the production functions and has focused on a central tendency, or *average* or *most likely* relationship constructed by intersecting data with a parametric function. Estimating production functions has been carried out by estimating the coefficients of regression equations, which describe the average tendency of the relationship between inputs and outputs. But as we have seen above, nonparametric specifications of production functions are also available. The purpose of efficiency analysis, based on frontiers, is to make a relative benchmark or comparison among units. Production frontiers, as well, may be specified by means of a *parametric* functional form for the frontier or *nonparametrically*, i. e., without a functional specification of the frontier.

Another useful distinction of frontier models is between *deterministic* and *stochastic* frontier models. In deterministic frontier models, such as DEA, all the deviation from the estimated production frontier is assumed to be inefficiency. There is no noise in this kind of model. On the other hand, stochastic frontier models, or stochastic frontier analysis (SFA) [24.25], assume there is some noise in the model. SFA models distinguish noise from inefficiency, but to do this they rely on the parametric specification of the functional form for the noise and on the functional form for the inefficiency. These functional specifications are added to the functional form specified for the production frontier. There are in the literature also *semiparametric* approaches that propose models in which some functional forms are parametrically specified and some others are left nonparametric. From the empirical point of view, the efficiency analysis approach offers techniques for estimating the *efficient* production frontier and for measuring and interpreting the relative efficiency of each unit as a distance with respect to this estimated frontier. We will come back to these distinctions in Sects. 24.6 and 24.7 highlighting their methodological challenges and their potential.

Some Features of Research Productivity from the Economics of Science

Let us focus mainly on scientific production in the public sector research system. The first part of this section is taken from [24.1]. Scientific production is not only a multi-input multi-output process, but the relation between inputs and outputs is nondeterministic, uncertain, lagged, nonlinear, and subject to important but subtle external effects.

We know from the *economics of science* [24.26] that a few stylized facts about individual productivity do exist [24.27]. First, the distribution of individual productivity of scientists is extremely skewed, with a small percentage of very productive scientists accounting for a disproportionate share of publications. Second, productivity declines over a scientist's life cycle [24.28]. Gender effects on scientific productivity [24.29, 30] have been recently investigated [24.31, 32] together with collaboration [24.33, 34] and funding [24.35]. These very basic features of scientific production make a representation in which the marginal rate of substitution between units of inputs is constant or independent on size, and in which interaction effects are zero, which is highly unrealistic.

How these individual-level factors combine on an organizational and institutional level is, in fact, a very open question [24.36]. Do people with the same individual productivity attract each other, or perhaps are hired according to a consistent quality strategy, so that in the end the same skewed distribution will also be observed across organizations and institutions? Or, quite to the contrary, do people with different individual productivities mix within research departments and institutes? What is the effect of the organizational setting on individual productivity? An important effect of the external environment of scientists has also been observed, in terms of complementary resources, time constraints, and social incentives at the level of department or institute [24.37–41]. External factors may create complementarities, which have a nonlinear effect. Under these conditions, the lack of a specification of the functional form is a clear advantage.

Research activities are intrinsically multi-output activities.

First of all, for a large part of the research system the allocation of the time of researchers takes place between research and teaching. Since the share of time is not fixed across disciplines and countries, it is sensible to take both outputs into consideration, when possible.

Second, within the narrow area of research, whilst the single most important output is clearly scientific publications, it is difficult to claim that other outputs such as patents, software, advisory work for the government, consulting, or technical assistance do not have any relevance with respect to research.

Finally, scientific publications cover a large range of specific outputs, such as papers in refereed journals, papers in technical or professional journals, notes, reviews, books, and edited books. How much worth is a book with respect to a paper in a refereed journal? Do more papers in the technical press compensate for fewer papers in academic journals?

In order to take into consideration the multi-output nature of research it is necessary to aggregate each type of output. Using a multi-output specification is clearly more appropriate.

The economics of science [24.42] reminds us that researchers conduct research for different reasons including their interest in *puzzle solving*, reputation based on the priority of their discovery, awards and recognition for their achievements, and also through publications, which has a key role for funding and promotion. Other incentives vary across fields. Research is a public good. This means that once it is public others cannot be excluded from its use (nonexcludable nature). This offers the possibility of *free-riders* behaviors and difficulty in capturing economic returns. Moreover, once public goods are produced, competitive markets fail to provide them efficiently. In research, reward is not for effort but for achievement.

What the economics of science tells us about the production of scientific research is that research does not only produce multiple *outputs*, but also involves multiple *inputs*, including knowledge, time, materials and equipment. Some inputs are embedded in people (knowledge and time in particular) and most of these inputs are expensive.

As observed by *Stephan* [24.42, p. 228]:

> Incentives and cost matter for science and economics is also about the allocation of scarce resources across competing wants and needs, economics is also about whether resources are allocated efficiently.

When concluding her book on *How Economics Shapes Sciences*, *Stephan* [24.42, p. 235] states three more general and difficult *efficiency* (in the narrow sense) questions that require further research. These are:

1. What is the right amount of money in terms of percent of the gross domestic product (GDP) to spend on university R&D?
2. What is the most efficient mix in terms of budget allocated to the different disciplines?
3. What is the most efficient structure for grants in terms of size, duration, criteria for evaluation and number of people involved?

Productivity is Just a Component of Performance

Generally, in this chapter, by performance we mean the results obtained by an activity. *Bazeley* [24.43], developing the work of *Åkerlind* [24.44], provides an attempt to conceptualize what research performance is. This is useful for our chapter showing that research productivity is just a component of research performance, which relates mostly to the output produced, but it does not coincide with research performance, which is a much broader concept.

In conceptualizing research performance *Bazeley* [24.43] identifies two basic components (research activity and making research visible), with six secondary-level dimensions. The four essential dimensions of the research activity (or components of research performance), identified by *Bazeley* [24.43] were:

1. *Engagement* (interest and involvement)
2. *Task orientation* (disciplined management, getting the job done)
3. *Research practice* (knowledge and skill, substantively and methodologically sound)
4. *Intellectual processes* (analytic capacity and creative thinking).

Two other dimensions (of which at least one is necessary) relating to the performance, or making research visible, component of research performance were *dissemination* (formal communication of research outcomes) and *collegial engagement* (sharing knowledge and expertise). Research performance was in addition seen to occur within conditions provided by an institutional context (education and training; opportunity and resources), and to bring about a range of outcomes (product, impact and reputation). Table 1 of [24.43, pp. 895/896] lists eight characters of researcher attributes: quality, ability, *productivity*, recognition, benefit, activity, satisfaction and approachability. It appears again, clearly, that productivity is just one component of research performance.

A simplistic economic view that considers research activity as any other economic activity and measures it through a basic production function, calculates simple partial productivity measures [24.8, 45]; although we do not share this approach, we admit that in certain contexts and for certain evaluation questions, with all the caveats of the case, it could be useful. What is important, in this case, is to clearly warn the users of the productivity measurement about the underlying assumptions, the strong simplifications and about the bias existing in using this measure in a research assessment. Much more caution should be added when individuals are the entity subject to the assessment, for which we know all the problems related to individual-level bibliometrics (see an outline in [24.46]) and ambiguities that bibliometric indicators may mask in assessing individual productivity [24.47]. An indicator, according to the Cambridge dictionary, is something that shows what a situation is like. *Van Raan* defines an indicator as [24.48, pp. 21/22]:

> The result of a specific mathematical operation (often simple arithmetic) with data. The mere number of citations of one publication in a certain time period is data. The measure in which such citation counts of all publications of a research group in a particular field are normalised to citation counts of all publications worldwide in the same field, is an indicator. An indicator is a measure that explicitly addresses some assumption.

24.2.5 Ambiguities of the Measurement of Research Productivity

Bonaccorsi and *Daraio* [24.1] discussed a general concept of *research productivity*. It is based on the relationship which exists between a set of inputs (or resources) used to realize a set of outputs (or products) in a given production process. In contrast to a standard production activity, the production process of the research activity is seen as being characterized by several conceptual and measurement problems, which affect any definitional elements of the productivity, namely the inputs, the outputs and their functional relation. Indeed, a research activity may be represented as a process, characterized by a multiple inputs–multiple outputs relation, in which both the inputs and the outputs are heterogeneous and sometimes incommensurable, the inputs–outputs relation is nondeterministic, and the output is lagged, but with a nonfixed lag structure.

As we will see in the remainder of this chapter (in particular in Sect. 24.6), the current changes in research assessment (that are discussed in the next section) have amplified the ambiguities and the problems related to the measurement of research productivity.

24.3 Research Assessment in the Current Time and the Need for a Framework

To understand and tackle the challenges of the measurement of research productivity we need to analyze the changes taking place both in the realization of the research activity and in the econometric measurement of productivity. In this section, we analyze the former, while the next section describes the changes applying to the latter.

24.3.1 A Simplified Overview

Table 24.2 summarizes the main trends in research assessment exploring a categorization in factors in terms of change and consequences produced on the research assessment. This categorization is just a way to provide an outline, without claiming to be either complete or robust. In fact, some changes may be also consequences and some consequences may be changes.

As observed by *Nowotny* et al. [24.50]:

> The emergence of more open systems of knowledge production (Mode-2 Science) and the growth of complexity and uncertainty in society (Mode-2 Society) are phenomena linked in a co-evolutionary process.

The changes in knowledge production has led to the so-called *postacademic science* [24.49, 50]. The context speaks of changing science. The emergence of mode-2 society raises acute issues of social justice, economic equality and the further democratization of

Table 24.2 A simplified overview of the current situation in research assessment (based on [24.4, Table 1])

Category	Description
Changes	Has changed the way in which the knowledge is produced, the dynamics of science and its interactions with society: *postacademic science* [24.49, 50]
	There is a crisis of *technoscience* (scientific research and technological innovation, focused on applications [24.51]) and science identified [24.52] in reproducibility, peer-review, publication metrics, scientific leadership, scientific integrity and the use of science for policy
	Advent of the big data era and its technological developments in research assessment (the *computerization of evaluative informetrics*) [24.10]
	Has changed the way in which science is communicated [24.53]
Consequences or effects	*On the demand side* (those that ask for research assessment): changes of the requests and the ways in which the assessment is carried out (has to be done): 1. Extension to societal value and value for money (*evaluation society*) [24.54, 55] 2. Performance-based funding [24.56, 57] 3. Requests for new and timely indicators in response to changing needs [24.58] 4. Increase of institutional and internal assessments.
	On the supply side (those that offer research assessment): proliferation of rankings (among many others [24.59]), development of Altmetrics [24.60, 61], open-access repositories [24.62, 63], new assessment tools—both commercial (InCites and Sci-Val) and freely available (Google Scholar citation), desktop bibliometrics ([24.64]; Publish or Perish software)
	On scholars: the increase of *publish or perish* pressure, impact on the incentives, behavior and misconduct, and increasing critics against traditional bibliometric indicators [24.65–73]
	On the assessment process: Increasing *complexity of the research assessment* linked to the *implementation problem* [24.2]; multidimensionality of the assessment of the research [24.74]; problems of data quantification, harmonization and standardization for different evaluation and assessment purposes [24.75–77]
	On the measurement of productivity/efficiency within an assessment process: The increasing complexity of the research assessment and the extension of the boundaries of the research activity and the interdependence with the society requires a more precise description and delineation of the *boundaries* of the production process whose productivity has to be measured before making the estimate, and to consider the *dynamics* of the inputs, outputs and their connection

knowledge. Contextualization means that the implications as well as the applications of scientific research have to be embraced. Contexts emerge in relation to particular problems for which they are or may become relevant. Contextualization means that the human element and subjective experience is seriously taken into account. Researchers have to use social knowledge. The more open and comprehensive the scientific community, the more *socially robust* will be the knowledge it produces. Producing reliable knowledge is not sufficient. Socially robust knowledge is requested. The reinterpretation of the boundary of the production of knowledge is essential to describe and represent the production process. As a matter of fact, science enters the agora, and the range of perspectives in the agora increases: there is an increasing role of the construction of narratives of expertise to deal with this complexity and uncertainty. Knowledge is distributed, contextualized and heterogeneous. *Bucchi* analyzed the crisis of the technocratic view of science and the emergence of participatory processes and consider these as [24.51, p. ix]:

> Epochal changes in the social role of science, and generally in the production of scientific knowledge, and such changes concern the nature itself of contemporary politics and democracy.

The increasing intersection and permeability of the boundaries between science and society impacts on the dynamics of science communication and challenges it, as illustrated by *Bucchi* and *Trench* [24.53]. We have now *plural* science and *plural* public (diversity and fragmentation of publics); the new mediations by digital media have produced the *crisis of mediators* (losing filters that guarantee the quality of information, the actual information overload demands new definitions of quality and standards for assessment), and the traditional sequence of the communicative process from the specialist discussion/didactic exposition to the public communication (*popularization)* of *ready-made science* are changing towards *engagements* in *science-in-the-making* processes. Indeed, the users of scientific information increasingly have access to science in its making and highly controversial debates among specialists. Strong forms of engagements include *participatory democracy* and *participatory communication* that are connected to citizen science and open science [24.78]. *Rethinking science* [24.50] goes hand in hand with *reinventing discovery* [24.78]. Last but not least, the *cultural contexts*, which expresses models, and visions of knowledge translation and transfer is becoming more and more important. Finally, public communication has become a global enterprise with some overall features and specific regional characterizations [24.53].

All these changes affect the assessment of research. The changes described in the upper part of Table 24.2 have different consequences as reported in the bottom section of the table. In particular, they increased the *complexity of the research assessment and the need for standards*. Evaluating research and its impacts is a real complex task. *Daraio* [24.2] observed that perhaps the key problem is that research performance is not fully quantifiable. Hence, research assessment has to deal with *nonfully* quantifiable concepts. This has a consequence on the measurement of research productivity. It has to be carried out in a careful way, taking into account an appropriate representation of the production process, which identifies what are the boundaries of what is measured and describes all the main assumptions behind the representation.

Daraio and *Glänzel* [24.76] showed that the complexity of research systems requires a *continuous information exchange*. This process is due to the communication and interaction process among all actors and agencies involved in the production, processing and application of knowledge. All data entries, all processing, development and application of data relevant for research, and technology and innovation have their own rules and standards. *Daraio* and *Glänzel* [24.76] identify some elementary *rules of interferences* expressed in terms of data definition and standard setting in the process of data integration for different purposes, including process monitoring, input–output monitoring, ex-ante and ex-post evaluation.

In this chapter we maintain that *standards* and *harmonization* should be applied as well to the methodological dimension (or aspects) of the research assessment process. Although this is difficult due to the different and changing purposes of the assessment, we propose here to *standardize the methodological steps* of the econometric measurement of productivity and efficiency according to a general framework that will be introduced in the next subsection.

24.3.2 The Need for a Framework

The assessment of research requires a *systemic* approach in which research activities are considered together with education and innovation activities. In *Daraio* [24.2] we showed that the formulation of models of metrics is necessary to assess the meaning, validity and robustness of metrics. Metrics are defined as indicators calculated and used in a research assessment.

It was observed that developing models is important for *learning* about the explicit consequences of assumptions, testing the assumptions, and highlighting relevant relations; as well as for *improving*, by documenting/verifying the assumptions, systematizing the problem and the evaluation/choice done, and making explicit the dependence of the choice to the scenario. Moreover, there are several *drawbacks* in modeling, which have to be taken into account. The main pitfalls relate to the targets that are not quantifiable; the complexity, uncertainty and changeability of the environment in which the system works, to the limits in the decision context, and, last but not least, to the intrinsic complexity of calculation of the objective of the analysis.

A Summary

Daraio [24.2] proposes the framework illustrated in Fig. 24.1 as a reference to develop models of metrics. The results presented in this section have previously been published in [24.3].

This framework is based on three dimensions:

- *Theory*, broadly speaking, identifies the conceptual content of the analysis, answering the question *what* is the domain of interest, and delineating the perimeter of the investigation.
- *Methodology* generally refers to *how* the investigation is handled, what are the kinds of tools that can be applied to the domain of interest, tools which represent the means by which the analyses are carried out.
- *Data*, largely, and roughly, are instances coming from the domain of interest, and represent the means by which the analyses are carried out.

Each dimension is composed of three main building blocks and identifies three operational factors for implementation purposes. The main building blocks of theory are:

1. Education
2. Research
3. Innovation.

The main building blocks of methodology are:

1. Efficiency
2. Effectiveness
3. Impact.

The main building blocks of data are:

1. Availability
2. Interoperability
3. Unit-free property.

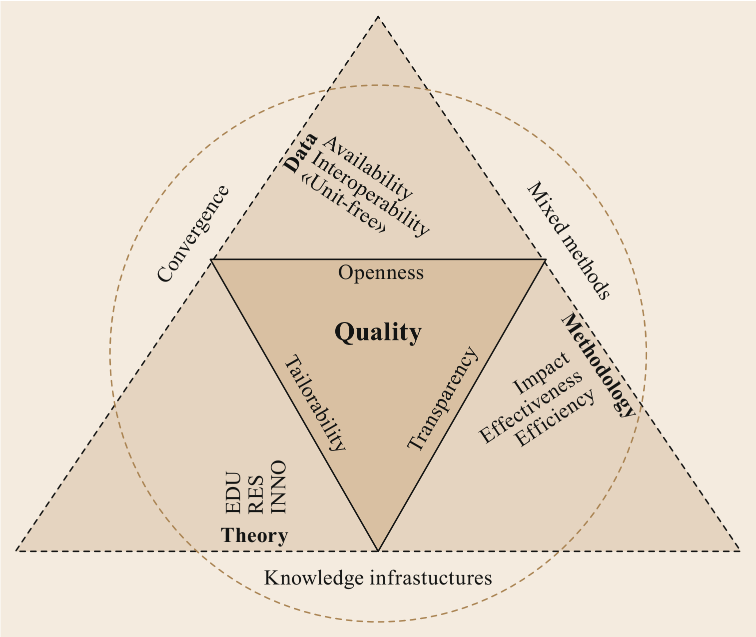

Fig. 24.1 A systemic framework for the development of research assessment models (after [24.2])

See Table 24.3 for their definitions.

The methodological dimension of this framework will be discussed in Sect. 24.6.

Daraio [24.2] asserts that the ability of developing (and afterwards understanding and using effectively) models for the assessment of research is linked and depends, among other factors, on the degree or depth of the *conceptualization* (formulation of the content of the general ideas and of the most important details) and *formalization* (refers to a defined structure), in an unambiguous way, of the underlying idea of quality. *Quality*, here, is intended as *fitness for use*.

The level of conceptualization and formalization of quality, however, is neither objective nor unique. It depends on the purposes and the subject or unit of the analysis (e. g., scholars, groups, institutions, up to meso or macro aggregated units, as regional or national entities) and it relates, in the end, to the specific evaluation problem under investigation.

In the next two subsections we report two examples of application of the proposed framework.

An Application of the Framework to the ANVUR's Activities

In a period of budgetary restrictions, policymakers need timely and inexpensive answers to their questions. While our framework highlights the need to invest in knowledge infrastructures as an investment for the development of a new generation of assessment models, it offers at the same time a pragmatic scheme to identify priorities in policy actions.

Coherent with our framework is the view of priority setting as a problem in system design, which is [24.80]:

> Best understood as a systemic process, with outcomes determined by the incentives and interrelationships of choice rather than by ex-ante calculation.

To show an example, we use the framework illustrated in Fig. 24.1 to frame the activities carried out by the Italian National Agency for the Evaluation of Universities and Research Centers (ANVUR). On the reform of the Italian system, see e. g., [24.81], while for some comparative analyses of the Italian system with France and UK respectively, see [24.82, 83].

In Fig. 24.2 we illustrate the main activities carried out by ANVUR so far, where Autovalutazione, Valutazione periodica, Accreditamento (AVA) stands for the evaluation of teaching, Valutazione della Qualità della Ricerca (VQR) for the evaluation of the quality of the research activity and Third Mission stands for the assessment of third mission activities of universities and research centers. ANPReS (Anagrafe nominativa dei professori ordinari e associati e dei ricercatori e delle pubblicazioni scientifiche) is an acronym that indicates the registry (Anagrafe) of the Italian scholars, foreseen in the current legislation but not yet implemented. For that reason, Fig. 24.2 reports it as a wide circle. Open Researcher and Contributor ID (ORCID) indicates the measure introduced by law to require each academic staff member to obtain an ORCID code, a successful

Table 24.3 Definition of the components of the framework [24.3, Table 1]

Dimension and component	***Definition***
1. *Theory*	Identifies the conceptual content of the analysis, answering the question *what is the domain of interest* and delineating the boundary of the investigation.
Education Research Innovation	These are the main conceptual blocks of theory. Their interrelations and their complementarities should be considered in a systematic way when assessing research.
2. *Methodology*	Identifies the range of methods, techniques and approaches that are relevant for the evaluation of research. It answers the question *how* the investigation is handled.
Efficiency Effectiveness Impact	These are the subjects of the assessment. They go from the *output* (baseline) that is the result of the transformation of inputs in outputs, to *efficiency*, which relates output to inputs with respect to an estimated efficient frontier, to *effectiveness*, which considers inputs, output and accounts for the aims of the activity, while *impact* refers to all contributions of research outside academia.
3. *Data*	Data are a relevant dimension often neglected in model building. Data have a problematic definition because this depends on their use not on inherent characteristics of the data [24.79, p. 74]. Data are instances coming from the domain of interest and represent the means by which the analyses are carried out.
Availability Interoperability *Unit-free* property	Refers to the usability of data, alternatives and choices that affect the data. This is the way in which heterogeneous data systems are able to exchange information in a meaningful way. Need of consistent and coherent observations across different levels of analyses.
Quality	*Fitness for purpose*. It is the overarching concept of the framework. It is also an attribute of the different dimensions of the framework.
Implementation factors	
Tailorability	Adaptability to the features of the problem at hand.
Transparency	Description of the choices made and underlying hypothesis masked in the proposed/selected theory/method/data combination
Openness	Accessibility to the main elements of the modeling.
Enabling conditions	
Convergence	Evolution of the transdisciplinary approach, which allows for overcoming the traditional paradigms, increasing the dimensional space of thinking.
Mixed methods	Intelligent combination of qualitative and quantitative approaches.
Knowledge infrastructures	Networks of people that interact with artifacts, tools and data infrastructures.

measure for the standardization and calculation of bibliometric indicators foreseen in the assessment exercise. Although rough and approximated, Fig. 24.2 immediately allows us to identify and indicate the priorities in the next planning of the activities, which are illustrated in Fig. 24.3 first along the data dimension, then along the methodology dimension (moving from the output towards efficiency, effectiveness and impact) and finally along the theory dimension.

A Doubly Conditional Performance Evaluation Model

This section is largely based on *Daraio* [24.4, 84]. We have seen that research performance is an articulated and complex concept [24.43] because the output of the research activity has some features that include complexity, uncertainty and indeterminacy.

Daraio [24.4] proposes a *doubly conditional performance evaluation model* as a *democratic evaluation tool* for *value creation* in a learning and participatory environment. It is considered as a revisited version of the Ricardo's approach of *comparative advantages* but in the context of a broader framework including theory, methodology and data dimensions. It is *doubly conditional* because the evaluation is conditioned twice: on the information *we have* and on the information *we do not have*. This model further operationalizes the doubly conditional performance assessment, identifying two kinds of conditions. The *internal conditions* include actors, processes, time, and results. These factors allow us to compare comparable entities, and to set appropriate reference sets. This is named as *internal conditioning* or normalization. There are in addition factors which account for the heterogeneity of the entity assessed, including the context, such as time frame, potential heterogeneity factors—other factors that may affect the performance not directly observed, standards (criteria or rules), and understanding incentives, actions and consequences that are named as *external conditioning* or contextualization. This model of performance evaluation, being based on a framework that allows us to describe and discuss the main assumptions of the

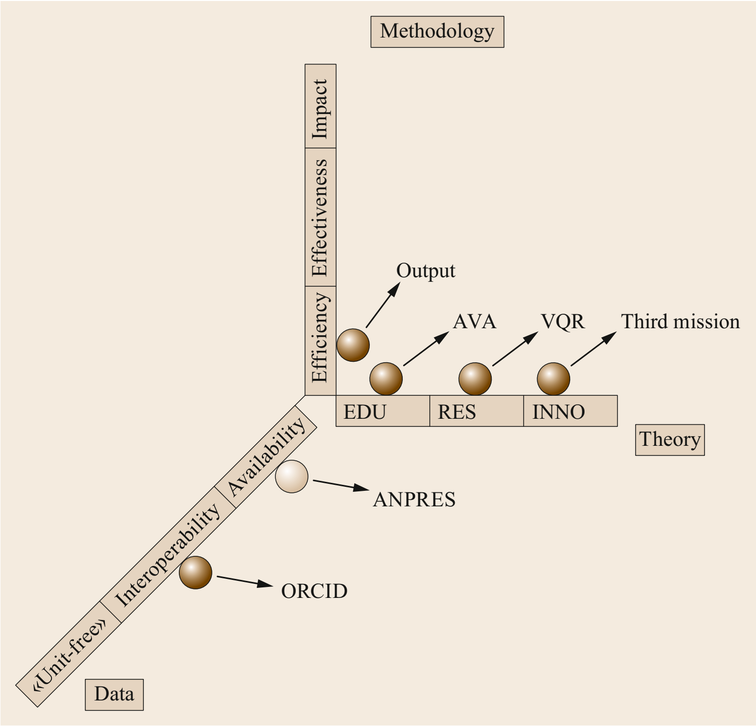

Fig. 24.2 A schematic map of the ANVUR's activities based on the framework illustrated in Fig. 24.1

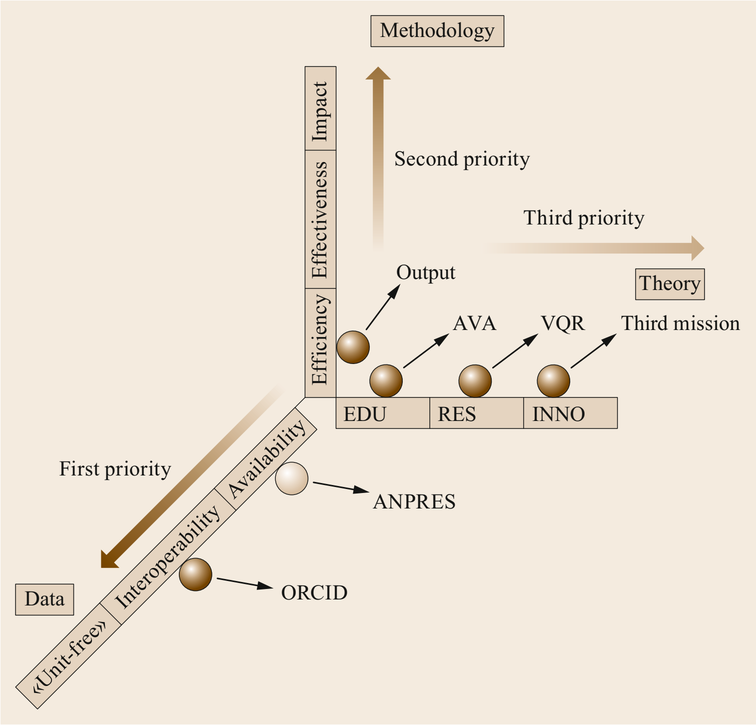

Fig. 24.3 Suggested priorities in the ANVUR's activities mapped in Fig. 24.2

model of the assessment, reduces the measurement of performance to a matter of appropriate normalization and contextualization.

This model may be helpful to *identify* the *components* of the analysis (in terms of theory-method-data characterization) that are *excluded* (what remains outside) in the specific context of the evaluation. It also helps to *interpret* the measure (or metrics or indicators) of research assessment calculated, and generates a *residual*, i. e., the part of the observed reality that is not accounted for—and thus *remains*, after the consideration of the relevant information is included.

The indicators empirically calculated can be interpreted as the *residual* or *our ignorance* on the phenomenon and enable one to identify the neglected aspects of the analysis carried out. This description of the model uses the term *residual* that is normally used in statistical analysis. Its use aims to underline a part of the observed reality that is not accounted for, but does not mean that this part is necessarily quantitative. The neglected component can be useful for suggesting alternative or additional dimensions of research assessment.

An underlying idea of this doubly conditional performance evaluation model is that *for each subject under assessment a dimension of performance can be found along which the evaluated entity can, in a relative way, outperform itself*. These are relevant factors among others for the development of a *participatory learning* role of the subjects involved in the research assessment exercise. A further discussion on the components of this performance evaluation framework will be presented in Sect. 24.7.

24.4 Economics and Econometrics in the Current Time

After the previous section, to understand the methodological challenges of economics and assessment, we need to understand the current evolution in the economics, econometrics and in the economic fields that may be related to research assessment.

Table 24.4 presents the enrichment of the definition of econometrics that took place over time. Starting from these definitions, we can try to understand what econometrics can offer to the evaluation of research. Econometric models are quantitative models that have been developed to model data and economic problems. As noted by *Baumol* and *Blinder* [24.88], economics is:

> A broad-ranging discipline, both in the questions it asks and the methods it uses to seek answers. Many of the world's most pressing problems are economic in nature.

Table 24.4 Definition of econometrics over time and other technical concepts. The section of the table on *other definitions* is taken from [24.84]

Definition of econometrics	Reference
Econometrics is the application of mathematics and statistical methods to the analysis of economic data	*Frisch* [24.85, p. 95]
Econometrics is the quantitative analysis of actual economic phenomena based on the concurrent development of theory and observation, related by appropriate methods of inference. The traditional econometric problems include: • Test of the optimizing behavior: parametric and nonparametric tests • Structural models and reduced form models • Estimation of technological relationships, more complex technologies • Choice of functional form • Estimation and aggregation • Hypothesis testing • Specification problems in econometrics.	*Samuelson* et al. [24.86, p. 142]
As a unified discipline, econometrics is still relatively young and has been transforming and expanding very rapidly. Major advances have taken place in the analysis of cross-sectional data by means of semiparametric and nonparametric techniques. Heterogeneity of economic relations across individuals, firms and industries is increasingly acknowledged and attempts have been made to take it into account either by integrating out its effects or by modeling the sources of heterogeneity when suitable panel data exist. The counterfactual considerations that underlie policy analysis and treatment valuation have been given a more satisfactory foundation. New time-series econometric techniques have been developed and employed extensively in the areas of macroeconometrics and finance. Nonlinear econometric techniques are used increasingly in the analysis of cross-section and time-series observations. Applications of Bayesian techniques to econometric problems have been promoted largely by advances in computer power and computational techniques. The use of Bayesian techniques has in turn provided the investigators with a unifying framework where the tasks of forecasting, decision making, model evaluation and learning can be considered as parts of the same interactive and iterative process, thus providing a basis for *real-time econometrics*	*Geweke* et al. [24.87]

Table 24.4 (continued)

Other definitions	Reference
Nonparametric methods	
Nonparametric statistical approaches are also named as *distribution-free* techniques because they do not require the specification of a functional form for the distributions of the variables analyzed and/or estimated. Nonparametric methods are often associated with techniques and tools that do not make numerous or stringent assumptions about the model underlying the empirical analysis. For this reason, compared to models underlying parametric methods, which rely on the specification and or assumptions about the functional form of the involved variables, the conclusions based on nonparametric inference are more general. Nonparametric tools are valid under less restrictive assumptions than classical parametric statistical tools. Frequently, nonparametric methods are associated with bootstrap and Monte Carlo techniques.	*Gibbons* and *Chakraborti* [24.89]
Bootstrap	
The bootstrap is a data-based simulation method for statistical inference. The essence of the bootstrap idea is to approximate the sampling distributions of interest by simulating (or mimicking) the data generating process (DGP), i. e., the statistical model of interest. Then, this sampling distribution is used to draw inference, which is used to calculate bias, confidence intervals and so on, on the quantity of interest. The aim of the bootstrap is to provide an approximation of the sampling distribution, which can be easily obtained by using Monte Carlo approximations.	*Efron* and *Tibshirani* [24.90]
Monte Carlo techniques	
Monte Carlo techniques deal with random experiments run on a computer. The main underlying idea is to repeat the experiment a large number of times to obtain many quantities of interest exploiting the law of large numbers and other methods of statistical inference. Monte Carlo techniques are used for sampling, estimation and optimization purposes for a variety of reasons, among which they are easy and efficient and provide insights into the randomness of the selected model. Monte Carlo techniques also permit us to have precise information on the accuracy or the efficiency of a given Monte Carlo estimator/algorithm, thanks to the mathematical and statistical justification underlying them.	*Kroese* et al. [24.91]

24.5 What We Could Learn from Economics and Management

We have seen in Sect. 24.2.2 that productivity measurement is a part of the research evaluation. The assessment process can be distinguished, for practical reasons, into three phases: design (ex-ante), implementation (in itinere) and conclusion (ex-post). In the planning phase, the adequacy of available resources with respect to the objectives to be achieved is analysed. In this phase, the assessment concerns the possibility of achieving the objectives and the necessary financial, human and time resources. The assessment *in itinere*, also called *formative evaluation*, establishes what works and what can be improved in the ongoing process. The ex-post assessment, also called *summative evaluation*, is carried out at the end of the process and concerns the obtained results, the outcomes [24.10].

As we have seen in the previous section, economics, in sum, deals with the allocation of scarce resources. It is connected with management that is related to *making human resources productive*, according to *Drucker* and *Maciariello* [24.92, p. xxvi].

Recent trends in management go from the Porter's competitive strategic environment [24.93–95] five forces (entry, internal rivalry, buyer power, supplier power, substitutes and complements) to the competition on analytics [24.96] to *beyond competitive advantages* [24.97] in terms of *value creation*.

Now let us see what aspects of the economic theory and management methods can be useful for the research evaluation process.

24.5.1 Strands of Economic Research

The main strands of economic research that can be useful, without claiming to be exhaustive, are:

1. *Microeconomics and economics of production* for the modeling of the production process and assessment of productivity
2. *Strategic analysis* for the management of the research assessment
3. *Cost–benefit analysis* about the research assessment process
4. *Measurement of the performance in the business sector* to find out, mutatis mutandis, similarities trends and lessons that can be learned
5. *Knowledge management and intellectual capital*, about the measurement of research productivity because research is connected to knowledge and intellectual capital.

Economics of Production and Economics of Science

The typical areas of economics concerned are the *economics of production* and the *economics of science*. They were introduced and discussed in Sect. 24.2.4. We will come back to this topic in Sects. 24.6 and 24.7.

Strategic Analysis

According to Chandler:

> Strategy is the determination of the basic long-term goals and objectives of an enterprise, and the adoption of courses of action and the allocation of resources necessary for carrying out these goals.

Strategy [24.98] is important for the management of the assessment process and for developing economic models that include different perspectives (mathematical perspective: to discover the logic of choices; psychological perspective: motivations and behaviors; organizational perspective; political science perspective; and so on). To this purpose, (economic) models must carefully identify:

Decision makers Who are they? Are their decisions fixed?,
Goals profit maximization, nonpecuniary interest. . . ,
Choices actions, strategic variables, time horizon and
Relationship between choices and outcomes what the mechanism is to translate specific decisions into specific outcomes; complication due to uncertainty related to taste, technology, choices of other decision makers . . .

A classical framework for analyzing strategy in industrial organizations [24.98] is based on four broad classes of issues:

1. *Boundary* of the institution (what should the institution do, how large should it be, and what business should it be in)
2. *Market and competitive analysis* (nature of the markets in which the institution competes and nature of competitive interactions among institutions in those markets)
3. *Position* and *dynamics* (position of the institution to compete, basis of its competitive advantage, how to adjust it over time)
4. *Internal organization* (organization of institution's internal structure and system).

We observe that some recent developments in econometrics and the availability of new data and information show converging movements with the economics of strategy summarized above. A positive definition of data includes [24.99]:

> Facts and statistics collected together for reference or analysis; data as representations, reinterpretable representation of information in a formalized manner, suitable for communication, interpretation, or processing, up to data as infrastructure.

In particular, the study of *heuristics* in decision making introduced by *Tversky* and *Kahneman* [24.100] extended *Simon*'s research on human-bounded rationality in problem solving [24.101–103] which led to the *satisficing* situation where people seek solutions or accept choices or judgments that are *good enough* for their purposes. The discussion on heuristics in human decision-making and of their inherent biases is extended in *Kahneman* [24.104] who, building on earlier contributions, describes two different ways of thinking, a *fast system*, characterized by fast, automatic, frequent, emotional, stereotypic subconscious and a *slow system*, characterized by slow, effortful, infrequent, logical, calculating conscious. On the basis of heuristics, *Kahneman* [24.104] asserts that the fast system involves the association of new information with existing patterns instead of building new patterns for each new event. These recent developments in behavioral economics and decision making could be further explored in combination with recently developed statistical and machine learning approaches [24.105–108]. Indeed, machine learning techniques, lying at the intersection of computer science and statistics, is at the core of artificial intelligence and data science, and is showing increasing potentialities [24.109, 110].

Cost–Benefit Analysis

The four main valuations of a cost–benefit analysis (CBA) have been identified in [24.111, p. 3]:

> 1 The relative valuation of costs and benefits at the time when they occur. 2 The relative valuation of costs and benefits occurring at various points in time: the problem of time preferences and the opportunity cost of capital. 3 The valuation of risky outcomes. 4 The valuation of costs and benefits accruing to people with different incomes.

The same authors [24.111, p. 4] describe the process of a cost–benefit analysis as organized into two phases:

> (a) *Value the costs and benefits* in each year of the project, (b) *Obtain an aggregate 'present value'* of the project by 'discounting' costs and benefits in future years to make them commensurate

> with present costs and benefits, and then adding them up. At each stage, the evaluation differs from commercial project appraisal because (i) costs and benefits to all members of society are included and not only the monetary expenditures and receipts of the responsible agency, and (ii) the social discount rate may differ from the private discount rate.

For more information, see e. g., *Boardman* et al. [24.112].

Weimer [24.113], in the introduction to the special issue on *Cost–Benefit Analysis and Public Policy* states that:

> CBA holds a prominent, but controversial, place among the techniques of public policy analysis. At one extreme, some economists view CBA as synonymous with good policy analysis. At the other extreme, a diverse group of political philosophers attack it as a technocratic undercutting of democratic values, a utilitarian threat to individual rights, or a crass debasing of public discourse. Yet, CBA is neither panacea nor fatal poison. Though often impractical to implement and rarely fully appropriate as a formal decision rule, it provides policy analysts with insights for organizing their thinking about the goal of efficiency and specific techniques to help guide the measurement and valuation of the impacts of policies in terms of the resources they require and the effects they produce.

Assessment and Management of Performance in Business

The following section presents results previously published in *Daraio* [24.4]. *Daraio* [24.4, 84] noted that in the evaluation of research, there has been an evolution from a traditional performance evaluation, based on traditional bibliometric indicators of number of publications and citations, towards a multidimensional performance model, which includes alternative and impacts metrics. According to *Ghalayini* and *Noble* [24.114], a similar pattern has been observed in business performance measurement. In the first phase (from 1880s to 1980s) the emphasis was on financial measures such as profit, return on investment, and productivity. The second phase started in the late 1980s as a result of changes in the world market. To regain a competitive edge, companies shifted their strategic priorities from low-cost production to quality and flexibility, but also implemented new philosophies of production management (computer-integrated manufacturing, just in time, total quality management and so on). These changes have revealed that there is a need to develop new performance measurement systems. As the *Performance Measurement Manifesto* [24.115, p. 131] states:

> At the heart of this revolution lies a radical decision: to shift from treating financial figures as the foundation for performance measurement to treating them as one among a broader set of measures.

In the Performance Manifesto the revolution is all about combining information systems and human resources (called a culture shock).

In the business literature [24.103, 116] there has been an evolution of the performance evaluation from the classical *shareholder* value approach (based on the maximization of profits) to the balanced scorecard approach [24.117], which extends the performance measurements to four dimensions (4-D). In addition to the classical economic perspective, they include also the other perspectives of internal process, of customers, and finally of the growth and learning. Recent examples of multidimensional performance evaluation models are the multistakeholder model by *Atkinson* et al. [24.118] and the performance prism model by *Neely* et al. [24.119]. The most recent trends in this sector are the inclusion of indicators of sustainability and the development of social corporate responsibility awareness.

In the assessment of research the Leiden manifesto [24.67, 68] can play, mutatis mutandis, the same role of the performance manifesto for the business sector.

Daraio [24.4] showed the extension of the principles of performance measurement of the business sector to the public sector, in the so-called new public management [24.120–122]. Recent trends, described at length in *Van Dooren* et al. [24.123] include a trend towards the *democratization* [24.124–127] linked to the need for a *citizen-driven* performance measurement.

From the *management of performance* in the public sector literature we can learn about the use of performance information in policy and management practice. *Van Dooren* et al. [24.123, p. 119, Table 6.1] for instance, list 42 potential uses of performance information including changing work processes, strategic planning, communication with the public to build trust, reporting and monitoring, accountability, clarifying objectives, cost–benefit analysis, staff motivation, nonmonetary incentives and so on. They consider three main uses of performance information. These are to learn, to steer and control and to give account. To these main uses, they connect the manifestation of functional or dysfunctional *effects*. As noted by *Van Dooren* et al. [24.123, pp. 183/184]:

> The literature on the dysfunctions of performance measurement is much richer than that on the

functions. It includes: i) manipulation of the measurement process (over and underrepresentation, failing measurement, *mushrooming* – increasing numbers which inflates their values of indicator sets, *polluted* performance information, unjustifiable aggregation or disaggregation of data, *misrepresentation* ranging from creative accounting to fraud, misinterpretation – incorrect inference about performance and ii) manipulation of the output (measure fixation – oversupply of products, loss of quality – myopia – short-termism, suboptimization, *cream skimming* or cherry picking, complacency – risk aversion and less excellence – organizational paralysis), as well as unintended consequences.

The outcome of these behavioral effects is the well-known performance paradox [24.128], which states that organizations adapt their behavior to reach the targets. This means that indicators, over time, lose their discriminatory power. Individual behavior is comprised of a more complex configuration of institutions that determine the conditionality of functions and dysfunctions, including but not limited to incentive structure, and other structural and cultural characteristics [24.123, p. 192]. *Van Dooren* et al. [24.123, p. 198] observe that:

> The occurrence of effects depends on the way performance information are used, besides some general cultural and institutional variables. Dysfunctional effects can be tackled by taking away the motive or the opportunity to behave dysfunctionally.

In discussing about the challenges and the future of performance management, *Van Dooren* et al. [24.123, p. 216] state that "Performance management systems need to be able to deal with the complexity in the environment". Performance management systems should facilitate learning and should be based on better quality data, more ownership, stronger leadership, integration, training and expectations management.

Knowledge Management and Intellectual Capital

The measurement of intellectual capital [24.129] is a prominent research area in knowledge management [24.130–132]. Measuring and managing the intellectual capital of *communities* is an original area of research that has the potential to *change how public sector planning and development is done* according to *Bounfour* and *Edvinsson* [24.133]. Intangibles and intellectual capital are important to the private sector and they are also important to the productivity and competitiveness of the public sector [24.134–136]. Within this area, it could be interesting to explore the principles of intellectual capital efficiency [24.137] and the value added intellectual coefficient [24.138] and their applicability within the assessment of research.

24.6 Methodological Challenges in the Assessment of Productivity/Efficiency of Research

In Sect. 24.3, following *Bonaccorsi* and *Daraio* [24.1], we stated that in contrast to a standard production activity, the production process of the research activity is characterized by several conceptual and measurement problems that affect any definitional elements of the productivity, namely the inputs, the outputs and their functional relation. The changes that occurred in the production and communication of science affect the representation of the production process and challenge the measurement of the productivity of research. In the following, we describe the main challenges in economic modeling, which may also be potential sources of *ambiguities* for the measurement of productivity/efficiency.

24.6.1 Changes and Challenges in Modeling

The assessment of productivity and efficiency is subject to different modeling changes and challenges. Some of them are summarized in Table 24.5.

The modeling challenges of Table 24.5 expand the problems already highlighted by *Bonaccorsi* and *Daraio* [24.1] that now are amplified by the need of clearly identifying and modeling the representation of the production process behind the measures proposed. There is a need to identify clearly the *boundary* of the activities to be measured. Now the representation of the research activity process is complicated by the evolution summarized in Table 24.5. The *multidimensional* nature of the research activity, its multiple inputs–multiple outputs, the nondeterministic relation between inputs and outputs that are heterogeneous and sometimes incommensurable, and the complex lag structure of the output in the current time are affected as in Table 24.5 and pose a series of conceptual and methodological problems. They will be analysed after the description of the advent of networks in economics, another challenge posed to the econometric assessment of productivity and efficiency.

Table 24.5 Changes and challenges of modeling

Changes (adapted from [24.139])	
From	**To**
Well controllable models of the past	Complex models of today
Weakly connected or independent system components	Strongly connected or independent model component
Dominated by the model components	Dominated by their interactions
Simple model behavior	Complex model behavior
Sum of properties of individual components characterizes model behavior	Emergent collective behavior implies new and often unexpected model behavior
Conventional wisdom works well	Counterintuitive behavior, extreme events are common
Well predictable and controllable in top-down fashion	Less predictable, management by setting rules for bottom-up self-organization
Challenges	
Challenges are in	**Source**
The formulation of the problem, selection and evaluation problems	*Doornik* and *Hendry* [24.140]
Theoretical selection of the model and appropriate estimation technique. Statistical model selection. Implementation of automated general-to-specific model selection (so-called *autometrics*)	*Doornik* and *Hendry* [24.140]
Significance versus spuriousness	*Ekbia* et al. [24.141]
Causation versus correlation	*Ekbia* et al. [24.141]

24.6.2 The Advent of Networks in Economics

The economic systems are more and more conceived *complex* ecosystem whose *operating models* have to be developed considering the interplay of many dimensions.

In economics we are witnessing the development and expansion of networks [24.142–144] up to the point that *Kirman* [24.145] posed the question about networks as *a potential paradigm shift for economics*.

As observed by *Mandell* and *Keast* [24.146], networks have been assessed on the basis of traditional measures while ignoring the importance of process variables and their impact on outcomes in networks. Furthermore, networks can be complex arrangements, operating within and across layers of interaction with diverse member expectations and goals. Within this framework, different types of evaluation processes are needed to incorporate the complex and unique characteristics of networks.

In this context, there is an interest in looking for new models of production process representation. This research could be connected to recent developments in econometrics of information [24.147, 148] statistical inference and machine learning [24.107, 108]. Within this framework, new *reuses* of concepts already known in the past may be helpful.

Let us consider for example, *Georgescu-Roegen*'s [24.149–152] model of *flows and funds*. It allows an analytical representation of the *organization* of the production process that goes beyond the relationship between the inputs and the outputs, which is typical of production functions and input–output analyses. It allows us to include the organization and time dimension of production processes [24.153]. The *flows and funds* model may be connected to the neo-Schumpeterian interpretative framework of production of new processes by means of creation and diffusion of knowledge [24.154] in which there is an *interplay* between capabilities, transactions and scale and scope to explain the boundary and the competitiveness of the analysed units [24.155]. *Fioretti* [24.156] operationalizes the *organizational aspects* of production (typical of the flows and funds model) by linking them to recent neural networks approaches.

There is a rich literature on the nonparametric estimation of efficiency based on networks, called network DEA. *Kao* [24.157] offers an overview of these models, which all aim to asses the performance of complex systems. *Daraio* et al. [24.158] propose a general framework that embraces the Georgescu-Roegen model with information theory and statistics of complex systems and thus allows us to estimate the interdependencies between productivity networks. They propose a pseudolikelihood approach to infer in a Bayesian context the topology of the network structure analyzing the interdependencies among productivity networks. This is a promising line of research to further explore.

24.6.3 Conceptual and Methodological Ambiguities

In the following, the line of argumentation as previously published in *Daraio* [24.2] is presented. Every model is subject to *uncertainty*, stemming from uncertainty in the input information fed to the model, e. g., from lack of data or understanding of the governing relations, the fact that the model is a *simplification* of reality involving important elements of *subjectivity*. It is therefore important to acknowledge and quantify the uncertainty in the results of models to ensure a transparent and high-quality usage of them. We will come back to modeling in Sect. 24.7.

Conceptual ambiguities are relative to the definition of the components: what do we measure and how do we measure it? Methodology, in this setting as in Table 24.3, identifies the range of methods (techniques or approaches) that are relevant for the evaluation of research. The methodological dimension should handle how to evaluate what, providing an appropriate account of reliability and robustness and uncertainty.

The discussion on methodology relates two general interconnected questions that are *what to assess* and *how to assess* [24.2]. These questions, in turn, are related to the organization of the assessment tasks and strategies (including *priorities setting*) and to the communication of the assessment results.

Daraio [24.2] distinguishes the *subject* of the assessment from the means of the assessment. The *subject* of the assessment is the thing that is being considered of the assessment (*what to assess*). The subject of the assessment is identified in outputs, efficiency, effectiveness and impact. The *means* of the assessment (*how to assess*) can be *qualitative* (including peer-review and case studies), *quantitative* (including econometric approaches and tools from the physics of complex systems) and *combined* (quantitative–qualitative) approaches, including the so-called informed peer-review. Evidently, the means should be chosen in accordance with the subject of the assessment.

The organization and the communication aspects of the evaluation, however, fall within the sphere of policy and governance. The framework illustrated in Fig. 24.1 proposes three building blocks for methodology: efficiency, effectiveness and impact, considering the outputs as a kind of baseline or step zero in the analysis. Table 24.3 provides a definition of these concepts. Moving from efficiency to effectiveness, including quality indicators to assess effectiveness instead of efficiency, is another important step, which may go further, up to including impacts.

Classical methods of impact assessment [24.159] are challenged by [24.160, p. 22]:

> [The] problem of evaluation [that] is that while the program's impact can truly be assessed only by comparing actual and counterfactual outcomes, the counterfactual is not observed. ... Finding an appropriate counterfactual constitutes the main challenge of an impact evaluation.

These classical methods appear inadequate to the checklist of *sensitivity auditing* [24.161–163], that is, a sensitivity analysis applied to the modeling phase.

Alongside the conceptual ambiguities, there are also methodological problems. See Table 24.6 for an outline.

24.6.4 Data Issues

The explanations outlined in this section are based on *Daraio* [24.2]. Data are a relevant dimension often neglected in model building.

The problems of data in econometrics have been analysed for many years in econometrics (the so-called *data constraints* described in [24.181, 182]).

Data have a problematic definition because it depends on their use not on inherent characteristics of the data [24.79, p. 74]. Their properties and their weaknesses affect both the modeling and the empirical results. The concepts of [24.79, p. 271] state:

> Big data, little data, and even no data remains poorly understood in the current big data era: Efforts to promote better data management, sharing, credit, and attribution are well intentioned, but stakeholders disagree on the starting points, the end goals, and the path in between. Lacking agreement on what entities are data, it remains difficult to establish policies for sharing releasing, deposing, crediting, attributing, citing, and sustaining access that can accommodate the diversity of data scholarship across domains. Sustaining access to data is a difficult and expensive endeavour.

Borgman [24.79, p. 287] states:

> Despite the overall lack of agreement, most scholars would like better means to manage whatever they do consider to be their data. Better management is likely to lead to more sustainable data and in turn to better means of discovering and sharing data. These, however, are expensive investments. Better access to data requires investments in knowledge infrastructures by research communities, funding agencies, universities, publishers, and other stakeholders.

We propose to characterize the data issues according to the main dimensions of data of our framework described in Sect. 24.3. They are availability, interoperability, *unit-free* property.

Table 24.6 Main features and typical problems of econometric approaches to assessing productivity

Reminder of basic notions	**Parametric versus nonparametric**	**Deterministic versus stochastic**
	In *parametric models* the frontier is a known mathematical function depending on some unknown parameters. Main advantages: the economic interpretation of the parameters and the statistical properties of the estimators. The main drawbacks are the choice of the function and the handling of multiple outputs cases. *Nonparametric models* do not assume any particular functional form for the frontier function. Main pros: robustness to model choice and easy handling of multiple inputs–outputs cases. Main cons: estimation of unknown functional (more difficult) and *curse of dimensionality* (that is typical of nonparametric estimators and means the need to have a large amount of data to avoid large variances and wide confidence intervals)	In *deterministic models* all the observations are assumed to belong to the production process with probability one. The main drawback is the influence of outliers. In *stochastic models* it is assumed that there may be noise in the data. The main drawback is the identification of noise from inefficiency.
	Production functions	**Production frontiers**
Object of the estimation	Average (representative) behavior, conditional expected value	Efficient frontier, best practice (envelope)
Methodological problems of most used approaches	**Methodological problems of parametric production functions**	**Methodological problems of nonparametric production frontiers**
	Identification: the fundamental issue of whether the parameters of interest in the model are estimable [24.164].	*Deterministic* nature. In this framework it is assumed that all deviations from the efficient frontier are owed to inefficiencies
	Misspecification concerns the problems and errors related to the assumptions made by the model. Empirically, misspecification errors are mainly related to the specification of explanatory variables, in particular, knowledge of which one of the variables to include and about the mathematical form of their inclusions	Difficult economic interpretation (due to the *lack of parameters*) of the production process in terms of, e. g., shape of the production function, elasticities, and so on
	A topic related to the previous one is the *exclusion of relevant variables* and the *inclusion* of *irrelevant* variables	*Exclusion of relevant variables* and the *inclusion* of *irrelevant* variables is an issue also for the frontier analysis
	Simultaneity in the relationship between variables could greatly affect the estimation of parameters creating a source of bias.	*Curse of dimensionality*. Shared by many nonparametric methods the curse of dimensionality means that to avoid large variances and wide confidence interval estimates a large quantity of data is needed
	Multicollinearity is the problem related to the existence of a linear dependence amongst the response or independent variables. The multicollinearity affects the problem of unidentifiability of the regression parameters.	Difficulty in making statistical inference, owing to its complex nature: nonparametric estimation in a space at $p+q$ dimensions (where p is the number of the inputs and q is the number of the outputs), based on very few assumptions.

Availability refers to general alternatives and choices that affect the data that have to be used, for instance (without being complete): sampling versus census, freely available versus controlled or undisclosed ones, data as consumption versus participation (see [24.141] for a critical discussion). Obviously, the minimal requirement for the elaboration of data refers to their availability in a usable way. This opens to the discussion on commercial versus publicly available (or open) data; institutionally provided data; and issues of privacy and confidentiality. *Interoperability* is the way in which heterogeneous data systems are able to communicate and exchange information in a meaningful way [24.183]. It is crucial for data integration of heterogeneous sources (see the discussion on continuity versus innovation in [24.141]). *Unit-free property* refers to the need to have consistent and coherent observations (instances of data) at different levels of analysis, to ensure robust empirical evidence of a given phenomenon. The unit-free property of data is somewhat interconnected to the possibility of multiscale modeling of the problem at hand. It clarifies the exigence of having data that are *independent* from the unit of analysis and hence can be used *coherently* in a multiscale model of the problem.

Table 24.6 (continued)

Proposed solutions and more general approaches	Proposed solutions and more general approaches	Proposed solutions and more general approaches
	Simultaneity could be controlled for by applying generalized methods of moments (GMM) [24.165]. GMM is a general statistical approach that subsumes different estimation methods of interest, such as least squares, maximum likelihood and instrumental variables (see [24.166] for an introduction to these methods).	The problem of *extremes or outliers* and *the curse of dimensionality* can be treated by applying *robust partial frontiers* (for an overview, see [24.13]). The order *m* frontiers for instance represent a more realistic benchmark. Instead of comparing the performance of each unit with the best performers, the benchmark is done against the expected value of an appropriate sample of *m* units, drawn randomly from the population. The method offers flexibility in choosing the level of robustness of the estimate, by varying the parameter *m*. Robust partial frontiers have the nice property of not being affected by the curse of dimensionality.
	Semiparametric methods [24.16, 167] may be applied to reduce the burden of the assumptions required for estimation and inference by parametric approaches	The problem of handling noise in this context is owed to the model not being identified unless some restrictions are assumed. See, e. g., *Aigner* et al. [24.168] for approaches that assume a parametric function for the frontier; or *Kneip* and *Simar* [24.169] for the case of panel data. More general results for handling noise in nonparametric frontier models have been introduced in [24.170, 171] that attempt to address the identification issue (i. e., distinguishing between what is noise and what is inefficiency) by assuming the less possible structure. *Kumbhakar* et al. [24.172], *Simar* and *Zelenyuk* [24.173], *Park* et al. [24.174] propose local likelihood approaches. Recently, *Florens* et al. [24.175] relaxed the normality of the error term, assuming only a symmetric error with unknown variance.
	Production functions may be estimated by nonparametric regression techniques that offer the following advantages [24.176]: 1. Allow us to estimate functions of greatest complexity 2. Offer the possibility to make predictions without relying on specific parameters 3. Identify spurious observations and outlying points 4. Represent flexible methods for data interpolation and missing values imputation.	The problem of lack of parameters for economic interpretation may be overcome by *parametric approximation of nonparametric and robust frontiers* that have been introduced by *Florens* and *Simar* [24.177] and extended to the multivariate input–output case in *Daraio* and *Simar* [24.13]. These techniques have not been applied so much up to now, but have a great potential.
		Recent development in statistical theory for efficiency estimators provided *statistical inference in nonparametric frontier models*. In particular, the development of new central limit theorems opened the door to testing hypotheses about the structure of production models (for an overview, see *Simar* and *Wilson* [24.178, 179]; an updated review can be found in *Mastromarco* et al. [24.180]).

The data problems and their impact on the measurement of research productivity and performance have been analysed both at the macro level [24.184, 185] and at the micro (institutional) level [24.186–188]. Most of the problems relate to the measurement of the inputs, and of the outputs to their combinations. Generally, being collected from different sources and almost independently, the combination of these data is affected by comparability and consistency problems. Recent experiences on the micro data related to European universities have shown that taking into account the different data quality aspects of the data [24.189], a data quality-aware usage of them it is still possible. Nonetheless, a lot of further work is required in this area.

24.6.5 The Implementation Problem

The implementation of the econometric models is a delicate activity. The problem of implementation consists of applying methods developed as *basic research* to concrete organizations/contexts. The main critical points are the *interaction* of method development with its useful application and that the implementation changes the organization. The identification of the *right* problem and the development of an *appropriate* model are then crucial determinants of success.

Our framework, introduced in Sect. 24.3, proposes three *implementation* factors:

1. Tailorability
2. Transparency
3. Openness.

(See Table 24.3 for their definitions.) According to *Daraio* [24.2] the more one is able to go to the deep, fine-grained end of the most atomic-level unit of analysis (i. e., the higher the level of tailorability), the higher the level of openness and transparency, and the better will be the conceptualization and formalization of *quality* within a model.

As far as the implementation of models of research assessment is concerned, *Daraio* [24.3]—to which the reader is referred to for a deeper discussion and a graphical illustration—has shown the interplay existing between the problem context, the abstraction/ontological commitments, and the social translations. These latter are in place in the assessment of research because research is a human activity.

24.7 Potential of Econometric Approaches and of Nonparametric Methods

24.7.1 Models for Research Assessment

Based on [24.2], it is argued here that a model is an abstract representation, which from a particular point of view and for a particular purpose represents an object or real phenomenon. The representation of reality is achieved through the *analogy* established between aspects of reality and aspects of the model. Econometric models are quantitative models: models in which the *analogy* with the real world takes place in two steps:

1. Quantification of objects, facts and phenomena in an appropriate way
2. Identification of the *relationships* existing between the previously identified objects, closest to the reality (that is the object of the model).

The practical use of a model depends on the different roles that the model can have (*all models are wrong, but some are useful* [24.190]) and from the different steps of the decisional process in which the model can be used.

Models may have four main roles:

1. Description
2. Interpretation
3. Forecasting
4. Intervention.

These roles may be correlated or not, depending on the objective of the analysis and the way the model is built.

To be successful the model has to take into account the specificities of the processes and systems under investigation. Behavior is free and finalized to given aims. History and evolution matter as the behavior of systems and processes change over time.

The *finalization* encourages a functional analysis of the systems: the external behavior of the systems may be explained by focusing the analysis on their aims and to their ways of interacting with the environment without entering into the details of the internal structures and organization (the organization becomes relevant only if it is a limit to pursue the objectives of the system).

The main difficulties which arise in modeling are:

1. The possibility that the targets are not quantifiable, or are multiple and conflicting; or that there are several decision makers with different interests
2. Complexity, uncertainty and changeability of the environment in which the controlled system works and thus the difficulty of predicting environmental stimuli, the consequences of certain actions, and responses to other decision makers in these actions
3. The limits (in particular of an organizational nature) with which the controlled system adapts to the directives of the decision maker
4. The intrinsic complexity of calculation of the optimum behavior.

The analyses of current changes in research and econometrics has lead us to consider the measurement of productivity/efficiency of research in a wider context.

The framework introduced in Sect. 24.3 and the evaluation model described in Sect. 24.3.2, *A Doubly Conditional Performance Evaluation Model* can be helpful in the development of models of research assessment.

24.7.2 Advanced Efficiency Methods

Nonparametric Methods

The evolution of econometric tools in recent years relates mainly to the development of nonparametric econometrics ([24.87], see definitions in Table 24.4). Nonparametric econometrics consist of the application of nonparametric techniques to analyze economic models and data. *Stock* [24.191] traces the development of econometric models from the traditional ones of the 1980s, mostly parametric, characterized by a linear functional form, to more recently developed nonparametric ones, thanks to the development of computer power and the advancements of mathematical and statistical research. *Stock* identifies one of the causes of the development of nonparametric models as dissatisfaction towards traditional parametric models that were not always a good approximation [24.191, pp. 84/85]:

> The past three decades have seen significant changes in the tools of econometrics, many motivated by a desire to minimize the effect of 'whimsical' assumptions on inference about the object of interest. By 'whimsical' I mean arbitrary assumptions that are subsidiary to the empirical purpose at hand, but which affect inference about the causal effect of interest. The new tools provide reliable inference without implausible subsidiary assumptions.

Today, nonparametric econometrics [24.16, 167, 192] is a well-established field both in theory and in practice.

We believe that nonparametric approaches are the most appropriate for research assessment for their generality. The success of the nonparametric approach is mainly due to the few assumptions required for specifying the data generating process (DGP). However, this approach presents also some limitations, namely the difficulty in carrying out statistical inferences, the curse of dimensionality, which are specific to the nonparametric estimators and the influence of extreme values and outliers, as outlined in Table 24.6.

As for higher education [24.3], the challenges determined by the advent of big data include the developments in scientific computing of simple techniques with a general applicability as the Monte Carlo tools; the availability of millions of data; and new administrative data available, which will allow us to overcome the traditional *curse of dimensionality* problem of nonparametric approaches, and will offer the possibility to extend and apply Bayesian inference and machine learning approaches [24.193]. Although these possibilities are mitigated by the dilemmas created by the big data [24.141] and the problems of data quality, data integration and model selection [24.140] are important open issues, and we see a great potential for nonparametric approaches in research assessment in the future. Big data need to be exploited [24.193–198]. However, taking full advantage of the potential of big data will require increasing sophistication in knowing what to do with the massive amounts of data that are now available [24.199]. This involves taking into account, depending on the field of application and of the context of data use, also the complementarities, the strengths and the pitfalls of the integration of big data with little data and not available and/or not usable data [24.200].

Evolution of Production Frontiers

The econometrics of production functions is different from that of production frontiers as the main objective of their analysis differs: production functions look at average behavior whilst production frontiers analyze the whole distribution, taking into account the best/worst behavior. Obviously, assessing the impact on the average performance is different from assessing the impact on the best/worst performance. Accounting for inequality and diversity is much more natural in a model based on best/worst performance frontiers than in a standard (average, representative) behavior. This is because in the former case the whole distribution is considered instead of only the central tendency. This distinction between *average* versus *frontier* is considered in recent theory of growth [24.201–203] and in the managerial literature [24.204].

All methods have advantages and disadvantages. As far as quantitative methods are concerned, different approaches, both parametric [24.205] and nonparametric [24.206–208] have been proposed, highlighting the changes required by the attempt to disentangle the impact of external heterogeneity factors on the efficient frontier from that on the distribution of inefficiency. This trend witnesses the need to move from the assessment of efficiency towards the assessment of impacts.

The traditional classification of frontier estimation methods in parametric versus nonparametric and deterministic versus stochastic is obsolete and no longer adequate to the changes and challenges summarized in Table 24.6. Table 24.7 shows some selected pioneering studies of the recent evolution of frontier approaches. *Daraio* and *Simar* [24.13] observed a general trend of

Table 24.7 Some precursors of the evolution in the frontier estimation (Source: [24.2, p. 20] with updates)

Approach	Main reference	Trend
Statistical approach to nonparametric frontier estimation	*Mastromarco* et al. [24.180], *Daraio* et al. [24.209]	Trend towards data-driven modeling
Models averaging in stochastic frontier estimation	*Parmeter* et al. [24.210]	Trend towards robustness of modeling
Using information about technologies, markets and behavior of institutions in productivity indices	*O'Donnell* [24.211]	Trend towards more comprehensive informational setup
From an implementation point of view, interactive benchmarking	*Bogetoft* [24.212]	Trend towards developing analytics for policy decision-making support
Moving from efficiency to effectiveness	*Simar* et al. [24.213], *Daraio* et al. [24.209], *Bădin* et al. [24.108, 206], *Daraio* and *Simar* [24.208]	Trend towards including (unobserved) heterogeneity, contextualization and estimating *quality* as unobserved heterogeneity factors and its effects, trend towards impact assessment

1. **Model development components:**
   a) *THEORY.* In the assessment of research have you considered all the systemic connections among education, research and innovation?
   b) *METHODOLOGY.* Have you identified the *subject* (what to assess) of the analysis and the *means* (how to assess–method) of it?

- ***Subject*** of the analysis may be:
  -*Output* of the assessment (baseline) result of a transfonnation process which uses inputs to produce products or services
  -*Productivity* partial or total factor productivity and *Efficiency* (productivity with respect to a reference)
  -*Effectiveness* considers inputs, outputs and account for the aims of the activity
  -*Impact* all conhibutions of research outside academia.
- ***Means*** of the assessment may be:
  -*Quantitative* approaches
  -*Qualitative* approaches
  -*Quali-quantitative* approaches.

   c) *DATA. 1) availability.* Have you assessed the usability of data?
   Consider: sampling vs census
   freely, controlled or undisclosed
   consumption vs participation
   commercial vs publicly available
   open, institutional provided
   privacy/confidentiality
   2) *interoperability.* Which level of interoperability do you have?
   3) *unif free property.* Are the data independent from the unit of analysis? What is the Ievel of their objectivity?

2. **Implementation factors:** tail or ability, openness and transparency. Assess the degree of the implementation factors (1 = very low, 2 = low, 3 = average, 4 = high, 5 = very high).
3. **Enabling conditions:** Convergence, mixed methods and knowledge infrastructure. Assess the presence of enabling conditioning (1 = not present, 2 = moderately present, 3 = present, 4 = high presence, 5 = very high presence).

Fig. 24.4 A preliminary checklist to develop econometric models for the assessment of research

convergence between parametric and nonparametric approaches, in that each one tries to overcome its limits, attempting to adopt the pros of the other approach. *Parmeter* and *Kumbhakar* [24.214] point to the great potential of nonparametric estimation in the stochastic frontier approach, while *Sickles* and *Zelenyuk* [24.215] summarize most recent developments in semiparametric models.

Now, it seems that we are going towards a multiple-mixed perspective (a mixture of parametric-nonparametric/deterministic-stochastic configurations). In this context, semiparametric approaches, including parametric approximations of nonparametric approaches may receive more and more interest from applied researchers. This evolution in the methodological development however is not always followed by the availability of software tools for empirical implementation. There are indeed many software options for running productivity and efficiency analysis (see a recent survey in [24.216]) although the quality of

Table 24.8 Doubly conditional performance evaluation model components and main questions for checklist development

Performance evaluation model component	Constitutive elements	Main question
Purpose of the assessment	Objectives, stakeholder and policy	*Why*
Level of analysis	Actors (micro level: scholars, organization; meso level: regional system; macro level: country)	*Who*
Object of the evaluation	Outputs, efficiency, results, effectiveness, impact	*What*
Means of the evaluation	(1. Qualitative, quantitative, mixed methods; 2 data)	*How*
Internal conditional factors	Actors, processes, time, results	*How, when and where*
External conditional factors	Time, context, other contextual factors, potential heterogeneity factors, criteria, rules, standards, understandings, incentives, actions, consequences	*How, when and where*

the available software tools is not assessed. *Daraio* et al. [24.216] point to the need to develop a repository and standards for checking the quality of the available software for running productivity and efficiency analysis.

24.7.3 A Preliminary Checklist

In this chapter we maintain that *standards* and *harmonization* should be applied as well to the methodological dimension of the research assessment process. We propose here to *standardize the methodological steps* according to our framework described in Sect. 24.3.

The preliminary checklist we propose aims to guide the development of econometric models of research assessment, and is reported in Fig. 24.4. It contains questions developers of econometric models should ask themselves and provide answers to, and it makes important analytical distinctions that should be taken into account during the development process.

Table 24.8 lists the main components of the doubly conditional performance evaluation model described in Sect. 24.3. The objective of this table is to facilitate the identification and choice of the main elements and relevant components of the econometric model for research assessment.

Once the econometric model has been developed (according to Fig. 24.4 and Table 24.8) the *sensitivity auditing* checklist of *Saltelli* et al. [24.162], which we report below, should be used to check the robustness of the model and assess the following aspects:

1. Use models to clarify, not to obscure: models as useful tools to represent and clarify reality
2. Adopt an assumption-hunting attitude: listing the underlying assumptions of each approach
3. Detect pseudoscience (uncertainty, spurious decisions, garbage-in garbage-out): make approximations by taking into account data representativeness and role of variables
4. Find sensitive assumptions before they find you: find the critical points in the theoretical framework that deserve attention
5. Aim for transparency: increasing the diffusion of the used model's basic ideas and avoiding jargon
6. Don't do the sums right but do the right sums: concentrate the analysis on the most important components/aspects
7. Focus the analysis: check sensitivity analysis not on one factor at a time but changing the different parameters together.

A second, complementary checklist useful to consider in this context is the *checklist of decision quality control* developed by *Kahneman* et al. [24.217], which is made of the following items:

- Self-interested biases
- Affect heuristic
- Group-think
- Saliency bias (analogy to a memorable case)
- Confirmatory bias
- Availability bias
- Anchoring bias
- Halo effect
- Sunk-cost fallacy, endowment effect
- Overconfidence, planning fallacy
- Optimistic biases, competition neglect
- Disaster neglect
- Loss aversion.

Of course, this is a first attempt and the proposed checklist should be corroborated and tested in the development of practical econometric models. Only by applying and developing/improving the proposed checklist we will be able to reach an acceptable standardized methodology. The collection, elaboration and diffusion of the information requested in the checklist could be very informative for our understanding and a correct development and application of econometrics models.

24.8 Conclusions

In this chapter, we have analyzed what is meant by measuring the productivity of research today, with the advent of the big data era and the fourth (information) revolution [24.5].

We have seen that we need to address the issue of measuring productivity in a broader perspective. We have presented a general framework and a doubly conditional performance assessment model (doubly conditional to the information considered and to those not included in the analysis model).

We have proposed a first checklist for the development of econometric models for evaluation of research.

Our proposed framework has three enabling conditions that foster the connection of the modeling activity with the empirical and policy worlds. They are:

1. *Convergence* (as an evolution of the transdisciplinary approach, which allows for overcoming the traditional paradigms, increasing the dimensional space of thinking)
2. *Mixed methods* (as an intelligent combination of quantitative and qualitative approaches)
3. *Knowledge infrastructures* (as networks of people that interact with artifacts, tools and data infrastructures).

Recent trends in research, economics and econometric theory show the growing need to adopt *broader perspectives*. Such prospects should embrace both the need to develop qualitative-quantitative approaches and to head towards *interdisciplinarity* and *convergence*. Qualitative-quantitative analysis offers strengths that offset the weaknesses of both quantitative and qualitative research [24.218]. Quantitative analysis is weak in understanding the context; qualitative analysis is weak because of personal interpretation difficulty in generalizing. Qualitative-quantitative analysis may act as *a bridge across adversarial divide, between quantitative and qualitative*, may encourages the use of multiple paradigms (beliefs and values), and be *practical* to solve problems, combining inductive and deductive thinking. It allows for the formalization of concepts and measurements. It offers the flexibility of qualitative research. It allows for accountability, and intended and unintended consequences.

Interdisciplinarity leads to the creation of a theoretical, conceptual and methodological identity, hence more coherent and integrated results are obtained. *Convergence* is [24.219]:

> The coming together of insights and approaches from originally distinct fields (...) provides power to think beyond usual paradigms and to approach issues informed by many perspectives instead of few.

Acknowledgments. We warmly thank Léopold Simar and an anonymous reviewer who helped us to greatly improve the content of this chapter. Michele Pezzoni provided helpful suggestions about the literature on determinants of scientific productivity. The financial support of the Italian Ministry of Education and Research (through the PRIN Project N. 2015RJARX7) and of Sapienza University of Rome (through the Sapienza Awards no. PH11715C8239C105) is gratefully acknowledged.

Cinzia Daraio

Department of Computer, Control, and Management Engineering
Sapienza University of Rome
Rome, Italy
daraio@diag.uniroma1.it

Cinzia Daraio is Associate Professor of Management Engineering at the Sapienza University of Rome, where she teaches productivity and efficiency analysis, quantitative models for economic analysis and management, and economics and business organization.
She specializes in science and technology indicators, higher education microdata, and methodological and empirical studies in productivity and efficiency analysis.
She is a member of the editorial board of *Scientometrics*, *Journal of Productivity Analysis, International Transactions in Operational Research*, and others.

25. Developing Current Research Information Systems (CRIS) as Data Sources for Studies of Research

Gunnar Sivertsen

Current research information systems (CRIS) are increasingly being used to standardize and ease documentation, communication, and administration of research. With broad coverage and sufficient completeness, data quality, and standardization, CRIS systems can also be used as data sources for studies of research. Making CRIS interoperable and comparable across institutions and countries is necessary for the further development of CRIS for research purposes. Integration of CRIS for administrative purposes is already on the European agenda. This chapter focuses on challenges and solutions to the development of internationally integrated CRIS. Most of the remaining challenges are not related to technical solutions, but to an efficient sharing and use of *contents*. The chapter starts with the situation at the international level before it moves on to an example of CRIS at the national level to describe challenges and possible solutions even more concretely. The last section of the chapter provides examples of the type of studies that can be performed if progress is made for internationally integrated CRIS.

25.1 Current Research Information Systems

Current research information systems (CRIS) are databases or other information systems used within and among research organizations to store, manage, and exchange data for documentation, communication, and administration of research activities. CRIS usually contain information about researchers and research groups, their projects, funding, outputs, and outcomes. In the most advanced versions, CRIS help produce integrated data for what used to be documents for separate purposes, such as individual applications for funding, institutional annual reports, project reports, CVs, publications lists, profiles of research groups, project reports, information for media and the general public, etc. Searchable bibliographic references may lead on to full texts in local repositories.

So far, most CRIS operate at the institutional level only. They are, however, becoming nationally integrated in an increasing number of countries, and there are initiatives to integrate them internationally as well. We will focus particularly on integration of CRIS in this chapter because it represents an important condition for using CRIS for more general purposes. With integrated CRIS providing data that are structured and quality assured for statistical purposes, research performing and funding organizations may also use CRIS for monitoring and evaluating research activities and outputs, allocating funding, supporting decision making on their policies and strategies, tracking researchers' careers, and describing their systemic role to policy-makers, stakeholders, and the public. With broad coverage and

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_25

sufficient completeness, data quality and standardization, CRIS systems can also be used as data sources for *studies of research*.

We are, however, not there yet. In addition to introducing CRIS developments and giving examples of their potential for providing data for studies of research, this chapter will focus on challenges and possible solutions related to CRIS integration. We observe the same main problems here as have been observed more generally by *Daraio* and *Glänzel* [25.1] in relation to data integration for research administration, evaluation, and policy. The problems are data quality, comparability, standardization, interoperability, modularization, classifications and concordance tables, comprehensiveness and completeness, and shared schedules for updating. The chapter presents initiatives to solve such problems and summarizes them with a few policy recommendations as part of the conclusions.

With the main problems solved, using CRIS data can overcome several of the limitations presently encountered in data sources for research administration, evaluation, and studies of research. A CRIS is not the same as a repository of publications or a bibliographic database. A CRIS unites all information sources that are relevant for the administration of research activities in one dynamic interrelated system. It is by constantly interrelating bibliographic information and other types of information representing the factors influencing scientific production that a CRIS can break new paths in studies of research activities. A CRIS has information about identifiable persons (not only authors) and institutional affiliations, titles, and positions (not only published addresses), as well as more complete economic information than is available in funding acknowledgements in publications. Such extended information may lead to other data (personal variables, backgrounds, resources, projects, networks, memberships) within or outside the CRIS system, which may serve more general studies of research based on social science methods.

Another strength of CRIS from the same perspective is the possibility of completeness in the coverage of the published literature. Coverage can go beyond the existing bibliographic data sources such as the Web of Science (WoS) and Scopus [25.2]. This may be important in research areas such as engineering science, social sciences, and humanities. While most types of bibliometric analysis, such as studies of collaboration and output profiles, can be performed by using CRIS data alone, there is both a limitation and a new option for citation analysis. The limitation is that CRIS do not index citations themselves. The data will need to be matched to another data source. The new option, however, is that CRIS makes it easier to attribute non-indexed publications and citations provided by Google Scholar or Microsoft Academic to persons and affiliations.

The use of CRIS for local institutional purposes has become widespread during the last decade and is now served by a commercial market of several professional providers of CRIS solutions. The development of CRIS for studies of research, however, is still in an early phase. The lack of data sharing options and comparability is still a major limitation. The data need to be available and comparable across local CRIS. This is so far only the case in a few countries that have managed to establish a national, non-commercial CRIS or a system for aggregating data from local CRIS. We will present examples of how such national CRIS are built and integrated and how they have already been used for studies of research, in Sects. 25.9–25.11 of this chapter.

As explained above, the major advantage of using data from CRIS in administration, evaluation, and studies of research would be realized only after establishing internationally integrated CRIS with comparable data. The feasibility of establishing a European integrated research information infrastructure, mainly for administrative purposes, was demonstrated in a report to the European Parliament [25.3]. In 2016, Science Europe published a *position statement on research information systems* inviting all research organizations to develop resilient information systems by adopting certain core principles and technical recommendations [25.4]. These two documents represent the point of departure for this chapter, and we will start by presenting them in more detail in Sects. 25.2–25.3.

The following sections will focus on what is needed for the *further development* of CRIS as data sources for studies of research. Several initiatives and solutions that may contribute to an internationally integrated CRIS will be described, starting with more general examples in Sects. 25.4–25.8. In Sects. 25.9–25.10, the chapter then moves on to an example of a CRIS at the national level to describe challenges and possible solutions even more concretely. Section 25.11 provides examples of the type of studies that can be performed if progress is made for internationally integrated CRIS, while Sect. 25.12 summarizes the chapter and discusses ways to move forward at the policy level.

The focus of the chapter will be less on *technical* solutions than on challenges and possible solutions related to creating comparable *contents* in CRIS. In our view, solutions that may provide the technical feasibility of an internationally integrated CRIS are already available to a large extent. As examples, an international standard for the technical format of a CRIS, the Common European Research Information Format (CERIF) and an international researcher identifier, the Open Researcher and Contributor ID (ORCID) are already in place. Such technical solutions are well documented elsewhere and will only be mentioned in the following. The emphasis of the chapter will be on challenges and possible solutions for CRIS data integration that are related to defining and standardizing data, ensuring their completeness and quality, and agreeing on sharing them. Here, the solutions will depend on the involvement of expertise in data analysis for research administration, evaluation and policy—and ultimately also on international policy level agreements.

25.2 The Need for Top-Down Coordination

In a report to the European Parliament in 2014 on *Measuring scientific performance for improved policy making* [25.3], the mandate was to explore the feasibility of a transnational system for collecting and monitoring research performance data (on inputs, outputs, and productivity) in Europe. The conclusion was that a European integrated research information infrastructure is not only technically feasible, but needed to achieve several benefits (cited from the document):

- For research institutions: The possibility directly to compare and benchmark research performance with other institutions in Europe, taking into consideration the different missions of the institutions, their research infrastructures and national environments, thus improving the awareness of the institution's positioning in the European research landscape—beyond the analysis of bibliometrics.
- For national funding agencies and policy makers: A comprehensive view of the complementarities of national research strategies versus other countries and the European Commission; improved basis for comparisons and benchmarking of national research performance with other countries, in line with the proper needs.
- For the European Commission: Improved efficiency in the collection of micro-data, improving data availability, reducing duplicates and enhancing the sustainability of data collection efforts.
- For the research performance assessment community at large: The basis for an improved understanding of knowledge exchange mechanisms in the European research system, providing a comprehensive view on input and outputs.

The benefit for studies of research could be added.

The study concluded that a possible lack of comparability of data in different systems does not constitute a major technical problem thanks to the use of semantic tools. This conclusion is perhaps a bit optimistic, although it refers to successful international initiatives and solutions such as CERIF, CASRAI, and ORCID, which we will present in the next section.

The most important recommendation of the study, in our view, is not to substitute for existing national research information systems, but to build an additional layer on top of them, which would comprise a distributed infrastructure, inter-connecting existing national research information systems. After the study was completed, the example of the VIRTA Research Information Management Services Finland [25.5], which we discuss in Sects. 25.6 and 25.7, has in practice demonstrated support for this recommendation. The same VIRTA project could now be used to test another conclusion from the study, namely that the costs of developing the integrating system would be relatively limited. As far as we can see from the VIRTA project, developing technical solutions seems to be less expensive than working for comparability of contents across countries. This learning might become tested once more in the experimentation with CRIS based on CERIF within the OpenAIRE project, see Sect. 25.3.

A third conclusion of the study is that, looking back at experiences so far, the distributed infrastructure for integration of CRIS will not be the result of a bottom-up process. European coordination is needed. Although we completely agree with this conclusion, it should be added that no CRIS would exist without local initiatives and developments. Moreover, internationally integrated CRIS will still need to serve local purposes and save labor–all the way down to the individual researcher. A bottom-up engagement will be needed in the implementation of the international infrastructure and its development towards increased usefulness for multiple purposes.

25.3 Towards Internationally Integrated CRIS

The conclusions of the report presented above are representative of a trend towards making existing or emerging CRIS interoperable rather than creating new databases. Only a decade ago, in 2009, the research councils of four European countries collaborated with the European Research Council on initiating a project that was typically named *Towards a bibliometric database for the social sciences and humanities—A European scoping project* [25.6]. One of the recommendations, to build a new, separate database for the social sciences and humanities, has not been followed up. Another recommendation, which has proved to be more forward-looking, was to build on existing or emerging national databases and standardize their data.

A similar recommendation, based on a more recent European project [25.7], resulted in a *Position statement on research information systems* by *Science Europe* [25.4], the new member organization for research funding organizations in Europe. The new document neither uses the word `database` nor expresses any limitation regarding area of research or level of coverage (local, national, institutional). Reflecting the present technical state-of-the art, with new options for big data exchange and with the agenda of open science, it simply *invites all research organizations to develop resilient research information systems* by following four core principles and some specific recommendations that may enhance their interoperability. The four core principles are (cited from the document):

- *Flexibility*. Research information systems should be flexible enough to allow for extensions in terms of the data objects covered, their definitions, metadata, and use of external data sources.
- *Openness*. Research information systems' data should be available for external use—in line with the principle *as open as possible, as closed as necessary* and EU Directive 2013/37/EU1—and their processing should never require the loss of ownership in underlying raw data by the originating institution.
- *FAIRness*. Research information systems should foster the *f*indability, *a*ccessibility, *i*nteroperability, and *r*eusability of the data that they store by implementing the FAIR guiding principles for research activity data [25.8]. The application of these principles is meant to cover all components of the research process, not only publications and their underlying data, to ensure transparency, reproducibility, and reusability of research.
- *Data entry minimization*. Research information systems should minimize the need for entering data and facilitate the reuse of data entered manually, in line with the motto *enter once, reuse multiple times*.

The statement furthermore recommends making use of available resources and initiatives towards standardization and interoperability. Here, we will only briefly mention five of these recommended resources, since they are already well documented online and in the literature. In our view, these already implemented resources solve different, limited standardization tasks and will be useful as parts of a more general solution:

- *CASRAI*. CASRAI is an international, non-profit organization working for standard information agreements among research information users. CASRAI agreements cover all types of information in the management of research.
- *CERIF* is a data model for building a CRIS with data on projects, people, organizations, publications, patents, products, services, and facilities (equipment in particular) with role-based, temporally-bound relationships. CERIF enables quality maintenance, archiving, access, and interchange of research information (also between CRIS) and supports knowledge transfer to decision makers, for research evaluation, research managers, strategists, researchers, editors, and the general public. CERIF is recommended by the European Union to its member states.
- *CrossRef* provides the technical infrastructure for linking references between scientific and scholarly publications (journal articles, books, conference proceedings, working papers, technical reports, data sets) using digital object identifiers (DOIs). CrossRef is provided by a not-for-profit association with members from the publishing industry.
- *DataCite* provides persistent identifiers (DOIs) for research data. DataCite is also a non-profit organization with the aim to help the research community locate, identify, and cite research data with confidence.
- *ORCID* provides a persistent digital identifier for individual researchers across the world. Among other things, ORCID may solve the problem with author name disambiguation in bibliographic data. ORCID is a non-profit member organization for research organizations, publishers, funders, professional associations, and other stakeholders in research.

EuroCRIS is the organization behind one of the five resources mentioned above, CERIF. The organization deserves more attention in this chapter because it has for a long time been the main international arena for professional and research-based developments of CRIS. EuroCRIS grew out of international collaboration on technical standards for exchange of research information that was encouraged and supported by the European Commission between 1987 and 2002 [25.9]. It is now a non-profit (and at the moment non-funded) member organization, which in addition to developing and maintaining CERIF, also hosts the major conferences and meetings for the European community of CRIS specialists.

EuroCRIS has so far been more successful in connecting people than in connecting CRIS with CERIF. This might be changing at the moment, since EuroCRIS is now joining the collaborating partners in the large-scale European OpenAIRE2020 project with the more general aim of promoting open scholarship and substantially improve the discoverability and reusability of research publications and data. OpenAIRE (openaire.eu) is a European infrastructure enabling researchers to comply with the European Union requirements for open access to research results. OpenAIRE collects metadata from a variety of data sources, i. e., publication repositories, data archives, and CRIS across Europe and beyond.

So far, the OpenAIRE search engine retrieves only freely available documents on the internet without any connection to organizational information. However, expertise from EuroCRIS has now contributed with OpenAIRE Guidelines for CRIS Managers. The guidelines specify the interoperability layer between CRIS and the OpenAIRE infrastructure. The information interchange is based on CERIF as a data model, the CERIF XML exchange format, and the open archives initiative protocol for metadata harvesting (OAI-PMH) for repository interoperability. The guidelines are intended mainly for implementers and administrators of CRIS who plan to communicate research information to OpenAIRE.

In a recently funded project, the implementation of these guidelines will now be tested using the local CRIS system at Radboud University Nijmegen, which is based on CERIF. The aim is to deliver structured CRIS information to the OpenAIRE aggregation. The project also includes collaboration with commercial CRIS vendors (Sect. 25.4) to support their effort towards achieving OpenAIRE compatibility.

The OpenAIRE and CRIS project is yet another example that the technical resources for interoperability are becoming available among research information managers and on a commercial market. However, the interoperability of CRIS is also about contents and will in the end depend on several other factors. We shall end this overview of initiatives and recommendations at the international level by pointing at three other such factors.

It has been shown by *Vancauwenbergh* et al. [25.10] that adopting the CERIF standard is not sufficient for efficient and accurate exchange of research information. Providers of information may use different words for the same concept and vice versa. There will be a need for definitions and a glossary, as well as a model for governance of research information and shared classifications to operationalize CERIF [25.1, 11]. The answer to the need for a more general model could be an approach to defining and specifying CRIS data based on an ontology-based data management (OBDM) model, see *Daraio* et al. [25.12] and the chapter on OBDM in this volume.

A second, related factor is that there will be a need for solutions and decisions that go beyond technical standards and address the same main problems observed by *Daraio* and *Glänzel* [25.1] in relation to data integration for research administration, evaluation, and policy, i.e, data quality, comparability, standardization, interoperability, modularization, classifications and concordance tables, comprehensiveness and completeness, and shared schedules for updating. We will address such problems in the second half of this chapter. To take one example, the problem of comparable subject classifications—which is mentioned in the *Position statement on research information systems* by *Science Europe* [25.4]—will be discussed concretely in Sect. 25.7.

The third factor concerns policies and decision-making at all levels. There needs to be a vision of improvement of research organizations through shared information and comparability, as well as a willingness to decide and invest in shared information systems, at the policy level. There also needs to be an interaction between research organizations, their funders, and the expertise in research information, documentation, indicators, and evaluation. Locally, there needs to be bottom-up engagement in finding shared solutions. Often, only local purposes are on the horizon, resulting in different and incompatible local solutions for the same general needs. While academics usually prefer global exchange of information and data, administrators tend to have an intramural perspective on information management. Moreover, as we shall see in the next section, the commercial market for CRIS favors a model for serving mainly local needs, while the data and the technical solution stay with each commercial provider. It is still unclear whether the solution for an internationally integrated CRIS can be provided by a commercial supplier.

25.4 Commercial Solutions to CRIS

CRIS may be the answer to internal needs for more professional information management within research organizations as well as to external needs for public information and for institutional data indicators in national research evaluation and funding systems [25.13]. Both types of needs are creating a rapidly expanding market for CRIS solutions in which the four most widespread products are *Pure*, provided by Elsevier, *Converis*, provided by Clarivate Analytics, *Elements*, provided by Symplectic, and *Researchfish*, provided by the organization with the same name in Cambridge, UK.

The first three of these products are designed to serve research administration purposes within research performing organizations. They typically connect all types of individual-level data on resources, activities, and outputs from internal and external data sources. They promise *an overview of all accomplishments, with advanced analytic reports of outputs and impact* (Converis), *a single point of organization, presentation, and reporting for all scholarly and research activities* (Elements), and *an evidence-based approach to your institution's research and collaboration strategies, assessment exercises, and day-to-day business decisions* (Pure).

Researchfish provides much of the same information but is designed in response to the needs of research funding and evaluation organizations. An interesting example of an implementation of Researchfish can be inspected at the Novo Nordisk Foundation, a large private funder of research in Denmark, which uses the system to collect data for impact assessment. Their solution is interesting from a data integration point of view by enabling researchers to enter an output or outcome just once and then re-use that data in reports to multiple funders, not only the Novo Nordisk Foundation, and for their own use, such as in CVs.

Presently, the trend is towards more comprehensive commercial CRIS systems serving several purposes. As an example, Elsevier is integrating Pure with other well-established and newly acquired products, such as Mendeley, SciVal, and Scopus, to be the information provider for all purposes in research activities and in research administration, evaluation, and funding.

Interestingly, all four of the above-mentioned CRIS products were originally designed by computer and information scientists or students at university campuses (in Denmark, Germany, and the UK) before commercialization. Several universities still maintain their locally designed non-commercial CRIS solution. At the national level, non-commercial solutions are more widespread than commercial solutions. Examples of non-commercial CRIS at the national level are the R and D information system in the Czech Republic, the Estonian research information system, and the Current Research Information System in Norway (CRISTIN).

While standardized CRIS solutions are commercially marketed across countries, they remain local silos of data. As an example, Denmark has eight universities, all of which are customers of Elsevier by using local applications of the Pure system. The applications are not integrated, although this would have been practical, since all eight universities use standardized procedures to collect bibliographic records through their Pure system for the Danish bibliometric indicator at the national level, which is one of the indicators in the performance-based research funding system in Denmark. The Ministry of Higher Education and Science had to build its own national database on top of the local Pure systems.

The reason for not providing integrated solutions on the commercial side seems to be that the standardized CRIS solutions are designed and tailored for a market of individual research organizations. Each customer is guaranteed that the information will not be shared with other customers. In addition, national needs in this area are often expressed through individual organizations. As an example, the research excellence framework (REF) in the UK requires that the data for the assessment is submitted by each university without being shared between them. Thus, each university must create or purchase its own solution to data production.

From a technical point of view, commercial solutions to CRIS are generally more efficient and advanced than non-commercial solutions. However, from the point of view of integrating CRIS and sharing data in an open space, only non-commercial solutions have solved the challenges so far.

25.5 Agreeing on Sharing Well-Defined Data

In several countries, research institutions may include information in their local CRIS that they would hesitate to make publicly available, particularly if they see their own institution as competing with other institutions for staff and resources. There may even be legal restrictions and privacy issues. Still, the existence of several non-commercial national CRIS already demonstrates that such problems can be solved technically and by agreements between the institutions. However, organizational and legal solutions in CRIS are much less shared and discussed at the international level than the general technical solutions are. As we shall see here, Germany has provided an example of how these matters can be brought to the international level.

National CRIS are typically more widespread among the smaller European countries with a unified research system than they are in larger countries with a more heterogenous and distributed research system. Agreements on sharing well-defined data may be more difficult to reach in larger countries and between countries. An important source of experience and learning in this respect, covering possible obstacles and achievements as well as necessary considerations in the process, is the national research core dataset project for the science system in Germany [25.14]. Germany has regionally funded universities as well as non-university research institutions with federal funding. As a federal state, Germany has lacked nationwide reporting standards and data on research activities and outcomes. The research core dataset project has worked on defining uniform classification systems, definitions of core concepts, assessment of local adaptation costs, decisions on what information will be useful to share, and issues dealing with central steering versus local autonomy and openness versus privacy. The experiences and solutions in the German project are, thereby, directly relevant for all the issues that still need to be solved for internationally integrated CRIS—even if the technical solutions are available and the open science agenda is acknowledged everywhere.

25.6 Testing Real Data Sharing in the Social Sciences and Humanities

The *European Network for Research Evaluation in the Social Sciences and the Humanities* (ENRESSH, The European Cooperation in Science and Technology (COST) action 15137) currently brings together more than 125 experts from 36 countries with the aim of developing and proposing best practices in the field of social sciences and humanities (SSH) research evaluation. One of the work groups is focused on information systems, databases, and repositories for publications and other outcomes of SSH research with the explicit aim of *designing a roadmap for a European database*. One already published result is an investigation of possible data sources, including CRIS, for scholarly publications in books [25.15]. Two other projects within the group are particularly interesting in the context of internationally integrated CRIS.

ENRESSH and the Centre for Research and Development Monitoring (ECOOM) at the University of Antwerp recently conducted a survey across Europe and found that 23 out of 39 countries have a database covering scholarly publishing in the humanities and social sciences beyond the references indexed in WoS or Scopus [25.16]. There is, however, large variability rather than standardization in how the data is defined and structured. As an important starting point for further progress, the survey also identified the presence of a legal framework and the specific responsible organization behind each national initiative.

A second interesting project [25.17] is being conducted by ENRESSH in collaboration with the Centre for Scientific Computing (CSC) in Helsinki, with support from Finland's Ministry of Education and Culture. CSC has developed and now operates the VIRTA publication information service, which provides a national-level solution for integrating publication information in Finland. It has already proved it can solve the problem that Finnish universities record their data in different types of commercial and non-commercial CRIS solutions. A wider application of the VIRTA concept at the European level has been tested by using real institutional data from CRIS in four countries, Belgium (Flanders), Finland, Norway, and Spain [25.18]. Some of the conclusions from the VIRTA pilot study with data from four countries are:

- The pilot study demonstrates that it is possible to integrate institutional publication data from different countries using the VIRTA model. This required the identification of data fields that all participating institutions and countries could supply (the *lowest common denominator*).
- The main challenge is that institutional and national data sources use different data models as well as different data collection and validation procedures. Agreed upon data definitions and classifications will be needed to solve this problem.
- It is also possible to increase the comparability of data by developing automated methods to restructure and reclassify data from different CRIS.

25.7 Subject Classification

Subject classification of organizations or outputs may be necessary to make data from CRIS useful for analytical purposes. Accordingly, the *Position statement on research information* from *Science Europe* [25.4], which was discussed in Sect. 25.3, suggests providing full documentation on classification systems, including subject definitions, and encourages cross-mapping between them. The CRIS that we want to integrate, or exchange data between, or compare data from, may have different types of subject classification systems [25.1]:

- *Cognitive* (content-related, used in libraries, bibliographic databases, patent and trade offices)
- *Administrative* (responsibility-related, used by authorities, funding organizations)
- *Organizational* (structure-related, used by institutions according to their internal organizational structures)
- *Qualification-based* (competency-related, reflecting the skills of individuals or groups of persons.

Subject classification is one of the typical unavoidable problems that arise as soon as the process of integrating CRIS moves from the technical solutions to dealing with real content. This situation was very concretely encountered and had to be solved in the VIRTA project described above. The bibliographic data from Belgium (Flanders) had an organizational classification, while the data from Finland, Norway, and Spain had different types of cognitive classifications. The problem had been encountered and solved ad hoc in an earlier study of CRIS data from Flanders and Norway [25.19], but it needed a more forward-looking solution for the VIRTA pilot study. A concordance was created using the revised field of science and technology (FoS) classification of the Organisation for Economic Co-operation and Development (OECD) [25.20].

Still, underlying the different classification systems, there may also be different methods for assigning fields to publications. For example, in Finland and Spain, fields are assigned cognitively to publications at record level. Norway uses the same method for book publications, but assigns fields for journal articles cognitively at journal level. In Flanders, as was mentioned, publications are classified on the basis of the organizational unit. In the case of journal articles, the *Norwegian* solution with a journal-level classification was chosen, however with the more principal choice of the OECD FOS classification as the basis for the concordance. This solution could not be implemented without a standardized register of journals, which leads to the next level for defining contents in integrated CRIS, which we will discuss in this chapter.

25.8 Dynamic Registers of Evaluated Scholarly Publication Channels

In any CRIS with bibliographical records, if the bibliometric analysis is to be taken beyond simple counts within types of publications (e. g., journal articles, book chapters, monographs), a dynamic register of publication channels with standardized titles, identifiers, and subject classifications is needed. To retrieve data and compare across different CRIS, a shared standardization of the registers will be needed as well. An example of a minimum of standardized information in this type of register would be:

- Publication channel type: Journal
- Title: Scientometrics
- ISSN: 0138-9130
- OECD FOS classification: 5.8 Media and communications.

Related to the problem of subject classification of publication channels is how to define those that meet scholarly standards, for example regarding peer review practices. Ulrich's periodicals directory covers more than 300 000 periodicals worldwide, but they are of all types and include popular magazines, newspapers, and professional journals as well as academic and scholarly journals. Whenever a particular selection of journals is not sufficient, e. g., WoS core collection with 18 000 journals or Scopus with a selection of 23 000 journals, there is the need to agree on the criteria for a wider selection of academic and scholarly journals. This need has been particularly apparent in the social sciences and humanities [25.2].

In response to the situation in the social sciences and humanities, the European Reference Index for the Humanities (ERIH) was originally created and developed by European researchers under the coordination of the Standing Committee for the Humanities (SCH) of the European Science Foundation (ESF). The ERIH lists, which initially mainly covered disciplines in the humanities, were first published by ESF in 2008, while revised lists were made available in 2011–2012. In 2014, the responsibility for the maintenance and operation of ERIH was transferred to the Norwegian Centre for Research Data (NSD), a non-commercial organization owned by the Norwegian Ministry of Education and Research. NSD also runs the Norwegian register of scientific journals, series and publishers as a resource for CRISTIN. The international register of journals and series at NSD is now called ERIH PLUS to indicate that it has been extended to the social sciences.

The relevance of ERIH PLUS to CRIS is that one of the aims is to provide a well-defined, standardized, and dynamic register of scholarly journals and series in the SSH, thereby making data available and comparable across different CRIS [25.21]. Although ERIH PLUS is limited to the humanities and social sciences, its six criteria for the inclusion of journals could be a starting point for defining scholarly and scientific journals more generally:

1. Explicit procedures for external peer review
2. Academic editorial board, with members affiliated with universities or other independent research organizations
3. Valid ISSN code, confirmed by the international ISSN register
4. All original articles should be accompanied by abstracts in English and/or another international language relevant for the field
5. Information about the affiliations and addresses of the authors should be published for each article
6. National level as a minimum: No more than two-thirds of the authors published in the journal are from the same institution.

Note that the last criterion ensures that the register will not be endless and that there is a proper basis for independent peer review. Criteria 1, 2, and 6, taken together, ensure that ERIH PLUS promotes research quality in the SSH. By allowing for journals published in the national languages, societal relevance is also promoted. Criteria 3–5, taken together, ensure that data will be efficiently relevant, searchable, and comparable across CRIS and other bibliographic data sources. They are also required for providing data for bibliometric analysis.

In a project presently funded by Nordforsk, the organization that facilitates and provides funding for Nordic research cooperation and research infrastructure, Denmark, Finland, Iceland, Norway, and Sweden together are creating one merged Nordic list of scholarly publication channels as a shared resource for their national CRIS. The criteria for inclusion are in concordance with the criteria used in ERIH PLUS. The Nordic list includes all areas of research, not only the social sciences and humanities, and it will be based on the OECD FOS classification.

25.9 Ensuring Comprehensiveness of Data in a CRIS

The preceding sections of this chapter have progressively dealt more concretely with contents-related challenges that need to be solved in an internationally integrated CRIS. As we now move on to the level of a national CRIS, we encounter specific problems and possible solutions that do not surface in international overviews of the situation. These problems are related to the completeness and quality of the data. There is a need to agree on definitions, instructions, and procedures to ensure data quality. There may also be a need to incentivize the data production to achieve completeness. These challenges are not technical, but the technical design of the CRIS can be part of the solution, e. g., by facilitating easy quality assurance in the data production line.

CRISTIN (the current research information system in Norway, cristin.no), the national CRIS of Norway, is an example of a CRIS with several years of experience with meeting and solving challenges with data quality and completeness. The system was developed in 2003 at the University of Oslo and used independently of each other by the four major universities until 2010. By that time, the government had facilitated a 2 year process in which it was agreed and specified how the local CRIS could become *one shared information system* for almost all public research organizations in the country, including universities, other higher education institutions, independent research institutes, and hospitals [25.22]. The system is now provided by the Norwegian government's Directorate for ICT services in higher education and research (UNIT).

Like most CRIS, the Norwegian system has daily updated, standardized, and searchable information about researchers and their affiliations, projects, and outputs. All kinds of outputs can be registered. The costs of running the national CRIS would not be legitimate without multiple use of the same data. References to publications are registered only once, after which they can be used in CVs, applications to research councils, evaluations, annual reports, internal administration, bibliographies for Open Archives, links to full text, etc.

A part of CRISTIN is called the *Norwegian Science Index*. Only in this part can one expect to find complete, quality-assured, and well-structured data that can also be used in bibliometric analyses. The Norwegian Science Index is based on particular definitions, instructions, and procedures to ensure data quality, because it is used as the basis for one of the indicators in performance-based research funding models that affect most of the participating research organizations in the higher education, independent institute, and health sectors. The link to funding also explains why completeness can be expected. We will discuss the issue of completeness first and then turn to how data quality is ensured.

The relation between CRIS data and funding is, in this case, known as the *Norwegian model* [25.13, 23, 24], which so far has been adopted at the national level by Belgium (Flanders), Denmark, Finland, Norway, as well as at the local level by several Swedish universities and by University College Dublin. The national model has three components:

A A complete representation in a national database of structured, verifiable and validated bibliographical records of the peer-reviewed scholarly literature in all areas of research.

B A publication indicator with a system of weights that makes field-specific publishing traditions comparable across fields in the measurement of *publication points* at the level of institutions.

C A performance-based funding model that reallocates a small proportion of the annual direct institutional funding according the institutions' shares in the total of publication points.

In principle, component C is not necessary to establish components A and B. The experience, however, in all the above-mentioned countries, is that the funding models in C support the need for comprehensiveness and validation of the bibliographic data in component A. In Norway, the bibliometric indicator based on CRIS data reallocates less than 2% of the total funding, but it still stimulates a completeness, which is valuable not only for the funding instrument, but also for all other uses of CRIS data. Without the link to funding, which was introduced for the higher education sector in 2004, CRISTIN would probably not have been restructured as a *shared* national system since 2010. One of the reasons for this investment was to provide for increased transparency, more uniform quality-assurance, and shared resources in the data production line.

Component B, the publication indicator, is the first bibliometric indicator to give a balanced representation of productivity in all fields [25.25]). It does so by building on a definition of outputs that includes publications not indexed in the WoS or Scopus. It applies an intermediate solution between whole counts and fractionalization in cases of co-authored publications, using the square root of the fraction. Bibliographic data from CRISTIN can, however, be used for any type of analysis or indicator. A few examples are given in Sect. 25.11 of this chapter.

25.10 Ensuring the Quality and Consistency of Data in CRIS

The possible link to institutional funding can also be discussed in relation to quality-assurance of the data. Most countries with a national CRIS have a funding model for research that makes use of it. In these countries, the quality assurance of the data is necessary for the acceptance and legitimacy of the funding instrument. Croatia and Estonia are presently examples of countries with a national CRIS not used for funding because the data quality is so far not trusted. WoS and Scopus are used instead for the funding instrument. These examples clearly indicate that once the decision is taken to use CRIS data for funding allocation, there is also a need to implement several measures to ensure data quality and consistency. We will return to the example of the Norwegian Science Index in CRISTIN to explain how this has been done.

The data for the Norwegian Science Index in CRISTIN are delimited by a definition of scholarly publications, the development of which representatives from all areas of research contributed to and agreed on before it was implemented in 2004. According to this definition, a scholarly publication must:

1. Present new insight
2. Have a scholarly format that allows the research findings to be verified and/or used in new research activities
3. Be in a language and with a distribution that makes the publication accessible for a relevant audience of researchers
4. Be in a publication channel (journal, series, book publisher) that represents authors from several institutions and organizes independent peer review of manuscripts before publication.

While the first two requirements of the definition demand originality and scholarly format in the publication itself, the third and fourth requirements are supported by a standardized dynamic register of approved scholarly publication channels at http://dbh.nsd.uib.no/kanaler/. Suggestions for additions can be made at any time through the same web page. This means that the two last criteria have a centralized solution. It is operated by NSD, the Norwegian centre for research data, in collaboration with the National Publishing Board, which has an academic representation across all major research areas and types of research organizations. The register now not only supports the CRIS and the definition above. It is also used for information about publication channels with open access, promoting those that fulfill the definition and excluding the exceptions. This task is now organized in collaboration with similar registers in the other Scandinavian countries and the Directory of Open Access Journals (DOAJ).

It is the responsibility of each institution to apply the two first criteria. Publication channels are usually hybrid. Not all articles in *Nature*, and not all books published by *Oxford University Press*, will fulfill the first two criteria. The institutions need to judge and select correct publication types when they register data for the Norwegian Science Index. They are aided in doing so in several ways:

- By agreement with Elsevier, data for publications with Norwegian affiliations that are indexed in Scopus, including publication type, are continuously imported to CRISTIN. Thus, around 75% of the publications need only be validated by the authors and the institutions.
- Depending on the size of the institution, each of them has appointed one or more administrative contact persons with a local overall responsibility for registrations in CRISTIN. These persons monitor the registration process in collaboration with people at CRISTIN. Cases of doubt will first be discussed with researchers in leading positions at their institution and then with the CRISTIN organization if needed. Cases of doubt will also be returned from CRISTIN after the annual registration process in April, when the institutions take formal responsibility for the data produced in the previous year.
- A document is provided with guidelines for registering research publications in the Norwegian Science Index. The guidelines present further and more detailed explanations with examples of the application of the definition above.

The methods for quality assurance and the incentives for completeness require resources as well as organizations with clear responsibilities. Guidelines for registration are often discussed among countries with national CRIS (e. g., Denmark, Finland, Flanders, Norway), and the countries inspire each other in their further development. The most elaborated guidelines presently that are also available in English, can be downloaded from the *Danish Ministry of Higher Education and Science* [25.26]. The guidelines include:

- An operational definition of research publications (similar to the Norwegian definition given above) with clarifications of each of the criteria, including examples and more detailed definitions, e. g., of peer review.
- Requirements for the registration of the authors of a publication, e. g., all authors must be registered in the same order as they appear in the publication.
- The criteria for inclusion in the register of publication channels.
- Descriptions of publication types to be included, and those not to be included, with explanations and examples of each type. This section is the largest part of the guidelines.

As mentioned above, a survey to 39 countries found large variability rather than standardization in how the data are defined and structured in national CRIS or bibliographic databases [25.16]. The Danish guidelines discussed here are closely related to an implementation of the *Norwegian model* (Sect. 25.9) and not typical of most CRIS. However, the problem with defining scholarly and scientific publications can be found in any CRIS that try to be interoperable with Scopus or WoS, which is exactly what the widespread commercial solutions to CRIS try to do.

25.11 Examples of Studies of Research Based on CRIS Data

The establishment of non-commercial national CRIS in some countries has supported an increase in output-based studies of research, particularly in the humanities and social sciences, where CRIS can provide a more complete representation of scholarly publications than we find in commercial data sources [25.27]. The field is quite new, with most of the publications having appeared only the last 2 years, after the establishment of the COST network ENRESSH mentioned above. The increased activity is now the basis for a new series of biannual conferences focusing on research evaluation in the social sciences and humanities (RESSH, established in Rennes in 2015 and continued in Antwerp in 2017).

The ECOOM group at the University of Antwerp is particularly active. This group developed and runs the Flemish bibliographic database for the social sciences and humanities (Vlaams Academisch Bibliografisch Bestand voor de Sociale en Humane Wetenschappen VABB-SHW) for a similar purpose to the Norwegian CRISTIN system, see Sect. 25.9. They use the data for studying several aspects of the publishing patterns of the social sciences and humanities that have rarely been studied before. Here are some examples:

The ECCOM group studied general changes in the publication patterns of the social sciences and humanities over a decade (2000–2009), finding growth in the output, particularly a steady increase in the number and proportion of publications in English, however with no overall shift away from book publishing [25.28]. They found almost identical evolutions in the use of English as a publication language by comparing data from CRIS in Flanders and Norway, however WoS coverage was stable for Norway but had been increasing rapidly for Flanders, probably because of differences in the parameters used for performance-based funding of universities [25.19]. Internationalization was also found in book publishing. Whereas peer reviewed books were increasingly published abroad and in English, non-peer reviewed book literature remained firmly domestic and published in the Dutch language [25.29]. Whereas the humanities are more continentally oriented in their book publishing, the social sciences are firmly Anglo-Saxon oriented [25.30]. A study of co-authorship patterns in the social sciences and humanities indicated that collaborative publishing in the SSH is increasing with a sharp decline in single-author publishing [25.31]. A study of 753 peer reviewed edited books and the 12 913 chapters published therein revealed that not only co-authorships, but also co-editing and publishing different chapters in the same books are indicators of scholarly collaboration in the social sciences and humanities [25.32]. The editors of scholarly books are mostly established researchers, produce more book chapters and monographs than do other researchers, and are more productive [25.33].

A new study based on CRIS data [25.34] investigates publication patterns in the language and type of social sciences and humanities across a much wider range of non-English speaking European countries, including Eastern Europe, i. e., Czech Republic, Denmark, Finland, Flanders (Belgium), Norway, Poland, Slovakia, and Slovenia. The study demonstrates that publication patterns are related not only to discipline but also to each country's cultural and historic heritage. This finding corrects an assertion in an earlier CRIS-based study [25.27] that publication patterns vary by discipline, but less across countries in the same discipline.

Also on the basis of CRIS data, other researchers have provided deeper insight into the publishing patterns of particular fields of research, such as political science [25.35, 36] and law [25.37].

There are some studies based on CRIS data that investigate policy-related questions across all fields of research, not only the social sciences and humanities. With data from the CRIS of the University of Helsinki, *Puuska* [25.38] examined the effects of a scholar's position and gender on publishing productivity in several types of scientific publications, such as monographs, articles in journals, articles in edited books, and articles in conference proceedings. *Aksnes* et al. [25.39] studied the mobility of researchers on the basis of CRIS data from the four main Norwegian universities.

Other studies have contributed to a critical examination of how CRIS data are used for statistics, evaluation, and funding in research management, most often with suggestions for further development of data and indicators [25.15, 40–44], sometimes only describing potentially negative effects of such use [25.45].

Finally, to illustrate in more detail that the use of CRIS data in studies of research may also have a broader interest beyond bibliometrics and studies of the social sciences and humanities in particular, we will end this chapter by presenting two examples showing that bibliographic data in CRIS can be combined with other data (personal variables, backgrounds, resources, projects, networks, memberships) within or outside of the CRIS system, thereby serving science studies more generally.

The first example is a little study of gender, age, and productivity that we did some years ago, based on data in the Norwegian CRISTIN system [25.46]. Here, gender, age, and complete records of all peer reviewed scientific publications are among the available information for each active researcher. We studied the productivity of 17 212 researchers (10 279 men and 6933 women) aged 27–67 who published in 2011. Altogether, they contributed to 12 441 unique publications. There was no double counting if two or more researchers contributed to the same publication. Instead, publications with multi-authorship were fractionalized by the number of authors. Figure 25.1 shows the result by presenting the women's share among Norwegian researchers and their publication output in each 1 year age cohort between 27 and 67.

We can see the gender gap decreasing as younger generations are recruited to research. We also observe that the difference in productivity between men and

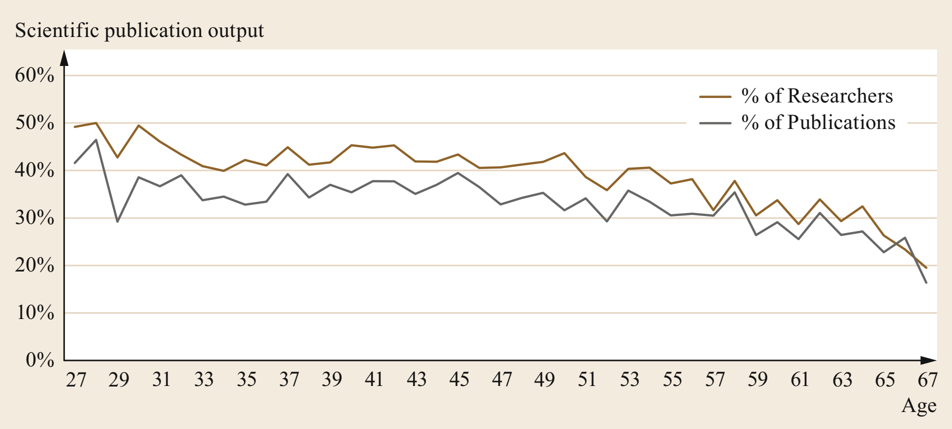

Fig. 25.1 Age and women's share of Norway's researchers and their total scientific publication output in 2011. Based on data from CRISTIN, representing more than 17 000 active researchers working at 160 different research institutions in Norway

women is somewhat larger in the younger age cohorts. This is not a new finding. The same observation and its possible explanations were studied more extensively in previous studies, e. g., by *Kyvik* and *Teigen* [25.47]) with the telling title *Child care, research collaboration, and gender differences in scientific productivity*. That study, however, was based on a survey and interviews with relatively few researchers. Figure 25.1 is based on complete data for all active researchers in a country. With the help of the CRIS system, we can see that the difference in productivity between men and women is so far consistent across all types of institutions (universities, university colleges, research institutes, hospitals) and across all fields of research (humanities, social sciences, health sciences, and natural sciences). This could be an indication that gender equality in research is dependent also on the degree to which gender equality has been achieved in society.

The last example is a research project that was presented at the 16th Conference of the International Society of Scientometrics and Informetrics (ISSI) in 2017 [25.48]. The project is a response to two independent studies that were first presented at ISSI 2015 and published the year after in PLOS ONE. *Larivière* and *Costas* [25.49] and *Sandström* and *van den Besselaar* [25.50] observe similarly that productivity among individual researchers is correlated with citation impact in large datasets from WoS. While the latter study draws the policy implication that productivity should be incentivized, the first study explains their findings by the Mertonian theory of cumulative advantages and maintains that research assessment should be qualitative and focus on research quality. Both studies are based on author name disambiguation in WoS data.

As acknowledged by the authors, there are several problems with studying individual productivity by using author name disambiguation. Here, CRIS can come to aid. In our study of the same general research question, we match WoS with records in The Norwegian Science Index and The Norwegian Research Personnel Register. Hence, we can study real persons, not just authors. We know their age, gender, position and affiliation, as well as their former career and educational background in the higher education sector. Productivity depends on what roles researchers actually take in research, what positions they have, what resources are available, and what they achieve in their careers. We also have a broader basis for measuring productivity across fields, building on the completeness of CRIS data. We found that productivity and citation impact is much less correlated if publications beyond WoS are also included in the measurement of productivity. We also found higher average citation rates among post docs than among professors. Young researchers are, on the average, more cited than seniors, if measured per publication. On the other hand, senior researchers and professors are more productive within WoS.

25.12 Conclusions

Well integrated and structured current research information systems on the institutional or national levels serve several purposes at all levels, from the need for the individual researcher to record and provide information about research activities and achievements in internal and external contexts, to the need for research information, statistics, and indicators at the institutional or national level. With sufficient data quality and completeness, they are promising also as data sources for studies of researchers and their activities, including bibliometric studies. The strength of these systems is related to the completeness of bibliographical records, the automatic disambiguation of authors/persons and addresses/affiliations, and the possibility of thereby connecting with other data describing the researchers, their institutions and resources, and the outcomes of their research.

CRIS would become even more interesting for studies of research if such systems were standardized and interoperable for exchanging comparable data on the international level. International integration of CRIS is already on the European policy agenda for several other reasons. This chapter has focused on factors that will determine the success of CRIS integration. Generally, *technical* solutions to different aspects of an integrated CRIS are already available. The challenge is instead to coordinate the processes and agreements that are needed before *contents* are well defined and can be efficiently shared in an integrated CRIS. The chapter has presented documents, projects, and CRIS implementations that concretely deal with the major challenges and represent solutions that can contribute to further advancement. It also presented examples of how CRIS-based data may be used in policy-relevant research that can enlighten questions that are otherwise not easy to approach.

One might ask why European-level support to developing technical solutions to CRIS integration has been successful only in creating the solutions themselves, not in actually integrating the systems or making them exchange information. The CERIF data model was developed with European support already 30 years ago, but has rarely been implemented. CERIF now has a new chance within the large-scale OpenAIRE project, which has mainly an open access agenda and will probably not solve what *Daraio* and *Glänzel* [25.1] list as the main problems in relation to data integration for research administration, evaluation, and policy as data quality, comparability, standardization, interoperability, modularization, classifications and concordance tables, comprehensiveness and completeness, and shared schedules for updating.

This chapter has described how such problems can be dealt with concretely. However, except for the bottom-up initiatives that we mentioned within the ENRESSH COST network and the Nordforsk network of Nordic countries, there is no follow-up of initiatives to address these problems at the international level. Just as the *European Scoping Project* [25.6] had no practical outcome, the *European Report on Measuring Scientific Performance for Improved Policy Making* [25.3] and *Science Europe*'s [25.4] *Position Statement on Research Information Systems* have so far not brought Europe many steps closer to CRIS integration.

We explain this somewhat depressing situation by the fact that there are three competing models that seem to be able to achieve the same goal—without being successful either. Including the model discussed in this chapter, we have the following four so far unsuccessful models:

- *The informatics model*, with CERIF and OpenAIRE given above as examples
- *The survey model*, with the European Tertiary Education Register (ETER) and U-Map/U-Multirank as examples
- *The commercial model*, with Converis, Elements, and Pure as examples
- *The open CRIS model*, with the VIRTA project presented in Sect. 25.6 as an example.

The strengths of the survey model and the commercial model is that they ensure that institutions can retain information in their local CRIS that they hesitate to share with other institutions or with the national level. The survey model is based on an agreed selection of items and indicators to provide information for. However, as shown in Sect. 25.5 with the research core dataset project in Germany, it would be possible to establish such agreements with an open CRIS model as well. It is technically feasible to share only parts of the information available in a local CRIS.

The additional strength of the commercial model is that it allows for tailor-sewed local CRIS applications of a technically very advanced general product that also exchanges information with other commercial and open information sources. These products immediately serve local research management with useful tools for strategic decisions and development. It may be seem to be an additional strength that the local information is not shared with other organizations except for the commercial provider, which in turn creates benchmarking information based on local information from all of its customers.

Hence, according to the commercial model, the total overview remains with the commercial provider and is not shared in the public space. This situation is satisfying if research organizations see themselves more as competitors than as partners within academia, which is increasingly the case. To counteract this trend and support the open CRIS model, there needs to be a vision of improvement of research organizations through shared information and comparability, as well as a willingness to decide and invest in shared information systems, at the policy level. There also needs to be an interaction between research organizations, their funders, and the expertise in research information, documentation, indicators, and evaluation.

Part D

Part D New Indicators for Research Assessment

26. Social Media Metrics for New Research Evaluation

Paul Wouters, Zohreh Zahedi, Rodrigo Costas

This chapter approaches, from both a theoretical and practical perspective, the most important principles and conceptual frameworks that can be considered in the application of social media metrics for scientific evaluation. We propose conceptually valid uses for social media metrics in research evaluation. The chapter discusses frameworks and uses of these metrics as well as principles and recommendations for the consideration and application of current (and potentially new) metrics in research evaluation.

26.1 Social Media Metrics and Altmetrics

Since the publication of the Altmetrics Manifesto in 2010 [26.1], interest in alternative measures of research performance has grown. This is partly fueled by the problems encountered in both peer review and indicator-based assessments, and partly by the easy availability of novel types of digital data on publication and communication behavior of researchers and scholars. In this chapter, we review the state of the art with respect to these new *altmetrics* data and indicators in the context of the evaluation of scientific and scholarly performance.

This chapter brings together three different strands of literature:

1. The development of principles for good and responsible use of metrics in research assessments and post-publication evaluations
2. The technical literature on altmetrics and social media metrics
3. The literature about the conceptual meaning of social media metrics.

The field of altmetrics has grown impressively since its inception in 2010. We now have regular altmetrics conferences where academic and commercial data analysts and providers meet. A number of nonprofit and for-profit platforms provide altmetrics data, and some

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_26

summarize these data in visually appealing statistical presentations. Some of the resulting altmetric indicators are now even incorporated in traditional citation indexes and are published on journal websites.

Notwithstanding this resounding success, we come to the conclusion that the term *altmetrics* is a misnomer and is best abandoned. Based on the published research since 2010, we have to conclude that there is no theoretical foundation or empirical finding justifying the lumping together of such various measures under the same term. We therefore propose to disaggregate the various data sets and indicators, in their use in research evaluation, in their conceptual interpretation and, last but not least, in their names. Many data and indicators (we use the term *metrics* to denote both *data* and *indicators*) that make up the altmetrics universe are actually data about social media use, reception, and impact. We suggest that it would be wiser to adopt the term *social media metrics* for these data and indicators, following a suggestion by *Haustein* et al. [26.2]. However, this is also not an umbrella term that can be used for all data and indicators currently denoted as altmetrics. As *Haustein* et al. [26.2] also indicate, some of these novel metrics are essentially web-based forms of traditional library data. And some data, such as Mendeley readerships, can be seen as a hybrid between bibliometric and social media data. Nevertheless, we think that introducing the term *social media metrics* would be helpful for understanding a large part of what is now simply labeled as *altmetrics*. We hope that this will stimulate the more accurate labeling of the remaining data and indicators. In this chapter, we will therefore use the term *social media metrics* whenever we refer to data and indicators about social media use, reception, and impact. We will restrict the term *altmetrics* to historically accurate references, since the term has been quite popular since 2010, and we do not want to rewrite history from the present.

The chapter is organized in six sections. The next, second, section explores the recent history starting with the Altmetrics Manifesto and puts this in the context of critiques of the traditional forms of research evaluation. The section shows the development of guidelines and principles in response to these critiques and mentions the concept of *responsible metrics* as one of the outcomes. The third section gives an overview of the currently available social media tools according to the data sources and discusses how they can characterize types of interactions as well as users. The fourth section zooms in on issues and actual applications of social media metrics. It reviews the technical characteristics of these data and indicators from the perspective of their use, the research questions that they can address, and principles for their use in evaluative contexts. In this section, we also spell out why the distinction between *descriptive* and *comparative* metrics may be useful. The fifth section discusses possible future developments including novel approaches to the problem of research evaluation itself. The sixth and last section details the limitations of the chapter and specifically mentions the need for more research on the use and sharing of data in the context of research evaluation. We end with the bibliography, which we hope will be especially useful for students and beginning researchers as well as for practitioners in the field of research evaluation.

26.2 Research Evaluation: Principles, Frameworks, and Challenges

26.2.1 Origins: The Altmetrics Manifesto

Altmetrics were introduced with the aim, among others, of improving the information used in research evaluations and formal assessments by providing an alternative to traditional performance assessment information. The Altmetrics Manifesto called for new approaches to fully explore the potential of the web in scientific research, information filtering and assessments. It characterized peer review as *beginning to show its age*, since it is *slow, encourages conventionality, and fails to hold reviewers accountable*. Citations, on the other hand, are *useful but not sufficient*. Some indicators such as the h-index are even slower than peer-review, and citations are narrow, neglect impact outside the academy and ignore the context of citation. The journal impact factor, which was identified by the manifesto as the third main information filter, is often incorrectly used to assess the impact of individual articles, and its nature makes significant gaming relatively easy. Since new uses of the web for data sharing and scholarly publishing have created new digital traces, these could be harvested and converted to new indicators to support researchers in locating relevant information as well as in evaluating the quality or influence of scientific work.

The idea that the web would lead to novel markers of quality or impact was in itself not new. It had already been identified by scientometricians in the 1990s [26.3–5]. This did not immediately change evaluative metrics, however, because data collection was difficult and the web was still in its early stages [26.6, 7]. Only after the development of more advanced algorithms by computer scientists did social media metrics turn into a real-world alternative in the area of scientometrics and research evaluation [26.8].

The emergence of social media metrics can thus be seen as motivated by, and contributing to, the need for responsible metrics. Its agenda included the study of the social dimensions of the new tools while further refining and developing them. Possible perverse or negative effects of the new indicators were recognized, but they were not seen as a reason to abstain from innovation in research metrics [26.8]. Experts in webometrics and scientometrics tended to be a bit more wary of a possible repetition of failures that had occurred in traditional scientometrics [26.9, 10]. As a result, the development of tools like the *Altmetric donut* did not completely satisfy the need for guidelines for proper metrics in the context of research evaluation, although they did open new possibilities for measuring the process and outcome of scientific research.

26.2.2 Standards, Critiques and Guidelines

This lacuna was filled by two somewhat independent developments. From the altmetrics community, an initiative was taken to develop standards for altmetrics indicators and use in the context of the US National Information Standards Organization (NISO) as a result of a breakout session at the altmetrics12 conference (http://altmetrics.org/altmetrics12) [26.11]. In parallel, guidelines were developed as a joint effort among researchers responsible for leading research institutions, research directors and managers, metrics and evaluation experts, and science policy researchers [26.12]. They mainly developed as a critique of the increased reliance on various forms of metrics in post-publication assessments, as in the *San Francisco Declaration on Research Assessment* (DORA) and the *Leiden Manifesto for research metrics* [26.13, 14]. It should be noted that these initiatives did not come out of the blue, but built upon a long trajectory in which the scientometric community had developed methodological standards and common interpretations of what the various indicators represent in the context of research evaluation. It led to a set of professional standards, some of them explicit, others more implicit, that guided the work of the most important metric centers [26.15, 16]. In general, the scientometric community had developed a consensus about the need to use bibliometrics as a complement to, rather than replacement of, peer review, which is summarized in the concept of *informed peer review*.

With the rise of the web and the wider availability of both traditional and novel metrics, the scientometric professionals lost their monopoly, and what was variously called *amateur scientometrics* or *citizen scientometrics* started to take off [26.15, 17–19]. This required a new approach and a more explicit nontechnical development of guidelines, for which the groundwork was laid at a series of conferences in the years 2013–2016 and in the context of the debates about the role of metrics in national research assessments, especially in Northwestern Europe.

The *San Francisco Declaration on Research Assessment* (DORA) [26.14] made 18 recommendations aimed at scholars, funders, institutions and research metrics providers. The most important recommendation was to avoid using the journal impact factor to judge the merit of individual articles or authors. Instead, article-level metrics were recommended. It also emphasized the value of all scientific outputs including data sets and software in addition to research publications. Openness regarding criteria in assessments and transparency of data and indicators is also an important theme in the recommendations.

26.2.3 Individual-Level Metrics

At the 2013 conference of the International Society for Scientometrics and Informetrics (July 2013, Vienna) and the 2013 Science and Technology Indicators/European Network of Indicator Designers (ENID) conference (September 2013, Berlin), another set of recommendations was discussed, specifically aimed at the use of indicators to assess the contribution of individual researchers [26.19].

A year later, the EU-funded project ACUMEN resulted in a more detailed evaluation guideline for both researchers and evaluators [26.20]. The core component is the *ACUMEN Portfolio*, which consists of several *pillars of evidence* (Fig. 26.1).

The basic idea of the ACUMEN approach is that evaluation is a form of communication in which the researcher herself should have a strong voice (and not only play the role of object of evaluation). The *career narrative* should be the main input for the assessment at the individual level, and qualitative and quantitative indicators can provide evidence for particular elements in the narrative. This supporting evidence is organized in three pillars:

1. Expertise
2. Output
3. Influence which enables a more flexible and modular approach to the indicators that may be used.

An important component of the ACUMEN Portfolio is the evaluation guidelines, which entail detailed advice on the merits of particular indicators covering

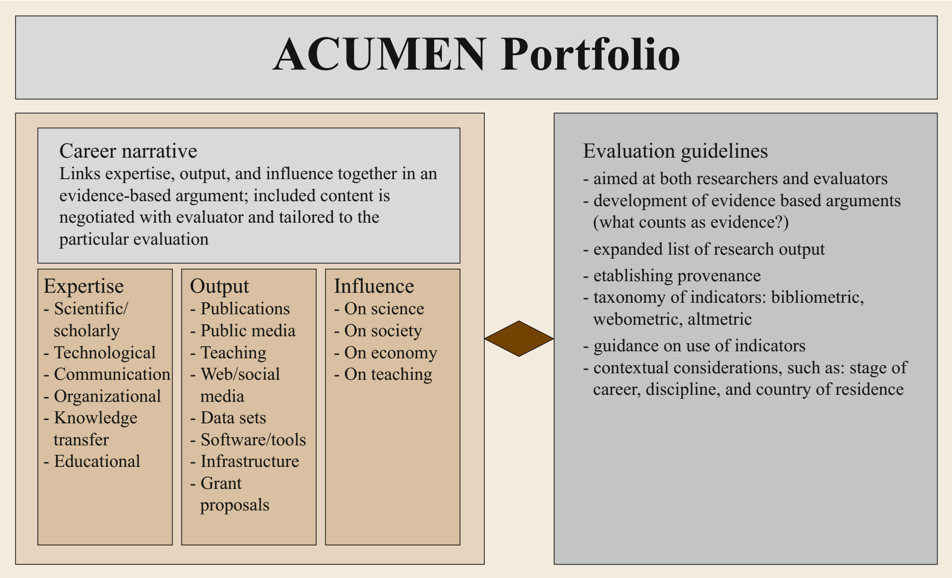

Fig. 26.1 The ACUMEN portfolio [26.20]

both traditional and alternative metrics. The guidelines are specifically aimed at both researchers under assessment and the evaluators, providing an extra layer of transparency. They are also based on the fact that researchers need to perform both roles.

26.2.4 Responsible Metrics

The Leiden Manifesto for research metrics was the result of the continuing discussion in the community of indicator specialists and scientometricians. They drew the conclusion that a public response in nontechnical terms was useful to counteract the spreading of badly used indicators in research evaluations [26.13]. The manifesto provides 10 principles that should be taken into account when using metrics in research assessment. These principles are not tied to a particular data set or assessment type. Currently, 18 translations of the manifesto have been published, which may be an indication of the need for this type of guidelines and information. Nevertheless, this does not prove that the principles are actually affecting research evaluation practices, since we may also witness symbolic adherence without changing the criteria for research evaluations or career judgments.

An even more generic framework to guide the application of quantitative indicators was laid down in the UK report *The Metric Tide* [26.12]. This was written at the request of the Higher Education Funding Council for England (HEFCE) to inform the debate about a possible replacement of the national research assessment process (which is based mainly on a massive peer review operation by panels of experts) by a metrics-based assessment. The report is not the product of one specific community, but the result of a truly interdisciplinary exercise in which researchers from a variety of fields worked together with indicators and policy experts. The report proposed to put central the concept of *responsible metrics*, echoing the notion of *responsible research and innovation* from the European science policy discourse.

The notion of responsible metrics, together with the empirical research reported in the *Metric Tide*, leads to 20 recommendations to all stakeholders in the UK research system. These recommendations support both DORA and the Leiden Manifesto and emphasize the need to put indicators in context. The research community is advised to "develop a more sophisticated and nuanced approach to the contribution and limitations of quantitative indicators". Transparency is also an important theme, with regard to both data and processes, and this should lead to a much improved research data infrastructure. The latter still lacks crucial components, especially in the area of indicators of the research environment, scientific instruments, and technical and institutional infrastructure. The *Metric Tide* pays special attention to altmetrics, with the question of whether they can complement traditional performance indicators. The overall conclusion is that current altmetrics cannot yet be used in most research assessments [26.9].

More specific to the context of altmetrics, an initiative to develop standards in altmetrics began in 2013, resulting in the *National Information Standards Organization (NISO) recommended practice, altmetrics definitions and use cases* [26.11]. The report comprises a detailed set of use cases in which the possibilities and limitations of a variety of altmetrics indicators for particular purposes by specific stakeholders is discussed. The NISO report also includes a code of conduct with respect to the responsible use of altmetrics data which focuses on transparency, replicability and accuracy of indicators.

26.3 Social Media Data and Indicators

The emergence of metrics of scholarly objects based on data from online social media platforms opened the possibility of analyzing new forms of interactions between different audiences and scholars (or scholarly products). These interactions are possible through the technical affordances allowed by these social media platforms, and have been conceived as "traces of the computerization of the research process" [26.21], resulting in the availability of different indicators based on user activity across the various online platforms. The NISO recommended practice, altmetrics definitions and use cases [26.11], defined altmetrics as:

> online events derived from activity and engagement between diverse stakeholders and scholarly outputs in the research ecosystem.

Social media metrics have also been discussed as a potential source of evidence in research evaluation, particularly in response to the quest for better metrics for measuring research performance [26.14].

Several advantages of social media metrics have been discussed, particularly over the more traditional approaches of research evaluation [26.10]. Among these advantages, *speed*, *openness* and *diversity* have been highlighted as some of the most important [26.10]. However, *Wouters* and *Costas* [26.10] also argued that for these new indicators to be realistically used in research evaluation, *transparency* and *consistency* are more important characteristics.

A theoretical framework for the use of altmetrics in evaluation was introduced by *Haustein* et al. [26.2]. Based on this framework, social media metrics can also be seen as:

> events on social and mainstream media platforms related to scholarly content or scholars, which can be easily harvested (i. e., through APIs), and are not the same as the more *traditional* concept of citations. [26.2]

This framework categorizes online acts upon *research objects*, including all forms of scholarly outputs (e. g., publications, but also data, code, etc.) as well as scholarly *agents* (e. g., scholars, funding agencies, research organizations). Thus, the realm of these new metrics would not be limited to the interactions with research outputs, but would include interactions with (and among) different scholarly agents, and the different forms of interactions could be characterized by the degree of engagement between the users with the scholarly objects.

However, in spite of these more conceptual discussions on the nature and characteristics of social media metrics, their strongly heterogeneous and ever-changing nature [26.22] has made the development of robust theories for the interpretation and evaluation of the activities and interactions captured by them very challenging.

26.3.1 Social Media Metrics Tools

In this section, the main characteristics of tools based on social media metrics are described. The purpose is not to discuss these tools as evaluative devices, but rather as sources of information on the relationships and interactions between science and social media. Thus, we take the approach that social media metrics are relevant sources for studying the interactions and relationships between science and social media, aligning more with what could be termed the *social media studies of science* [26.23] than with sources of scientific recognition or scientific impact. Moreover, our aim is not to focus on the currently available *altmetrics sources* but on the concepts behind these sources. Thus, although the current tools, sources and platforms collecting and providing social media data may disappear or change in the future (in what *Haustein* [26.22] has labeled the *dependencies* of altmetrics), many of the events and acts currently captured by *altmetrics data aggregators* could still be relevant in the future. For example, if Mendeley disappears, the idea of an online reference manager would still be feasible—with users from all over the world saving their documents—and counts of the number of different users (and types of users) saving these documents would still be possible should other new platforms be created. Moreover, while most common social media metrics tools usually refer to online events that exist around *scholarly outputs* (usually journal articles), there are also tools that focus on the activities of *scholarly agents*, particularly individuals. These tools and their main conceptual social media significance are described below:

- *Online reference management, social bookmarking and tagging tools*. Several online reference managers allow the counting of the number of times publications have been saved, bookmarked or tagged by different users of the platform. For instance, the *readership* counts provided by Mendeley (http://www.mendeley.com) include total number of users who have saved (added) a document to their private libraries. In addition, Mendeley offers some statistics on the academic status (students, professors, researchers, librarians, professionals, etc.), discipline and country of the users, as well as tags assigned to the publications they have saved. Other tools such as BibSonomy (https://www.bibsonomy.org/), Zotero (https://www.zotero.org) and CiteULike (http://www.citeulike.org/) also offer information on the posted counts/users, tags, posting history and user's info, plus the bibliographic information of the bookmarked or saved documents, although their APIs (application programming interfaces) are not yet fully developed [26.22].
- *Microblogging tools* (Twitter (https://twitter.com), Weibo (https://www.weibo.com), etc.) offer the possibility of disseminating information in small messages (e. g., the current 280-character limit for Twitter; before 2017 it was 140). In addition, these tools are aimed at broadcasting, filtering and establishing interactions among their users. For example, through the use of symbols such as @ or # in Twitter, it is possible to target other Twitter users (tweeters) and create messages (tweets) that are easy to filter or disseminate (retweet) to other users through the use of specific tags (the # symbol for thematic tags or the @ symbol to target other users). These tools also offer possibilities for *following* other users and *liking* (or appraising) other users' messages within the platform. Most microblogging tools offer the possibility of linking to external objects, which may be publications (e. g., through their Digital Object Identifier (DOI)) or other scholarly agents (e. g., scholars' websites, university websites). These technical options, or *affordances*, open the possibility to generate multiple indicators (e. g., the number of (re)tweets, likes, or followers around any particular scholarly object). An advantage of these platforms is that they provide rich information on users, tweets and locations through both their web interfaces and their APIs (Twitter streaming API, REST API with rate limit, or the commercial GNIP API (https://dev.twitter.com/docs) or Weibo open API (http://open.weibo.com/wiki/API%E6%96%87%E6%A1%A3/en)), thus making their data accessible and analyzable (although the different platforms may impose restrictions on the amount of data obtained).
- *Blogs and blog aggregators*. A number of blog platforms and blogging tools focus on peer-reviewed research, for example http://ResearchBlogging.org or http://ScienceSeeker.org. Blogs, and particularly scientific blogs, are an emerging means of disseminating discussions on scholarly materials [26.24] to other academics or the general public. Typical metrics that can be obtained from these platforms include blog mentions (e. g., the mentioning of a researcher or a university) or blog citations (e. g., citations to other scientific outputs). Information from blogging activities is usually available through their web interfaces or APIs.
- *Social recommendation, rating and review services*. Here we find some scholarly oriented tools such as F1000Prime (http://f1000.com/prime/about/whatis/how), which is a post-publication peer review service offering access to metrics such as views and downloads, as well as recommendation scores of biomedical literature, reviewed by their appointed users, together with information (labels or tags) on their type of recommendation (e. g., for teaching, controversial, new findings). Other academic platforms include Publons (https://publons.com/home/), which was recently acquired by Clarivate Analytics, and PubPeer (https://pubpeer.com/), which offer post-publication peer comments and scores for scholarly biomedical or multidisciplinary publications. A more general platform is Reddit (https://www.reddit.com/dev/api), which provides information such as comments and votes to the posts provided by its users. Some of these tools offer open APIs (Reddit), while for others (Publons or PubPeer) access is available only on request.
- *Wikis and collaborative content creation*. These platforms are seen as "collaborative authoring tool[s] for sharing and editing documents by users" [26.25]. A common metric available through these sources includes mentions of scholarly objects. For example, Wikipedia citations or mentions are available via its API (https://www.mediawiki.org/wiki/API:Main_page), enabling the analysis of the number of citations that scholarly publications have received in Wikipedia.
- *Social networking platforms* (e. g., LinkedIn (https://www.linkedin.com/), Facebook (https://www.facebook.com/)). These generalist platforms allow their users to connect, interact and communicate in many different ways (messaging, sharing, commenting, liking, etc.). Information on their users, activities and their geolocations are

typically available through their web interfaces or APIs (e. g., Facebook Graph and Public Feed APIs (https://developers.facebook.com/docs/graph-api) or LinkedIn API (https://developer.linkedin.com/docs/fields).

- *Social networking platforms for researchers* (e. g., ResearchGate (https://www.researchgate.net/) and Academia.edu). These tools provide information on scholars and their outputs and affiliations, and offer different metrics at the individual, institutional or country levels. This type of platform, inspired by the more generalist social networking platforms, aims at facilitating networking and communication among scholars, finding academic content, experts or institutions, and as sharing and disseminating their research with peers. ResearchGate (RG) offers different indicators including the RG Score (a measure of reception of a researcher's publications and her participation on the platform) and RG Reach (a measure of visibility of a researcher's publications on the platform), together with other indicators such as the number of citations, reads, downloads, h-index and profile views. It seems that the RG Score is influenced by a researcher's academic and online activities, and hence it is suggested to reflect a combination of scholarly and social networking norms [26.26, 27]. Other platforms such as Academia.edu provide information on mentions of a researcher's name by others, on the *readers* (including views, downloads and bookmarks of a researcher's publications), profile views and visitors per date, country, cities, universities, job titles, etc., some of which are available by monthly subscription.
- *Altmetrics data aggregators*. These are tools such as Altmetric.com, Lagotto (http://www.lagotto.io/), PLOS ALM (Article-Level Metrics) (https://www.plos.org/article-level-metrics), Plum Analytics (http://plumanalytics.com/) and ImpactStory (https://impactstory.org/) which aggregate metrics for scholarly materials from different sources. Examples of the metrics provided by these aggregators include *views*, *saves*, *citations*, *recommendations* and *discussions* around scientific publications by PLOS ALM and Lagotto, or those of *usage*, *captures*, *mentions*, *social media* and *citations* by Plum Analytics. Altmetric.com provides a composite weighted indicator (*Altmetric Attention Score*) of all the scores collected around scientific outputs (https://www.altmetric.com/about-our-data/the-donut-and-score/). Although most of these aggregators are based on a similar philosophy (to capture online events around scholarly objects), they often differ in the sources they track (publications with a DOI or PMID [PubMed identifier], etc.), the methodologies they use to collect the data (using public or commercial APIs, etc.) and the way they process and report the metrics (e. g., raw vs. more aggregated indicators). They usually also differ in terms of their updates, coverage and accessibility [26.28].

26.3.2 Characterizing Interactions and Users in Social Media Metrics

The relationships between scholarly objects and social media users can be characterized from two different perspectives: the *typologies of social media users* who interact with the scholarly objects, and the *typologies of social media interactions* that are established between the social media users and the scholarly objects:

- *Typologies of social media users*. The analysis of social media users has been approached from various perspectives, and a general framework (unified media-user typology) has been suggested for unifying all media user types based on user frequency, variety of use and their content preference [26.29]. According to [26.29], the term *user typology* is defined as the:

  > categorization of users into distinct user types that describes the various ways in which individuals use different media, reflecting a varying amount of activity/content preferences, frequency and variety of use

  which could be influenced by psychological, social and cross-cultural factors [26.29, 30].
  In the realm of social media metrics, different user typologies have been identified in the literature. For example, Mendeley users have been studied based on the information that they have provided about themselves on Mendeley (self-classified as *students*, *researchers*, *professors*, etc.) [26.31–33]. Tweeters have also been categorized as *influencers/brokers*, *discussers/orators*, *disseminators/bumblers* or *broadcasters*, based on the combination of the number of followers and their engagement with the publications [26.34–36]. Altmetric.com also categorizes tweeters as *researchers*, *science communicators*, *practitioners* or *general public*, based on the tweeters' descriptions. Other efforts have focused on the study of scholars active on Twitter [26.37–39].
- *Typologies of social media interactions*. How social media users interact with the scholarly objects can provide valuable information with which to characterize the indicators. *boyd* and *Ellison* [26.40]

argued that although social media tools have some common features (such as creating a profile for making connections), they differ in terms of the way users interact with the platform. For example, *bridging* and *bonding* refer to different forms of ties established among different users on social media [26.41, 42], based on the following/followees model in Twitter [26.43]. Thus, according to *Hofer* and *Aubert* [26.42], the use of Twitter is mainly influenced by *bridging* ties (i. e., following users from different networks with the aim of broadening the information flow) rather than *bonding* (i. e., following like-minded people for gaining emotional support). This form of follower/followee interactions is also very central in several science-focused altmetrics platforms such as ResearchGate or Mendeley. *Robinson-Garcia* et al. [26.44] have proposed the analysis of the relationship of follower/followees on Twitter as a means to identify potential traces of societal interactions. Another example includes the analysis of interactions via other social media platforms (like Facebook) between students and their instructors [26.45]. More focused on the context of social media metrics, *Haustein* et al. [26.46] established three main categories of engagement (or interaction) between the users and the scholarly objects: *access* (related to viewing, downloading and saving), *appraise* (mentioning, rating, discussing, commenting or reviewing) and *apply* (using, adapting or modifying). Typologies of blog posts have been discussed based on the content and motivations of the bloggers (e. g., discussions, criticisms, advice, controversy, triggers) [26.47]

26.4 Conceptualizing Social Media Metrics for Research Evaluation and Management

In order to discuss potential uses of social media metrics, we need to understand the reliability and validity of social media indicators for evaluative purposes. Section 26.4.1 discusses the criteria that social media indicators should meet in order to be considered valid indicators. Section 26.4.2 explains to what extent indicators should be homogeneous in their composition [26.48]. Finally, the dependence of social media metrics on external data providers and the technical quality of the data is discussed in Sect. 26.5.

26.4.1 Validity and Reliability of Social Media Metrics

In the discussion around the possibility of altmetrics as new sources of indicators for research evaluation, *Wouters* and *Costas* [26.10] suggested that altmetrics "need to adhere to a far stricter protocol of data quality and indicator reliability and validity". According to *Gingras* [26.48], in order to be valid, indicators should meet three essential criteria:

1. *Adequacy*
2. *Sensitivity*
3. *Homogeneity*.

The concept of validity relates to an indicator's success in measuring what is expected to be measured [26.49]. The notion of adequacy indicates how the indicator captures the reality behind the concept intended to be measured. Along similar lines, as suggested by *Nederhof* [26.50] regarding bibliometric indicators, the main question is to what extent social media indicators are valid as measures of research performance. In scientometrics, citations have been assumed to be imperfect proxies of intellectual influence or scientific impact. This imperfection is derived from the fact that quite often this is not the case, citations may be perfunctory, and the choice of citations involves a substantial degree of arbitrariness by the authors, thus deviating from the idea of citations as measures of intellectual influence [26.51–54].

In the case of social media metrics, this issue is more complicated, as it is not clear to what extent these indicators are even remotely related to the concept of scientific impact. On the one hand, indicators such as Mendeley readers or F1000Prime recommendations have a closer relationship with scientific impact, as they have a strong scholarly focus. Indicators derived from platforms such as ResearchGate or Academia.edu can also be expected to have a closer conceptual link to the traditional concepts of scholarly impact and performance. However, the lack of studies based on these platforms renders any consideration of them merely tentative. On the other hand, social media indicators derived from sources such as Twitter or Facebook are more difficult to relate to the concepts of scientific impact and scholarly activities. These indicators are usually thought of as measuring types of interactions that are not (directly) related to research performance.

The second criterion highlighted by *Gingras* [26.48] is sensitivity or inertia, understood as the *resis-*

tance to change of indicators. According to this notion, a good indicator should vary "in a manner consistent with the inertia of the object being measured". In the case of traditional bibliometric indicators, they usually have a slow inertia. They typically don't suffer from sudden and drastic changes, and although there are sources that may distort some of the indicators, most of them respond to an inertia that seems to align with the common perceptions of how scientific impact or performance also changes. Mendeley readership and F1000Prime recommendations have a similar inertia as citations [26.55–57]. However, the sensitivity and inertia of social media metrics can be challenged by three main issues:

- *Speed*. Traditionally considered one of the most important advantages of social media metrics, as they tend to happen faster than citations, their speed is also one of their most important limitations [26.10]. For example, indicators based on social media platforms like Twitter can change dramatically in a matter of hours as a result of controversies triggered by the publications, mistakes in the papers, or even jokes.
- *Superficiality*. The faster nature of most social media metrics may indicate a lower engagement of the users with the scholarly objects, which may be related to a higher level of superficiality in the appraisal of the objects. For example, Twitter users may massively (and suddenly) (re)tweet a publication without any intellectual engagement with it.
- *Small changes*. Given the fact that many of these indicators tend to present low values [26.46], small changes in the values of the indicators could have large effects. For example, a small increase in the number of (re)tweets, or a few additional mentions in blogs, may cause substantial changes in the indicators (e. g., drastically increasing their percentile value). Due to the strong skewness of most social media indicators [26.58], for most publications, just a few additional scores would propel a publication from a lower percentile to a higher percentile. For example, the paper https://www.altmetric.com/details/891951#score was tweeted by just two Twitter users on 15 December 2017, which positioned the paper in the 54th percentile according to Altmetric.com, while the paper https://www.altmetric.com/details/3793570#score was mentioned by four tweeters (i. e., just two additional tweeters), classifying it in the top 25th percentile (on 15 December 2017). These examples illustrate the strong sensitivity of these indicators to small changes, also illustrating the ease with which they can be manipulated [26.10, 59].
- *Reliability*. The sensitivity notion described by *Gingras* [26.48] can also be related to the reliability of indicators. Reliability is the extent to which an indicator yields the same result in repeated measurements. In the case of bibliometrics, the citation process is considered to be stochastic [26.50]. Papers of equal impact do not necessarily receive identical numbers of citations, since multiple random factors come into play (e. g., biases of the citers, publication and citation delays, coverage issues). Social media metrics are generally less reliable due to the stronger dependence on the consistency and accuracy of the data collection methodologies [26.28] and the low coverage of publications by social media sources [26.46, 60].

26.4.2 Homogeneity (or Heterogeneity) of Altmetric Indicators

This concept of homogeneity is especially important with respect to composite indicators that combine different measurements into a single number, thus "transforming a multidimensional space into a zero-dimension point" [26.61], although composite indicators are still possible when important mathematical and conceptual limitations are met. Research has shown significant heterogeneity in social media metrics [26.2, 10, 22] and a variety of relationships among them [26.34, 35]. In general, citations and Mendeley readerships are the most closely related indicators [26.62, 63]. Similarly, F1000Prime reviews are conceptually similar to peer review indicators [26.64, 65]. However, indicators based on Twitter, blogs or news media are both conceptually and empirically different from citations [26.60, 66] and also differ among themselves. These indicators capture different types of impacts. Therefore, constructing composite indicators and mixing these indicators for research evaluation should be discouraged. Maintaining the various altmetrics scores as separate entities is the best choice for ensuring transparency in assessment approaches. Examples of composite altmetrics indicators include the Altmetric Attention Score and the RG Score, which lump together fundamentally different metrics (Twitter, blogs, views, etc.) [26.2]. Although the calculation formula for the Altmetric Attention Score is disclosed (unlike the RG Score, which has remained a black box), the validity and application of this composite indicator for evaluative purposes is unclear.

In addition, we would like to call attention to problems related to the lack of *internal homogeneity* within a single indicator for many social media indicators. Perhaps the clearest example is the inclusion of tweets and retweets in the same indicator. Although both tweets and retweets come from the same platform, they arguably have different roles and should therefore be valued differently [26.67]. Other examples include the count for all of Mendeley readership in the same indicator, combining academic users (professors, PhDs, etc.) with nonacademic ones (e. g., librarians, professionals, students), or the aggregation of Facebook shares, likes and comments in a single indicator [26.22]. A lack of internal homogeneity may have a dramatic effect on the comparison of metrics from different data aggregators [26.28]. Therefore, transparency on the part of data providers in how indicators are structured and calculated is fundamental to the ability to judge the validity and replicability of social media metrics [26.22].

26.5 Data Issues and Dependencies of Social Media Metrics

As pointed out by *Haustein* [26.22], a central issue that must be considered for any application based on social media metrics is the direct dependence on altmetrics data aggregators, which themselves are dependent on other major social media data providers (Twitter, Facebook, etc.). Thus, any application of social media metrics is potentially limited by the decisions, strategies and changes on the part of any of these actors [26.68]. As a result, variations in their policies may mean the disappearance of a data source (e. g., in recent years of the existence of Altmetric.com, sources such as Sina Weibo and LinkedIn have stopped being covered, and the online reference manager Connotea has been discontinued [26.22]), restrictions on a type of analysis (e. g., current data restrictions regarding dates in Mendeley hampers analysis of readership trends) or a complete modification of the concept of impact or activity being measured (e. g., the conflating of posts, shares and likes from Facebook in a single indicator may confound the meaning of the indicator). Regarding data quality issues, a critical limitation is the dependence on unique identifiers of scientific publications such as DOI or PMID. Publications without any of these identifiers are excluded from the tracking algorithms of altmetrics data aggregators. Mentions of scientific publications must also include a direct link to the scientific publication. Mentions of publications using only their titles or other textual characteristics, or links to versions of the publication not covered by the altmetrics data aggregators, will be ignored.

26.6 Conceptualizing Applications of Social Media Metrics for Research Evaluation and Management

In this section we conceptualize some applications of social media metrics. Although most of our examples are taken from actual practices, the aim is to provide a perspective that could transcend current tools and databases. Thus, regardless of the future availability of the current tools, we consider that most conclusions would remain relevant, should similar tools (or variations of current tools) still be in place and accessible.

In order to provide a comprehensive conceptualization of applications of social media metrics, we need to discuss the main types of possible applications. In the field of bibliometrics, a differentiation has been made between *descriptive bibliometrics* and *evaluative bibliometrics* [26.69–71]. According to *Van Leeuwen* [26.71], descriptive bibliometrics are related to top-down approaches able to provide the *big picture*. This more descriptive notion of bibliometrics is also related to the contextual perspectives recently proposed in scientometrics [26.72]. We speak of evaluative bibliometrics if bibliometrics is used to assess the research performance of a unit of analysis (research teams, research organizations, etc.), often in a comparative framework. For example, different units can be compared in terms of citations or publications, or a unit can be compared with a specific benchmark (e. g., the average citation impact in the field(s), as is done for *field-normalized* indicators). The problem with the descriptive/evaluative dichotomy is that it is not always possible to clearly distinguish the two approaches. In practical terms, any bibliometric description can become an evaluative instrument. For example, the mere reporting of the number of publications of a university department may turn into an evaluative indicator if is compared to other departments (or a benchmark) and used, for example, to allocate resources.

Therefore, we propose that a distinction be made between *descriptive* and *comparative* approaches. As descriptive approaches, we consider those approaches that focus on the analysis and description of the activities, production and reception of scholarly objects for different units of analysis, together with the analysis of the dynamics and interactions among different actors and objects. As comparative approaches we consider those approaches that are (mainly) focused on the comparison of outputs, impacts and actors, often in the context of evaluation. Simply put, descriptive approaches are related to questions of *who*, *when*, *how* and *what*, while comparative approaches are concerned with questions of *fast(er)/slow(er)*, *high(er)/low(er)*, *strong(er)/weak(er)* or just *better/worse*. Of course, comparative approaches are by definition based on some form of descriptive input data. Both descriptive and comparative approaches can be used as tools in research evaluation, but they can also be used for other purposes (e. g., knowledge discovery).

Social media metrics have typically been discussed in light of their potential role as a replacement for citations for comparative and evaluative purposes [26.1]. Less research has focused on the potential value of social media metrics from a more descriptive perspective. In Table 26.1 we summarize a general framework of potential applications for social media metrics based on the descriptive/comparative dichotomy.

26.6.1 Descriptive Social Media Metrics

As shown in Table 26.1, descriptive approaches use basic analytical indicators such as total count summaries, trend analysis and thematic landscapes, as well as network approaches that consider the dynamics and interactions between different social media agents and scientific outputs. Similar to bibliometric indicators, descriptive indicators can be calculated with the objective of identifying general patterns in social media reception of scientific publications of a given unit. In Table 26.2 we present an example: basic descriptive indicators for three major data sets comprising publications from Africa, the European Union (EU28) and the United States (USA) covered in the Web of Science (WoS) for the period 2012–2014, and that have a DOI or PMID.

We would like to emphasize that certain elements must be taken into account when reporting social media metrics. It is important to disclose the total output analyzed (indicator *P* in Table 26.2). In our case, as we have worked with data collected from Altmetric.com (until June 2016), only publications with a DOI or a PMID have been tracked in this source. Thus, the data set is reduced to only publications with an identifier traceable by this data provider (indicator *P*(DOI/PMID) in Table 26.2).

In the second section of the table, we explore the total social media counts that are obtained for each of the sets of publications. Thus, TTS counts all the Twitter mentions (in this case combining both original tweets and retweets) for the publications. TBS is the total blog citation score, TNS is the total news media mentions score, TPDS is total policy document citations score and TWS is the total Wikipedia citations score. There are other indicators that also could have been calculated based on Altmetric.com, such as those based on Facebook, Google Plus or F1000Prime. For a discussion of other social media metrics, we refer here to *Costas* et al. [26.73].

In the third part of the table, we calculate the averages of the different scores per publication. Simply put, each of the total scores is divided by the number of publications that could be tracked (*P*(DOI/PMID)). Thus, we can talk about the mean Twitter score (MTS), for example, or the mean blog score (MBS). Obviously, the mean is not necessarily the only statistic we could have calculated. Other descriptive statistics such as median, mode or min–max values could have been obtained.

Finally, in the fourth section of the table, we present another possibility for basic social media metrics. Given the strong skewness of most altmetrics indicators [26.58, 74] as well as their sparsity [26.75], mean values can be strongly influenced by outliers (e. g., extremely highly tweeted publications), an issue that is not uncommon among this type of indicator [26.60]. In addition to the use of median- or percentile-based indicators to help mitigate the problem, indicators of the coverage of the publications with a given degree

Table 26.1 Conceptualization of descriptive and comparative *social media metrics* approaches

Descriptive social media metrics	Comparative social media metrics
• Descriptive social media indicators (nonnormalized), e. g.: – Total counts, coverage – Trend analyses • Social media metrics landscapes – Thematic landscapes – Geographic landscapes • Network approaches, e. g., communities of attention, Twitter coupling, hashtag coupling	• Normalized indicators, e. g.: – Mendeley field-normalized indicators – Percentile-based indicators (e. g., Altmetric Attention Score) • Social media-based *factors* (e. g., Twimpact factor, T-factor) • Composite social media indicators (e. g., RG Score, Altmetric Attention Score) • Comparative network indicators (e. g., relative centrality)

Table 26.2 Examples of basic descriptive altmetrics indicators for Web of Science publications (with a DOI or PMID) from Africa, EU28 and USA (2012–2014)

1) Output					
Unit	***P***	***P* (DOI/PMID)**			
Africa	125 764	104 008			
EU28	1 605 393	1 305 391			
USA	1 686 014	1 281 624			
2) Total counts					
Unit	**TTS**	**TBS**	**TNS**	**TPDS**	**TWS**
Africa	190 737	6126	11 291	886	2154
EU28	2 034 833	67 262	118 568	4153	23 126
USA	3 461 227	136 682	263 517	4964	32 647
3) Averages					
Unit	**MTS**	**MBS**	**MNS**	**MPDS**	**MWS**
Africa	1.83	0.06	0.11	0.01	0.02
EU28	1.56	0.05	0.09	0.00	0.02
USA	2.70	0.11	0.21	0.00	0.03
4) Coverage					
Unit	**PP(t1) (%)**	**PP(b1) (%)**	**PP(n1) (%)**	**PP(pd1) (%)**	**PP(w1) (%)**
Africa	27.0	2.7	2.1	0.6	1.2
EU28	28.5	2.7	2.3	0.2	1.2
USA	37.4	5.1	4.5	0.3	1.8

P: Total publications of the unit
P(DOI/PMID): No. of publications with a DOI or a PubMed ID
TTS: Total Twitter mentions score
TBS: Total blog citations score
TNS: Total news media mentions score
TPDS: Total policy document citations score
TWS: Total Wikipedia citations score
MTS: Mean Twitter mentions score
MBS: Mean blog citations score
MNS: Mean news media mentions score
MPDS: Mean policy document citations score
MWS: Mean Wikipedia citations score
PP(t1): Proportion of publications with at least one tweet mention
PP(b1): Proportion of publications with at least one blog citation
PP(n1): Proportion of publications with at least one news media mention
PP(pd1): Proportion of publications with at least one policy document citation
PP(w1): Proportion of publications with at least one Wikipedia citation

of metrics can be provided. In Table 26.2 we give the proportion of publications that have at least *one* mention in each of the metrics (i. e., one tweet, one blog citation, etc.). Thus, we can see that about 27% of African publications (with a DOI/PMID) have been tweeted at least once, while 5.1% of all US publications (with a DOI/PMID) have been cited at least once in blogs. The use of the at-least-*one*-mention option (represented by the value 1) coincides with the absolute coverage of publications in each of the social media sources. However, this value of 1 could have easily been changed by any other value (e. g., 2, 3, a particular percentile, the number of only original tweets (i. e., excluding retweets)). Moreover, coverage indicators can also be subjected to normalization (e. g., the equalized mean-based normalized proportion cited (EMNPC), as suggested by [26.75]); however, more complex indicators such as these introduce a more comparative nature, in which the coverage of units is compared to a global reference.

Trend Altmetrics Indicators

In addition to the basic indicators discussed above, it is possible to provide trend analysis (Fig. 26.2), giving social media time series data with properties that differ from bibliometric indicators. However, the data collected by most of the altmetrics data aggregators are very recent, and the application of trend analysis is therefore relatively limited. Moreover, uncertainties regarding methodological changes in social media data

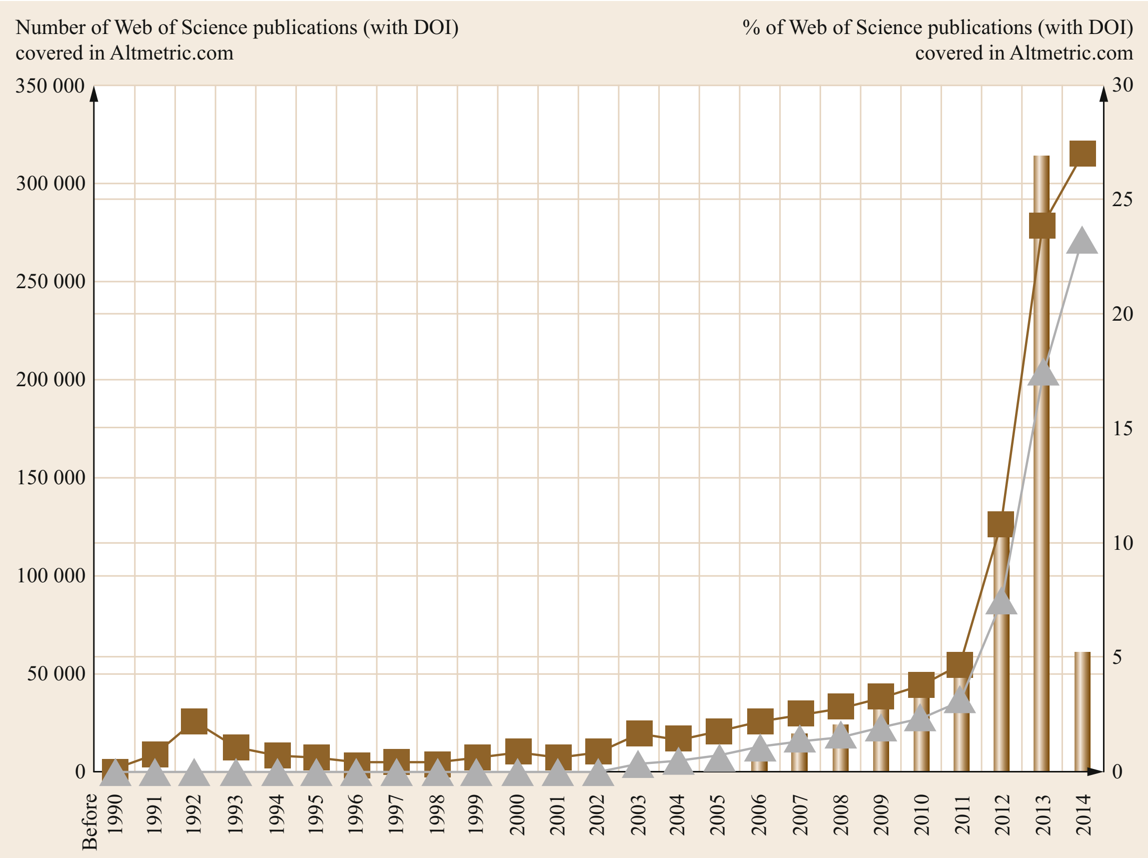

Fig. 26.2 Number and share of publications from Web of Science (DOI) with coverage in Altmetric.com, 1980–2013 (after [26.60], with permission from Wiley). Altmetric.com started their data collection in July 2011

collection warrant caution in the interpretation of trend analysis. For example, trend analyses may be influenced by improvements in the algorithms for identifying mentions of scientific publications by the altmetrics data aggregators, thus not reflecting genuine trends in the indicators themselves.

Although Mendeley data are conceptually close, albeit not identical, to citations, their time series properties are very different [26.55–57]. This can be seen in Fig. 26.3 below. In contrast to citations, which are generally higher (and never decrease) as time goes by, Mendeley readership values can decrease, as Mendeley users can delete publications from their libraries or fully erase their Mendeley profiles.

Longitudinal Analysis—Social Media Histories

Similar to citation analysis, in which it is possible to study the impact of scientific publications longitudinally over time (in so-called *citation histories* [26.76]), *social media* or *reception histories* are also possible. Examples are the analysis of the accumulation of Mendeley readership, blog citations or tweets over time for any set of publications. The time stamps of the tracked events are generally highly accurate (e. g., the exact time a tweet was sent, or when someone saved a document in her Mendeley library), thus enabling longitudinal trend analysis. However, the following problems challenge the development of longitudinal analysis of social media metrics:

- *The lack of openly available diachronic information*. In the case of Mendeley, concrete information on when the readership was produced is not available through their public API. This creates difficulties in both the calculation of longitudinal readership analysis and the potential determination of *readership windows* (e. g., variable or fixed windows could also be established, similar to citation windows [26.77]). This lack of diachronic information about Mendeley readership hinders the development of studies on the potential predictive power of early Mendeley readership for later cita-

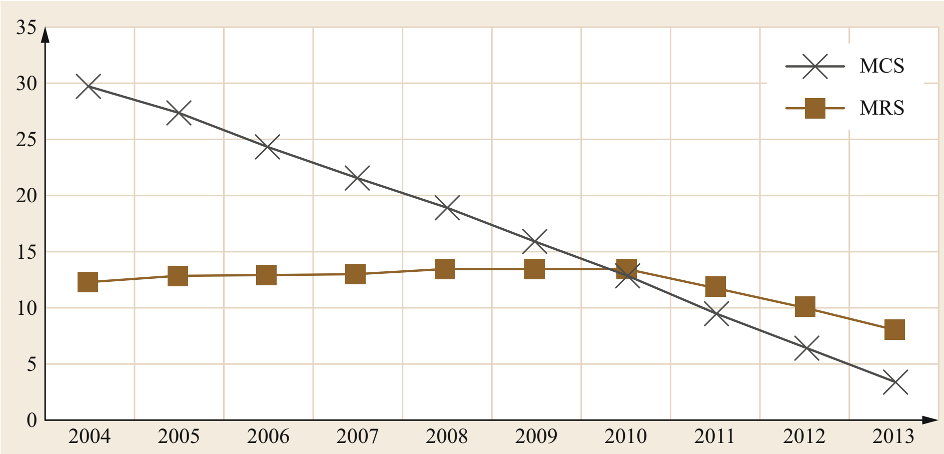

Fig. 26.3 Distributions of mean readership score (MRS) and mean citation score (MCS) indicators for the WoS publications over time (x axis shows the publication years and y axis shows the mean scores for citations and readership) (after [26.57], with permission from Wiley)

tions. A possible solution is the repeated tracking of readership counts for publications over time, as was done for example in [26.56, 78].

- *Indeterminate publication time of scientific outputs*. Although in bibliometrics the use of the publication year of scientific outputs is the most common approach for determining the starting moment of a publication, there are important inconsistencies in the publication dates of scientific articles [26.35]. This is caused by the gaps between the actual moment a publication becomes accessible to the public (e. g., through the *online first* option of many publishers, or through its publication in a repository) and the official publication in a scientific venue (e. g., journal, conference, book). These inconsistencies are even more challenging when working with social media metrics. Given that social media interactions usually take place earlier and faster than citations, accurate knowledge of the actual time that a publication became available to the public is critical to establishing accurate time windows for the analysis of the social media reception of publications.

Social Media Metrics Landscapes

The possibility of providing different types of analytical landscapes based on social media metrics is one of the most interesting types of descriptive approaches. Conceptually speaking, there are two general landscape typologies: thematic landscapes and geographic landscapes (the two can be combined).

Thematic Landscapes. In scientometric research, thematic classification is an important asset, enabling the analysis of the structure and dynamics of scientific disciplines [26.79]. In media research, the introduction of thematic perspectives is also important. Social media metrics (e. g., Twitter, Facebook) have a stronger presence among social sciences and medical and health sciences [26.46, 73]. Figure 26.4 gives an example of an advanced social media thematic landscape. It presents tweets to all African and EU28 countries' publications (same publications as discussed in Table 26.2) using a publication-level classification comprising more than 4000 *micro-fields* and described in [26.79]. This is the same classification scheme used for the field-normalization of citation indicators applied in the Leiden Ranking (http://www.leidenranking.com/information/indicators). The size of the nodes represents the African and EU28 outputs published in that particular micro-field, while the color represents the share of those publications that have received at least one tweet (this is the indicator PP(tw1) discussed in Table 26.2). The nodes (fields) are positioned on the map according to their direct citation relations using the VOSviewer clustering method as described in [26.79, 80], based on the overall Web of Science database (period 2000–2016).

In Fig. 26.4, some of the most important topics of both African and EU28 research can be seen on the left-hand side of the map, which is the part of the map that concentrates most health-related and social sciences topics. The differences between public and scientific interest in topics between Europe and Africa become visible on these maps. Twitter reception of Africa's output gives priority to HIV-related topics as well as diseases such as tuberculosis or malaria. Other topics with a strong presence on Twitter with African participation refer to the ATLAS collaboration and the Higgs boson research (right-hand side of the map). In EU28 countries, psychological issues (emotions, depression, bulimia), cancer and obesity are among the main topics with large scientific production and strong presence on Twitter [26.81].

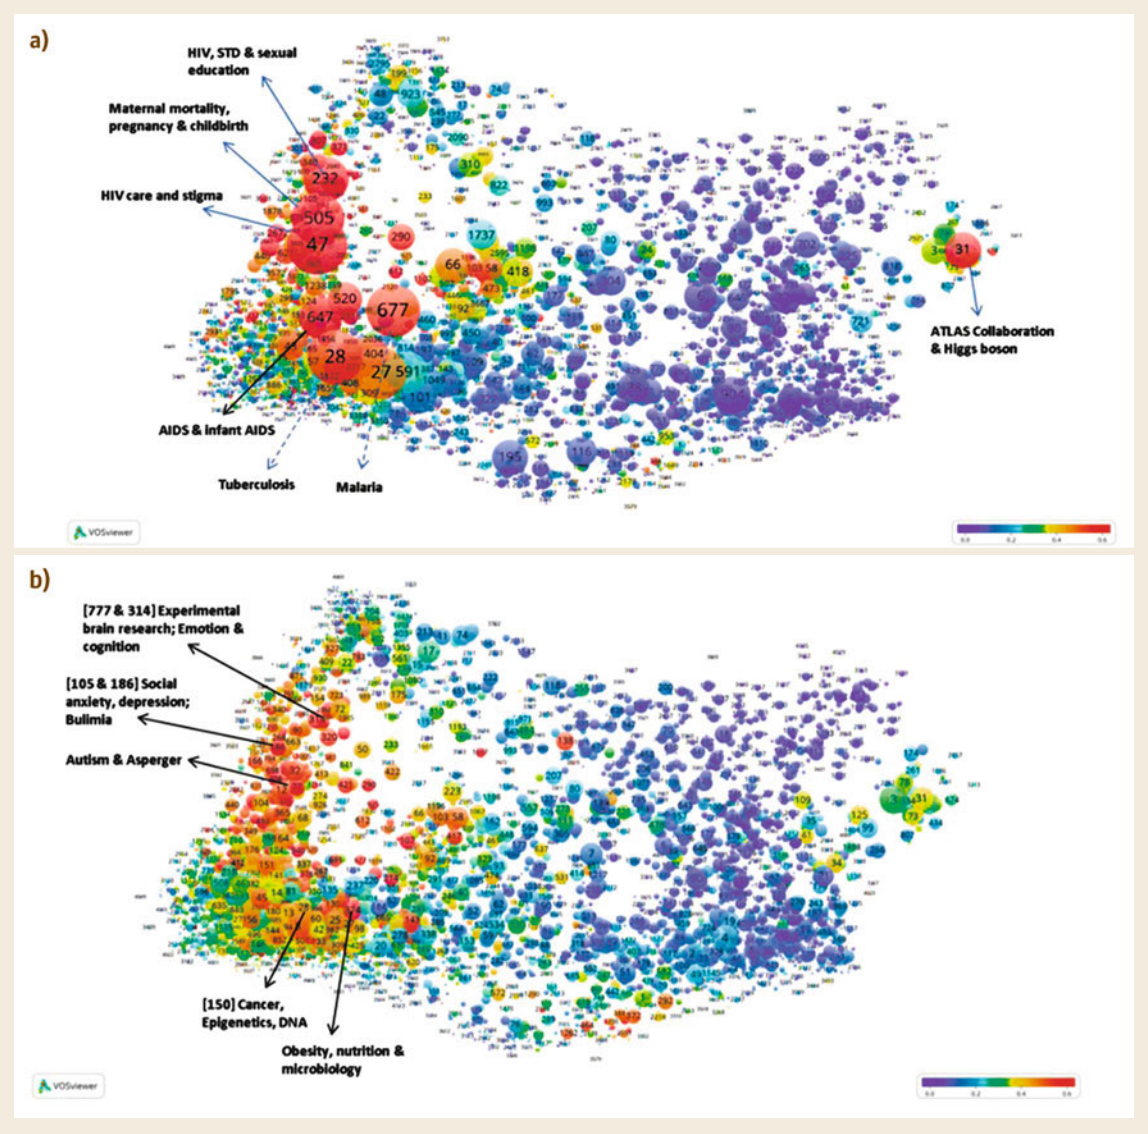

Fig. 26.4a,b Tweets thematic landscape of African publications **(a)** and EU28 publications **(b)**. Nodes represent fields (clusters of publications closely related by direct citation relations) and position on the map by the strength of their citation relations

Geographic Landscapes. In addition to thematic landscapes, it is possible to introduce a geographic dimension in the analysis of social media metrics. The geography can be determined by the geo-location of the entities reflected in the publications under analysis (e. g., authors, affiliations, funders, journals, or even the geography of the research itself, such as malaria in Africa researched by Dutch scholars). Alternatively, the geo-location of the different types of users who interact with the publications through the various social media platforms can serve as the basis for the landscapes. Thus, it is possible to study what the Mendeley users from South Africa read, or what publications are being tweeted from Nigeria. This particular type of analysis has two fundamental challenges: 1) the lack of disclosure of geographic information for all social media users (e. g., not all users in Mendeley, Facebook or Twitter disclose their geo-location), and 2) the variable granularity of available geographic information (e. g., not all users disclose their full geographical information; some provide only country-level information, while others also disclose region or location).

Figure 26.5 presents a world map showing the share of publications with at least one tweet (i. e., the PP(tw1) indicator as discussed in Table 26.2) across the countries of the authors. Red indicates higher PP(tw1) values, and blue indicates lower values.

As shown in Fig. 26.5, several African countries have a relatively high proportion of publications mentioned at least once on Twitter. Publications from Anglo-Saxon (e. g., USA, UK, Australia) and Northern European countries (e. g., the Netherlands, Denmark) are also tweeted frequently. The indicator PP(tw1) presented in Fig. 26.4 does not consider differences between fields, years or languages. Therefore, only the major patterns of the share of publications with some Twitter discussion can be extracted from it. However, the graph could also be obtained normalizing by fields, periods of time, or tweets from relevant tweeters (e. g., academic tweeters or tweeters from the same country as the authors of the papers).

Network-Based Indicators

The third type of descriptive social media metrics comprises network-based approaches. These are focused on analyzing the relationships and interactions among the different actors. These are the least developed, and more research will be necessary to fully grasp the possibilities of these analyses. In this section we will focus on just three basic examples of current applications:

1. The analysis of *communities of attention* [26.34]
2. *Hashtag coupling analysis* [26.82]
3. *Reading/reader pattern analysis* [26.83–86].

Communities of Attention. The analysis of *communities of attention* refers to the analysis of different communities of users active in social media platforms (e. g., tweeters, bloggers, Facebook users, etc.), and their interactions with scientific outputs or entities. This type of analysis goes beyond the analysis of *follower/followees* that many platforms allow, to include other types of interactions. Figure 26.6 presents the example of the Twitter community of attention for the set of African publications discussed in Table 26.2. In this network map tweeters are clustered together when they tweet the same publications, thus suggesting common scientific interests among them.

Figure 26.6 shows several clusters of Twitter users (communities) around African publications. Specifically, there is a strong user cluster (around @HIV_insight) with clear interest in HIV research, surrounded by other Twitter users related to AIDS research and sexual and medical topics. The yellow cluster

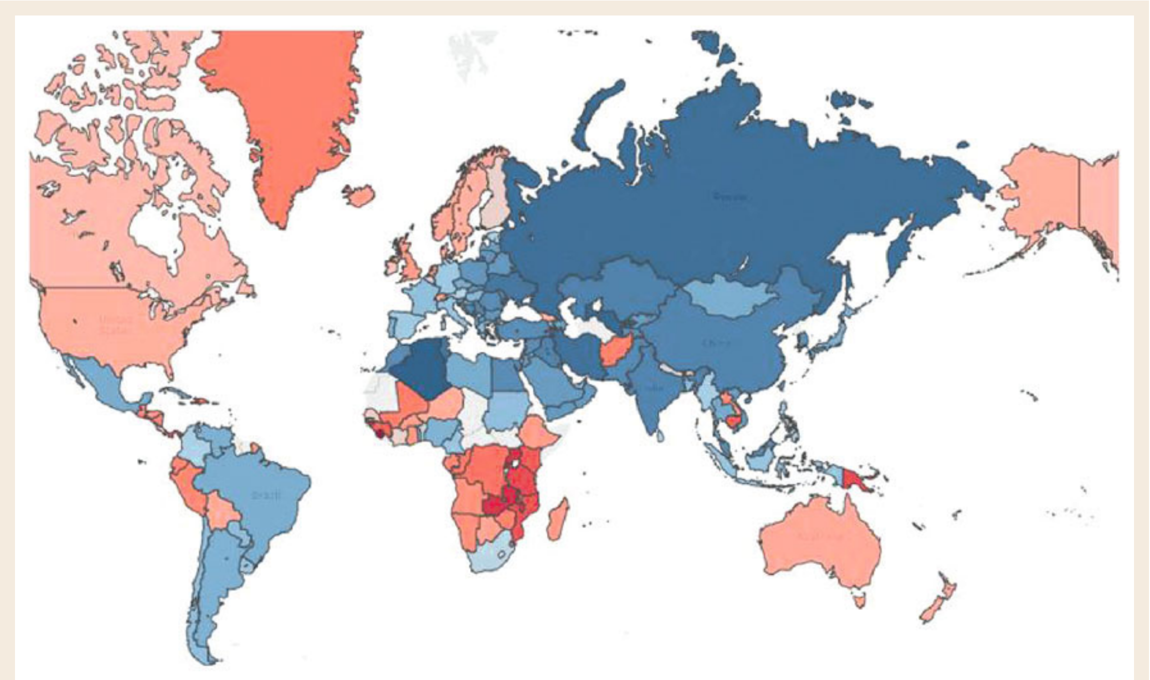

Fig. 26.5 Global map of the share of WoS publications (with a DOI/PMID, period 2012–2014) with at least one Twitter mention (PP(tw1)) across the countries of the authors. Threshold for *red*/*blue* differences is 34% (i. e., PP(tw1)< 34% *blue*, PP(tw1)≥ 34% *red*)

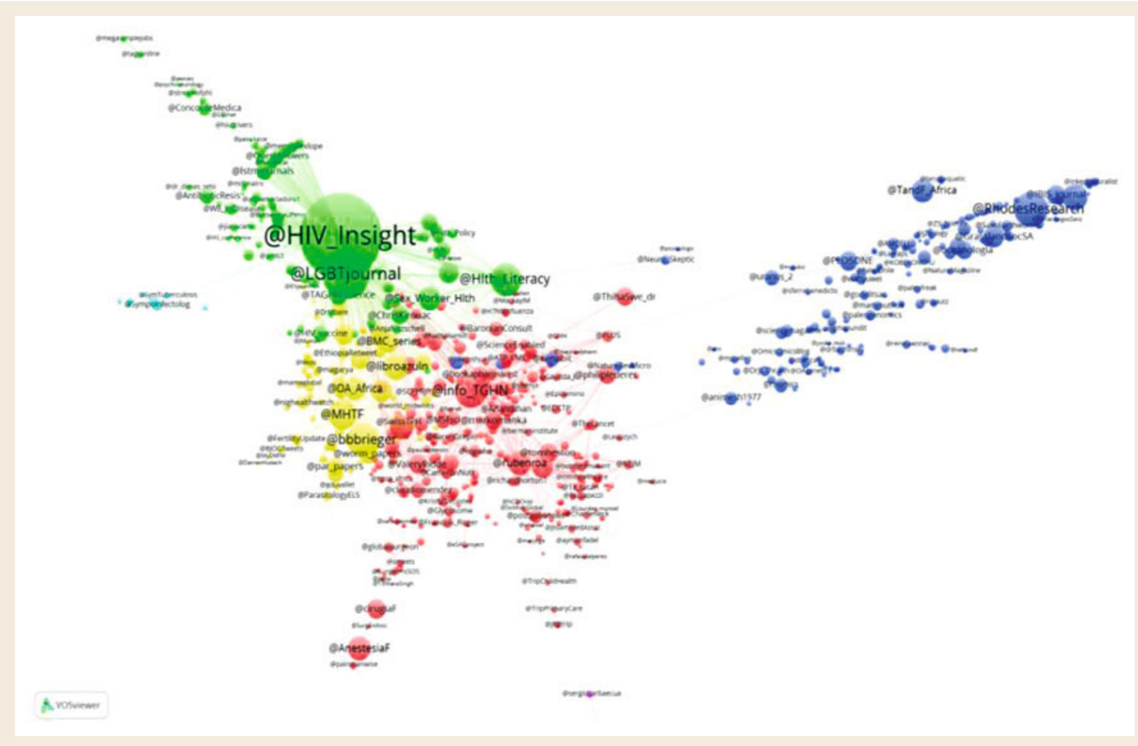

Fig. 26.6 Main Twitter community of attention map of African publications. Nodes are Twitter users; linkages/proximity of the nodes is determined by the number of common publications they have tweeted. Position of nodes in the map: VOSviewer clustering method

combines multiple users related to publishing issues. The dark blue cluster concentrates multiple users from a more multidisciplinary nature (e. g., the Twitter account of PLOS ONE). Conceptually speaking, this type of analysis does not need to be restricted to Twitter. It can be applied to any type of social media users (e. g., bloggers, Facebook users, Mendeley users).

Hashtag Coupling Analysis. This analysis is based on the *hashtag* affordance available on Twitter. Hashtags are used by Twitter users to link their tweets to broader *conversations*, expanding the potential exposure of their tweets to users beyond their original set of followers. When tweeters link the same set of publications to different hashtags, they are creating a network of related conversations. This type of analysis enables the study of the different existing conversations around scientific topics and can inform communication offices, students or researchers about specific hashtags related to their scientific topics or areas interest. It may also help scholars interested in disseminating important scientific results on Twitter to improve their communication strategy (e. g., by liking their tweets and publications to relevant hashtags). In Fig. 26.7, an example of Twitter hashtag coupling analysis is presented for the most frequent hashtags linked to scientific publications covered by Altmetric.com [26.82]. In the blue cluster it is possible to see how research linked to #prostatecancer or #oncology has also been linked to the broader hashtag #cancer. Similarly, #openaccess and #OA (green cluster) are coupled, as they are linked to a similar set of publications.

Reading/Reader Pattern Analysis. Data extracted from reference manager tools such as Mendeley or CiteULike have been used for knowledge domain detection or for finding common interests among their users [26.84, 87]. The idea is similar to cocitation [26.88, 89]. Those publications with high cooccurrence among different users' profiles are considered to be more similar in terms of their thematic subject [26.84]. The network of user groups in Mendeley saving the same set of publications showed that students and postdocs have more common topical interests than other user groups [26.83]. Others visualized readership activities and topics of interest among Mendeley users using the text mining functionality of VOSviewer, and

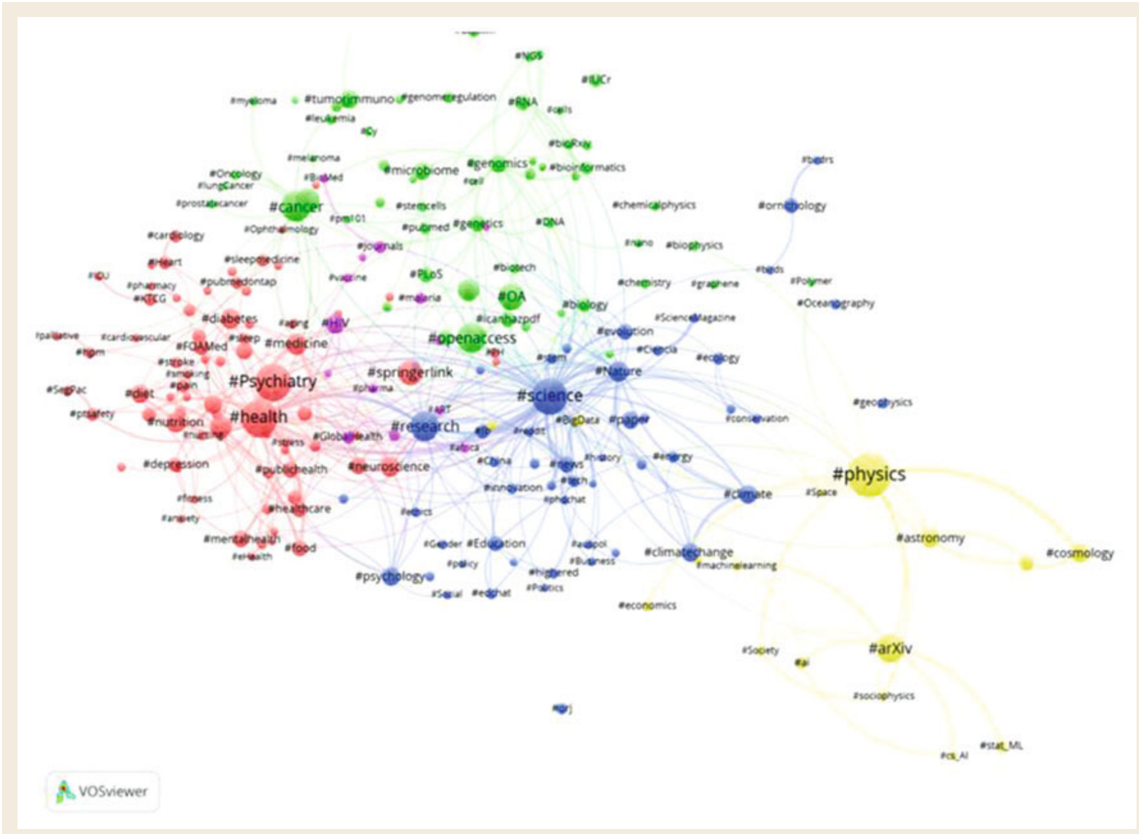

Fig. 26.7 Network map of the most common hashtags around publications mentioned in Twitter and covered by Altmetric.com (2012–2016). *Nodes*: hashtags linked to more than 2000 publications in Altmetric.com. *Colors*: VOSviewer clustering result. *Edges*: publications in common between hashtags. Location of nodes in the map: VOSviewer clustering method

showed disciplinary differences in readership activity and topical interests [26.85].

26.6.2 Comparative Indicators

As presented in Table 26.1, comparative approaches use advanced indicators incorporating normalization features, such as field-normalized Mendeley indicators [26.90] or percentile-based indicators (e. g., Altmetric.com). The use of social media metrics as an evaluative device is the most problematic, since evaluative analysis requires higher levels of precision, validity and reliability. Moreover, the measurable concepts underlying most social media metrics are not clear [26.10]. Social media metrics for evaluative purposes can be distinguished in two groups: those that are conceptually similar to citations or peer review judgments (e. g., Mendeley or F1000Prime recommendations), and those that are not (e. g., Twitter or Facebook mentions).

Social Media Metrics Similar to Citations or Peer Review

Indicators such as readership in online reference managers (e. g., Mendeley or Zotero) and post-publication peer review platforms (e. g., F1000Prime, PeerJ or PubMed Commons) are conceptually close to citations and peer review judgments. Mendeley is used mainly by academic users [26.31, 32, 91], often in a pre-citation context [26.2]. Thus, both readership and citations may capture dimensions of *scientific influence*. Readership and citations are moderately correlated [26.55, 63, 92–94], more than other social media metrics [26.60, 95]. This suggests the potential relevance of Mendeley readership indicators as surrogates for citation-based indicators. This stronger correlation has encouraged field normalization of these indicators similar to citation indicators [26.90, 96], thereby opening the door to their use in more evaluative contexts. However, although close, citation and readership are still different. As argued by *Costas* et al. [26.74], the existence of two related but different metrics competing to capture the same concept may create conflicts (e. g., when one of the indicators points to high performance and the other to low performance). Given the higher engagement of an author citing a document in contrast to a Mendeley user saving a document [26.2], it is reasonable to argue that a citation is more valuable than a Mendeley readership. However, as argued by *Costas* et al. [26.58, 74], readership counts in Mendeley may be more meaningful than perfunctory citations [26.54]. This suggests that if the counts in Mendeley would include more qualitative aspects (e. g., indications of the time spent by the users in a given publication, or whether the users have made comments, notes, highlighted passages, appraised the text, etc.), the readership counts might be more informative in an evaluation context [26.97].

Other indicators for evaluative contexts include F1000Prime recommendations of publications provided by high-level appointed *experts*. This is a form of post-peer review evaluation, and these indicators are potentially interesting for quality judgment. However, they have two disadvantages. The first is the low number of publications reviewed and recommended in these services [26.65, 98], and the second is the weak correlation between these indicators and citation indicators [26.62, 65, 99], suggesting that they are related but not interchangeable indicators.

Social Media Metrics Dissimilar to Citations or Peer Review

Social media metrics, unlike citations or peer review, are not clearly related to scientific performance. Nevertheless, despite this limitation, some of these indicators have been proposed for evaluation. Indicators based on the h-index formula have been suggested (e. g., T-factor, see [26.100]; T-index [26.101]), as well as indicators inspired by the impact factor (Twimpact factor [26.102]), implicitly suggesting some straightforward comparability among them. Social media metrics do not relate directly to *scientific performance* (i. e., scientific impact or quality), but they may be related to *societal impact* [26.103]. However, even the concept of societal impact is quite nebulous and not easy to grasp. As a result, the jury is still out on the question of whether social media metrics are useful for research evaluation purposes.

To be useful for evaluation, most social media metrics must be conceptualized beyond the traditional research evaluation approaches. Thus, social media metrics may be relevant for evaluating the social media engagement of universities [26.44] or the public understanding of or engagement with science of different social media communities. From a policymaker perspective, social media metrics may also be used to evaluate *scientific literacy* among social media communities.

26.7 Prospects for Social Media Metrics in Research Evaluation

In the previous sections, we discussed the main characteristics, issues and practical possibilities related to social media metrics for research evaluation and management. Most social media metrics do not currently have practical application in the more traditional research evaluation approaches (i. e., those that would typically be based on peer review or citation analysis), perhaps with the exception of Mendeley and F1000Prime reviews. Therefore, the potential relevance of these indicators as scientific evaluative devices is still uncertain.

In this section, we take a more prospective (reflexive) perspective, in which we try to discuss and conceptualize potential (alternative) evaluative applications of social media metrics based on a fundamental understanding of their social media nature. We introduce more innovative perspectives on how different social media metrics could be used for new forms of evaluation. For example, a research organization that wishes to increase its visibility on Twitter as a means of expanding its social media visibility among broader communities of attention may use indicators such as PP(tw1) and communities-of-attention analysis to assess the realization of such an aim.

26.7.1 Understanding the Nature of Social Media Metrics for Research Evaluation

Current research evaluation methods do not focus on communication by social media, and instead are focused on the scholarly dimensions (although they are usually biased toward journal publications). Based on this dichotomy, we can introduce a novel approach for consideration of social media metrics. This perspective is related to the *foci* of the indicators. The *foci* of the different social media metrics can be determined based either on the aims of the platform (e. g., Twitter, Facebook have a purely social media focus) or on the nature of the indicator that is produced (e. g., the number followers in ResearchGate is a social media indicator, while the number of citations provided in the same platform could be seen as a scholarly indicator). Thus, we distinguish social media metrics with a stronger *social media focus* from social media metrics with a stronger *scholarly focus*. As *social media focus*, we understand the orientation of the tools, platforms, data and indicators that capture the interactions, sharing and exchange of information, ideas, messages, news, objects, etc. among diverse (online) users, and not necessarily restricted to scholarly users. As *scholarly focus*, we refer to those tools, platforms, data and indicators that are more oriented toward the management, analysis and evaluation of scholarly objects, entities and activities. Thus bibliometrics, citations and peer review can be considered as fundamentally having a scholarly focus.

Figure 26.8 illustrates the different foci of the most important bibliometric and social media metrics arranged in four quadrants based on their scholarly or social media focus. In the bottom-right part of the figure, we find the evaluative bibliometric and peer review indicators (represented by the databases Scopus and WoS and peers evaluating papers) with a strong scholarly focus (and low social media focus). In the top-left quadrant we find the platforms with the strongest social media focus (e. g., Twitter, Facebook, LinkedIn or Stack Exchange Q&A). These tools allow for the interaction and exchange of information among their users, but none of them have a genuinely scholarly focus (although the realm of social media metrics would confine itself to the interaction between these tools and scholarly objects). They have the largest distance from the scholarly-focused indicators. The main reason for this distance lies in the open, multipurpose and heterogeneous character of these platforms. Anyone can create a profile on Twitter, Facebook or LinkedIn and tweet or mention a scientific publication. Acts derived from these platforms, as argued in *Haustein* et al. [26.2], are driven by norms substantially different from those implicated in the act of citing (or peer review of) a publication.

In the bottom-right quadrant, in addition to the traditional bibliometrics (e. g., based on Scopus or Web of Science) and peer review, we also find F1000Prime recommendations and Mendeley readerships [26.31, 32, 91, 104–106], both with a reasonably strong scholarly focus (both are used mostly by scholars and are about scholarly outputs), although they also have some social media focus (e. g., both are user-generated, and interactions among users and outputs are possible). Wikipedia citations, while different from those found in scholarly publications (in theory, any person can write citations in a Wikipedia entry, although with some supervision), can still be considered similar enough to scholarly citations to be included in this quadrant.

In the top-right quadrant are platforms that combine both a strong social media and scholarly focus, such as ResearchGate and Academia.edu. These platforms are multipurpose, and their indicators are quite varied.

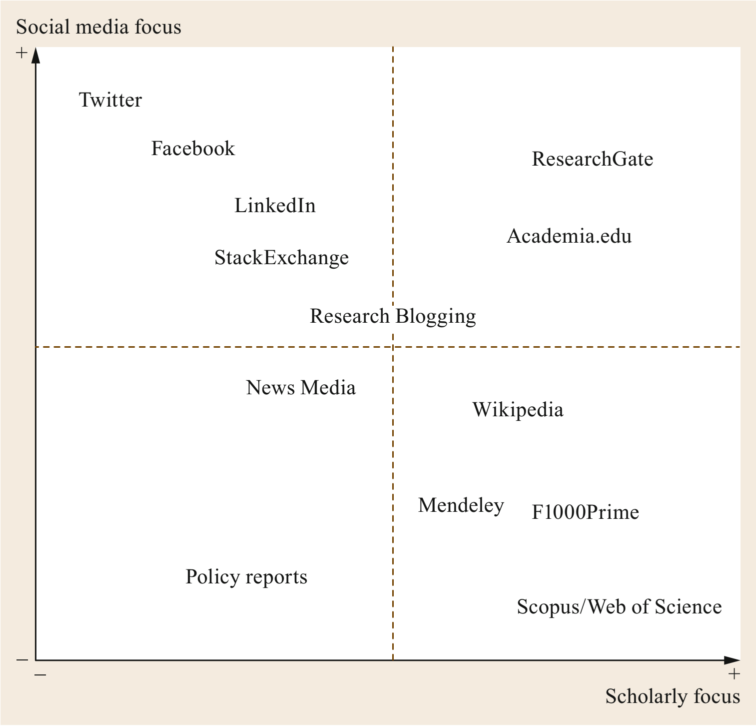

Fig. 26.8 Metrics characterized by their focus: social media or scholarly

These indicators can be grouped into those with a social media focus (e. g., the follower counts of scholars, number of endorsements, counts of Q&As on ResearchGate or the profile visits and mentions on Academia.edu) and those with a more scholarly focus (e. g., the counts of publications or citations, downloads and views on ResearchGate or Academia.edu). The RG Score combines elements from both these social media and scholarly foci into a single indicator, thus suggesting its potential unreliability.

In the bottom-left quadrant we find indicators that do not necessarily have either a social media or scholarly focus. An example is citations from policy documents (currently collected by Altmetric.com). Policy citations are of course relevant from several perspectives (e. g., policy impact, societal impact), but they are not created under the same norms as scholarly citations. Moreover, they do not have a social media focus (i. e., different types of users are not entitled to interact with the scholarly material discussed in the policy document). This calls into question whether policy document citations can be considered social media metrics at all.

In the center of the graph (Fig. 26.8) are mentions in blogs and news media. The central position of these indicators is explained by the fact that bloggers and science journalists could use scientific objects to support their arguments in their blog posts or news items and, as argued in *Haustein* et al. [26.2], could be driven by "similar *norms* as scholars", although not necessarily the same. Thus, these indicators would represent a bridge between the scholarly and social media foci.

26.7.2 Proposing Alternative Forms of Research Evaluation Based on Social Media Metrics

Based on the previous model, indicators with a stronger scholarly orientation would be more suitable for research evaluation (comparable to how citations and peer review are used). Thus, Mendeley readership and F1000Prime recommendations, and to some extent Wikipedia citations as well, could be seen as new tools for evaluating research [26.97]. As the social media focus of the indicators increases, one should consider how this would influence the evaluation (e. g., how nonacademic users in Mendeley could affect the indicators or how Wikipedia citations could be biased by nonacademic Wikipedia authors). Those social media metrics are more difficult to incorporate into the more traditional scholarly evaluations. However, social media metrics capture interactions between social media users and scientific objects. The relevance of social media activities is expanding in many walks of life, particularly in the dissemination of ideas, awareness and discussion of current issues, or sharing information, news and content. Many scholars, universities and scholarly organizations are mindful of their presence and image on these platforms. It is therefore not unreasonable to claim that the social media reception of scholarly objects can be seen as a nontrivial aspect of scientific communication. Monitoring the coverage, presence and reception of scientific objects on social media can then be seen as a novel element in research evaluation. The focus would not be on the scholarly impact or quality of the production of a research unit, but rather on the social media reception of its outputs.

New evaluations would include questions such as *How is the output of my university being discussed on Twitter? Are my publications visible among the relevant communities of attention? Do these communities engage with the publications? Is the social media reception and engagement of my output positive? Are the scholars of my unit active on social media? Do they contribute to disseminate their research and engage with broader communities to explain, expand or clarify their work? How are the social media communication strategies at the university working? etc.*

Table 26.3 Conceptualization of new social media metrics applications

Social media dimension	Example indicators (for a given research unit)
Coverage and presence of scholarly objects on social media	No. of publications mentioned on Twitter, Facebook etc. No. of scholars with a Twitter account Growth in % of publications mentioned on Twitter
Reception and attention on social media	No. of tweets to a given publication No. of tweets to a given publication with some degree of engagement No. of tweets to publications from highly followed tweeters
Engagement of social media users with scholarly objects	No. of tweets to a given publication containing comments, hashtags or remarks from the users
Communities of attention around scholarly objects	No. of tweeters tweeting the publications of the unit No. of highly followed tweeters tweeting the publications of the unit
Landscapes of social media attention around scholarly objects	No. of tweets to the outputs from the different fields of activity of the unit No. of tweets to outputs of the unit from social media users from different countries

Clearly, the questions above are new, and they may not be relevant for many research managers, but if social media matters, then social media metrics also matter. From this point of view, it is possible to conceptualize novel forms of research evaluation based on social media metrics. Table 26.3 summarizes (not exhaustively) some of the dimensions and indicators that can be considered in this social media evaluation of scientific objects of a given research unit.

26.8 Concluding Remarks

This chapter has brought together three different strands of literature:

1. The development of principles for good and responsible use of metrics in research assessments and post-publication evaluations
2. The technical literature on social media metrics and altmetrics
3. The literature about the conceptual meaning of social media metrics.

Thus, the chapter does not cover all forms of alternative research evaluations. For example, the increasing need for sustainable data infrastructure around data sets and the need to standardize the citation of data sets falls outside the scope of this chapter, although it is clearly of the utmost importance for the future of research evaluation. The need for data sharing and availability according to the findability, accessibility, interoperability and reusability (FAIR) principles requires a separate chapter. We have also not dealt with the interesting challenges that will be presented by the development of cloud computing in the context of research instruments and infrastructures for the conduct of research evaluations in the next decades. Nevertheless, by focusing on the novel measurement approaches that have developed as a result of the shift in research activities to the web, we hope the chapter has made clear how these data and indicators can be applied for practical purposes (and also how not to use them).

Our main proposal is to define the metrics formerly known as altmetrics primarily on the basis of their origin: as data and indicators of social media use, reception and impact in the context of academia. This both restricts and enables their use in research evaluations. Social media plays an important role in scientific and scholarly communication. It enables a faster distribution of data sets and preliminary results, and a greater level of access to formal research publications. It would therefore make sense to include this dimension of social media activity in research assessments whenever scientific communication is deemed relevant (of course this is not up to metrics experts to decide). We have sketched the outlines of such applications and have indicated the technical and conceptual challenges that need to be addressed.

Second, we propose to hold social media metrics accountable to the same principles of responsible metrics as are deemed valid for all performance metrics. As will be clear, although many social media indicators are easily available, they often fail with respect to transparency and openness. We find this ironic, given the original intent of social media metrics to open up the process of research evaluation.

A recent paper discussed the application of the 10 principles of the Leiden Manifesto for research metrics to social media metrics [26.107]. Like other metrics, social media metrics should only be used within the framework of *informed peer review*, and advanced normalized indicators are seen as preferred. The context of the research unit under evaluation should be taken into account. The use of altmetrics data should be transparent and freely accessible. As with traditional bibliometric indicators, false concreteness should be avoided. Systemic effects must be taken into consideration, and this may be more urgent for social media indicators since they are more easily gameable than citation indicators.

The currently developed principles for responsible metrics, therefore, do not need to be changed in order to be valid for social media metrics. But a large number of social media metrics seem to fail some of the principles, in particular, ironically, concerning the requirements of transparency, openness and manipulability. To address this, we may need a next-generation data infrastructure for social media metrics. Lastly, we propose discarding the term *altmetrics* and systematically starting to speak about specific *social media metrics* [26.34, 35], or even more generally, about *social media studies of science* [26.23, 81]. This then leaves sufficient space to develop new forms of indicators for scholarly objects (including publications, data sets and code, as well as scholars, scholarly organizations, etc.) and the use of research without conflating them with social media indicators.

Acknowledgments. The authors would like to thank Ludo Waltman for his critical comments on this chapter.

Rodrigo Costas is Senior Researcher at the Centre for Science and Technology Studies (CWTS) at Leiden University (the Netherlands). Rodrigo is also an Extraordinary Associate Professor at the Centre for Research on Evaluation, Science and Technology of Stellenbosch University (South Africa). He holds a PhD in Library and Information Science from the CSIC in Spain. His areas of expertise include the fields of information science, scientometrics, and social media metrics.

27. Reviewing, Indicating, and Counting Books for Modern Research Evaluation Systems

Alesia Zuccala, Nicolas Robinson-García

In this chapter, we focus on the specialists who have helped to improve the conditions for book assessments in research evaluation exercises, with empirically based data and insights supporting their greater integration. Our review highlights the research carried out by four types of expert communities—the *monitors*, the *subject classifiers*, the *indexers*, and the *indicator constructionists*. Many challenges lie ahead for scholars affiliated with these communities, particularly the latter three. By acknowledging their unique yet interrelated roles, we show where the greatest potential is for both quantitative and qualitative indicator advancements in book-inclusive evaluation systems.

27.1 Evaluating Scholarly Books

Since antiquity, books have evolved remarkably. The earliest *books* were first carved onto clay tablets, and then painted onto papyrus scrolls. In China they were cut into a woodblock, and later, the Europeans printed full manuscripts with ink on paper. Now we have electronic books, or e-books, available online for download. In light of these transformations, seminal volumes have also been written about the history of the printing press [27.1], book publishing [27.2], and book classification systems [27.3], including new perspectives on the book in the digital era [27.4]. There is much to learn from this history in order to review, indicate, and count books for modern research evaluation systems.

A valuable starting point is recognizing that books, tightly bound for centuries, are somewhat paradoxical: the information they contain can have the power to liberate. Books have been and continue to be change agents in society [27.1]. They change the way that humans think and feel, remind us of our triumphs and follies, and can start a debate or incite a revolution. Some books are lauded; others are not. Some have even been banned from public consumption. Yet, all because of Gutenberg's printing press [27.1, p. 520]:

> A new kind of collaborative venture in data collection [was] set in motion even before laboratory facilities were built, or new observational instruments had been invented. The shift from script to print helps to explain why old theories were found wanting and new ones devised even before telescopes, microscopes, and scientific societies appeared. Gutenberg's invention not only preceded Galileo's tube; it was a more versatile data aid and affected a wider range of data. Some professors shunned controversy and withheld treatises from the press just as some refused at first to look through the telescope. But none failed to consult printed reference guides or preferred to have to copy out tables by hand. Whatever views were held concerning Aristotle, Ptolemy or Galen, whatever objections were posed against using vernaculars or courting publicity; printed maps, charts, and diagrams found rapid acceptance from all.

With this level of acceptance comes great responsibility on the part of evaluators. Books, in essence, capture the efforts of scholars concerned with various types of human endeavors [27.5]. Yet, for many years, the

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_27

evaluation community has focused on journal articles rather than books. Since the 1960s, the journal article has taken precedence as "a written and published report describing original research results" [27.6, p. 8]. In this regard, books and book publishers lag behind, even though they

> stand at a crucial crossroads in the production and distribution of knowledge in any society. They are in a position to decide what is *in* and what is *out* of the marketplace of ideas. [27.7, p. 14]

In addition to the journal article, this means that the book needs to be delineated or more clearly defined. In the simplest of terms, *Williams* et al. [27.8] note that "what differentiates a book from a periodical or long report" is that it qualifies for and has an ISBN. *Basili* and *Lanzillo* suggest that an authored book, or monograph, may be defined as [27.9, p. 162]:

> The product of an intense but wide-ranging, systematic and unified research examination of an area of study. Each element contributes to forming the complex of the work, which could not be successfully communicated through the publication of separate parts.

The monograph's purpose is to present

> what the scholar concludes is the truth about some set of historical events, the characteristics of some work of art or literature, or the biography of a historical figure, an artist, or a writer. [27.10]

Hence, with a series of scholarly monographs we can piece together the story of a research discipline—i. e., how it has evolved in different regions, over a specific time period, and within a particular interpretive community [27.11].

In recent decades, the research evaluation community has questioned the value of the book. Adding to this problem has been the decline in sales of scholarly monographs since the 1980s [27.2], including a shift on the part of some researchers toward publishing more journal articles [27.12]. Surrounding such publication practices there has also been a lack of stable methods and indicators available to properly assess the monograph's value, impact, or influence. Still, research evidence indicates that authored books prevail, and will continue to prevail, because they hold meaning for certain research communities, distinct from those observed in journal literature [27.13–15].

To evaluate scholarly books and account for the influence they have had on their readership, a balancing act is required. On one hand, the evaluative process should respect all that an authored book represents in *qualitative* terms, both to the writer and to his/her audience. Book reviews help maintain this respect for quality, since the process of reviewing can be at the same time descriptive, appreciative, and critical. On the other hand, emergent digital tools are now inspiring researchers to devise new ways of assigning symbolic forms of credit to them en masse. Google, for example, wants all books around the world to "stand up and be counted" [27.16]. Clarivate Analytics' decree has been less direct, though critics of the expanding commercial Book Citation Index℠ have much to say about the opportunities and limitations associated with "putting books back into the library" [27.17, 18].

In this chapter, we review some of the approaches taken thus far to evaluate books both qualitatively and quantitatively. Our focus is on the cluster of information specialists without whom the practice of research evaluation would not prosper:

1. *The monitors*
2. *The subject classifiers*
3. *The indexers*
4. *The indicator constructionists*.

This work also provides suggestions for future evaluation systems dedicated to safeguarding book-oriented research fields, so that they can continue to develop progressively. As with any guide for evaluation, the "crucial issue at stake is not whether scholars' practices change", but that the application of any specific tool of measurement "enhances research performance and scholarly progress in general" [27.19, p. 578].

27.2 The Monitors

A monitor may be described as someone who observes, keeps track of, or surveys the progress or quality of something over time. In this sense, many researchers have played monitoring roles for wider aspects of the research evaluation systems and for books as well. There is a need for monitors because they show us what is possible to evaluate, where data/information is lacking, and what could be improved upon in the future. While monitors often detect the potential for qualitative or quantitative indicators, they usually do not focus on developing them fully for formal use. They are the historical benefactors of our current system, having brought us to where we are today with the evaluation of books and book-oriented research fields.

Long before the creation of commercial book indexes—i. e., Clarivate Analytics' Book Citation Index℠ and Elsevier's Scopus—researchers were less interested in metrics for books, and focused more on the uses (or misuses) of published book reviews [27.20]. For librarians in particular, the book review was and still is considered a valuable aid for building book collections [27.21–23]. Within many library communities it has therefore become essential to study the review culture as a unique form of discourse, and to consider the merits of applying standards for reviewing [27.24–27]. However, with scholars also reading and making use of book reviews [27.28, 29], researchers further recognize that even though a review is not an original work, it can still transfer useful information and ideas. For instance, there is an expectation that a review based on a book published in history will appear in a history journal, but a review could be written about the same book and be published in a political science journal as well. *Lindholm-Romatschuk* [27.30] explains this transfer in terms of "intradisciplinary and interdisciplinary information flows" [27.30, p. 86].

Another critical stage in book-based evaluations took place in the 1970s, when researchers began to dissect book reviews using different methods of content analysis [27.31–34]. Most of this early work had to be done manually, using data sets of approximately 1000–2000 reviews. Although researchers today have better technologies for working with data, the first content-based studies marked the beginning of a positive trend toward an "informed sociology of the review process" [27.35, p. 114].

The research of *Champion* and *Morris* [27.32] and of *Bilhartz* [27.31] highlights the degree to which specific time periods have had an effect on review discourse. While book reviews of the 1960s tended to be *gentlemanly* and mostly favorable, those published in the late 1970s and 1980s, specifically for the field of history, increasingly devoted more space to "critiquing rather than simply summarizing a book's content" [27.31, p. 527]. *Bilhartz* [27.31] found specifically that reviewers of the 1970s "took a strong interest in originality of method". However, "more than in any previous decade", reviewers of the 1980s "expect[ed] histories to have a sharply focused and well-analyzed thesis" [27.31, pp. 527–528]. *Snizek* and *Fuhrman* [27.35] consequently hypothesized and later found that favorability in a published book review was significantly and positively correlated with both the age and experience of the reviewer.

Gradually, the monitoring phase shifted when information scientists decided to test quantitative techniques for assessing books. *Eugene Garfield* [27.36], creator of the first Science Citation Index, suggested that the creation of a book index would support the *biblio* or book-oriented side of *biblio*-metrics, but, in the absence of this tool, researchers turned to journal indexes in order to analyze book publication, citation, and book review counts [27.37–41]. Some scholars were working with books as distinct study objects [27.42, 43], while others wanted to give more credit to the book as the principal form of publication across the humanities and/or social sciences [27.44–46].

With this preliminary stage of book-oriented metrics came the notion that both the humanities and social sciences were at risk of being poorly represented and unfairly assessed [27.47]. What some of the first *biblio*-metricians did, essentially, was to bring to light critical questions about how to assess the social sciences and humanities, primarily because they can be more theory-oriented, and progress more slowly than the sciences [27.48]. Emphasis was placed on scholars from certain disciplines who might be sharing information using media other than journals (i. e., books!), or contributing to local outlets, including those directed to a non-scholar public [27.38, 49]. This led to a significant debate concerning the development and use of alternative databases, like Google Books [27.50], or relying more seriously on the open access movement and institutional repositories [27.51–54].

Today, the evaluation community can turn to the Book Citation Index℠, and researchers also have the possibility of assessing publication and citation counts for books using the Elsevier Scopus database. But commercial databases of this nature are a type of *library*, and as researchers subscribe to or become patrons of these unique digital *libraries*, it will be increasingly necessary for them to understand how books are categorized and indexed. This cannot be taken for granted, and in fact with the first Science Citation Index, it was also a primary issue.

27.3 The Subject Classifiers

When *Eugene Garfield* [27.55] first conceived of *a new dimension in documentation through the association of ideas* (i. e., the Science Citation Index), he reflected on the following [27.55, p. 108]:

> If one considers the book as the macro unit of thought and the periodical article the micro unit of thought, then the citation index in some respects deals in the submicro or molecular unit of thought. It is here that most indexes are inadequate, because the scientist is quite often concerned with a particular idea rather than with a complete concept. *Thought* indexes can be extremely useful if they are properly conceived and developed.... One of the basic difficulties is to build subject indexes that can anticipate the infinite number of possible approaches the scientist may require.

Clearly, subject areas of *thought* were foremost in Garfield's mind, and like the indexes created for journals, subject-based catalogs for books were developed primarily for retrieval purposes. Unlike journals, subject classifications have not yet been used in the development of metric evaluations. However, early monitoring pertaining to book publication and citation counts suggests that a book citation index might indeed be used for this purpose. It is therefore useful to compare subject classes/categories designed for journals with those conceived for books, although a history of the latter is older.

Throughout the 16th and 17th centuries, books held in traditional library stacks were not open to the general public, and were available only to special users. Once opened, it became important to position books on the shelves so that patrons could locate them in relative terms. Melville Dewey, inventor of the *Dewey Decimal Classification System*, recognized that books could be grouped together on the basis of similar topics. In 1876, he published the first classification and subject index for books and pamphlets. Several editions of his classification system were published in both English and French (i. e., the French *Classification Decimal*), including an abridged edition, a library edition, and a bibliographic edition, which later became known as the *Universal Decimal Classification*.

After Dewey's death in 1931, the editorship of his classification volumes fell to the Library of Congress. By the time the 16th and 17th editions were published, Dewey's system had been widely adopted by general libraries, but a new Library of Congress Classification (LCC) had also been devised for larger, research-oriented libraries. Both the Dewey Decimal Classification System (DDC) and the Library of Congress Classification (LCC) system possess comparable subject codes and descriptors [27.56]. The LCC, however, adds an extra Cutter number (a Cutter number refers to the system developed by Charles Ammi Cutter, who invented the *Cutter Expansive Classification System*), which is used to represent a book's author, title, or organization name. While the DDC and LCC are the predominant systems for classifying books in the United States, other libraries around the world also use them. In countries that do not use a Latin alphabet, alternative systems have been created, such as the Book Classification for Chinese Libraries (BCCL) in China and the Library-Bibliographical Classification (LBC) in Russia.

Classification systems for journals also support the retrieval of journals and articles based on fields/subjects, but they are used for evaluation purposes as well. It is in this realm that classification approaches matter greatly: "reference standards obtained from questionable subject assignment might result in misleading conclusions" [27.57, p. 357]. According to *Glänzel* and *Schubert* [27.57], classifications may be produced at different levels of scholarly communication. One may take a cognitive approach, a pragmatic approach, or a scientometric approach. Both the pragmatic and scientometric approaches relate primarily to bibliometric practices, with the first related to journals and the second, individual papers. Commercial journal citation indexes currently use pragmatic subject codes for journals, and typically each subject area is also linked to observed citation patterns. Indexers who monitor these patterns may assign journals to more than one subject category or code (e. g., in Scopus, *The New England Quarterly—A Historical Review of New England Life and Letters* belongs to the history All Science Journal Classification (ASJC) code 1202 and the literature code 1208).

When comparing journals to books, classification systems like the DDC and LCC also produce a code, each approximately 6–10 digits in length. For example, the LCC number for the book titled *Uncensored War: The Media and Vietnam* is DS559.46.H35 1986. Here, the pragmatic approach to classification is also retrieval-based, but it is further subject to *literary warrant*: an LCC can only be produced on the basis of what the classified literature and controlled vocabulary of that time warrant [27.58, 59]. The first two lines, separated by a decimal, refer to the subject of the book. The third line represents the name of the author, and the last line is the book's publication date. When the library patron finds this call number in a catalog, he or she can go to a section of the library and locate the exact book.

Replicas of the same book may be on the shelf, including others related to the same topic, but the book does not appear in two different shelf locations (e. g., the history and the political science shelving areas), even if it contains information pertaining to both subjects. In sum, books differ from journals because they are normally fixed to one subject class or category.

Fast-forward to the digital age and the new Book Citation Index℠, and it is still unclear what Clarivate Analytics means by *putting books back into the library*. How will this new digital *library* contribute to an evaluation context? More specifically, how can traditional subject classification systems for books, like the DDC and LCC, support *metric* evaluations? At present, none of the traditional book classification schemes have been incorporated into the Book Citation Index℠. Instead, one finds categories and keywords, which have yet to be fully explained. For example, one can look for the book *Epicureans and Atheists in France, 1650–1729* [27.60] in a traditional library catalog, and the classification will be either an LCC B573.K67 2016 or DDC 194–dc23 (see http://lccn.loc.gov/2016008144). In the Book Citation Index℠, this same title is simply classified under the following key terms: `history`; `philosophy`; `religion`.

The level of granularity afforded by classifications such as the LCC and DDC is thus overlooked and may be problematic for book metrics, given what we know for journals. The classification of journals by field/subject is considered "one of the basic preconditions of valid scientometric analyses" [27.57, p. 357]. Journal categories are used, for example, to map the structure of science [27.61, 62], to normalize impact factor values, and to aid in the calculation of impact factor windows [27.63–65]. So far, little research has been done to reflect the role of subject classifications as a precondition for book or *biblio*-metrics [27.66–68]. This is in part due to the current structure of the Book Citation Index℠. A solution is needed, particularly for the social sciences and humanities, since these fields are more strongly represented in this index than in any other databases of the Web of Science [27.18, 66].

To circumvent the classification problem, at least two approaches have been employed. The first, devised by *Glänzel* et al. [27.67], was to match the current Web of Science classification scheme to 74 subfields from the modified Leuven-Budapest classification scheme. With this combined classification approach, clear differences were found for the citation impacts of humanities books versus those of journals in the same field. Another method involves the use of an application programming interface (API) to match titles of cited books retrieved from Scopus to the same titles recorded in the OCLC-WorldCat union catalog [27.68, 69]. Following this matching process, *Zuccala* and *White* [27.68] were thus able to classify a selection of titles from Scopus history journals (published in 1996–2000 and 2007–2011) according to their respective DDC classes.

27.4 The Indexers

While a subject classification system is essential to both the retrieval and evaluation of books, a metadata framework designed to catalog them is also needed. We separate the indexers from the subject classifiers because the decisions that these specialists make with regard to metadata also affect the practice of *biblio*-metrics, but in a different way. In short, the data that can be analyzed is only as good as how accurately it has been indexed; hence the process of indexing thousands of books in the Book Citation Index℠ has become both a research topic and a subject for serious scrutiny [27.18, 70, 71].

Not long after the Book Citation Index℠ was launched, *Gorraiz* et al. [27.18] performed some test analyses and found that "out of the almost 30 000 *books* retrieved [for] the publication period 2005–2011, only about 1100 provide[d] author affiliations" [27.18, pp. 1390–1392]. In addition to missing address information, the researchers noticed that the term `book` as a registered document type had the potential to be confusing, especially if edited books were not carefully delineated from the whole book content of monographs. In cases where there was no clear delineation, there was further potential for false interpretations: for example,

> selecting *books* as document type and sorting the results by most cited... present[ed] a list of the most cited books as a whole, but disregard[ed] all the citations to single chapters.... Similarly, sorting *book chapters* by times cited omit[ted] whole-book citations. [27.18, p. 1392]

Index-focused research also suggests that there can be a problem with underrating or overrating the citation impact monographs if individual chapters from specific monographs are counted separately [27.70].

In comparison to journal articles, monographs are difficult to index because they typically belong to bibliographic families [27.71]. Unlike journal articles, they can be revised and reprinted as new editions. In the past, many book catalogs have benefited from guidelines such as the Functional Requirements for Bibliographic Records (FRBR) [27.72, 73]; hence *Zuccala* et al. [27.71] suggest that the Book Citation Index℠ can benefit as well. With *Tillet*'s [27.72, 73] conception of the FRBR model, every monograph in a bibliographic family is a physical entity or *manifestation*, with its own International Standard Book Number (ISBN). If several different *manifestations* share the same intellectual properties, they are *expressions* (editions), and together all derivative *expressions* (editions) relate to one *work* [27.71]. A *work* is therefore the progenitor for a bibliographic family—the starting point for all ideational and semantic content [27.74]. Any new *expression*, or edition, of a monograph that deviates significantly from the progenitor is called a new *work*.

The Book Citation Index℠ might potentially be revised to follow FRBR, so that every *expression*, or edition, of a monograph is indexed according to its full set of manifestations (i. e., all ISBNs per physical type), its own unique *expression* identifier, and its shared *work* identifier. For each manifestation of a particular book there is, however, a specific problem to consider. Books, unlike journal articles, do not have their own unique Digital Object Indicators (DOIs). Currently, the ISBN is the most frequently used identifier for retrieving and matching identical book titles recorded in different databases [27.69, 75]. It is important, however, to recognize that (a) ISBNs do need to be registered, as this gives a clear idea of how many times a book has been reprinted, and (b) publication and citation counts should not be calculated at the level of the ISBN, as this does not correspond to the intellectual content of a work, but rather its physical container. With a proposed FRBR-guided version of the Book Citation Index℠, all ISBNs per book would be present, but the addition of new identifiers means that bibliometricians might have more accurate options for counting books at either the *expression* level or the *work* level. *Zuccala* et al. explain why this matters [27.76, p. 156]:

> The value in calculating indicators at different bibliographic levels is that it can help to identify whether or not a specific expression or edition of a monograph is receiving more attention than the work as a whole. For instance, one specific expression of a work may be cataloged in libraries, used, referred to, or reviewed more frequently than another. This could be the literal translation of a non-English edition of a work to English, with the new English-language edition potentially having a wider appeal. For some types of translated works, in fact, an author might even have more than one metric profile.

27.5 The Indicator Constructionists

Indicator constructionists are researchers who develop indicators for use in quantitative research evaluation systems. This group of experts differs from the monitors because they are less intent on describing approaches to *biblio*-metrics and more committed to identifying and promoting real methodological solutions. Progress in this regard has been greatly aided by technological advancements and the emergence of new data sources, for example, the Book Citation Index℠, the Scopus index of books, Google Books, Google Scholar, OCLC-WorldCat, Goodreads, Amazon Reviews, and national academic repositories [27.68, 77–79].

The process of evaluating books depends, however, on more than just data. When a particular data source is used to advance an indicator, advocates of that indicator need to reflect to some degree on a theory [27.80, 81]. According to *Zuccala* [27.81], the main task of the humanistic *biblio*-metrician, or book evaluation specialist, is not to simply "expand his/her metric toolkit, but to first examine the term *indicator*" [27.81, p. 159]. *Gingras* [27.80] upholds this notion by explaining that if an indicator serves as a proxy for a concept, it must be closely aligned with the concept or object that it is designed to measure. The primary, ongoing difficulty is that "the reality behind the concept [might] change over time and/or place" [27.80, p. 113]). In *Van der Weel*'s *Changing out textual minds*, we are reminded of this fact for books [27.4, p. 2]:

> Digitisation of textual transmission is proceeding so rapidly that already the consequences are huge and all-encompassing, indeed revolutionary. As reading practices move on line the once discrete products of the print world all become part of the digital textual *docuverse*, and that docuverse in turn becomes part of the all-digital array of mediums converged on the WorldWide Web.

Will bibliometric evaluations manage to keep up with this revolution?

In terms of data and theory, the research community thus far has taken two paths toward developing book indicators. One route has been to focus on the traditional citation—e. g., extracting citations to books as non-sourced items in commercial indexes [27.43, 82, 83]. The other has been to avoid the citation and focus on book reviews [27.78, 84], publisher quality, and specialization [27.85, 86], and library holding counts [27.87, 88].

27.5.1 Citations

In principle, a new data source like the Book Citation Index℠ could seem like the perfect solution for developing indicators for books. Still, there are certain factors to take into account. Research has shown that citation patterns for books differ from those of journal articles [27.15, 85, 89], and that in comparison to journal articles, the citation age for books is longer [27.67]. The role that a book plays within a particular scholarly communication system also differs depending on the discipline under study [27.50]. And even within different disciplines, there can be citation effects related to book types [27.90, 91], language and internationalization [27.92], and variations in authorship patterns [27.93].

With the Book Citation Index℠, the drawbacks to developing new indicators rest with the selection bias of monographs published in the English language, a high concentration of books printed by large publishers, and unclear distinctions between different editions and translations of the same monograph [27.76, 85]. There is, however, at least one benefit to this index, in that it enables large-scale comparative analyses of citation distributions for both monographs and journal articles [27.67, 94].

In 2004, Google launched two revolutionary services: Google Books and Google Scholar. Both services not only offer quick and easy access to scientific literature, but also give researchers an opportunity to engage in full-text searching. This in turn enhances the ability to capture citations from a great variety of research sources. The downside to these platforms is that mechanisms by which researchers can identify citations often produce false positives and prevent opportunities for large-scale analyses [27.50]. Thus, when using Google Books or Google Scholar, researchers suggest that it may be wise to use citation data only as a complement to peer review [27.95].

Citations have been used outside the scholarly communication system to assess the non-scientific impact of research where scholarship may be targeting a non-scholarly public, intentionally or not. For instance, citations from Wikipedia, which are now part of the set of indicators offered by the platform Altmetric.com, have been suggested as a means to capture extra evidence of impact [27.96]. The issue of scarce counts, however, makes the *Wiki-cite* unreliable for use in a real research assessment exercise. There are also many syllabuses and teaching materials that include citations to research, which means that books may be further measured in terms of their educational impact [27.79]. Since correlations between educational-based and research-based citations tend to be low, educational impact is arguably a different type of measure, warranting further investigation on its own.

27.5.2 Publisher Prestige or Quality

With the study of books, an analogy may be drawn between journals and publishers. However, unlike measures for journals—i. e., the journal impact factor (JIF) [27.97], the source normalized impact per paper (SNIP) [27.98], and the SCImago Journal Rank (SJR) [27.99]—there is currently no similar impact-based quantitative indicator for books. The main focus, therefore, has been to assess publisher prestige or quality instead of impact, and to direct this toward expert (scholars') opinions rather than citations [27.100, 101]. Proponents of this research area argue that citation data does not accurately capture the impact of books, and that this is particularly the case in many humanities disciplines, where the goal is not to create impact per se, but to influence further academic thinking and/or debate [27.102]. The expert-oriented approach is or has largely been inspired by the work of *Nederhof* et al. [27.103], who first studied publisher quality within the field of linguistics. In this study, scholars from the Netherlands, Flanders, and worldwide were invited to participate in a survey. With the results, *Nederhof* et al. [27.103] were able to differentiate among the three populations and gain insight into the locality of prestige, language biases, and disciplinary differences—all issues considered to be highly relevant within the social sciences and humanities [27.44].

As a result, we have seen at least one indicator that has been developed and proposed for the evaluation of book publisher *quality* and *prestige*. In the research by *Giménez-Toledo* et al. [27.101], 14 questions were sent to various academics/scientists from different research fields as part of a survey that was structured in three blocks:

1. Profile of the respondent
2. Evaluation of the quality of a publisher with scientific publications
3. Evaluation of the publishing process of a publishing house with scientific publications [27.101, p. 67].

Following the survey, the data were used to calculate what the authors term an "*Indicator of Quality* *for Publishers according to Experts (ICEE)*" [27.101, p. 68].

Not all scholars agree with the focus on publishers in the development of book metrics. *Verleysen* and *Engels* [27.104] indicate, for instance, that publishing houses are not the most suitable level of aggregation, and argue that it is impractical to perform a *quality analysis* for each and every book title after it has been published. As a compromise, they suggest creating a label for peer-reviewed monographs so as to ensure that researchers and evaluators know that a certain level of formal quality has been ascertained prior to publication. In this way, greater emphasis is placed on the precondition for book quality rather than a metric analysis of quality ex post facto—a point which continues to be under international discussion [27.100].

Yet another area of interest has been the study of publisher specialization [27.101, 105, 106]. To understand specialization, one approach has been to take a specific unit of analysis, such as the book chapter, and develop mapping techniques designed to visualize their disciplinary profiles [27.107]. Network maps, which follow directed citations to books from journals, have also been used to identify the specialization of both commercial and university presses [27.86]. In the research of *Mañana-Rodríguez* and *Gimenez-Toledo* [27.105], the tension between publisher specialization and multidisciplinarity has been measured using what the authors call an "entropy-based indicator" [27.105, p. 19]. When a publisher publishes books in fewer fields, its specialization increases, whereas its multidisciplinary profile may also increase if there is unevenness in its distribution of titles across different fields.

To date, only a few publisher rankings have been produced, and only for certain research fields [27.86, 108]. Within a specific time frame, a ranking of publishers may be calculated on the basis of their overall citations received or average citations per book [27.86]. However, if a ranking is based on citations, typically the most powerful English-language publishing houses are listed. This is because a large majority of publishing houses tend to have high rates of un-citedness [27.89]. Citations only reveal a small portion of what is happening in the publishing industry. A careful ranking procedure must therefore consider the fact that every publishing house or press differs in terms of economic capital, symbolic capital, and geographical reach [27.2, 86].

27.5.3 Book Reviews

According to *Lindholm-Romantschuk* [27.30], the difficulty attached to finding an appropriate quantitative indicator for assessing book quality is that processes of formal assessment are and already have been taking place. For many years, "the evaluation of scholarly monographs [has been] contained within the system of academic reviewing" [27.30, p. 36]. Book reviews still play an important role in the reception of scholarly monographs, but the lack of esteem attached to reviews has sometimes led to legitimate concerns regarding their judicious value [27.20]. It can be useful, therefore, to filter out specific types of reviews by focusing on those that are more *scholarly*, or at least those that researchers agree upon as having familiar or trusted scholarly characteristics [27.28, 39]. Evidence of scholarliness can be assessed, for example, by the degree to which a reviewer includes references to other academic sources in addition to the book under review [27.84].

Yet another way to import book reviews into an evaluation context is to make use of them as *mega-citations*. *Zuccala* et al. [27.109] have introduced a theory of *mega-citation* which explains how book reviews may be transformed into quantitative indicators based on a full-text analysis of reviewer comments. One drawback to working with *mega-citations* is that full-text reviews published in journals are largely inaccessible in electronic form. In light of this problem, some bibliometricians have found that public and socially motivated book reviews are a better option, particularly those published on sites such as Amazon.com or Goodreads. Public reviews are especially useful for indicating the degree to which a scholarly book has become visible online and has become a topic for social engagement [27.75, 110]. Both scholarly and public reviews can always be used in conjunction with other types of indicators (e.g., publisher quality and/or citations), but for improving the coverage of books in commercial citation indexes, preference is given to the scholarly review [27.111].

27.5.4 Library Holding Counts

To date, the most promising of all book-based indicators is the library holding count [27.71, 87, 88], which *White* et al. refer to as the *libcitation* [27.88, p. 1083]. A theory of libcitation rationalizes that a holding count or set of holding counts in library catalogs might be used to indicate and calculate the perceived cultural benefit of a book or books. The advantage of this measure is that it "can make an author in the humanities look good", particularly if (s)he is not well represented in other types of databases such as Web of Science, Google Scholar, or Scopus. *White* further explains that [27.88, p. 1084]:

> On the book front, libcitations reflect what librarians know about the prestige of publishers,

the opinions of reviewers, and the reputations of authors. The latter may be colored by, for example, authors' academic affiliations, previous sales, prizes, awards, distinguished appointments, mass media coverage, Web presence, and citedness. All of these are signals of what readers are likely to want, and librarians must be attuned to them.

When working with this indicator, at least two different methodological approaches are possible. *Torres-Salinas* and *Moed* [27.87] focus on library holding counts at the publisher level, while *White* et al. [27.88] propose developing it at the book level. At the book level, holding counts have much more power to discriminate between books than citation counts. Records for books tend to be more plentiful in library catalogs than in citation indexes, particularly in a union catalog like OCLC-WorldCat [27.112]. Libcitation counts for individual scholars or academic departments can be field-normalized or assigned to percentiles just as citations are. By determining how many libcitations a book needs in order to reach a 90th- or 50th-percentile cutpoint in its main Dewey class, one can observe its cultural impact, or degree of fame relative to other titles from the same class [27.71]. Research also points to the fact that libcitations and citations can be statistically correlated, but one is likely to find a weak, albeit significant result [27.68]. Both the citation and the libcitation capture a certain amount of scholarly impact in common, but this seems to be truer when holding counts are obtained from academic libraries rather than other types of libraries. Another study using the PlumX suite of altmetrics, now shows that out of 18 types of indicators for books, including citations, downloads, views, and social media mentions, the most informative is the library holding count [27.113].

27.6 Integrating Book Metrics into Evaluation Practices

For some time, the social sciences and humanities have been either only partially assessed or neglected entirely due to the lack of data available for developing promising book metrics. Acceptance of this fact grew in part because of the increasing value of journal articles (in most fields), notwithstanding the long tradition of relying on journal citation indexes for many international research evaluation procedures. Fortunately, this did not stop some of the early bibliometric monitors from examining the role of books in book-oriented research disciplines, nor did it prevent commercial organizations like Elsevier and Clarivate Analytics (formerly Thomson Reuters) from addressing the data gap by developing a Scopus index of books and Book Citation Index℠. Subject classifiers and indexers now have ample reason to step to the forefront, not only to apply research to these indexes, but to lead the bibliometrics community forward to an improved situation, one in which the metric exploration of books and their publishers is no longer an aspiration, but an established reality.

Still, the integration of books into evaluation practices will never be left solely to commercial data providers or researchers. National policymakers are stakeholders in the evaluation game and also play a role. Research by *Giménez-Toledo* et al. [27.77] and *Williams* et al. [27.8] provides valuable overviews of how countries across Europe have recently been implementing policies and strategies for book-based evaluations. In the United Kingdom, most scholarly books are submitted to panels C (social sciences) and D (humanities) of the panel-based Research Excellence Framework (REF). Since the panels (as well as sub-panels) take into consideration what is most valued in these broader disciplines, a qualitative approach to evaluation is used. A different approach is taken in Spain, Denmark, and Finland, where evaluation procedures for books are based on league tables or *authority* lists of publishers. Panels of experts are recruited here as well, but are invited to participate in the development of such lists. The publisher lists are then used to benchmark the value of a monograph submitted to each country's respective evaluation exercise. Other countries like Flanders (Belgium) implement a point system by which a book's value is weighted (e. g., monographs receive four points, while edited books receive one point). Norway uses a mixed-methods approach, where publishers and journals are divided into two levels, where a level 2 designation is the most selective. Depending on the level, a monograph will receive either five points (i. e., for a book with a level 1 publisher) or eight points (i. e., for a book with a level 2 publisher). Denmark generally follows Norway's approach; hence, with a similar system, a fraction of funding each year is allotted to Danish university departments that achieve the highest numbers of points.

More often than not, these evaluation policies are designed for practical purposes. Again, it is simply impractical to assess the individual contribution, quality, influence, or impact of every monograph at a national or international level. This issue, together with the uncertainty of applying citation analysis to books, and criticisms coming from social scientists and humanities researchers, has prevented the widespread development and use of citation-based indicators. Policymakers have thus been keen to disregard the citation, including many other practices, in favor of focusing on publisher status (i. e., as per the league, or *authority* tables). As a result, certain challenges related to book metrics have yet to be addressed. We are presently at the stage where disparities in data coverage [27.113] and low correlations between citations to books and alternative indicators of their impact [27.68, 96, 110] remain difficult to interpret. With citation indicators alone, differences per database at least show moderately significant correlations [27.95].

From a research perspective, it is clear, then, that more work is needed to improve upon the subject classification of books, both in commercial and in national indexes, and to ensure that record keeping is complete (e. g., indexes that include author affiliations and show how books belong to bibliographic families). Scholars who work with these indexes—i. e., the indicator constructionists—are urged to remain steadfast at uncovering, refining, and emphasizing different elements related to the influence or impact of books. Their biggest challenge, however, may not be technical or data-oriented, but cultural, in nature.

Citation-based indicators have long been associated with research assessment schemes directed toward the natural and exact sciences. Journal articles and their citations received accommodate research communities grounded upon previous work and rapid progress: a Kuhnian model of normal science. By contrast, books and their reviews fit within a *social* view of scholarship. Here the standards are based on the perceptions of peers; it is the academic peer who determines the value of a work. In theoretical disciplines, where books are most prominent, this community-based reflexivity, inherent in the overall reflexive nature of the social sciences and humanities, is likely to remain a primary strength [27.114]. When bibliometric approaches to evaluation focus on complementing this strength, and also recognizing a book's broader (i. e., educational, social, literary) influence or impact, book-based scholarship will evolve not in response to perceived faults in the evaluation system, but because different aspects of the truth will become more evident.

elrobinster@gmail.com

Nicolas Robinson-Garcia is a postdoctoral researcher at the School of Public Policy from the Georgia Institute of Technology in the United States. He holds a PhD in Social Sciences from the University of Granada (Spain). He is currently interested in the development of quantitative methods to analyze scientific mobility flows as well as the analysis of new data sources and methods to trace societal engagement of researchers.

28. Scholarly Twitter Metrics

Stefanie Haustein

Twitter has unarguably been the most popular among the data sources that form the basis of so-called altmetrics. Tweets to scholarly documents have been heralded as both early indicators of citations and measures of societal impact. This chapter provides an overview of Twitter activity as the basis for scholarly metrics from a critical point of view and equally describes the potential and limitations of scholarly Twitter metrics. By reviewing the literature on Twitter in scholarly communication and analyzing 24 million tweets linking to scholarly documents, it aims to provide a basic understanding of what tweets can and cannot measure in the context of research evaluation. Going beyond the limited explanatory power of low correlations between tweets and citations, this chapter considers what types of scholarly documents are popular on Twitter, and how, when and by whom they are diffused in order to understand what tweets to scholarly documents measure. Although the chapter is not able to solve the problems associated with the creation of meaningful metrics from social media, it highlights particular issues and aims to provide the basis for advanced scholarly Twitter metrics.

28.1 Tweets as Measures of Impact

Enabled by the digital revolution, the open access and open science movement, big data and the success of social media have shaken up the scholarly metrics landscape. Academic careers are no longer shaped only by peer-reviewed papers, citation impact and impact factors; university managers and funders now also want to know how researchers perform on social media and how much their work has impacted society at large.

Bibliometricians have started to adapt to the policy pull and technology push and expanded their repertoire of scholarly metrics to capture output and impact beyond the ivory tower, so far that some speak about a scientometric revolution [28.1]. Metrics are no longer restricted to formal parts of communication but expand beyond the borders of the scholarly community [28.2]. Similarly to how the Science Citation Index formed the field of bibliometric research and research evaluation, the altmetrics, or more precisely the social-media metrics landscape is being heavily shaped—if not entirely driven—by the availability of data, in particular via automated programming interfaces (APIs) [28.3, 4].

Twitter has arguably been at the epicenter of the earthquake that has shaken up the scholarly metrics landscape. The majority of altmetrics research has either focused on or included Twitter (see [28.5] for a review of the literature). Following a general definition of scholarly metrics which include activity on social media [28.3], scholarly Twitter metrics are defined as "indicators based on recorded events of acts [on Twitter] related to scholarly documents [. . .] or scholarly agents [. . .]" [28.3, p. 416].

Although findings of an early study had suggested that tweets were a good early indicator of citations for papers published in the *Journal of Medical Inter-*

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_28

net Research [28.6], the generalizability of this claim was refuted by low correlations reported by more representative studies [28.7, 8]. Low correlations between tweets and citations did, however, spark hopes that Twitter activity was able to reflect impact on users and use beyond citing authors—a new type of previously unmeasurable impact—possibly on society at large. Twitter's popularity in the altmetrics realm has essentially been caused by two factors, which are both heavily influenced by technology and the data push and policy pull described above:

1. A significant number of scholarly articles are shared on Twitter, producing a measurable signal.
2. Twitter is a social media platform created for and used by a wide and general user base, which theoretically has the potential to measure impact on society at large.

As tweets represent an "unprecedented opportunity to study human communication and social networks" [28.9, p. 1814], Twitter is being used to analyze a variety of social phenomena. Centering on either the message (i. e., the tweet, its content and associated metadata) or social connections (i. e., the network of follower-followee relations), tweets have been used to show discussions during upcoming elections, how people communicate during natural disasters, political upheaval, cultural events and conferences and have even been used to predict election outcomes and the stock market [28.10, 11].

While only a small share of academics use Twitter for scholarly communication [28.12, 13] and to diffuse scientific publications [28.14], more than one fifth of recent journal articles are being tweeted [28.15], which adumbrates that it is non-academics who engage with scholarly publications on Twitter. At this point, social media-based indicators have flourished rather as vanity measures—culminating in a tongue-in-cheek metric called the Kardashian Index [28.16]—than as validated indicators of societal impact. Even though altmetrics have left their mark on the scholarly publishing and metrics landscape [28.17], they have not (yet) established themselves within the reward system of science, where citations remain the only hard currency [28.18, p. 1523]:

> Neither Twitter mentions nor Facebook 'likes' are, for now at any rate, accepted currencies in the academic marketplace; you are not going to get promoted for having been liked a lot, though it may well boost your ego.

Still, almost all big publishing houses now report some form of article-level metric based on social media activity, including tweets. Despite the lack of validation and a clear definition regarding the type of impact measured, the number of tweets are thus already used as scholarly metrics "in the wild" [28.19].

This chapter aims to contribute to the understanding of Twitter and Twitter-based metrics with a particular focus on their potential and limitations when applied as scholarly metrics. To provide some context for the meaning of scholarly impact measures derived from tweets and Twitter activity, this chapter describes Twitter's role in scholarly communication. It depicts how Twitter is used in academia and how scholarly contents are diffused and discussed in tweets. The chapter provides an overview of the literature of Twitter use by the scholarly community and scholarly output on Twitter. The latter part is supported by empirical results based on an analysis of 24 million tweets mentioning scientific papers captured by the data provider Altmetric.com. Both the review of the relevant literature and the patterns extracted from the Twitter data are intended to contribute to the understanding of what type of scholarly contents are diffused on Twitter, who is diffusing them, when and how. This will help to assess Twitter metrics as valid impact indicators and to interpret their meaning.

28.2 Twitter in Scholarly Communication

Twitter launched in 2006 as a public instant messaging service and evolved from an urban lifestyle social network, where users would update their friends about what they were doing, to a platform for communicating news and events used by 500 million users worldwide, or 23% of US adults online [28.20]. Although other microblogging platforms (e. g., Sina Weibo, Tumblr, Plurk) exist, tweeting has become a synonym (and preferred term) for microblogging and Twitter the most popular service. Until recently, Twitter constrained microposts to a maximum length of 140 characters, a restriction that originates from the 160-character limit of text messages. In 2017, the restriction was increased to 280 characters. Users can follow each other and create user lists to manage the updates they receive from other Twitter users. Similarly to regular blogs, microblogs are ordered sequentially in reverse chronological order and, due to their brevity, usually appear more frequently [28.21], making Twitter the "most dynamic and concise form of information exchange on social media" [28.22, p. 5]. While the brevity of tweets is seen as a restriction by some, others perceive it as a particular advantage [28.23, p. 10]:

> The brevity of messages allows [tweets] to be produced, consumed, and shared without a significant amount of effort, allowing a fast-paced conversational environment to emerge.

Tweets have three major specific affordances, which facilitate communication on the platform: retweets (RTs), user mentions (@mentions) and hashtags (keywords following #). All of these functions originated within the Twitter user base and were eventually adopted by Twitter, representing a co-creation of functions by users and developers. Twitter provides three main levels of communication: interpersonal communication on the micro level, meso-level exchanges of people who are directly connected through their network of followers and followees, and hashtag-centered macro-level communication which enables exchanges among all Twitter users with common interests [28.24].

In academia, Twitter is used to disseminate and discuss scholarly outputs and other relevant information; maintain collaborations or find new ones; as a virtual "water cooler" [28.25, p. 347] for social networking with colleagues; to increase student participation in teaching; as a back channel at scientific conferences to foster discussions among conference attendees and those who participate remotely; and to increase visibility and reach wider audiences [28.13, 25–29].

28.2.1 Twitter Uptake

Twitter is used by various stakeholders in the scholarly community, including individual researchers and academics, journals and publishers, universities and other academic institutions, as well as at scholarly conferences. From the perspective of using Twitter activity as the basis for scholarly metrics, it is essential to know Twitter uptake in academia, as it informs about biases and differences between disciplines and other user demographics, which may have a direct effect on derived metrics.

Scholars on Twitter

In the scholarly context, Twitter use by academics lags behind its uptake among the general public. Although the majority of researchers are aware of the platform, most do not make use of it in a professional context, giving it the reputation of a hype medium in academia [28.13, 30–32]. A certain reluctance in academia to use Twitter might be caused by its perception as a shallow medium that is used to communicate "pointless babble" [28.33, p. 5] rather than informative content [28.10]. Described as "phatic" [28.34, p. 396], Twitter is less about what people tweet rather than how they are connected.

Reported Twitter uptake shows extreme variations depending on user demographics—in particular disciplinary orientation—and when a study was conducted; it usually stays behind use of other social media. For example, a survey among 2414 researchers conducted in 2010 demonstrated that while more than three quarters used social media, less than one fifth were on Twitter [28.12]. A more recent study conducted by *Nature* also showed that Twitter was among the least used social media platforms in academia: while almost half of 3027 science and engineering researchers regularly used ResearchGate, only 13% regularly visited Twitter [28.13]. At almost one quarter of regular users, Twitter uptake was higher among the 482 social science and humanities scholars participating in the same survey [28.13].

Depending on the sample and when the survey was conducted, Twitter uptake varied heavily between a few percent to more than one third of surveyed scholars using Twitter, which calls the representativeness of findings into question. Moreover, surveys vary in terms of whether or not they differentiate between general Twitter uptake, Twitter use for scholarly communication and professional purposes or active versus passive use, which further complicates comparison and generalization of findings regarding Twitter uptake in academia. Twitter represented the social media tool with the highest difference between awareness and use. Although known by 97% of university staff in Germany, as few as 15% used Twitter and 10% used Twitter in a professional context [28.32]. A similar use-to-awareness ratio was found by other studies, for example, at Finnish universities [28.31] or researchers surveyed by *Nature* [28.13], and academic staff in Germany [28.35].

Most studies found self-reported Twitter use in academia at around 15%; an uptake of 13–16% was reported for surveys based on 215 health services and policy researchers [28.36], 454 geographers [28.37], 1058 UK academic staff [28.38] and 3027 scientists and engineers [28.13], while uptake was lower (7–10%) for academics in Germany [28.35] and the UK [28.12, 39]. Although 18% used it, Twitter was the least popular social media tool of 345 European scholars [28.40]. The highest Twitter use was reported for a survey of 126 Finnish university staff at 23% [28.31], 1910 professors at US universities at 32–23% for professional purposes [28.41], 382 urologists attending a conference at 36% [28.42] and 71 participants of the 2010 *Science & Technology Indicators* (STI) conference in Leiden at 44% [28.43].

As an alternative to determining Twitter uptake through self-reported use in surveys, studies have also assessed the extent of scholarly microblogging based on Twitter activity of scholars. Identifying scholars on Twitter is challenging, as the 160-character Twitter bio and the provided user name are often the only basis for identification. Most studies thus search for Twitter users based on a list of names of academics [28.44–48] or apply snowball sampling starting from a set of known scholars on Twitter [28.49–51]. Searching for a list of 8038 US and UK university staff, *Priem* et al. [28.47] found Twitter accounts for 2.5% of them. Although the authors admit that their study underestimated Twitter use, it reflected that the microblogging platform is not popular in academia and thus confirms the findings by most surveys. Investigating Twitter use in the scientometric community, *Bar-Ilan* et al. [28.52] found Twitter profiles for 9 of the 57 presenters at the 2010 STI conference.

Other than searching for known scholars on Twitter, some studies try to extract information from Twitter to identify scholarly users. The most common approach is to classify users based on searching for specific words in the Twitter bio. Retrieving users whose Twitter bio contained words such as *university*, *PhD* or *professor*, *Barthel* et al. [28.53] identified scientists' Twitter accounts with a precision of 88%. False positives contained university accounts or those of non-academic staff at research institutions. Recall cannot be determined in such studies as the number of false negatives, that is the scientists on Twitter who do not include any of the queried keywords in their self-descriptions, remains unknown.

Altmetric also applies a keyword-based approach to categorize Twitter users as *scientists*, *science communicators (journalists, bloggers, editors)*, *practitioners (doctors, other healthcare professionals)* and *members of the general public*. It should be noted that Altmetric's *general public* category includes all users that cannot be classified as belonging to any of the other three groups and is therefore not a good indicator of how much an article has been tweeted by members of the general public. An obvious limitation of the keyword approach is that it is unable to capture scholars who do not identify themselves as such or who do not use the terminology or language covered by the list of keywords. However, many scholars seem to reveal their professional personas on Twitter. Ninety percent of doctoral students funded by the Canadian Social Sciences and Humanities Research Council (SSHRC) identified as academics on Twitter [28.48], 87% of surveyed US university professors claimed to mention both their professional title and place of work in their Twitter profiles [28.41] and 78% of Twitter users who self-identified as a physicians used their full names [28.49]. This willingness to reveal their scholarly identities on Twitter suggests that scholars make use of the microblogging platform in a professional context at least to some extent.

Ke et al. [28.54] took advantage of crowdsourced Twitter lists to identify scholars. Based on a method introduced by *Sharma* et al. [28.55], they identified scientists on Twitter with an approach based on membership in scientific Twitter user lists. Other studies have estimated Twitter activity by scholars by analyzing users who engage with scholarly content on Twitter. *Hadgu* and *Jäschke* [28.56] applied machine learning to automatically identify scholars on Twitter based on a training set of users whose tweets contained a computer science conference hashtag, while others selected users who have tweeted scientific papers [28.51, 57–60]. Since the latter type of studies focuses on categorizing who is tweeting about scholarly contents rather than estimating Twitter uptake in academia, these studies are discussed in more detail below.

Scientific Conferences

Twitter does particularly well in fostering communication among people participating in shared experiences [28.10], which may be why tweeting at scholarly conferences has been one of the earliest and most popular uses of Twitter in academia. Almost every scientific conference today has a specific hashtag to connect attendees and those interested but not able to attend in person, thus expanding the conference audience to include remote participants [28.61–63]. Apart from increasing the visibility of presentations, tweeting at scientific conferences has introduced another level of communication, creating back-channel discussions online among participants complementing presentations and discussions which take place at the meeting. Conference tweets usually directly refer to presentations and discussions during sessions and sometimes summarize key take-away points [28.64–66]. Other motivations for tweeting at a scientific conferences were to share information and learn about discussions in parallel sessions, networking with others and feeling a sense of connectedness, as well as note-taking [28.65]. A significant number of tweets associated with two medical conference were uninformative or promotional [28.45, 67].

Due to the ease of collecting tweets with a particular hashtag, as well as Twitter's relative popularity in the context of scientific conferences, there are countless studies analyzing scholarly Twitter use based on tweets with conference hashtags [28.62–72].

Similar to the overall uptake among scholars, Twitter activity at conferences differs among disciplines as well as individual conferences, and has increased over the years. Overall, only a small share of conference participants contributed to discussions on Twitter: Less than 2% of attendees of the *American Society of Nephrology*'s 2011 conference [28.45] and less than 3% of participants of the 2012 *Winter Scientific Meeting of the Association of Anesthetists of Great Britain and Ireland* tweeted [28.65]. Another medical conference in 2013 reported higher Twitter engagement, as 13% of conference attendees tweeted using the conference hashtag [28.66]. Longitudinal studies also observed an increase in Twitter activity at conferences over the years [28.64, 66, 69]. For example, 2% of conference participants tweeted at the *2010 Annual Meeting of the American Society of Clinical Oncology*, while 5% contributed to conference tweets in 2011. Similarly, the number of tweets nearly doubled from 4456 tweets in the first to 8188 in the following year [28.64]. A similar increase was observed for the 2011 and 2012 annual meetings of the *Radiological Society of North America* [28.69]. Conference-related discussions on Twitter are not restricted to in-person attendees. In fact, at some conferences the majority of Twitter users only participate remotely [28.62].

Just as with other social media and information in general, tweeting activity is usually heavily skewed with a few users contributing the majority of tweets at conferences [28.64, 66, 67]. Tweeting about a conference has been shown to lead to an increase in the number of followers regardless of attending in-person or remotely. Follower counts grew particularly for speakers and in-person attendees, while the number of followers grew least for remote participants [28.62]. Most organizers of scientific conferences embrace the potential of increasing visibility and outreach and thus encourage tweeting through a conference-specific hashtag. Some also specifically display conference-related tweets in real time and thus make tweeting activity visual to participants who are not on Twitter [28.62, 63, 68, 70].

Journals and Publishers

Twitter's technological features afford direct connections and two-way conversations between users, changing what was traditionally known as a unidirectional sender-audience relationship. Opposed to traditional publishing and mass media, Twitter has given rise to personal publics of audiences [28.73]. This direct link between the sender and receiver has changed the relationship with audiences; for example, musicians use Twitter to market their own brand and respond to @replies from fans to seek out in-person interactions [28.74]. TV audiences turn Twitter into a virtual lounge room when they connect with other users discussing TV events in real time [28.75]. Similarly, discussions of scientific publications can now happen publicly, when readers share their opinions on Twitter. A specific use case are Twitter journal clubs, an adaption of small-group in-person journal clubs that are particularly common in the medical sciences [28.76–80]. Twitter journal clubs are used to discuss and review recent publications and educate researchers and practitioners; in the medical sciences they also have the advantage over their offline predecessors to directly involve patients [28.77]. Often these journal clubs are initiated or at least supported by journals to promote their publications. A journal club initiated by a gynecology journal showed that discussing papers and making them freely available has boosted their Altmetric scores [28.76]. Twitter journal clubs also motivated authors of discussed papers to create Twitter accounts [28.78].

With journals and authors on Twitter, readers can get in touch directly and involve them in discussions using @mentions, tearing cracks in the wall of traditional gatekeeping, as "Twitter makes it possible to directly connect journal readers at various stages of training with authors and editors" [28.77, p. 1317]. Many journals and publishers have started to use Twitter as a marketing instrument to increase online visibility and promote published contents. These accounts can be used to create a personalized audience relationship and to foster interaction among readers. Similar to the mix of professional and personal interactions by academics on Twitter, the lines between scholarly communication and marketing campaign are blurred for accounts maintained by journals and publishers. Almost half of the 25 general medicine journals with the highest impact factor in 2010 had a Twitter presence [28.81], while Twitter uptake was lower for other sets of journals: 24% of 33 urology journals [28.82], 2 of the top 10 ophthalmology journals [28.83], 16% of 100 *Web of Science* (WoS) journals [28.84] and 14% of 102 journals specialized in dermatology [28.85] maintained an account. As most of these studies focused on the top journals according to the journal impact factor, Twitter uptake might be biased towards high-impact journals and slightly lower when including others. The variation suggests similar differences between disciplines as observed for Twitter uptake by individual scholars and conferences.

While most journal accounts are used to share articles and news [28.86] and often tweet the article title [28.87, 88], some journals have incorporated tweeting into the formal communication process. In addition to regular abstracts, they ask authors to write so-called tweetable abstracts that meet the 140-character restrictions, which are used to attract readers on Twitter [28.44]. Twitter even interfered with the journal's role in scholarly communication, when a genomics paper was criticized and corrected results posted in a tweet, leading to a conflict with the authors of the criticized paper [28.89].

Even if a journal is not represented by a proper Twitter account, it is likely that its publisher is. *Zedda* and *Barbaro* [28.86] found that Twitter adoption was particularly common among 76 publishers in science, technology and medicine; 89% had official Twitter accounts, exceeding the presence on any other social media platform, and 74% had embedded tweet buttons that allowed readers to directly share publications on Twitter. Promotion of publications by publishers seem to be welcomed by authors, as a survey by *Nature Publishing Group* revealed that almost one fifth of authors would consider it a very valuable service if publishers promoted papers using marketing and social media [28.90].

As shown in the analysis of Twitter accounts diffusing scientific articles below, accounts maintained by journals and publishing houses are responsible for a significant amount of tweets mentioning scientific articles. Once Twitter metrics are being used to evaluate journal impact, these types of self-tweets might be considered as a type of *gaming* in a manner similar to journal self-citations and citation cartels to boost the impact factor [28.91, 92]. With publishers invested in the success of their journals, *tweet cartels* and *tweet stacking* in analogy to their citation equivalents are easily conceivable and even easier to implement. While the WoS excludes journals from the *Journal Citation Reports*, which have been caught increasing their impact factors artificially, companies like Altmetric.com and Plum Analytics do not (yet) intervene in such self-promotional activity.

Universities and Academic Libraries

Scholarly institutions are affected by Twitter's impact on academia on two levels: they exploit the microblogging platform to increase their visibility (and that of their members) and provide guidelines and recommendations for their members to navigate the new communication space. The Association of American University Professors updated their report on *Academic Freedom and Electronic Communication* [28.93] in reaction to a university rescinding a tenure-track job offer to an English scholar who had made an anti-Semitic comment on Twitter [28.94]. The updated report emphasized that professors enjoy academic freedom even when they comment on social media and particularly addressed the blurring of boundaries between private and professional opinions on social media. It stressed how, in this new context, comments are particularly prone to be misunderstood and misinterpreted, as they are often taken out of context [28.93, p. 42]:

> Electronic communications can be altered, or presented selectively, such that they are decontextualized and take on implicit meanings different from their author's original intent. With the advent of social media, such concerns about the widespread circulation and compromised integrity of communications that in print might have been essentially private have only multiplied further.

The report further recommends that universities and other academic institutions, along with their staff, develop policies that address the use of social media. In general, academic institutions lack specific social media guidelines or address social media in policies. Although more and more institutions adopt specific policies [28.95], only half of US doctorate-granting universities had a social media policy, while rates were even lower for other universities and colleges. At the same time, Twitter was specifically mentioned in more than 80% of policies [28.96].

The majority of university Twitter accounts apply a so-called megaphone model of communication, where news and information concerning the institution are broadcast following a traditional communication model [28.97, 98]. Universities use Twitter for public relations, dissemination of news and events, and as recruitment [28.97]. Ninety-four percent of 474 US university admission officers reported that their institution had a Twitter account [28.99] and 96% of the websites of 100 US colleges linked to Twitter [28.100]. On the departmental level, it was less common to be represented with an organizational account, as only 8% of 183 US radiology departments had a Twitter presence [28.101]. Twitter was also commonly used for faculty development at medical schools [28.102]. Analyzing the Twitter activity of 29 Israeli universities and colleges, *Forkosh-Baruch* and *Hershkovitz* [28.103] found significant differences between both types of institutions. Colleges were more likely than universities to post social tweets. While almost half of the tweets by universities focused on research conducted elsewhere, colleges focused more on reporting the work by its own researchers.

Twitter was also frequently used by academic libraries as a marketing instrument, to communicate with patrons, to announce new resources and promote services [28.104–106]. On par with Facebook at a 63% adoption rate, Twitter was the most commonly used social media platform among 38 surveyed academic libraries from different countries [28.107], while all of the 100 US university libraries analyzed by *Boateng* and *Quan Liu* [28.104] maintained a Twitter presences. In Canadian academic libraries, Twitter adoption was lower at 47% [28.108].

28.2.2 Twitter Use

Apart from Twitter uptake, scholarly Twitter metrics are further influenced by *how* Twitter is used. Academics use social media to share information, for impression management and to increase their visibility online, to network and establish a presence across platforms, to request and offer help, expand learning opportunities, or simply to be social [28.25]. Twitter specifically was used mostly to tweet work-related content, discover peers working on similar research, follow research-related discussions and get recommendations for papers [28.13].

One central motivation for tweeting among scholars is to communicate and explain their work to laypeople. As many science communicators are active on Twitter, they help to bridge the gap between the scholarly community and the general public. Science communicators were the largest user group of 518 Twitter users mentioned in tweets by 32 astrophysicists [28.50]. An evolutionary biology professor valued Twitter to communicate his work to the general public [28.61, p. 453]:

> Twitter and regular blogging are more effective than anything else I do to publicize a paper, which was really surprising to me [...]. If you do it right, Twitter is an effective way of telling people about your work.

However, most researchers still preferred traditional media over Twitter to promote their research [28.109].

Even when identifying professionally on Twitter, a large share of tweets by scholars are not related to their work or academia in general [28.13, 32, 41, 110, 111]. The *Nature* survey found that 21% of scientists who used Twitter regularly did not use it professionally and 28% said that they never posted content about their work [28.13]. *Bowman* [28.41, 112] reported that, while 29% of American university professors used Twitter strictly in a professional way and 42% used it for both for personal and professional reasons, the vast majority of tweets were coded as personal (78%) rather than professional (19%). Again, large variations can be observed between disciplines as well as individual Twitter users [28.42, 47–49, 51, 111]. Examining more than half a million tweets from 447 researchers, *Holmberg* and *Thelwall* [28.51] found that less than 4% of tweets were classified as scholarly communication and results varied between disciplines ranging from less than 1% for sociology up to 34% for biochemistry. A study on emergency physicians' tweeting behavior found that 49% of their tweets were related to health or medical issues, 21% were personal, 12% self-promotional and 3% considered unprofessional as they contained profanity, were discriminatory or violated patient privacy [28.49]. In a sample of tweets by funded doctoral students in the social sciences and the humanities in Canada, 4% of tweets were related to their thesis, 21% to the discipline and 5% to academia in general, while 70% of tweets were coded as non-academic [28.48]. Personal use also prevailed among 382 urologists [28.42].

These findings highlight that even when scholars identify professionally on Twitter and use the platform for scholarly purposes, many tweets will be irrelevant to scholarly communication and should thus be excluded from a scholarly indicator perspective [28.21, p. 98]:

> The lack of a dividing line between scientists and non-scientists, as well as the great variety of topics that even scientists tweet about mean that Twitter is not comparable to the orderly world of science publishing, where every piece of information is assumed to be relevant. Instead, a typical user's timeline is likely to be populated both by scholarly content and personal remarks, more or less side by side.

Due to their brevity and the fact that when analyzing tweets they are often taken out of context, categorizing tweet content is as difficult as it is to classify Twitter users [28.41]. Distinguishing between scientific and non-scientific tweets is especially challenging [28.51].

Large variations can also be found between individual tweeters in terms of how often they tweet. A group of astrophysicists analyzed by *Haustein* et al. [28.110] tweeted, on average, between 0 and 58 times per day. Tweets to scientific papers have been shown to peak shortly after their publication and decay rapidly within just a few days. For example, 80% of *arXiv* submissions received the largest number of tweets the day after they were published [28.113]. Similarly, the tweeted half-life was 0 days for papers published in the *Journal of Medical Internet Research* [28.6], and 39% of a sample of tweets linking to a scholarly document referred to those published within one week before [28.14]. Determining the delay between publication and first tweet as well as half-lives on Twitter is, however, challenging due to the ambiguity of publication dates [28.114].

Since not all Twitter use culminates in a tweet, a large share of activity remains invisible and thus unmeasurable. In fact, passive use prevailed among UK doctoral students on Twitter [28.30] and seems to be common for scholarly use of social media in general. While most academics access and view information, only a minority actively contributes by creating content on social media [28.38, 39]; less than 2% of 1078 UK researchers surveyed actively contributed daily [28.38].

Tweeting Links

The most frequent use of Twitter among researchers in higher education was to share information, resources or media [28.25]. A survey among US university professors revealed that embedding URLs was the most commonly used Twitter affordance. Half of the survey participants claimed to tweet links either sometimes, mostly or always [28.41]. Links are a common way to send more information than 140 characters would fit. Addressing the length limitation, a scholar explained [28.61, p. 453]:

> It is a double-edged sword. The majority of my tweets are pointers to other resources, so there is a headline—an enticement in other words—and a link to the resource. You don't need more than 140 characters for that.

Weller and *Puschmann* [28.115] refer to links in tweets as "external citations" [28.115, p. 2]. Studies about scholars on Twitter show that they make frequent use of tweeting URLs, as the share of tweets with links exceeds that observed for general Twitter users [28.23, 75]. About one third of 68 232 tweets sent by 37 astrophysicists [28.110] and 38% of 22 258 tweets posted by Canadian social sciences and humanities doctoral students contained links [28.48]. Tweeting links was even more popular among scholars studied by *Weller* and *Puschmann* [28.115] and emergency physicians analyzed by *Chretien* et al. [28.49], as 55% and 58% of their tweets, respectively, contained URLs. Links were much more common when a sample of 445 US professors tweeted professionally: 69% of professional tweets contained URLs, while only 15% of personal tweets did [28.41]. Tweets with the #www2010 and #mla09 conference hashtags linked to a website in 40% and 27% of the cases, repeating each unique URL less than three times [28.63].

Priem and *Costello* [28.14] found that 6% of a sample of 2322 tweets by academics containing a URL mentioned a scholarly publication, 52% of which were first-order and 48% second-order links (i. e., via another website) to the document. Similarly, *Holmberg* and *Thelwall* [28.51] found that scholarly tweets frequently contained a link to scholarly publications via a blog post about the paper. First-order links were significantly more likely to refer to open access articles [28.14]. Tweets containing the #iswc2009 conference hashtag linked to applications (e. g., online services or research projects; 31%), the conference website (21%), blog posts (12%), slideshows (12%) and publications (9%) [28.71]. Blogs were the most common linked resources in conference tweets analyzed by *Weller* and colleagues [28.63], while news websites were a frequent link destination of tweets sent by Canadian doctoral students, even when discussing scholarly topics [28.48].

When linking to scholarly papers, tweets often contained the paper title and rarely expressed any recommendation or sentiment [28.87, 88]. The great majority of tweeted articles were published very recently [28.6, 14, 51]. According to surveys asking about motivations for using social media, finding relevant publications and staying up to date with the literature was found to be a frequent, albeit passive, use of Twitter [28.13]. A Columbia university professor in biology and chemistry describes how they used Twitter to be alerted about the literature [28.61, p. 452]:

> Sometimes four or five people I follow will mention a paper that I did not come across and I will look it up. I think I am much more up to date on science literature since I started following Twitter.

A study by *Tenopir* et al. [28.38] found that academics on Twitter read more scholarly publications, which seems to confirm the use of Twitter as a publication alert service. At the same time, as the analyses by *Priem* and *Costello* [28.14] and *Letierce* et al. [28.71] show, the share of tweets linking to academic papers is low, suggesting a rather passive use: scholars follow links to tweeted articles but do only infrequently distribute them themselves. This suggests that a significant part of Twitter use cannot be captured by scholarly Twitter metrics.

Retweets

Retweets represent a specific form of diffusing information, as users forward messages sent by others. As such, they do not represent an original contribution by the retweeting user. Since retweets directly quote another users text, they can be seen as "internal citations" [28.115, p. 3] on Twitter. An analysis of retweets demonstrates how information circulates within a specific user community [28.116]. A common disclaimer that *retweets do not equal endorsements*, adapted from early Twitter use by journalists, emphasizes that tweets are forwarded to increase information diffusion. Once a frequent part of Twitter bios, the disclaimer has now been established as common sense and is no longer needed [28.117].

As sharing information is one of the main motivations for scholarly Twitter use, retweeting is likely to be common among tweeting academics. Conference participants interviewed by *Letierce* and colleagues retweeted "tweets that are close to their interest or tweets that speak about their own work or research project" [28.71, p. 7]. Studies showed that retweeting is less common than other affordances used by scholars on Twitter, but exceeds expectations of a random sample of tweets in 2009, in which as few as 3% were retweets [28.23]. Between 15% and 20% of tweets sent at scientific conferences were retweets [28.71]; similarly, 15% of 68 232 tweets by a group of 37 astrophysicists were retweets [28.110]. Retweeting was more common among 28 academics analyzed by *Priem* and *Costello* [28.14], as 40% of tweets were retweets. Similarly, 37% of 43 176 tweets by Canadian doctoral students were retweets, while 10% of their tweets were retweeted [28.48]. At the same time, the share of retweets at a radiology conference was 60% [28.69]. Asked about Twitter affordance use, 14% of US professors said that they mostly or always retweeted, and 34% that they sometimes retweeted [28.41]. These professors were more than twice as likely to retweet when their tweets were classified as professional rather than personal [28.41]. These differences again demonstrate that tweeting behavior differs depending on who is tweeting and in what context.

The majority of retweets sent by scholars from ten disciplines contained links, while conversational tweets (i. e., @mentions) were less likely to contain links [28.51, p. 1035]:

> This clearly shows that researchers [...] frequently share web content and forward information and content they have received from people they follow on Twitter, while links are not that often shared in conversations.

Links to papers were significantly less likely to be retweeted: while 19% of tweets with links to scholarly publications were retweeted, the retweet rate was twice as high in the overall sample of tweets analyzed by Priem and Costello [28.14]. This is in contrast to a random sample of more than 200 000 tweets, over half of which contained a URL [28.23]. A random sample of 270 tweets linking to scientific journal articles found that many were modified retweets of tweets originating from the journal's own Twitter account [28.88].

From the perspective of scholarly metrics, a distinction should arguably be made between tweets and retweets, as the latter reflects a rather passive act of information sharing [28.118]. Although with each retweet the visibility of the tweet and the information it contains (e. g., the link to a publication) increases, retweets represent diffusion of information rather than impact. As retweeting requires even less effort—as little as one click since the implementation of the retweet button—than composing an original tweet, Twitter metrics should distinguish between tweets and retweets to reflect these different levels of user engagement [28.119].

Followers, @mentions and @replies

Scholars on Twitter actively seek new connections and connect others [28.25]. Twitter is built in a way that information is spread via user networks. This means that users receive updates from those they follow and diffuse their messages to those they are followed by, creating a personal public [28.73]. Selecting who to follow and who one is followed by are thus essential to communicating on Twitter. Twitter users build a reputation based on both their number of followers and followees. A parallel can be drawn to authors' citation identity and citation image based on which authors one cites and is cited by [28.120, 121].

The purpose of expanding one's social network and finding peers was apparent in a study of 632 emergency physicians on Twitter: those who included work-related information in their Twitter bios had more followers and the most influential users in the network were connected to at least 50 other emergency physicians [28.122]. Similarly, conference participants on Twitter saw a significant increase in their number of followers, particularly when they were also presenting [28.62]. The average number of followers of 260 physicians analyzed by *Chretien* et al. [28.49] was 17 217 with a median of 1426, indicating the typically skewed distribution of followers among Twitter users.

In addition to broadcasting one's message via retweets on a meso level of communication, Twitter users can also directly address users with @mentions or @replies on an interpersonal level. Both replies and mentions thus represent a particular type of tweet that focuses on conversation rather than broadcasting [28.123]. Like most Twitter affordances, these types of tweets were also developed by the user base before being implemented by Twitter. While @replies happen in response to a tweet and are only visible on the timeline of the tweeter who sent the original tweet, @mentions refer to tweets that contains another user's Twitter handle, which triggers a notification to inform them about being mentioned [28.24]. About one third of tweets in 2009 included another user name [28.23]. A random sample of tweets without an @mention were mostly about the tweeting user's experience, while those with an @mention were more likely about the addressee. In fact, more than 90% of @mentions functioned to address another user, while 5% worked as a reference [28.123].

The great majority of tweets sent by social sciences and humanities doctoral students referred to other Twitter users, as 72% of the 43 176 tweets sent contained other user names [28.48]. Conversational tweets were also popular among a group of tweeting astrophysicists. Of the 68 232 tweets, 46% were @replies or @mentions (61% including RTs), making it the most frequently used Twitter affordance. Conversational tweets were particularly common among those who tweeted regularly or frequently [28.110]. Most of these mentions referred to science communicators (24%), other astrophysicists (22%) or organizations (13%) on Twitter [28.50].

Conversational tweets hardly contained links [28.51], and among tweets linking to publications, only 8% were @replies [28.14]. Opposed to hashtag use, retweeting and embedding URLs, @mentions were the only affordance that were less likely to occur in professors' professional tweets (56%) than those identified as personal (67%), which suggests that when professors discuss their work, they are less likely to address or reference other users directly than when they tweet about private matters. However, mentioning other users was still more common in their professional tweets than retweeting and using hashtags [28.41].

Hashtags

Similar to retweets and @mentions, hashtags are a user-driven Twitter affordance. Hashtags are keywords following the #-sign, which facilitate connections between users interested in the same topics. Conversations revolving around hashtags represent the macro layer of Twitter communication [28.24]. Holmberg and colleagues suggest that "hashtags may resemble the traditional function of metadata by enhancing the description and retrievability of documents" [28.50, p. 3].

Hashtag use seems to be less common than that of other Twitter affordances among academics. Sixty-one percent of surveyed US-American university professors declared that they rarely or never used a hashtag [28.41]. This might be because scholars are either less familiar with this Twitter-specific affordance or they do not wish to expand conversations beyond their personal publics defined by their follower networks. Although actual hashtag use was low by the US professors analyzed by *Bowman* [28.41], they were more likely to use hashtags in their tweets identified as professional (28%) than those coded as personal (17%).

An early large-scale study found that among a random sample of 720 000 tweets, only 5% contained a hashtag [28.23]. Almost one quarter of tweets by astrophysicists contained a hashtag [28.110], but hashtag use varied significantly among different clusters of the follower network [28.50]. The same share of hashtags (25%) was found for tweets of SSHRC-funded doctoral students; on average each hashtag was mentioned 2.8 times [28.48]. It is problematic to infer hashtag use from most other studies on scholarly tweets, as data collection itself is often based on a specific hashtag, such as a conference hashtag [28.63, 71].

28.2.3 Reluctance Against and Negative Consequences of Using Twitter

When using tweets as the basis to measure scholarly impact of any sorts, it is essential to consider who is not on Twitter and why academics might be reluctant to join the microblogging platform. Twitter is a platform where "content is not king" [28.34, p. 395] and has been perceived as "shallow media, in the sense that it favors the present, popular and the ephemeral" [28.10, p. xiv]. Early Twitter studies which identified the majority of tweets to be "pointless babble" [28.33, p. 5] or "daily chatter" [28.124, p. 62] casted doubt on the value of Twitter as a meaningful communication medium [28.10]. This reduction to banal content has led many in academia to consider tweeting a waste of time and to therefore reject Twitter as a means of scholarly communication [28.125]. In particular, the 140-character limit of tweets has many scholars doubting Twitter's usefulness for research. This may be why Twitter is one of the best known and at the same time least used social media platforms in the scholarly community [28.13, 30–32, 125].

The adoption of new technologies is often met with functional and psychological barriers. Lack of time and skills and negative perceptions of platforms have been identified as barriers to using social media in academia [28.126]. Reluctance often stems from the notion that tweeting wastes precious time and introduces challenges that come with the blurred boundaries of professional and personal communication. This mix of professional and personal identities on Twitter specifically has been revealed by many studies and has been identified as a potential reason not to use Twitter in academia. Even though in the general public, Twitter uptake is higher among young adults, it is often early career researchers who are more reluctant to tweet about their work [28.127, 128]. Young academics feel the highest pressure to publish in high-impact journals and limit their time spent on social media, and feel more vulnerable when publicly exposing their ideas, particularly to uncertain audiences [28.128–131]. An academic interviewed about the future of scholarly communication expressed their concern regarding the use of Facebook and Twitter for work purposes [28.129, p. 97]:

> There's this research group in my area and, for some reason, they're really into Facebook. So they want to do a lot of discussions on Facebook and that type of thing. But I really just don't have time. It's like Twittering. I just can't ... There needs to be a little bit of space where I can actually think about something. And I think for some people, they're just wired in such a way that they like that constancy, and they are also able to actually say something intelligent quickly. And I'm not like that. I have to be a little bit more deliberate and think about things a little bit more. And so I can't Twitter ... I need some time to reason...

However, early-career researchers were often more likely to find social media useful in the context of scholarly communication and collaboration [28.36, 38, 132]. *Bowman* [28.41] identified a u-shaped relationship between Twitter use and academic experience: US professors seven to nine years into their academic careers were more likely to use Twitter compared to those with fewer and more years of experience. A humanities scholar addressed the issue of blurred boundaries on Twitter [28.127, p. 59]:

> I think it can be distracting, especially to grad students, when they're trying to navigate, when they're needing to learn, adopt, and use these new technologies, but at the same time learn to discriminate among technologies that are more for social things but are being used in the name of research. The lines are too blurry.

The tension that arises between scholars who take to Twitter and those who are reluctant to discuss scholarly matters on social media is demonstrated by an incident where a genomics paper published in *PNAS* was criticized on Twitter for flaws in study design and analysis casting doubt on its conclusions. The tweet sent by a genetics researcher at the University of Chicago included charts and tables from a reanalysis of the *PNAS* paper's data, which he published in the open access and open-peer review journal *F1000Research*. The tweet and reanalysis provoked many responses on Twitter and in the comment section of the *F1000Research* paper, some of which demanded the retraction of the *PNAS* paper [28.89], while the *PNAS* authors accused the critic of violating the norms of science by taking to Twitter.

The clashing of personal and professional and the fuzzy boundaries between the two has also lead to severe negative consequences for scholars. Tweets by faculty have caused outrages among students, other faculty members, university administration and the public at large. Identifying professionally on Twitter has affected the academic careers of some scholars and, in a certain case, controversial tweets have provoked death threads [28.133]. Tweeting had serious effects on the career of a tenured University of New Mexico psychology professor, who had fat-shamed students on Twitter: "Dear obese PhD applicants: if you didn't have the willpower to stop eating carbs, you won't have the willpower to do a dissertation #truth." The professor was asked to apologize and had to undergo sensitivity training, while his work was monitored and he was banned from working on the graduate students admission committee for the rest of his career [28.96, 134, 135].

In another incident, an English professor lost his tenure-track position offer from the University of Illinois at Urbana-Champaign due to a tweet that was interpreted as anti-Semitic [28.94]. In response to withdrawal of the job offer by the University of Illinois, the American Association University Professors updated their report on academic freedom to reinstate that academic freedom applies to comments made on social media [28.93].

28.3 Scholarly Output on Twitter

As this chapter discusses scholarly Twitter metrics, it focuses on how scientific papers are diffused via tweets. Although, as described above, only a small amount of scholars' tweeting activity involves linking to publications [28.14, 71], tweets to journal articles represents one of—if not the—most popular altmetric. This might be due to the significance of publications in peer-reviewed journals in scholarly communication as well as the ease at which tweets that mention or link to document identifiers (e. g., the Digital Object Identifier DOI) can be retrieved. Another reason that Twitter-based altmetrics—and, in fact, all altmetrics—gravitate towards journal articles is that they aim to complement existing bibliometric measures, which reduce scholarly output in a similar manner.

In the following, the altmetrics literature is reviewed to provide an overview of currently used scholarly Twitter metrics for journal articles. As the majority of available studies only scratch the surface of what can potentially be extracted from Twitter activity, the literature review is complemented by an analysis of tweets collected by Altmetric.com. This analysis goes beyond tweet counts and correlations with citations and aims to reflect the *What*, *How*, *When*, *Where* and *Who* of scholarly publications shared on Twitter. This includes what types of documents are tweeted, how Twitter affordances such as hashtags, retweets and @mentions are used to share them, when and where articles are tweeted and who is tweeting them. Although this chapter is not able to provide solutions to problems associated with creating meaningful metrics from tweets, particular limitations and pitfalls are highlighted, while demonstrating the potential of available data. Together with the findings on Twitter use described above, the chapter tries to provide context to aid in the interpretation of different metrics. It thus aims at improving the understanding of what Twitter-based scholarly metrics can and cannot reflect.

28.3.1 Data and Indicators

The analysis of tweets that mention scholarly documents is based on Twitter data collected by Altmetric.com until June 2016, which contains 24.3 million tweets mentioning 3.9 million unique documents. Altmetric started systematically collecting online mentions of scholarly publications in 2012 and is a particularly valuable data source for tracking Twitter activity related to scholarly output, as it continuously stores tweets that mention scholarly publications with a DOI. Through accessing tweets through the Twitter API firehose, Altmetric circumvents the usual issues of Twitter data collection that researchers are confronted with when using the freely available Twitter APIs. While the Twitter *Streaming* API limits access to a random sample of 1% of tweets, the *Representational State Transfer* (REST) API is rate-limited and the *Search* API restricts access to only the most recent tweets relevant to a particular query [28.136]. As Altmetric started data collection in 2012, Twitter activity is incomplete for documents published earlier.

Altmetric's Twitter data is matched to bibliographic information from WoS using the DOI. This match between document metadata and tweets affords the possibility to determine the amount of scholarly output that does and does not get tweeted. The link to WoS data also provides access to cleaner and extended metadata of tweeted documents, such as the publication year, journal, authors and their affiliations, and a classification system of scientific disciplines. At the same time, the match of the two databases also excludes tweets to publications not indexed in WoS and thus comes with the known restriction and biases of WoS coverage. This is why the following analysis describes results for two datasets, the first containing all 24.3 million tweets covered by Altmetric (dataset A), and the second the 3.9 million tweets mentioning documents with a DOI, covered by WoS and published in 2015 (dataset B). The number of unique documents in dataset A is based on the Altmetric ID. As Altmetric.com's metadata is based on multiple sources, one publication might be treated as two documents, particularly if it has multiple versions, such as a journal article on the publisher's website and a preprint on *arXiv*. Similar duplications are possible but less likely in dataset B, which is based on unique identifiers and cleaner metadata in WoS.

In the following, a set of descriptive indicators are used based on tweets to scholarly documents and associated metadata. Table 28.1 provides an overview of each metric. As described above, the focus here is on journal articles but the metrics can, nevertheless, be applied to any scholarly document or other research object such as scholarly agents including "individual scholars, research groups, departments, universities, funding organizations and others entities acting within the scholarly community" [28.119, p. 376]. Similar to most bibliometrics, the metrics described in Table 28.1 can be applied to any aggregated set of documents, such as all documents relevant to a certain topic, published in the same journal, by the same author, institution, country or in a specific language.

28.3.2 What Scholarly Output Is Tweeted?

As shown above, only a small share of tweets sent by scholars actually link to scholarly output. Tweets linking to blogs or other websites are often more frequent than those linking to scientific publications. At the same time, the great majority of altmetric studies on Twitter focus on peer-reviewed scientific journal articles with a DOI, which represent one of the main limitations of currently captured altmetrics [28.3, 137–139].

In comparison to other common altmetrics, Twitter is the platform which exhibits the second largest activity related to scientific papers, following the social reference management platform Mendeley [28.15, 140]. The disciplinary differences in Twitter uptake described above are equally visible, and likely resulting in large difference in Twitter coverage between scientific disciplines. In the majority of studies, usually between 10% to 30% of selected documents were mentioned on Twitter at least once [28.7, 8, 15, 19, 141–144]. As the majority of tweets linking to scholarly papers occurs immediately after publication [28.6, 113] and Twitter activity increased annually, Twitter coverage increases by year of publication, with the most recent papers being more likely to be tweeted and older papers hardly getting shared on Twitter [28.8]. For example, while more than half of 2015 PLOS papers were tweeted at least once [28.53], Twitter coverage was at 12%

Table 28.1 Scholarly Twitter metrics associated with scholarly documents

Type of metric	Scholarly Twitter metric	Description
Tweets	Twitter coverage	Percentage of documents with at least one tweet
	Number of tweets	Sum of total number of tweets
	Twitter density	Mean number of tweets per document
	Twitter intensity	Mean number of tweets per tweeted document
Retweets	Share of retweets	Percentage of tweets that were retweets
	Retweet density/intensity	Mean number of retweets per document/tweeted document
Users	Number of users	Unique number of users associated with a document
	User density/intensity	Mean number of users per document/tweeted document
	Mean number of followers	Mean of the number of followers of users tweeting a document
Hashtags	Hashtag coverage	Percentage of documents with at least one hashtag
	Number of hashtags	Unique number of hashtags associated with a document
	Hashtag frequency	Sum of total number of hashtag occurrences
	Share of hashtags	Percentage of tweets with at least one hashtag
	Hashtag density/intensity	Mean number of hashtags per document/tweeted document
@mentions	@mention coverage	Percentage of documents mentioning a user name
	Number of mentioned users	Unique number of users mentioned in tweets associated with a document
	@mention frequency	Sum of total number of @mentions
	@mention density/intensity	Mean number of @mentions per document/tweeted document
Time	Tweet span	Number of days between first and last tweet
	Tweet delay	Number of days between publication of a document and its first tweet
	Twitter half-life	Number of days until 50% of all tweets have appeared

for those published in 2012 [28.19]. Similarly, 13% of 2011 [28.7], 16% of 2011–2013 [28.145] and 22% of 2012 WoS documents [28.15] had received at least one tweet, while Twitter coverage increased to 36% for WoS 2015 papers in dataset B (Table 28.2).

Coverage varied between disciplines and journals, but also between databases and geographic regions. Twitter is blocked in countries like Iran and China, which reflects on the visibility of their authors and papers. For example, the share of tweeted papers was low for papers published by authors from Iran [28.146]. Such geographical biases affect Twitter visibility and need to be taken into account when comparing Twitter impact of documents, authors and institutions from different countries. For example, as few as 6% of Brazilian documents published 2013 and indexed in SciELO [28.147] and 2% of a sample of Iranian papers covered by WoS had been tweeted [28.146]. On the contrary, at 21% Twitter coverage of Swedish publications seems to be more in line with general findings [28.143]. As the sample of Iranian publications included documents published between 1997 and 2012, and 98% of tweeted papers were published between 2010 and 2012, both geographical and publication date biases influence Twitter coverage.

Particularly high coverage was found for *arXiv* submissions [28.113, 148]. This high activity was, however, not caused by high Twitter uptake in the physics, mathematics and computer science communities, but created by Twitter bots [28.149]. The extent of such automated rather than human activity and its implications for the meaning of scholarly Twitter metrics are further discussed below.

While Twitter coverage describes the extent to which a set of documents gets diffused on Twitter, Twitter density (i. e., the mean number of tweets per paper) reflects the average tweeting activity per document. In general, each paper receives less than one tweet on average, with large variations between disciplines (see below). As Twitter density is influenced by Twitter coverage and thus particularly low when only a small share of papers gets tweeted, Twitter intensity reflects the average tweeting activity for tweeted papers only, excluding non-tweeted papers [28.15]. The number of tweets per paper is usually heavily skewed, much more than citations. For example, 63% of tweeted biomedical papers were only tweeted once [28.8].

A similar distribution can be observed for the two datasets described above (Fig. 28.1). The 24.3 million tweets in dataset A mentioned 3.9 million documents (based on Altmetric ID), 43% of which were tweeted once, 19% twice, 10% three times, while only 4% of documents received more than 25 tweets. The document with the most Twitter activity was mentioned 35 135 times by 144 users, with one user tweeting 34 797 times. This highlights that the number of distinct users per document might be a better proxy of diffusion than the total number of tweets.

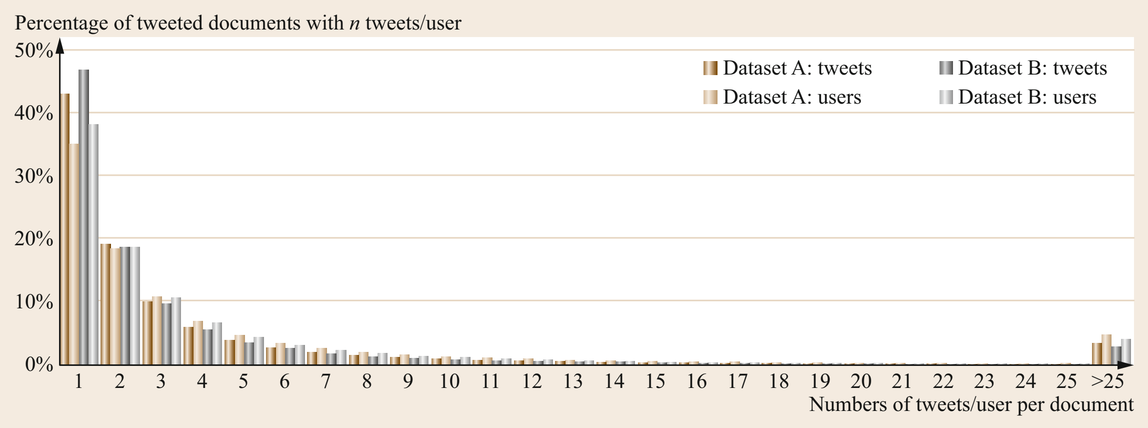

Fig. 28.1 Number of tweets and users per tweeted document for datasets A and B

Tweets in dataset A were sent by 2.6 million users and link to 3.9 million documents, amounting to a Twitter intensity of 6.2 tweets per tweeted paper. The number of users is based on unique Twitter handles included as *Author ID on Source* in Altmetric's Twitter data. Since the data does not include Twitter's unique user ID, users might be counted more than once if they changed their Twitter handle. Very likely caused by the 140-character limitation, less than 1% of tweets link to more than one document. As shown in Fig. 28.1, the distribution of number of users per document is even more skewed with 47% of all documents tweeted by a single user only. The distribution for WoS 2015 papers (dataset B) is similar but slightly less skewed for documents (based on WoS identifier) mentioned in one tweet and by one user only; 35% and 38% of documents were tweeted once or by one user, respectively. The total of 3.9 million tweets were sent by 601 290 users mentioning 548 841 documents, which corresponds to a Twitter coverage of 36%, intensity of 7.2 and a density of 2.6 tweets per document.

Disciplines and Journals

Twitter activity varies among disciplines and even journals of the same field. As there is no gatekeeping in Twitter, these variations might not be entirely due to actual impact of a particular journal but can be heavily influenced by individuals and marketing strategies of publishing houses or other stakeholders. Despite these variations, studies have shown that multidisciplinary and biomedical journals as well as social science publications are particularly visible on Twitter, while the so-called hard sciences are tweeted about less [28.8, 15, 19, 53, 140–144, 150, 151].

Previous findings are corroborated by the analysis of discipline and journal-based tweeting activity in dataset B. As shown in Table 28.2, over one third of 2015 documents in WoS have been tweeted, which represents a significant increase compared to papers published in the previous years. Twitter coverage shows large variation between disciplines, from 59% of publications in biomedical research, health and psychology, to less than 10% in mathematics and engineering & technology. This supports previous findings that Twitter activity is particularly elevated around publications from the biomedical and social sciences [28.7, 15].

It should be emphasized that Twitter activity in the arts and humanities cannot be generalized, as DOIs are not commonly used in these disciplines. While overall, 76% of all documents had a DOI, as few as 19% of all WoS-indexed journal articles in the arts were linked to this unique identifier. DOI use does not only differ between disciplines but also by country or language of publication, which is why results may be biased in these regards as wells. Considering *National Science Foundation* (NSF) specialties with more than half of its papers having a DOI, Twitter coverage was highest in parasitology (78%), allergy (76%) and tropical medicine (70%) and lowest in metals & metallurgy (1%), miscellaneous mathematics (2%), mechanical engineering (2%) and general mathematics (3%). With more than 10 tweets per document, Twitter density was highest in general & internal medicine (13.5) and miscellaneous clinical medicine (12.3).

At a Twitter coverage of 100%, 198 of 9340 tweeted journals had all of their documents diffused on Twitter, which strongly suggests a systematic and automated diffusion, possibly by a dedicated account maintained by the journal or publisher (see below). Among journals with at least 100 papers with a DOI in 2015, *JAMA* and *Biotechnology Advances* had the highest

Table 28.2 Dataset B: Twitter activity for WoS articles published in 2015

Discipline	Papers 2015		Tweeted papers		Tweets				Users

[a] Results are too low to be representative of the publication output of the respective description.

Twitter density at 115.4 and 113.2 tweets per paper, respectively. With more than 10 000 unique Twitter users, *PLoS One*, *BMJ*, *Nature*, *Science*, *PNAS*, *NEMJ*, *JAMA*, *Lancet*, *Scientific Report*, *Nature Communications*, *JAMA Internal Medicine*, *PLOS Biology*, *British Journal of Sports Medicine*, *Cell*, *Biotechnology Advances* and *BMJ Open* were tweeted by the largest audience on Twitter (Table 28.3). These journals reflect large multidisciplinary and biomedical journals with large readership, which have been previously identified as highly tweeted, possibly because they exhibit a particular relevance to people's everyday lives [28.140]. Almost all of these journals maintain official Twitter accounts appearing among the three most tweeting users, which suggests that Twitter has become an important platform for journals and publishers to promote their contents. The number of unique Twitter users, particularly for the general science journals, seems to be low in comparison to global readership. For example, while *Nature* claimed to have 3 million unique visitors per month [28.152], as few as 42 365 Twitter users mentioned a 2015 paper. However, the numbers seem to be in line with print circulation [28.153].

Going beyond peer-reviewed journals indexed in WoS, other sources (based on Altmetric metadata) of scholarly documents are also frequently shared on Twitter. In fact, the largest number of tweeted documents in dataset A came from *arXiv*: a total of 319 411 *arXiv* submissions were tweeted 1.1 million times by 110 134 users. As shown in Fig. 28.2, the number of tweeted documents and unique users derivate particularly for the most popular sources. Although *arXiv*, *PLoS One* and *SSRN* are the most popular platforms according to the number of tweeted documents, *Nature*, *The Conversation* and *PLoS One* are tweeted by the largest number of users.

The majority of popular sources are peer-reviewed journals indexed in WoS, which also lead the ranking in dataset B (see above). Apart from these, links to repositories for documents (arXiv, SSRN, bioRxiv) or data (figshare, Dryad), as well as to websites like *The Conversation* or *ClinicalTrials.gov*, are also frequently tweeted. It should be mentioned that the document metadata in Altmetric is based on a variety of sources and thus shows some inconsistencies. For example, the source is unknown for 6% of tweeted documents and 4% of tweets in dataset A, and some sources appear in various spellings. Therefore, the number of distinct sources (49 379) or journal IDs (28 457) represents an overestimation of different sources. These inconsistencies can also be found in the publication year and other document metadata, which are essential to characterize what kind of scholarly output has been diffused on Twitter.

Table 28.3 Twitter metrics for journals with the largest Twitter audience based on number of users (≥10 000 users) including three most active users

Journal	Twitter coverage (%)	Tweets N	Density	Intensity	%RTs	Users N	Top 3 most active users (according to number of tweets; official journal accounts are marked in italic)

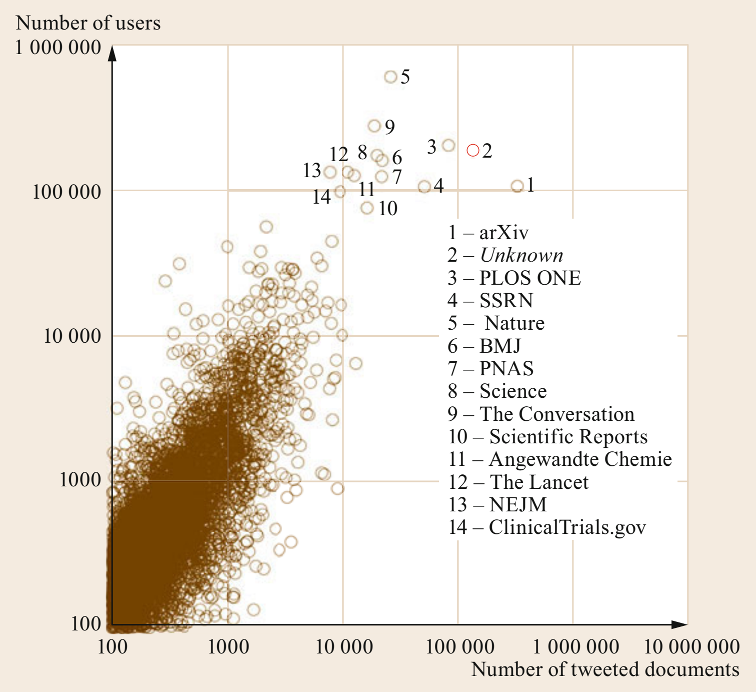

Fig. 28.2 Number of tweeted documents and unique users per source in dataset A (≥100 tweeted documents)

Document Characteristics

Besides disciplinary and topical differences, studies have also focused on determining what type of documents are popular on Twitter. Papers with particularly high Twitter visibility often had humorous or entertaining contents rather than scientific merit [28.8, 154]. A study that coded title characteristics of 200 highly tweeted papers found that 16 included a cultural reference (i. e., proverbs, idioms, fictional characters, music) and 13 were humorous or light [28.155]. *Bornmann* [28.156] reported that among papers recommended on *F1000*, those labeled as *good for teaching* were frequently tweeted. *Andersen* and *Haustein* [28.142] found that meta-analysis and systematic reviews received significantly more tweets than other medical study types.

Marking a clear distinction from citation patterns, particularly high Twitter activity was found for document types that are usually considered *uncitable* [28.15]. For example, Twitter coverage for news items was twice as high as that for all documents. Twitter density was highest for news items (3.0), editorial material (1.6) and reviews (1.4), by far exceeding the overall average of 0.8 tweets per document. The success of these document types on Twitter suggests that [28.15, p. 8]:

> documents that focus on topical subjects, debates and opinions, which are probably presented in simpler and less technical language, are more likely to appear and become popular on Twitter.

Publications with shorter titles, fewer pages and references tend to receive more tweets, while the opposite tendencies are usually observed for citations [28.15].

Similarity to Other Types of Usage

Since altmetrics were proposed as an alternative or complement to traditional bibliometric indicators, most studies analyze to what extent these new impact metrics correlate with citations. The motivation behind correlation studies lies in determining whether tweeting patterns are comparable to citing behavior. Positive correlations between citation and tweets would indicate that tweets measure something similar to but much earlier than citations, making tweet-based indicators predictors of impact on the scholarly community [28.6]. Early studies argued that low or negative correlation coefficients would indicate a different type of impact than that on citing authors, and possibly an impact on society in general.

The first study analyzing the relationship between tweets and citations found a significant association between highly tweeted and highly cited papers published in the *Journal of Medical Internet Research*, as highly tweeted publications identified 75% of those which were later highly cited [28.6]. However, this claim was based on 55 papers in a journal which itself maintained a strong Twitter presence. For a set of 4606 *arXiv* submissions, tweets were a better predictor of early citations than downloads [28.113]. The generalizability of the finding that tweets were early indicators of citation impact was later refuted by a large-scale analysis based on 1.3 million documents, which found low correlations overall between tweets and citations [28.8].

Correlations between tweets and citations vary between datasets due to particular differences between disciplines or journals, but are low overall, between 0.1 and 0.2 [28.7, 8, 15, 19, 53]. It should be noted that correlations are affected by low Twitter coverage and thus differ whether untweeted papers are excluded or included from the analysis [28.15]. Instead of replacing citations as a faster and better filter of relevant publications, as was suggested in the altmetrics manifesto [28.157], the number of tweets seem to mirror visibility on other social media platforms, in particular Facebook, rather than visibility within the community of citing authors [28.15, 53]. If nothing else, the difference between tweet and citation counts as reflected in low correlations might be due to the fundamental difference between the act of citing and tweeting [28.119].

A moderate negative correlation was found comparing publication output and tweeting activity of a group of astrophysicists on Twitter, suggesting that researchers who tweet a lot focus their efforts on communication and outreach rather than publishing peer-reviewed articles [28.110]. This inverse relationship between a researchers' standing in the scholarly community and their visibility on Twitter has led to the so-called Kardashian Index, a tongue-in-cheek indicator that reveals that those who tweet more publish less and vice versa [28.16].

Rather than correlating tweets and citations, *Allen* et al. [28.158] aimed to measure the effect of promoting articles on social media (including Twitter) on usage statistics. Comparing the number of views, downloads and citations of randomly selected articles published in PLoS One before and after promoting them on social media, article views and downloads increased significantly, but citations one year after publication and social media metrics did not.

28.3.3 How is Scholarly Output Tweeted?

Not the least due to the evaluation community's focus on counts, altmetrics research has focused much less on tweet content than on correlations and other quantitative measures. Among those looking at tweet content, the focus has been on the analysis of Twitter-specific affordance use [28.41, 63]. This includes in particular the use and analysis of hashtags, retweets and @mentions, which are further described below.

Analyzing 270 tweets linking to journal articles, *Thelwall* et al. [28.88] found that 42% contained the title of the article, 41% summarized it briefly and 7% mentioned the author. As few as 5% explicitly expressed interest in the article. While sentiment was absent in the great majority of tweets, 4% of tweets were positive and none negative. Similarly, a large-scale study that automatically identified sentiments in tweets using *SentiStrength* found that the majority of tweets were neutral and that, if sentiment was expressed, it was positive rather than negative [28.159]. Based on 192 832 tweeted WoS documents published in 2012, 11% of 487 610 tweets were positive, 7% were negative and 82% did not express any sentiment after removing the article title words from tweets. Tweets linking to chemistry papers were the least likely to express sentiments [28.159, 160].

Retweets and @mentions

As described above, retweets and @mentions represent a particular form of conversational tweets, which seemed to enjoy particular popularity among academic Twitter use. Half of the 4 million tweets linking to 2015 WoS papers were retweets (Table 28.2), which suggests that a significant amount of tweeting activity reflects information diffusion that does not involve much engagement. Compared to the studies investigating retweet use among general Twitter users [28.23] and academics [28.14, 48, 71, 110], the share of retweets among tweeted journal articles is rather high. The percentage of retweets tends to be lowest in disciplines with low Twitter coverage, which suggests that users in disciplines with low Twitter uptake do not use it as much for information diffusion, possibly because they are not as well connected. In 32 of 120 NSF specialties with DOI coverage above 50%, retweets exceed original tweets (Table 28.2): retweeting was particularly common in miscellaneous zoology, general & internal medicine, miscellaneous clinical medicine and ecology with retweet rates above 60% and low in solid-state physics, inorganic & nuclear chemistry, chemical physics and applied chemistry with less than 20%.

Hashtags

Thirty-one percent of the 24.3 million tweets captured by Altmetric until June 2016 contained a hashtag, which is comparable to other studies on hashtag use by academics [28.48, 110], but far higher than the 5% among a random sample of tweets in 2009 [28.23]. 401 287 unique hashtags were mentioned 12.6 million times, which amounts to an average occurrence of 31 per unique term. A total of 105 705 unique hashtags were used in tweets linking to 2015 WoS papers. While 33% tweets contained a hashtag, 46% of all articles were described with at least one hashtag. Each hashtag was mentioned on average 21 times for a total hashtag frequency of 2.2 million. Hashtag frequency is extremely skewed, as 3% and 6% of hashtags are responsible for 80% of hashtag occurrences in dataset A and B, respectively. For example, the most popular hashtag in dataset A was used 162 754 times (1.3% of all occurrences), while 169 992 hashtags only occurred once. Figure 28.3 demonstrates on a log-log scale the number of tweets in which hashtags were mentioned, as well as the number of distinct users mentioning each hashtag. While in general, a linear relationship can be found between the number of occurrences and users, a few popular hashtags are tweeted only by limited number of users, indicating a smaller community.

The most popular hashtags in dataset A were #science (Table 28.4, 1.3% of hashtag occurrence), #cancer (0.9%), #physics (0.8%), #openaccess, #health (0.7%), #paper, #oa and #research (0.5% each). The occurrence of #oa as well as #openaccess among the most frequent hashtags reflects the known heterogeneity of folksonomies and the need for *tag gardening* when trying to analyze topics [28.161]. WoS 2015 papers (dataset B) were most frequently tagged as #cancer (1.0%), #health, #openaccess, #science (0.9%), #FOAMed, #Diabetes, #ornithology and #Psychiatry (0.6%). The order changes when considering the number of unique users instead of tweets per hashtag. Among hashtags that occurred at least 1000 times, the largest discrepancy between the number of tweets and users can be observed for #genomeregulation (1924 tweets; 10 users), #eprompt (2281; 17 users) and #cryptocurrency (4515; 38 users), which were, on average, tweeted more than 100 times by the same users. On the contrary, the user–hashtag ratio was lowest for #Fit (4818; 4743), #StandWithPP (*Stand with Planned Parenthood*; 1060; 972), #dataviz (1010; 912), #coffee (1517; 1246), and #PWSYN (title of popular science book *The Patient Will See You Now*; 1017; 834), which indicates widespread adoption among Twitter users. Accordingly, these hashtags are more general and less scientific.

Table 28.4 shows hashtag-based stats for both datasets. As to be expected, hashtag frequency and the number of unique terms is greater for dataset A, as it covers all documents in Altmetric and the whole timespan, while dataset B is restricted to WoS documents published in 2015. On average, each hashtag occurred in 21 tweets, was used by 13 users to tag 7 documents and 4 journals indexed in WoS. As shown by the per-

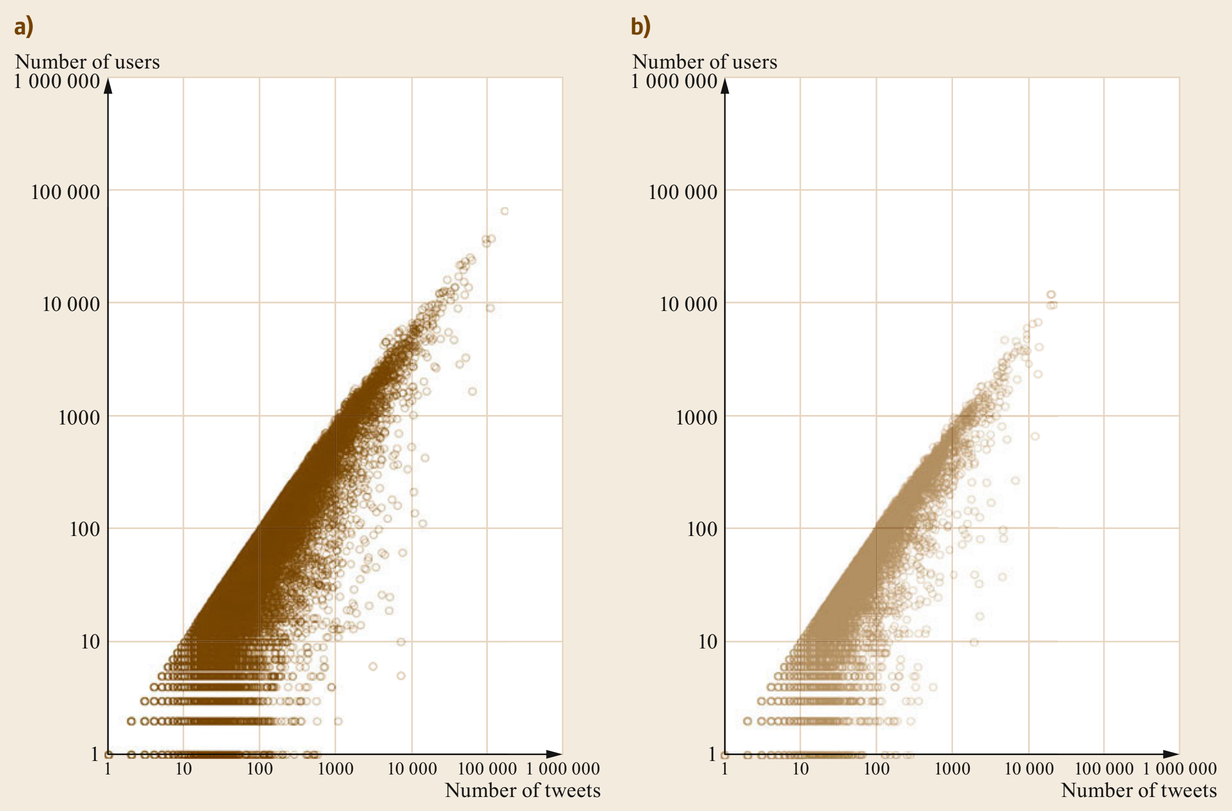

Fig. 28.3a,b Number of users and number of tweets per hashtag for all tweets captured by Altmetric **(a)** and for tweets to 2015 WoS papers **(b)**

Table 28.4 Hashtag statistics for datasets A and B with most frequent hashtags based on number of tweets

Most frequent hashtags	Statistics of hashtag frequency	Number of tweets	Number of users	Users per hashtag	Number of documents	Number of journals	Tweet span
Dataset A							
#science	Mean	31	17	1	11		233
#cancer	*Standard deviation*	*617*	*237*	*4*	*209*	n/a	*459*
#physics	Minimum	1	1	1	1		0
#openaccess	Maximum	162 754	65 334	1425	54 845		1825
#health	99th percentile	395	229	6	129		1746
#paper	90th percentile	20	15	2	8		1036
#oa	75th percentile	5	4	1	2		182
	50th percentile	2	2	1	1		0
Dataset B							
#cancer	Mean	21	13	1	7	4	102
#health	*Standard deviation*	*222*	*111*	*2*	*73*	*19*	*192*
#openaccess	Minimum	1	1	1	1	1	0
#science	Maximum	21 122	12 056	274	9765	1684	1723
#FOAMed	99th percentile	311	186	5	92	49	831
#Diabetes	90th percentile	20	15	2	7	6	381
#ornithology	75th percentile	6	5	1	2	2	130
	50th percentile	2	2	1	1	1	0

centiles, hashtag occurrence is extremely skewed. On the individual level, the number of users, documents and journals associated with a hashtag can provide information as to how general and widespread a hashtag is, or how specific and relevant to only a small group of users. The timespan, that is, the number of days between the first and last occurrence of a hashtag, indicates its topicality or timeless relevance. For example, among hashtags that occurred at least 1000 times, #diet, #water and #nutrition were used during the course of more than four years to describe 2015 documents, while #XmasBMJ lasted only 73 days. The first tweet linking to a 2015 WoS paper with the #diet hashtag appeared 17 November 2011. The discrepancy between tweet date and publication date can be described by the lag between online date and journal issue date (see [28.114] for an analysis of the publication date problematic).

28.3.4 When is Scholarly Output Tweeted?

Tweet activity related to scholarly documents has been shown to occur shortly after publication and disappear within a few days [28.6, 113]. Tweeted half-lives and delay between publication and first tweet can thus be measured in hours rather than days. This short-lived attention also points to Twitter being used to diffuse new papers instead of discussing them intensely.

It is, however, challenging to accurately calculate delay and decay for all publications in WoS as the publication date of the journal does not sufficiently represent when a publication was actually available. Even with the more accurate article-level information of online dates, there are issues to determine the actual date of publication, as demonstrated by tweets mentioning articles before they were supposed to be published [28.114]. Due to the inaccuracy of available publication dates, tweet delay and tweeted half-lives are not computed.

As shown in Fig. 28.4, there are clear differences between weekdays and weekends, reflecting patterns of the work week, which has also been shown to have an effect on journal submissions [28.162] and download patterns [28.163]. During the week, tweeting activity increases from Monday (14% of tweets) to a peak on Wednesday (18%), and decreases again towards the weekend. Twitter users tweet, on average, 23% more about scholarly documents on a Wednesday and 41% less on a Sunday. Figure 28.4 also shows the different magnitude of Twitter activity among years, as well as an overall increase throughout each year. While a general increase from January to December can be observed for each of the four years of tweets, the general trend also reflects the academic year: activity is higher in spring and fall and drops slightly in summer and particularly during the winter break during the last two and first weeks of each year. Considering that Twitter activity often climaxes the day of or day after publication, the season and weekday of publication might influence a document's visibility on Twitter [28.114]. *Zhang* and *Paxson* identified Twitter bots based on tweeting patterns that were too regular to be human [28.164].

28.3.5 Where is Scholarly Output Tweeted?

Twitter provides the possibility to geotag each tweet with precise latitude-longitude information of a user's current location. However, since this function is not activated by default, it is only rarely used. Less than 5% of tweets contain geo coordinates [28.165, 166], which is why geotags of tweets are not a reliable source to determine where scholarly output is tweeted. Another data source to determine the geographic distribution

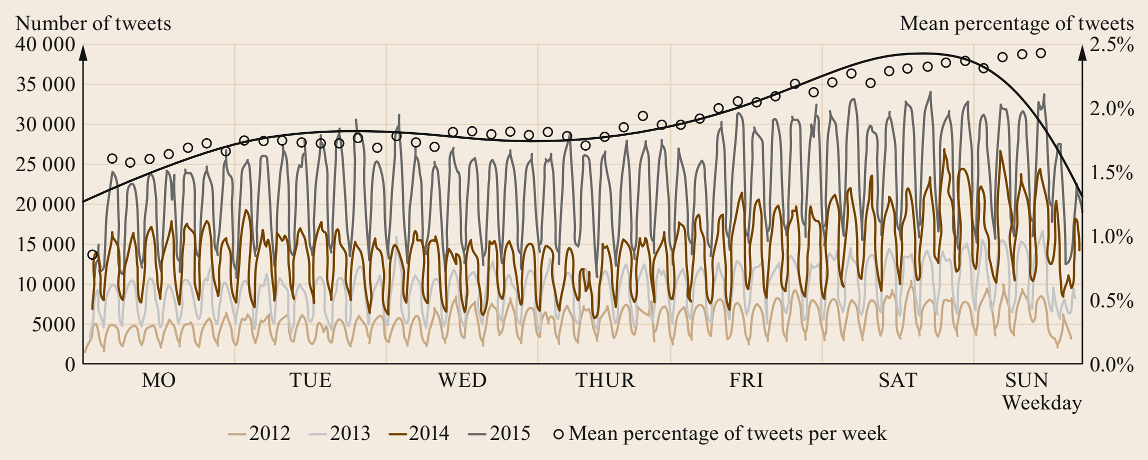

Fig. 28.4 Number of tweets per week day per year and mean of the weekly percentage per year

of Twitter users is to analyze the location information provided in the Twitter bio. However, since the profile location is usually not automatically generated but freely edited by users, it cannot be used without extensive data cleaning. *Takhteyev* et al. [28.167] showed that 8% of a sample of 3360 Twitter profiles contained specific latitude-longitude information, 57% named a location and 20% a country, while 15% used fictional places (e. g., Hogwarts) or too general descriptions to determine the users' whereabouts. Using this profile information, Altmetric is able to determine location information for two-thirds of its tweets. It becomes apparent that in many cases information is not accurate enough to determine the exact location, as remote locations in the UK and Kansas are among the most frequent tweet locations [28.168].

Due to these limitations, the analysis of where users tweet scholarly documents is restricted to the country level (Table 28.5). Altmetric provides location information for 57% of users, 58% of tweets and 71% of documents (dataset A) and 58% of both users and tweets and 70% of documents for the WoS subset (dataset B). Users from the US are overrepresented, as 20% of tweets are sent by Twitter users with an identified location in the US, followed by the UK (8%), Canada (3%), Japan, Australia and Spain (2% each). A similar distribution can be observed for the 2015 WoS articles (dataset B), as the top 10 countries by number of users stay the same, although the UK, the Netherlands, Spain and Canada, and to a lesser extent Australia and Germany, gain in percentage of users, while India, France, Japan and the US lose in comparison to dataset A. While altmetrics have been marketed as democratizers of science evaluation in terms of having the potential to correct for biases created by WoS and other US and English-centric journal databases, these results show that, when it comes to Twitter, known biases persist or are even intensified on social media.

28.3.6 Who Tweets Scholarly Output?

One of the main motivations for considering tweets as an altmetric indicator is that Twitter is used by the general public and thus, at least theoretically, offers insight into how non-academics engage with scholarly output. In order to separate tweets by the public from those sent by members of the scholarly community, Twitter users have to be identified and classified as such.

Identifying Users who Tweet Scholarly Content

One of the main challenges of determining the type of impact reflected by tweets to scientific papers is to identify who is tweeting. While Mendeley provides certain standardized user demographics such as academic status, discipline or country for users associated with a paper, the classification of tweets by user type is restricted to Twitter bios. These self-descriptions are 160-character texts, which provide users with the space to present themselves to other users of the microblogging platform.

Applying a codebook to determine who tweets scientific papers based on Twitter username, bio and photo, a sample of 2000 accounts tweeting links to articles published in *Nature*, *PLoS One*, *PNAS* and *Science*, *Tsou* et al. [28.60] found that almost one quarter of accounts were maintained by an organization.

Table 28.5 Top 10 countries by number of users for dataset A and B

	Dataset A			Dataset B			
	Documents	Tweets	Users		Documents	Tweets	Users
Number of unique items	3 903 064	24 343 105	2 622 117		548 841	3 960 431	601 290
Some country information	71%	58%	57%		70%	58%	58%
Missing country information	69%	42%	44%		77%	42%	42%
Top 10 countries by number of users							
US	33.0%	19.8%	20.1%	US	36.2%	19.5%	19.4%
UK	21.6%	11.0%	8.3%	UK	27.4%	12.3%	10.6%
CA	7.9%	2.9%	3.1%	CA	9.3%	3.1%	3.4%
JP	4.3%	1.8%	2.3%	ES	9.6%	3.3%	2.7%
AU	6.5%	2.9%	2.3%	AU	7.6%	2.5%	2.4%
ES	7.5%	2.8%	2.2%	JP	4.4%	1.5%	2.0%
FR	5.3%	1.5%	1.4%	NL	4.0%	1.0%	1.3%
IN	2.6%	0.7%	1.1%	FR	7.9%	1.6%	1.2%
NL	3.5%	1.0%	1.1%	DE	5.6%	1.1%	0.9%
DE	4.1%	1.0%	0.9%	IN	3.4%	0.7%	0.9%

Among these were mainly non-profits (42%), corporations (29%) and universities (13%), while many were also classified as news, media or outreach institutions (19%). Among the 1520 accounts identified as individuals, two thirds were male. One third of the users were identified as having a PhD and 12% as students. This amounts to almost half of all identified individuals having completed or pursuing a doctorate degree, which stands in glaring contrast to about 1% of the US population with a PhD [28.60], strongly suggesting that it is the scholarly community rather than the general public who tweets links to scientific papers.

Applying a similar codebook to a random sample of 800 accounts tweeting 2012 WoS papers, 68% of accounts were maintained by an individual, 21% by an organization, while 12% could not be identified [28.169], corroborating the findings by *Tsou* et al. [28.60]. Among individuals, 47% used professional terms (e. g., doctor, MD, photographer) to describe themselves, 22% identified as researchers (e. g., scientist, professor, postdoc), 13% as science communicators (e. g., writer, author, journalist, blogger) and 7% as students (e. g., grad student, PhD candidate). Reflecting the blurred boundaries between personal and professional communication, many individuals used words from more than one of these categories to describe themselves. For example, 8% of accounts were classified as researchers and professionals and 5% as professionals and science communicators [28.169]. Science communicators were also the largest group of Twitter users mentioned by astrophysicists [28.50]. Although labor-intensive and based on little more than 160-character self-descriptions, the above studies show that it is feasible to extract members of academia from users tweeting scholarly documents. Keyword-based searches can be applied to identify scholars in larger samples, but are limited by either low recall or low precision depending on the particular query [28.53].

It is considerably more challenging to identify members of the general public. Although many Twitter bios contain terms depicting personal lives (e. g., father, wife, yoga lover), the presence of these terms does not necessarily mean that accounts are maintained by non-academics, because scholars often describe themselves in both a personal and professional manner on Twitter [28.41, 48, 59]. Similarly, it is challenging to distinguish members of the public based on an indeterminate list of terms of non-academic professions (e. g., consultant, photographer), especially when also considering accounts in languages other than English. Even the comparably straight-forward identification of a researcher who strictly identifies as such on Twitter, becomes problematic when they shared a paper out of private interests. For example, a tweet by a physicist might actually reflect engagement by the public rather than scholarly communication, if they tweeted about a cancer study as a member of a patient group rather than in their academic role.

An alternative to classifying users based on publicly available information is to approach them directly and ask them who they are. *Alperin* [28.57] pioneered such a survey method on Twitter which, with the help of an automated Twitter account, asked users who had tweeted a *Scielo Brazil* paper whether they were affiliated with a university. Such a direct approach might also be helpful for determining the motivation for a user to tweet a specific paper, helping to quantify and distinguish different types of tweets, such as endorsement or critical discussion, diffusion or self-promotion. Author self-citations or self-tweets accounted for 7% of a sample of 270 tweets [28.88].

The 24.3 million tweets captured by Altmetric were sent by 2.6 million users. Looking at the most active users who tweeted more than 1000 times during the whole period covered by Altmetric (Table 28.6), the presence of accounts automatically diffusing scholarly articles on Twitter becomes apparent [28.149]. In fact, 15 of the 19 most productive accounts in Table 28.6 with more than 25 000 tweets self-identified as bots (see below).

Classifying Users by Twitter Activity

Instead of classifying users according to their self-descriptions, accounts can also be grouped based on their activity. Dividing Twitter accounts into three groups of top 1%, 9% and 90% of users (according to number of tweets) helps to distinguish lead and highly active users from less active ones [28.170]. This classification provides insights into tweeting behavior of different types of users. Separating the 601 290 users in dataset B by number of tweets linking to a 2015 WoS article, 6016 lead users, 54 535 highly active and 540 739 least active users can be identified. Lead users contributed between 84 and 19 973 tweets, with a median of 149 tweets per user, had on average 935 followers (median = 935; mean = 3862) and tweeted the 2015 papers during an average tweet span of 598 days. Highly active users contributed between 9 and 83 tweets (median = 16), had less followers (median = 442.5; mean = 2136) and shorter tweet spans (mean = 388 days), while least active users tweeted up to 8 times (median = 1), had 212 followers and were active for a period of 58 days.

Lead (top 1% of users), highly active (9%) and least active (90%) users contributed 43%, 31% and 25% of tweets to the entire set of 2015 WoS papers, respectively (Fig. 28.5). Interestingly, these percentages differ among NSF disciplines with least active users overrep-

resented among those tweeting literature from professional fields, social sciences, psychology and earth and space. On the contrary, lead users were overrepresented in chemistry, physics, mathematics and engineering & technology, which were the fields exhibiting the lowest Twitter coverage, density and number of unique users (Table 28.2). Assuming that the general public is least active when it comes to tweeting about scholarly papers, they are more likely to engage with articles published in journals from the professional fields and social sciences and less likely to tweet chemical papers. The high presence of lead users in chemistry and physics might, at least partly, be caused by accounts promoting these papers automatically, such as @blackphysicists and @MathPaper, which were the two most active accounts in dataset A, tweeting 51 and 67 scholarly documents per day (Table 28.6).

Twitter Bots

Automated Twitter accounts have become prevalent on Twitter [28.171]. About one fifth of tweets sent during the 2016 presidential election were estimated to be sent by bots [28.172] and almost one quarter of tweets in 2009 came from accounts tweeting more than 150 times per day. *Ferrara* et al. [28.173, p. 96] define social bots as "a computer algorithm that automatically produces and interacts with humans on social media, trying to emulate and possibly alter their behavior". Automated Twitter accounts can be further distinguished between useful bots and antisocial or spambots [28.171, 173].

Bots are also infiltrating academic Twitter. Among a random sample of 800 Twitter accounts captured by Altmetric, 8% seemed completely and 5% partially automated [28.169], while automated accounts who self-identified as such were responsible for 9% of tweets to *arXiv* submissions [28.149]. *Shuai* et al. [28.113] even removed half of the tweets to a sample of tweets to documents on *arXiv*, as they were created by bots. Regardless of whether Twitter accounts that automatically tweet scientific papers are considered useful or spam, it is safe to say that their automated tweets do not reflect *impact*. In the context of altmetrics and tweets to scientific papers, bot activity thus needs to be at least identified, if not entirely removed in an impact assessment. Although spammers and excessive self-promotion was identified as a challenge by Altmetric, they still considered gaming a rare and easy-to-identify threat in 2013 [28.174].

Twitter's terms of service specifically address automation. While prohibiting spam, Twitter encourages automated tweets if they "broadcast helpful information" [28.175]. However, what is considered spam continuously evolves as users apply "new tricks and tactics" [28.176] to adapt to or circumvent Twitter rules. Twitter bots can be identified based on specific regularities in their tweeting behavior, such as the frequent and repetitive use of the same hashtags, URLs, tweet format and content, and regular temporal activity, as well as the follower/friends ratio, @mentions to non-followers or account suspensions [28.171]. Sixteen percent of Twitter accounts were identified as automated based on not-uniform-enough or too-uniform tweeting patterns to be stemming from a human [28.164]. Social network indicators based on the Twitter follower and friend network are considered more robust measures, as they are harder to influence [28.177]. The *BotOrNot* algorithm additionally considers linguistic features and tweet sentiment to detect automated Twitter accounts [28.178]. However, as these spamming measures get known and integrated by Twitter to block spam accounts, bots employ more sophisticated algorithms to avoid getting caught, resulting in an arms race between those who create and those who seek to identify Twitter spam.

Analyzing the most active users who have tweeted at least 1000 times (dataset A), a keyword-based query searching the Twitter bio as well as user name and handle revealed that among 2043 accounts, 248 identified themselves as automated (Fig. 28.6) and 305 as journal or publisher accounts (Fig. 28.7). These make up 30% and 11% of the tweets sent by the 2043 most active users (Table 28.7), which correspond to 7% and 3% of the entire 24.3 million tweets to scholarly documents in dataset A. The median number of followers is significantly lower than other accounts (Table 28.7) and as few as 6% of the 1.8 million tweets sent by the 248 accounts contain @mentions. If scholarly bots do mention other users, they often seem to reference journals such as @hiv_insight, which frequently mentions @PLoSMedicine, @STI_BMJ and @JAMA_current. Other than social bots in the general Twittersphere, scholarly bots seem to not try to emulate human behavior or game the system. They rather resemble RSS feeds tweeting the paper title and a link, often specifying what type of information they diffuse. Some even provide instructions to create similar feeds. For example, the Twitter bio of @asthma_papers reads "RSS feed for #asthma papers in #Pubmed. Create a feed of your own using instructions here: https://github.com/roblanf/phypapers".

$n = 1490$	Mean	5236	2408	2.9	1278
59% of tweets	*Std dev*	14 091	3670	*9.3*	*496*
	Min	0	1000	0.6	8
	Max	228 224	92 583	297.3	1826

Considering that scholars use Twitter to diffuse information and stay aware of relevant literature, automated accounts might be considered useful. However, bots have shown to be harmful to society, when they are used to influence public opinion and behavior such as political opinions or elections [28.172, 179–181] or manipulation of the stock market [28.173]. If Twitter impact became part of the scholarly reward system, Twitter bots might be able to similarly influence opinions or shape outcomes of certain research metrics.

28.4 Conclusion and Outlook

This chapter provided an overview of the use of Twitter in scholarly communication. By demonstrating *who* uses Twitter in academia and for what reasons, *what* types of scholarly outputs are diffused *how*, *where* and *when*, it aimed to add context and help to interpret any scholarly metrics derived from this and similar types of social media activity.

Research evaluators and managers were particularly excited at the prospect of an easily accessible data source that would be able to capture traces of the societal impact of research. However, perhaps unsurprisingly, the majority of tweets stem from stakeholders in academia rather than from members of the general public, which indicates that the majority of tweets to scientific papers are more likely to reflect scholarly communication rather than societal impact. At the same time, Twitter uptake in academia lacks behind Twitter user by the general public. Twitter activity is influenced by geographical and disciplinary biases and publication date. Known biases towards US and UK sources persist, rather than democratizing scholarly communication and the reward system of science.

The majority of tweets linking to scientific articles appear shortly after their publication; tweeting half-lives can be measured in hours rather than days. Moreover, one can observe weekday as well as seasonal patterns, with Twitter activity peaking Wednesdays and in the fall, and plummeting during the weekends and holiday season. Journal and publisher accounts, along with Twitter bots, contribute significantly to tweeting activity linked to academic papers, which suggests that a significant extent of tweeting activity serves promotional purposes or is automated, and reflects neither societal nor scholarly impact. A large share of tweets contains hashtags and mention either the title or a short summary of the paper they referred to. Half of all articles linking to 2015 WoS papers were retweets and the majority contained no sentiments. These tweeting characteristics emphasize particular low engagement of users linking to journal articles. The main motivation for researchers to use Twitter is information diffusion, networking and to stay up-to-date with the literature. However, the sheer brevity of tweets makes intense discussions the exception rather than the rule on Twitter.

As citation behavior and motivations for citing or not citing certain sources are biased and influenced by many factors other than a paper's significance, not every citation represents impact. However, each scholarly author is bound by scholarly norms to participate in the citation process. In some rare cases, where scholars tweet corrections to publications or journals provide tweetable abstracts and organize journal clubs, Twitter has started to be integrated in or even replace certain functions of formal journal publishing. However, in most fields, tweeting does not yet play an important role in scholarly communication. In most disciplines, Twitter uptake is low and the platform is only used in a passive or infrequent manner, or tweets reflect only a part of informal scholarly communication, such as conference chatter. Moreover, Twitter uptake varies between disciplines, countries, journals and individuals, and can be easily influenced and manipulated. The presence of automated Twitter accounts which promote certain contents becomes particularly problematic when tweet counts become the basis for measures of impact.

This is not to say that Twitter should be completely disregarded as a data source for scholarly metrics. Rather, the microblogging platform should be approached critically in terms of what kind of use and user populations it captures. By reviewing the role of Twitter in scholarly communication and analyzing tweets linking to scholarly documents in depth and beyond crude counts, this chapter attempted to provide the basis for more sophisticated and well-balanced approaches to scholarly Twitter metrics.

Stefanie Haustein

School of Information Studies
University of Ottawa
Ottawa, Canada
stefanie.haustein@uottawa.ca

Stefanie Haustein is Assistant Professor at the University of Ottawa School of Information Studies, teaching research methods and evaluation, social network analysis, and knowledge organization. Her research focuses on scholarly communication, bibliometrics, altmetrics, and the role of social media in academia. Stefanie co-directs the ScholCommLab, is an associate member of the Centre interuniversitaire de recherche sur la science et la technologie (CIRST), and affiliated researcher of the Observatoire des sciences et des technologies (OST).

29. Readership Data and Research Impact

Ehsan Mohammadi, Mike Thelwall

Reading academic publications is a key scholarly activity. Scholars accessing and recording academic publications online are producing new types of readership data. These include publisher, repository, and academic social network download statistics as well as online reference manager records. This chapter discusses the use of download and reference manager data for research evaluation and library collection development. The focus is on the validity and application of readership data as an impact indicator for academic publications across different disciplines. Mendeley is particularly promising in this regard, although all data sources are not subjected to rigorous quality control and can be manipulated.

29.1 Introduction and Overview

The act of reading an academic publication is a key point at which knowledge is transferred from the author to someone else. With the prevalence of the web and social web, scholars now often read and register academic publications online, leaving electronic records of their activities. This readership data can reveal which outputs are used as well as give insights how the scientific enterprise works. It is important to exploit such information to improve research evaluation practices and to investigate how science communication is evolving. The main advantage of using readership information rather than citations is that reading occurs before citing and can, therefore, give more timely information. A second advantage is that the reading public for academic research is wider than the citing public, since it includes students, professionals, and others.

This chapter reviews research about download and readership data for academic outputs from the perspective of its value for research evaluation. It is mainly concerned with journal articles, but books and conference papers are also briefly mentioned. The chapter has extended coverage of readership information from on-

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_29

line reference managers, such as Mendeley, because of their practical value for research assessment. It also discusses publisher usage data, since *using* an article in this context often means reading it.

The usage statistics component complements the *Usage Bibliometrics as a Tool to Measure Research Activity* chapter in this Handbook (Chap. 33), which gives an extended case study of arXiv and analyzes research evaluation at a more systemic level. The current chapter also discusses usage data from the academic social network sites ResearchGate and Academica.edu, which are changing the way in which articles are discussed and shared. Previous works reviewed usage bibliometrics [29.1], readership metrics [29.2], and social media metrics [29.3]. This chapter updates the previous readership metrics chapter [29.2] with newer topics and findings. It is intended for research evaluators, scientometricians, and bibliometricians, as well as those interested in recent changes in the scholarly communication ecosystem.

This chapter opens with a discussion of reading, terminology, and research impact assessment to set the context for the ways in which readership data may be used. It continues with a discussion of online usage data from publishers and repositories, before analyzing the effect of online reference managers on the availability of readership data and discussing social networks. Finally, the chapter discusses research evaluation applications.

29.2 Reading Research: Background and Terminology

Although knowledge has traditionally been communicated in human societies orally and by imitation, the written record is a cornerstone of modern science. Academics read scholarly publications to inform themselves for their current research, for current awareness purposes, to support their teaching, or to help them fulfil a professional advisory role related to their expertise. In addition, other professionals may read journals to inform their day-to-day practice. This is the case for medical doctors, who need to be aware of the latest developments in medical practice that are relevant to their role or expertise [29.4]. For example, 73% of non-publishing Canadian physicians read journal articles [29.5], and hospital residents consider journal articles to be valuable sources of information [29.6]. Information about which academic documents are read and by whom can help the librarians that buy them, the managers and policy makers that need to evaluate the impact of the research produced, and the scholars that investigate science itself.

Many different terms have been used for reading-related data, especially within electronic contexts. The most general is perhaps *usage*, which does not imply a reason why an item was accessed but is often employed in digital contexts as an umbrella term to describe accesses of all kinds of digital resource. It is helpful to use more specific terms, when justifiable, to aid interpretation.

The more explicit term *download* refers to a local copy being taken of an electronic resource, such as a journal article, whether by a human or a robot. The terms *hit* and *view* refer to online accesses of electronic information without necessarily downloading it. For example, a digital library visitor might *view* a web page containing the title, abstract, and metadata of an article and then *download* a full-text copy of the article to their local computer. The term *full-text download* [29.7] can be used for emphasis. Although the term download usually connotes accessing a full text version of an article, some publishers provide non-downloadable full-text copies of articles, and readers may view full-text articles online without downloading them to their local computer storage [29.8].

The most specific term is *read/reader/readership*, which implies that the item accessed has been read by a human. This term can be justified for a data source if it is reasonable to believe that the items accessed will usually be read. For example, it would be reasonable to believe that a book is usually read when it is borrowed from a library. Thus, borrowing statistics could be claimed to be (non-exhaustive) reading indicators. In contrast, most accesses of documents on some websites may be from web crawlers, and so it would not be reasonable to interpret download counts as readership counts (but see the paragraph below). Moreover, human users may also systematically download journal articles if they are concerned that their access will be interrupted before they know which articles to read [29.9]. To describe download counts as a readership indicator, evidence would be needed to connect downloads to reading. Thus, if full-text downloads from a specific source are likely to be of human origin and frequently lead to reading, then it would be reasonable to refer to full-text downloads as readership data.

More specifically, and following an argument for citations [29.10], to be a readership *indicator*, download or access counts should positively correlate with reader numbers, even if not all downloads/accesses lead to reading. If this condition is fulfilled, then the counts convey information in an information theoretic sense about how often an item has been read. To give an example, a positive correlation implies that if article X has more accesses than Y, then there is a greater than 50% chance that X has been more read than Y. In general, the higher the correlation, the higher this chance is. Aggregating sets of documents also, in general, increases this chance. Thus, a moderate positive correlation between accesses and reading would give a high chance that research group A's outputs had been read more than research group B's outputs if they had been accessed more on average. In practice, the exact number of readers of any academic document is never known because of ways of accessing documents that cannot be tracked, such as from print copies of journals. Statistical correlations, therefore, need to be supported by arguments that the untracked readings are rare compared to the tracked readings, or that the tracked readings are likely to be a relatively unbiased sample of all accesses. Alternatively, if the tracked accesses can be directly shown to correlate with research impact or value, then this additional step is unnecessary.

29.3 Readership Data from Libraries

Two traditional sources of journal readership data are sales and library circulation information—either the number of libraries that hold a journal or circulation data for that journal. Both give journal-level rather than article-level evidence and are limited by the increasing share of reading that occurs online. For university libraries, the main journal readers are students, who are likely to be readers but not citers [29.11], and it is not clear whether they are also the main consumers of academic journals, or whether there are disciplinary differences in this. These students are likely to have different uses for academic journals, and librarians need to consider this factor when analyzing readership evidence to build collections [29.12].

Circulation information has been analyzed for a long time [29.13] from practical [29.14] and mathematical modeling [29.15] perspectives to support librarians [29.1]. Some examples illustrate the approaches used and give a background for more current strategies.

The earliest usage records kept by libraries were lending or reshelving statistics, and these have been used as proxies for usage or readership data for books and journals [29.16], even though they do not cover all ways in which they may be read [29.17]. This data has been shown to correlate positively with Journal Impact Factors (JIFs), at least when comparing journals from the same discipline, and journals from specialisms that are similarly served by the library [29.18, 19]. This might be due to some readers subsequently citing articles in the journals or more cited journals tending to have more useful information. For example, *Nature* and *Science* target non-citing audiences in parallel with the acknowledged high quality of their scholarly content. In contrast, other journals primarily target a professional audience (e. g., nurses, librarians, lawyers) and may be less concerned with attracting an academic readership. High correlations between online downloads and local readership information in one context give some evidence that downloads can be good indicators of readership [29.9].

Inter-library lending information and direct observations of library users can also give readership information, although the latter is too time consuming to be routinely used [29.20].

29.4 Research Impact Assessment

The publication of peer-reviewed research is a critical scholarly activity, and the analysis of scholarly publications is important for assessing the research impact of scholars or teams in most disciplines. This assessment can be qualitative, quantitative, or both. It can be combined with other sources of evidence or judgements and it can be made for formal evaluations, formative self-evaluations, or to investigate an aspect of science or science communication.

29.4.1 Peer Review

Peer review is the central evaluation mechanism for modern science [29.21]. The value of research is judged by experts from the same field because non-specialists are less able to understand the work or its contribution to scholarship. Ultimately, however, the scholarly community is collectively responsible to the governments or others that fund them, and so experts may adjust their expectations in response. For example, this may lead a community to regard work as better if it offers societal benefits.

Peer review is also at the heart of the publication system, with journal articles usually being subject to critical evaluation before a decision is made about whether to accept them, and the same is often true for monographs [29.22]. It is also central to research funding applications [29.23], perhaps as one of a checklist of attributes to assess. In some countries, peer review is used to periodically assess research to allocate block research grants. In the UK, the Higher Education Funding Council for England (HEFCE) uses panels of field experts to evaluate the quality of research from government funded universities and other academic organizations to share out funding on a merit basis [29.24].

The main disadvantage of peer review is that it is slow and expensive, consuming a substantial amount of expert time [29.25, 26]. It is also fallible because reviewers may be consciously or unconsciously biased against others' work based on personal characteristics, research competition, or the research paradigm followed [29.27]. Moreover, even expert reviewers can disagree about the merits of papers [29.28]. Nevertheless, peer review is often the most credible single source of evaluation evidence for academic research.

Although peer review primarily assesses prior work rather than predicting future performance, experts can also assess applicants' plans if these are relevant for appointments and promotions.

29.4.2 Citation Analysis

Citation-based indicators are the primary quantitative tools to evaluate research, whether on their own, to support human judgments, or to cross-check reviewers' opinions [29.29]. Citation data may come from a recognized citation index, such as the Web of Science (WoS), Elsevier's Scopus, or Google Scholar. There are also specialist citation indexes for some fields and others with a national or linguistic scope, such as the Chinese Citation Index.

The best-known citation indicator is the JIF, which estimates the average number of citations to recently-published articles in a journal. The JIF is informally used as an indicator of the quality of a journal perhaps because of its simplicity and intuitive reasonableness. Nevertheless, there are numerous problems with the accuracy of the calculations and their ability to reflect impact [29.30, 31]. There are also major problems of over-interpretation, leading to inappropriate uses [29.32, 33], such as those that ignore disciplinary differences.

The average number of citations per publication is known to vary by field and year, and so it is not reasonable to compare the average citation count between groups of publications. Field normalized indicators, such as the Mean Normalized Citation Score (MNCS) [29.34] and the Mean Normalized Log-transformed Citation Score (MNLCS) [29.35, 36] solve this problem by normalizing citation counts for the publishing field and year, so that a score of 1 always means citation impact equal to the world average.

For individual authors, the h-index has become popular [29.37], although it is biased towards senior researchers and male researchers.

All citation-based indicators suffer from several weaknesses. At a theoretical level, citations may reflect scholars acknowledging prior work that has influenced them [29.38], but they are not used systematically for this, can be influenced by spurious factors, and can be negative [29.39, 40]. Moreover, citations only reflect knowledge advancement rather than wider contributions to academia or society [29.41, 42]. For example, academic publications can be used in education, the professions [29.43], and to inform about health [29.44, 45]. The people affected in these cases may be thought of as *pure readers* in the sense of consuming academic outputs without subsequently citing them [29.46, 47]. Governments and research funders may explicitly state the need to consider non-academic impacts in their evaluations [29.48, 49], [29.50, para.1].

An important practical drawback of citation-based indicators is the considerable time that they take to accumulate. A research team might think of an idea, submit a grant proposal, get funded, carry out their research, submit a write-up to a journal, get it reviewed and accepted, and then wait for the article to be published online or in a formal journal issue. This process might take several years, and several more years would be needed before their article has attracted a reasonable number of citations from others, who had read their work and then followed the same process to conduct related research. A citation window of 3 years is sometimes recommended for research evaluations [29.51]. Thus, whilst academic evaluations often have the aim of predicting future research excellence so that it can be funded, or the promising academic can be appointed/promoted, in practice, citation-based indicators reflect performance that occurred several years in the past.

29.5 Online Access and Download Data

In response to the time delay and limited impact coverage problems of citation analysis as well as the expense of peer review, science policy-makers and managers may seek alternative indicators to reflect wider types of research impact or to give earlier evidence of impact [29.52–54].

Another important driver towards new indicators is the changing nature of scholarly communication, with increasingly diverse types of scholarly output being published online and valued even if they are rarely cited [29.55, 56]. In parallel, an increasing amount of scholarly communication takes place in public and online, leaving traces that may be used to evaluate its importance [29.57].

Given that an academic publication must be accessed and read to be valuable but that not all readers are citers, it is logical to look to access and readership data for evidence of the wider impacts of publications [29.2]. This information can also ameliorate the time delay problem of citation analyses, because an article must be read before any action can be taken based on its contents. Hence, unless the impact of an article is predicted from its metadata (e. g., from JIFs), evidence of downloads or readership gives the earliest impact evidence. Away from research evaluation, this argument has also been made for library collection development. At the level of entire journals, readership and citation may be thought of as two separate, overlapping dimensions of the impact of research and giving librarians or evaluators information about both can help them to make more informed choices [29.58, 59].

Although rarer in research evaluation contexts, the importance of readers is a natural concern for scholars, who may submit to journals partly based on the readership that they hope to gain [29.47], librarians who choose journals primarily to service their potential readers, and editors or publishers that monitor the overall audience or sales of a journal as an indicator of its value or health [29.60].

Readership data reflect something different from citations, even when only considering academic journal articles and restricting attention to academic readers. This is because there are some types of articles that are often read but rarely cited, such as a series of annual summaries of astrophysics [29.61].

29.5.1 Online Access and Download Data for Journal Usage Assessment

Statistics about local online accesses of journals are the modern way for librarians to monitor readership levels, although they are not comprehensive. Libraries keep print copies of journals, researchers and faculty may subscribe to individual serials, and educators may photocopy articles for students. In addition, article preprints may be shared from institutional and subject repositories and home pages, as well as by email and post. These uses will not normally be recorded electronically by a library or publisher but online accesses are, nevertheless, likely to give more comprehensive and timely information than library circulation data. Online usage data may be able to separate out people that browse journals from those that read articles by accessing their full text, giving more substantial information than circulation data. Local data is more relevant to libraries than generic publisher data that covers all uses, because each library serves a user community that has specific information needs, including research interests and educational provision. Moreover, local usage data seems to be more tied to reading, since robots would presumably rarely access local library copies of articles, even though humans may still systematically download them [29.9].

Online usage information originates from the log file of a web server recording accesses of journal pages or downloads of electronic copies of articles. There are many technical pitfalls with this information, including accesses by robots and repeated accesses by individuals for spamming purposes or by accident, and so online accesses do not equate with human readership. Since publishers gain extra sales if their access statistics are higher, they do not have an incentive to clean their data from spurious downloads before delivering it to libraries or others. There have been initiatives to standardize the process of cleaning the data to ensure that compliant publishers generate credible and comparable final statistics for their end users. The main initiative for this is COUNTER, which standardizes the reporting of usage information [29.62, 63].

As discussed above, usage data is inaccurate, because it is always an incomplete record of readership, and there will also be unrecorded readers. In addition, there are other important limitations that apply to some or all contexts.

For all applications, the lack of contextual information with most usage data (Mendeley and questionnaire data are exceptions) is an important restriction. Librarians may consider usage by faculty to be more valuable to the university mission than uses by students, at least on an individual level, but can rarely distinguish between the two in their data. In addition, no current major data source gives evidence about how a document was used by the reader [29.1]. This is an advantage of citations, because, in theory, the reason for a citation can be deduced from the accompanying text.

29.5.2 Online Access and Download Data for Research Evaluation

The shift to electronic publishing has led to the widespread availability of electronic access information at the level of individual articles, such as from publisher websites. This has made usage or readership data a practical source of evidence for research evaluations. In many cases, usage and readership information can be used in a similar way to citations for impact assessment, although it has different advantages and limitations. It has also not become as generally accepted as citations for this purpose. For example, the JIF is much more widely reported and recognized than any of the proposed usage-based alternatives.

For research evaluations rather than collection development purposes, statistics that are available for entire journals but not individual articles are unhelpful, although monograph circulation data can help research evaluation in the arts, humanities, and some social sciences [29.64].

Also, for research evaluation purposes, the limited nature of local access data from individual libraries for journal articles can be resolved by forming a consortium of libraries to share data [29.65] or by substituting publisher statistics. The former may be a realistic possibility for libraries that already have a common infrastructure to access electronic journals and so that data sharing can be added as an additional service rather than a completely new contribution.

Whatever the source of usage data, its principal advantage over citations for research evaluations is timeliness, because usage logically comes before the publication of citations. A second advantage is scope, because usage data includes, but does not differentiate, readers that do not cite the work. Hence, usage data may provide a timelier source of impact evidence with a wider scope. The reason why it is rarely preferred to citations is that it is much easier to manipulate, and so it is not credible enough for formal research evaluation purposes, even if from a COUNTER-compliant source. Nevertheless, it can be valuable for informal evaluations, self-evaluations, and assessments of the science system, as well as to cross-check the results of peer review or citation analysis.

Because of the accuracy limitations of usage data, it is important to assess whether it gives evidence of academic impact before it is used for article-level research evaluations. The primary strategy so far for this is to assess the extent to which article-level usage statistics correlate with citation counts. A perfect correlation cannot be expected because of the absence of pure readers from citation statistics, but a moderate or high correlation would suggest that the usage source assessed is not too affected by manipulation or fake data from robots. In contrast, a correlation close to zero would suggest that either there are many readers that have very different needs to citers or that the results have been intentionally or unintentionally manipulated.

Correlation analyses have mostly found moderate or high correlations between downloads and citations, which tends to confirm the value of usage data. A small study ($n = 153$) of article downloads in their first week found a moderate correlation (Pearson $r = 0.5$) with WoS citations 5 years later [29.66]. Similar correlations have been found for downloads of articles in the physics preprint server arXiv in the first 6 months and their citations after 2 years [29.67], for Research Papers in Economics (RePEc) preprint downloads and citations [29.68], and for PLoS PDF downloads and citations [29.69]. In contrast, a correlation of only 0.1 was found between early downloads (2 months) and later citations (25 months) for the fast, organic chemistry journal *Tetrahedron Letters*, suggesting that for this journal, early accesses represent a different type of use to citation [29.70]. For downloads within Elsevier's ScienceDirect and Scopus citation counts, the two correlate in all disciplines at the level of journals and articles; early downloads also correlate with later citations. These correlations vary in strength by discipline; they are lowest in the arts and humanities (0.2–0.3) and reach as high as 0.8 (life sciences). Despite this, the most downloaded articles tend to differ from the most cited articles for individual journals [29.71]. Confusingly, a study of Chinese journals found higher correlations between downloads and citations within the arts, humanities, and social sciences than for other academic disciplines [29.72].

At the level of journals, various download-based indicators have been defined in similar ways to the JIF, including the Usage Impact Factor [29.65] and the Download Immediacy Index [29.73]. Correlation tests have been used to help assess the value and validity of download-based indicators, with typically weaker results than at the level of individual articles [29.74] and with some negative correlations. Usage data for the Rouen University Hospital digital library had a low positive correlation with JIFs in one study [29.75], and correlations were not significantly different from 0 for JIFs and Concordia University chemistry and biochemistry journal usage data [29.11]. A comparison of JIFs with aggregate full text download data for a set of universities found low negative correlations, suggesting that journals most used by students (the main downloaders) were the least cited [29.76], see also, [29.65]. Thus, whilst download data seems to reflect a high degree of scholarly impact at the level of individual articles, when articles are aggregated into journals, scholarly impact is substantially less important, and download data may predominantly reflect educational value.

Electronic usage data can sometimes incorporate information about the origins of the users from the internet address of their computers. It is, therefore, possible to break down the readers of an article by institution and country and perhaps also organization type, if this data is made available by publishers or web server operators [29.61, 77]. This can reveal where articles and journals have had impact. This may be relevant to national funding bodies that want to demonstrate international impact or, conversely, want to make sure that the home nation rather than a competitor is benefiting from their investment.

29.5.3 Limitations of Online Usage Data

As discussed above, usage data can include false hits, whether robot accesses or downloads by people who did not intend to read the article, and articles can be accessed from multiple print and online sources [29.78]. These limitations apply unequally between journals and even between articles, so it is not fair to compare the impact of articles using any source of download data. For example, one article's publisher download count may be half that of another because it is available free online from the author, or is available in print in addition to electronic versions [29.79]. The main disadvantage of download counts from a research evaluation perspective is that they are easy to manipulate unless extensive measures are taken to protect them [29.80]. An additional disadvantage is that the data is not transparent, because publishers do not share the identities of those that accessed an article, and so authors and evaluators have no means of verifying downloads.

29.6 Readership Data from Online Reference Managers

In addition to manual methods to collect readership information, such as surveys, reader observation and reshelving information, and computerized methods, such as library, publisher, or repository download statistics, the web has made possible an additional indirect method to find whether an article has many readers: online reference managers. A reference manager is a program that records metadata about some or all the resources that a person is interested in, typically to keep track of what they have read and to automatically generate reference lists for their documents, whether they are journal articles, conference papers, books, or reports. Reference managers like EndNote, RefWorks, CiteULike, Connotea, Mendeley, Bibsonomy, and Zotero all perform this role in different ways.

If it is assumed that reference manger users tend to record articles that they have read, then the collective databases of reference managers form a large source of information about what has been read by whom. Some reference managers do not share this information but others, such as Mendeley and Bibsonomy, do, and so reference manager records are an alternative source of readership information [29.81].

At first glance, reference manager data is an unpromising source of readership evidence. Not all readers use reference managers, and so they form an incomplete readership record. No reference manager is dominant, and so if one is used as a data source, then its information will be partial even with respect to all reference manager users. Reference manager users are likely to be a biased subset of all readers, because technophobes might avoid learning a new program and people who do not write documents that include references would have little need for them.

Nevertheless, some reference managers have an advantage over download data: their information is freely available from a single source (rather than multiple publishers), they are not affected by multiple copies of articles being available (e. g., preprints in repositories), and they seem to give more definite evidence of readership than downloads, because the latter could be from a crawler or a casual user. For this reason, they can be a more realistic data source for research evaluations than download data.

Data from reference managers that are also social websites and provide an Applications Programming Interface (API), such as Mendeley, CiteULike, and Bibsonomy, fall within the scope of altmetrics [29.82]. These are indicators derived from data harvested from social web sites via APIs. The altmetrics movement has led to the creation of many new indicators. Indicator companies, such as Altmetric.com, ImpactStory.org, and Plum Analytics, systematically collect altmetric data (including from reference managers) and make it available to publishers, scholars, and institutions [29.83]. Altmetric.com, for example, attempts to provide accurate and transparent article-level indicators [29.84]. Although it includes readership data from

Mendeley, it treats this as a secondary data source, since it is not transparent (i. e., does not reveal the identity of readers). In addition, there are public initiatives to harvest and share altmetric data, such as the one from PLoS [29.85].

The promise of altmetrics is that it will deliver faster impact evidence that encapsulates wider types of impact [29.54, 86]. Within this, reference manager data fits as a fast and wider source of evidence, since reference manager users may be students [29.87] and other non-publishing article readers. Each altmetric has its own strengths and weaknesses, and potentially reflects a different type of impact. For example, tweet citations [29.88] seem to reflect attention rather than impact and are probably the fastest indicator to accrue. Reference manager data can, therefore, be thought of as an alternative to download counts as a source of readership evidence, or as a type of altmetric to be analyzed in parallel with other altmetrics.

29.6.1 Online Reference Managers: Background

Online reference managers have broadly similar functions, but each has its own software design, individual features, and user demographics. The national, disciplinary, and age composition of the adopters of each one is likely to be influenced by its age, national and disciplinary origins, and the fit of its affordances within disciplinary missions. For example, most have Western origins and did not prioritize language support, which may have alienated potential users in China, Russia, and Japan. User demographics are unknown for most, however. The descriptions below of some of the major social sites give a flavor of their differences, but their capabilities evolve over time and so may have changed now. All are online social reference managers in the sense that they manage references, are online, and allow users to create a public profile:

- Bibsonomy (www.bibsonomy.org) manages web bookmarks as well as references and incorporates social features [29.89–91]. Users typically have about 20% more references than bookmarks [29.91]. Probably like the other sites, most references are for journal articles [29.92]. Bibsonomy provides a copy of all its data free for researchers (www.kde.cs.uni-kassel.de/bibsonomy/dumps/).
- CiteULike (citeulike.org) is free, has the basic reference manager capabilities described above, and allows users to annotate references and share them with others [29.93]. It also has discussion fora and blogs [29.94]. Because of its communication and sharing capabilities it is also a type of academic social web site.
- Mendeley (Mendeley.com) is a free reference manager [29.95] that has been bought by Elsevier and offers social networking features, such as the ability to follow other users, as well as discussion groups and the ability for users to list their own publications. It, therefore, serves as an academic social network site as well as a reference manager, although its social features do not seem to be extensively used [29.96]. Mendeley offers a free and comprehensive API to access its readership data for all articles in its catalogue, so that anyone can find out how many Mendeley users have recorded any given document within their libraries. Although Mendeley does not report which users have registered each document, it gives a breakdown of user types by status (e. g., undergraduate, professor, other professional), geographic location (country), and main academic discipline [29.97].
- Zotero (www.zotero.org) is a free, open source reference manager that originated as a Firefox web browser plugin but is now available as a separate program. It has features to support group discussions and group reference sharing.

In addition to the above, RefWorks is a reference manager owned by ProQuest, and EndNote is owned by Thomson Reuters. Neither share readership data publicly at the time of writing.

29.6.2 Online Reference Managers: Coverage

Readership data from online social reference managers need to be publicly available, or at least shared with researchers, and to have many records to be useful. If a site has few users, then these are likely to be a very biased subset of readers, so the results may be misleading. For example, article readers tend to be from the same country as the authors [29.98], so any national readership biases will translate into international readership indicator biases. If most articles do not have a record of readers in the site, then its data is unlikely to be powerful enough for research evaluation purposes unless used on a large scale to compare average reader counts (e. g., using the equalized mean-based normalized proportion cited (EMNPC): [29.36, 99]). Of the online reference managers sharing data, Mendeley has the widest coverage and probably the most users. It had records for 80% of PLoS articles compared to 31% for CiteULike [29.86] and indexed more *Nature* and *Science* articles [29.100]:

- Bibsonomy: Bibsonomy has much lower coverage of physics journal articles 2004–2008 than CiteULike and probably less than 1% [29.78]. Journal articles comprise half (47%) of the items recorded, with conference papers (25%) and books (12%) also being common [29.92].

- CiteULike: Most (65%) PloS Biology articles have a record in CiteULike [29.85]. Less than 3% of physics articles 2004–2008 are in CiteULike [29.78].
- Mendeley: Virtually all (97%) articles from *Journal of the American Society for Information Science and Technology* 2001–2011 [29.101] and *PloS Biology* (95%) have a record in Mendeley [29.85]. Most (66%) PubMed articles 2010–2012 that are also in the WoS have a Mendeley record [29.102]. For Scopus medical fields, 78% of articles had at least one reader [29.103]. Another study found high coverage for WoS Medicine 2008 articles (72%) but lower (about a third) for physics, chemistry, engineering, and technology [29.104]. Less than half of recent social sciences WoS articles (44%) are in Mendeley, varying from psychology (54%) to linguistics (34%), and only 13% of humanities articles were indexed, from education (34%) to literature (4%) [29.105]. Nevertheless, 61% of Swedish humanities journal articles from 2012 were in Mendeley [29.106]. Compared to other altmetrics from Altmetric.com, Mendeley had the highest coverage (63%) of a large sample of WoS articles [29.107]. Very few books have records: only 7% of recent WoS science and medicine volumes [29.108]. Thus, whilst Mendeley has wide coverage overall and particularly for medicine, it is weak in the humanities and very weak in some disciplines and for books. This may have changed since the studies described here however.
- Zotero. No coverage information is available.

29.6.3 Online Reference Managers: Correlation with Citation Counts

When a new indicator is proposed for an aspect of research evaluation, then the logical first method to assess whether it has any value is to calculate its correlation with citation counts on the basis that a positive result would be evidence that the data was not random and related to scholarly impact in some way [29.109]. Even though a negative or zero correlation is also consistent with a new indicator reflecting a completely different type of impact, in practice, most types of impact relate to each other to some extent, and so this test is reasonable. There is extensive evidence of this type for Mendeley and a little for CiteULike. For Mendeley, readership counts correlate positively and moderately strongly with citation counts (and peer-review judgments) in most fields, with the arts being the main exception:

- CiteULike records and citations have a significant positive correlation for *Science* and *Nature* [29.100]. Usage data dominated by CiteULike have low Spearman correlations (0.1) with JIFs for physics journals [29.78]
- Mendeley records and citations have a significant positive correlation for *Science* and *Nature* [29.100], for *PLoS ONE*, *PLoS Biology*, and *PLoS Pathogens* articles [29.86] and for selected genetics and genomics articles [29.110]. Mendeley readers have a moderate overall correlation (0.5) with WoS article citations [29.107]. For PubMed articles 2010–2012 in WoS, Spearman correlations between Mendeley readers WoS citations were positive and statistically significant in all broad disciplines except the arts. They varied from 0.2 (humanities) to 0.6 (engineering and technology), with an average of 0.5 [29.102]. For WoS articles from 2008, five social science fields had Spearman correlations of 0.4–0.6, and five humanities fields had Spearman correlations of 0.4 or 0.5 [29.105]; see also [29.111]. Similar correlations were found for science and medicine fields (0.4 or 0.5) except for engineering and technology (0.3) [29.104]. Within medicine, the correlations later (and for narrower fields) rose to 0.7 [29.103]. The most systematic analysis so far checked 325 narrow Scopus fields, finding strong positive correlations in almost all [29.112]. For books, correlations between Mendeley reader counts and citations are about 0.1 [29.108]. Engineering conference papers have a very low correlation with citation counts [29.113].

A more direct source of evidence of the value of readership counts is their correlation with peer review scores. Peer review judgments are impractical to obtain for large samples of articles unless the data is a by-product of a research evaluation. For articles published in 2008 and submitted for evaluation by subject experts in the UK's Research Excellence Framework (REF) 2014, correlations between Mendeley reader counts and expert ratings in 33 of the 36 fields examined were positive, with the highest being for clinical medicine (0.4) and the lowest for music, drama, dance, and performing arts (−0.1) [29.114]. Given that these articles were selected by their authors for being high quality, the correlations are likely to substantially underestimate the underlying level of agreement between peer judgement and Mendeley reader counts, and so this is strong evidence that in most fields Mendeley reader counts reflect the quality of journal articles. A weaker corroborating piece of evidence is that UK clinical guideline references have more Mendeley readers than comparable articles do [29.115].

29.6.4 Online Reference Managers and Reading

References can be logged within a reference manager by users who have not read them [29.116] or as part of training exercises [29.117], and so it is not clear that it is reasonable to characterize reference manager data as "readership counts". The best way to find out why users enter reference data is to ask them. A survey of Mendeley users found that most (85%) added articles to cite them, but many also added articles for professional (50%) or teaching (25%) purposes. Moreover, most added articles that they had read or intended to read. Thus, Mendeley readership data clearly represents readership and a wider type of impact than scholarly impact, although mainly still within a broad academic context [29.118]. Some articles are added for educational reasons, having many readers but few citations [29.119].

Since undergraduates use reference managers, it is logical to look to readership data for evidence of educational reading. This is undermined by evidence that undergraduates and researchers tend to register similar articles [29.35].

29.6.5 Online Reference Managers: Reader Types and Demographics

Readers of research can originate from any country in the world, from any discipline, from any academic status. They can also be professionals using the information for their work or could be members of the public with an interest in a specific topic or fact. Within these groups, some read more academic research than others, and even when considering academic researchers alone, younger researchers read and cite more [29.120, 121]. Undergraduates sometimes read scientific papers but their reading is often directed by their lecturers [29.122, 123]. To interpret the type of impact reflected by readership data, it is, therefore, important to investigate the nature of people that use online reference managers. Partial information is known for Bibsonomy and Mendeley.

In terms of geography, almost half of all Bibsonomy users are from Germany [29.91], undermining its value for general impact assessment. Probably all the major services have relatively low numbers of users from China and from countries with little scientific publishing or a low level of technology use in universities.

In terms of work status, Mendeley includes substantial numbers of undergraduates and Master's students and few non-academic users. In science, it is dominated by young users: PhD students, postgraduates, and postdoctoral researchers [29.104]. In contrast, successful senior researchers seem to avoid it [29.124], and so there is an age/seniority bias.

29.6.6 Online Reference Managers: Timeliness

Mendeley readers appear about a year before citations, on average. For four library and information science (LIS) journals, the number of citations reaches the number of readers after about 7 years [29.125]. A similar pattern of initially higher readership counts than citation counts has been found for 50 fields, although the number of years needed for citations to overtake readers varies by discipline [29.126]. Early Mendeley readership counts are also better predictors of later high citation counts than are journal impact factors or citations [29.127]. All this evidence supports the conclusion that Mendeley readership counts give statistically stronger impact evidence than citation counts in the first few years after publication.

It is common for articles to have Mendeley readers as soon as they are formally published because of the prior sharing of preprints [29.128]. This makes it possible to conduct evaluations of them immediately upon publication, if these evaluations do not require the statistical power of high average readership counts.

Most importantly, the higher number of Mendeley readers than citations in the year following publication makes Mendeley reader counts correlate more strongly than citation counts with peer-review judgments of the quality of journal articles [29.114].

29.6.7 Online Reference Managers: Research Evaluation Applications

Readership data is useful for research evaluation applications where timeliness is important and there is little risk of deliberate manipulation of the data. This excludes formal exercises where those evaluated are told the data sources in advance but allows their use for more routine academic progress monitoring.

Mendeley readership counts are useful for national-level evaluations for governments to compare their progress against that of their competitors. The goal of such evaluations is to inform policy decisions or to assess the effect of recent policy changes. For the latter case in particular, timely data is essential. Mendeley readership data is preferable to citations because of its timeliness but has the limitation that it is influenced by different levels of national uptake from its users. This is a problem because of the tendency for people to read articles from their own country. It is possible to circumvent this issue with a modeling approach to measure the amount of bias in caused by the readership demographics and then correct for them, but this strategy is imperfect because it requires assumptions or information about the evolution of national uptake of the site over time [29.129].

Funding councils are also logical users of readership data. These may monitor the average impact of the research that they fund to identify which funding streams are most successful and whether the average impact of their funded research has changed over time. Web indicators can be useful for these, because the time lag of citations would delay decisions about changing ineffective funding strategies [29.130] as well as for evidence of societal research impact [29.131]. National biases in uptake and the bias towards younger users are relatively minor problems for this, and so Mendeley readership data is a better source than citations (e. g., [29.36]), although it does not reflect societal benefits or many professional uses.

One recent application harnesses readership data purely for its early impact evidence in comparison to citation counts, emphasizing the importance of the publication lag for citations. It used reader counts for early evidence of the success of an article promotion strategy in a randomized controlled trial [29.132].

29.6.8 Illustration of Mendeley Data

Three documents were compared with Mendeley data to illustrate some of the features of Mendeley and some of the factors that should be considered when interpreting its data. Three important scientometric papers were selected for this comparison. The first is an old *Nature* article discussing citation analysis from the perspective of non-scientometricians concerned about its uses. The second is the well-known Leiden Manifesto. The third is an article about altmetrics (Table 29.1).

All three articles have high numbers of readers and Google Scholar citations. Other factors being equal, older articles should be more cited, so it seems likely that the second and third articles, from 2015, will eventually be more cited than the first one from 2002. The two newer articles already have more Mendeley readers than the first article (The counting house). This is partly because Mendeley identified readers before citations, and so newer articles take less time to catch up with older articles in terms of reader counts. It is also partly because the counting house article was published years before Mendeley was released, so its peak years of use would have preceded the existence of substantial numbers of Mendeley users.

Mendeley data includes users' professions (Fig. 29.1). Most strikingly, the altmetric article is most used by librarians. Presumably this is due to the proliferation of altmetrics in publisher websites. In contrast, professors seem to be more concerned with traditional citation-based indicators.

Mendeley data includes users' declared country of origin or work (Fig. 29.2). It seems that some countries that are taking citation analysis seriously, such as Brazil, are not concerned with altmetrics. In contrast, Canada and The Netherlands seem to be more interested in altmetrics than citation analysis, although both countries have active researchers working in both areas. The *counting house* article seems to be particularly influential in the USA, but it is not clear why.

There are substantial disciplinary differences in the uptake of the articles (Fig. 29.3). The altmetrics article has attracted the most attention in the social sciences and computer science, although both categories might be due to library and information science researchers, since this field falls within both. The citation analysis articles are of interest in the agricultural and biological sciences. This is unsurprising given the origins of the San Francisco Declaration on Research Assessment (DORA) within the life sciences (the American Society for Cell Biology), indicating an unease with misuses of citation analysis within this discipline. Figure 29.3 also confirms that all three articles have attracted substantial interest outside of their home disciplines.

29.6.9 Investigating Science with Online Reference Manager Data

An interesting application of readership data is to track the flow of knowledge between fields. There is a long tradition of using citations to track knowledge flows by interpreting a citation from an article in field A to a paper in field B as knowledge flowing from B to A [29.133]. The same is possible for readership data when the domains of the readers of an article are known.

Table 29.1 Mendeley readers and Google Scholar citations for three scientometrics articles

Title and authors	Year	Readers	GS cites	Reads/cites
Citation analysis: The counting house *by* Adam, D.	2002	173	576	0.30
The Leiden Manifesto for research metrics *by* Hicks, D., Wouters, P., Waltman, L., De Rijcke, S., Rafols, I.	2015	634	474	1.34
Do altmetrics correlate with citations: Extensive comparison of altmetric indicators with citations from a multidisciplinary perspective *by* Costas, R., Zahedi, Z., Wouters, P.	2015	389	251	1.55

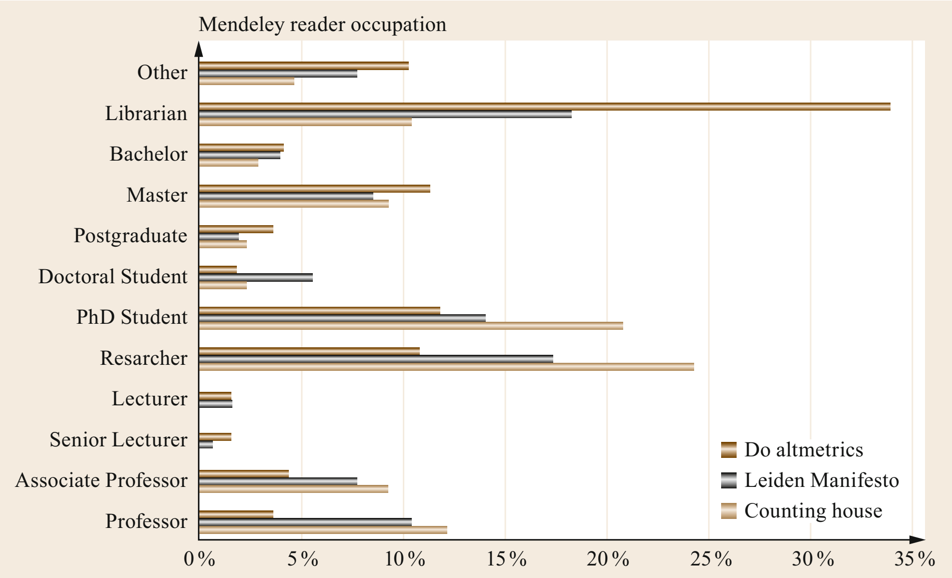

Fig. 29.1 All Mendeley reader occupations for three scientometric articles

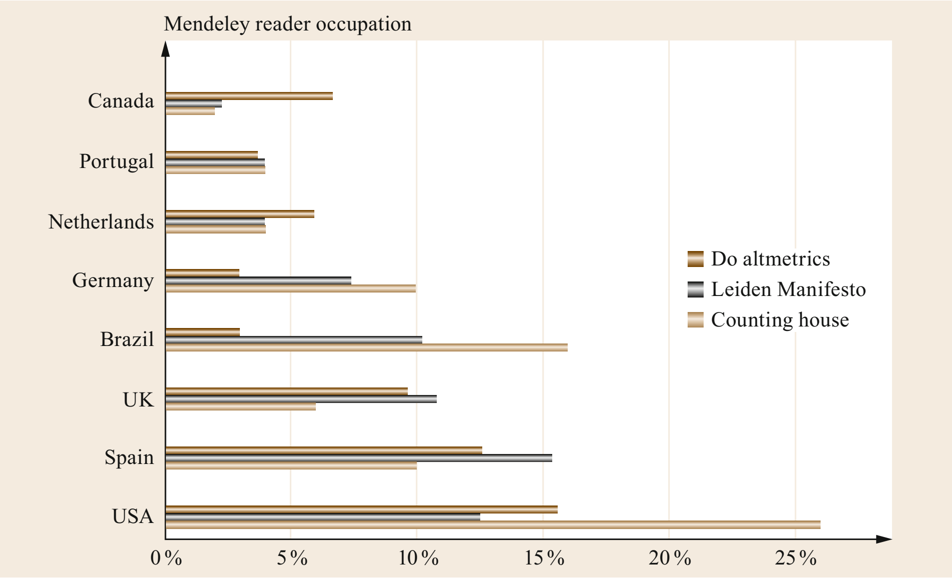

Fig. 29.2 Countries of Mendeley readers for countries with at least ten readers

The advantages of using readership data for this are timeliness and its ability to capture slightly wider impact because of the inclusion of students. A lot of data is needed to give good results however, which was a problem with one CiteULike study [29.134]. An investigation comparing knowledge flows based on Mendeley readership data with citation-based knowledge flows found differences suggesting that researchers in some fields, including business, read widely but cited narrowly [29.105].

A related application is the discovery of research clusters by identifying groups of articles read by the same user and then clustering them based on co-readership information [29.135], although this seems to be no longer possible with Mendeley.

Readership data has also been used to investigate academics through their reference lists, when these are public [29.92], to evaluate journals through the extent to which they are read [29.78] and to support literature search systems [29.136].

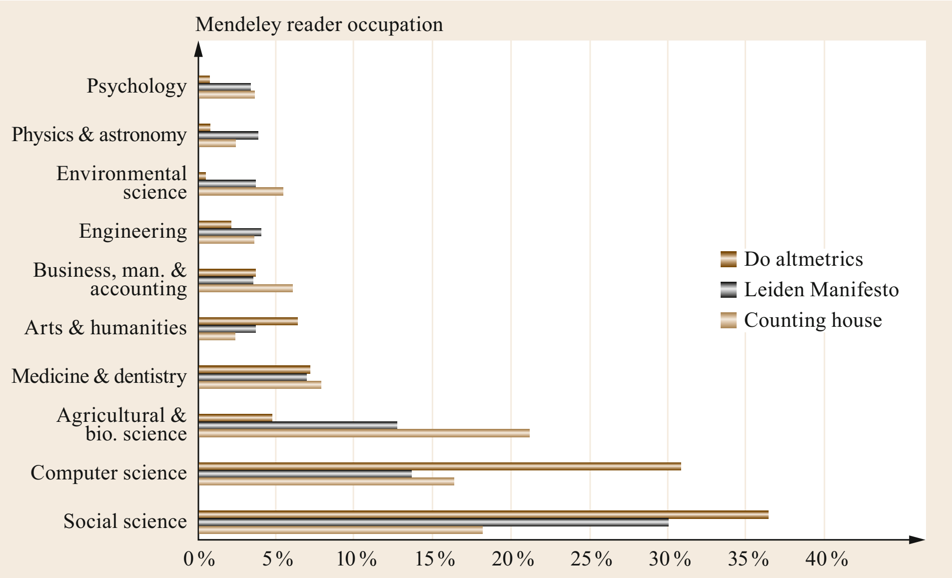

Fig. 29.3 Disciplines of Mendeley readers for the top ten disciplines

29.6.10 Advantages and Disadvantages of Reference Manager Data Compared to Citation Counts

The timeliness, wider impact, and reader demographic information advantages of readership data from all sources have already been mentioned, as have the disadvantages that it is sometimes not transparent and always open to manipulation, with a biased user base. Some additional factors are important to consider when evaluating readership data. The advantages are listed first:

- Traditional citation indexes, such as WoS and Scopus, have national biases and limits in coverage [29.137] whereas there are no restrictions on the articles that may be added to reference managers.
- Readership data is often free whereas citation indexes, except Google Scholar and Microsoft Academic, tend to charge for access.
- Readership data is relatively easy to access on a large scale from sites with an API. For example, the free Webometric Analyst software can download Mendeley records via its API from the articles' DOIs and/or metadata.
- Readership data tends to be more numerous than citation counts (e.g., [29.138]), except for older articles, and tests using it can, therefore, be statistically more powerful.

There are also additional disadvantages with readership data:

- Whereas, in theory, it is possible to find out how a work has been cited by reading the text accompanying the citation, references are rarely annotated with information that reveals why a publication was selected. Reviews are annotated readings, and these are available from sites like Goodreads and Amazon for books [29.108, 139].
- Despite the recognized national biases in citation indexes, Mendeley readership data seems to be more nationally biased than citation counts [29.140].
- Some altmetric sources of readership data can give inconsistent results [29.141], and there is a need for standardization between data providers and sources [29.142].
- Younger readers are more represented in Mendeley [29.104], and the share of younger readers may vary by narrow field and publication year.
- Differences in adoption levels and behaviors across disciplines is a complicating factor when interpreting the results of any multidisciplinary analysis [29.83].
- Some publication information entered by users to record their references is incomplete, leading to missed data [29.143]. This may be more frequent for documents with mathematical titles or in languages that are not represented by the ASCII character set.

29.7 Usage Data from Academic Social Network Sites

The online environment for science communication is continually evolving, and usage data is now not only available from publishers, academic repositories, and reference managers but also from some academic social network sites. Both Academia.edu and ResearchGate allow members to log their own papers and add them to their profile pages (as Mendeley also does now). They also provide usage data on these records in the form of download or view counts. They differ from reference managers by focusing on each author's own publications rather than their references of (presumably) mainly other scholars' works. Thus, their usage data has essentially the same nature as the download and access statistics of publishers or repositories, even though their appearance is more like Mendeley. Academic social network sites are in competition with publishers as sources of published academic research and, because of this, undermine the comprehensiveness of publisher data, apparently irrespective of copyright concerns [29.144].

For research evaluation purposes, academic social network sites are not good sources of usage indicators because they have an incomplete collection of articles and do not make their usage data easily available for researchers. Nevertheless, they are important because they have many members and their scores are apparently taken seriously by many researchers [29.145–147].

ResearchGate article views correlate positively with Scopus citations and seem to reflect a wider set of users than publishing academics, putting them on a par with other sources of usage data [29.148]. ResearchGate also provides citation counts for uploaded articles by extracting citations from all articles uploaded to the site. Although it indexes fewer citations than Google Scholar, it finds more early citations than WoS and Scopus, suggesting that many authors upload preprints to the site [29.149]. There are differing national levels of uptake of ResearchGate, which will bias its data, but despite being a type of web social network site, its data does not seem to favor younger users [29.150].

There is less research about Academia.edu, but, like ResearchGate, its scores seem to favor senior academics. They also tend to favor women, perhaps due to their greater communication expertise in the social web [29.151].

29.8 Summary

This chapter has summarized research into readership data, including usage data, with a focus on research evaluation applications but also covering collection development applications. In theory, these data are preferable to citation counts because they capture more uses of scholarly documents, such as from students and professionals. Although there is a little evidence to support his conjecture, readership data seem to primarily reflect scholarly uses in most fields. Both readership data from reference managers and usage (download/view) data from publishers have the advantage of giving early impact evidence compared to citations because of the delays associated with the publication cycle. This is due to articles being read a year or more before the citations generated by the reading, if any, appear in a citation index. Nevertheless, both download data and reference manager data can be manipulated, and whilst they are useful for informal evaluations and investigations into science itself, they should not be used for formal evaluation when those assessed can influence the data.

Readership data from reference managers have the additional promise that they can reveal something about the demographics of the readers, including their discipline, nation and job type. This can help with investigations of science communication. Download data in many cases have the practical limitation that a set of articles may originate from many different publishers, which complicates accessing them, and the data may not be fully comparable. In contrast, it is reasonable to collect reference manager readership data from a single site, such as Mendeley via its API, making them a practical source of readership information.

Ehsan Mohammadi
School of Library and Information Science
University of South Carolina
Columbia, SC, USA
ehsan2@sc.edu

Ehsan Mohammadi is an Assistant Professor at the iSchool at the University of South Carolina, USA. Ehsan holds a PhD in Information Science from the Statistical Cybermetrics Research Group at the University of Wolverhampton, UK. He has served as a reviewer for several journals. His research interests are scholarly communication, social media, online information behavior, open science, information visualization, and health informatics.

Mike Thelwall
Faculty of Science and Engineering
University of Wolverhampton
Wolverhampton, UK
m.thelwall@wlv.ac.uk

Mike Thelwall, Professor of Data Science, leads the Statistical Cybermetrics Research Group at the University of Wolverhampton, UK, which he joined in 1989. He is also Docent at the Department of Information Studies at Åbo Akademi University and a research associate at the Oxford Internet Institute. His received his PhD was in Pure Mathematics from the University of Lancaster. Mike has developed tools and methods. He is an Associate Editor of the Journal of the Association for Information Science and Technology and sits on the Editorial Boards of the Journal of Informetrics, Scientometrics, and the Journal of Information Science. He was a member of the UK's independent review of the role of metrics in research assessment (2014–15) and is a member of the UK Forum for Responsible Research Metrics.

30. Data Collection from the Web for Informetric Purposes

Judit Bar-Ilan

This chapter reviews the development of data collection procedures on the web with an emphasis on current practices, data cleansing and matching, data quality and transparency. There are several issues to be considered when collecting data from the web. Transparency is essential to know what is included in the data source, how recent and comprehensive the data are, what timeframe is covered etc. Data quality relates to reliability and accuracy. Mistakes are inevitable, data providers, aggregators, and researchers all make mistakes, but these mistakes should be reduced to a minimum so that meaningful conclusions may be reached from the data analysis. Extensive data cleansing before starting the analysis is needed to try to correct mistakes in the data. When several data sources are used, data from different sources should be matched, and duplicates should be removed.

30.1 Background

Until the 1980s—not all that long ago—data collection was mostly done manually from printed sources. The science citation index (SCI), originally produced by the Institute for Scientific Information (ISI), first became available on CD-ROM (compact disc read-only memory) in 1988, and in 1997 the ISI Citation Indexes were rebranded as Web of Science (WoS) and became available on the web. This was the start of a new era, with not only a few institutions receiving data on magnetic tapes, but many researchers and decision-makers with subscriptions to the WoS getting easy access to a wealth of data. Other bibliographic databases also became available on the web. At the same time the Internet and the web also served as data sources, and informetric methods were applied to analyze data collected from the web. Similarities between the web-graph and citation networks were found. This led to the development of a new branch of informetrics: webometrics. Data for webometric purposes are mainly collected through either crawling or utilizing web search engines. In 2004 two new citation databases were launched, Scopus and Google Scholar, introducing new data collection challenges and opportunities (later, Microsoft also joined the bibliometric data providers by launching Microsoft Academic Search). At the same time the web has become more

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_30

and more interactive (also known as Web 2.0) allowing easy creation of user-generated content (e. g., blogs), having commenting capabilities, online reference managers and social media services, academic and not necessarily academic. These new web-based platforms are also used for disseminating and discussing academic research. The discussions, comments, tweets, likes, followers, views and downloads, postpublication online peer review, readership counts, etc. can serve as early signals of appreciation and impact as opposed to citations in peer-reviewed publications which take much longer. In addition, not all users contributing to these activities are authors of future publications, and therefore analysis based on Web 2.0 data sources supplement the traditional citation-based methods in bibliometrics and research evaluation. This youngest branch of informetrics was named altmetrics in 2010. The new data sources often have APIs (application programming interfaces) that allow downloading of large quantities of data. In addition to the raw altmetric data sources, there are also aggregators like http://Altmetric.com and PlumX.

30.2 Early Studies

The World Wide Web (web in the following) was founded in 1989 by Tim Berners-Lee and the first textual web browser was introduced in 1991 [30.1–3]. The web really started to take off around 1995, when graphical browsers were introduced and commercialization began.

One of the first studies on web data utilizing bibliometric methods was presented by *Ray Larson* [30.4]. He was interested in pages on geography, and used the then state-of-the art search engine, AltaVista to retrieve pages on the topic. One hundred fifteen results were listed. After the author reviewed the relevance of the results, about 40 pages remained. Links from these pages were extracted and filtered to include only pages judged most relevant to the topic. This procedure resulted in 34 core documents and a *colink* analysis was conducted, utilizing AltaVista's backlink search feature. Two sites, A and B are colinked if there is a third site, C, that links to both sites, and the strength of the colinkage is a function of the number of sites that link both to A and B. To create the raw colinkage matrix, links to all pairs of core documents were searched. It took 5 hours to complete the data collection process. It should be noted that the link: feature of AltaVista and later of Yahoo! was an excellent feature for bibliometric and webometric purposes, but neither of these search features exist anymore. Google never had a comprehensive backlink search, and now the link: search operator has been seemingly depreciated, since it does not appear in the list of current search operators [30.5].

The next milestone was two papers by *Peter Ingwersen*, the first one with his student, the late *Tomas Almind* [30.6], where they showed that informetric methods can be utilized on the web. They compared references in scholarly papers to links on the web, showed both the similarities and the differences between the two ("citation databases are retrospective, whereas the web is constantly in real time" [30.6, p. 406]). As a case study, they compared Denmark's share of the web to other Nordic countries. For data collection, they used now nonexistent sources: the search engines Lycos and AltaVista, and the Nordic web index. Data were collected several times over 2 years and growth trends were tracked. Other characteristics of the web pages were also shown. The second major contribution of *Peter Ingwersen* [30.7] to webometrics (roughly defined as informetric methods applied to the web) was the definition of the WIF (web impact factor) as an analogue to the journal impact factor (JIF). The definition of the WIF is the number of link pages pointing to the entity (site or country) divided by the size (number of pages) of the entity on the web.

Alistair Smith [30.8] refined the concept by differentiating between external links (links from another domain or site) and selflinks (links emanating from the given web site or domain) and claimed that external WIFs are more meaningful. He calculated the WIFs of New Zealand universities and compared them to the number of publications and to the number of publications/faculty member in the university. He found no correlation between the two. As in most of the studies at the time AltaVista was used for data collection. *Mike Thelwall* [30.9] showed that the coverage of country domains of the web by search engines is far from uniform, which makes a difference in the calculation of the WIF. His data collection strategy was querying the domain name server for domains, and then checking whether the domain is indexed by AltaVista.

Another early study [30.10] searched for names of five well-known full professors in information science, using the five major search services at the time: Excite, Infoseek, Lycos, WebCrawler, and Yahoo!. Eleven types of mentions (invocations) were defined. Slightly different search strategies were used for each search tool, to retrieve comprehensive lists of mentions. The largest category of mentions were conference-related activities.

30.3 Applying Bibliometric Laws to Data Retrieved from the Web

Ronald Rousseau [30.11] also explored sites referring to other sites (through links) and called these links "sitations", and showed that Lotka functions apply both to the domain distribution of search results and to sitations. The data collection tool was AltaVista.

At about the same time, I showed [30.12] that bibliometric laws apply to Usenet newsgroups (the forerunners of discussion lists, forum, and social media platforms). Usenet is a sort of electronic message board, with a hierarchical arrangement of the categories, called Usenet groups. A group roughly corresponds to a journal and a message to an article published in a journal. The major difference is there is no barrier to send a message to a newsgroup if the message is on topic (if the group is moderated). This is quite similar to the current discussions on social media platforms. Usenet newsgroups existed long before the web, but became easily searchable through the web using first the AltaVista search engine, and later Google. This work explored the temporal characteristics of interest in an event (the *mad cow* disease) and the distribution of Usenet messages on the topic between the different groups. The results showed that the messages were distributed more or less according to Bradford's law, and the interest in the topic rose and then died down quickly.

30.4 Longitudinal Studies

Bar-Ilan [30.13] collected information from several search engines on the late mathematician, Paul Erdős. At that time using a few tricks, it was possible to retrieve from the search engines all the results for a given query (maybe not for very popular topics). The aim of the study was to show how the great mathematician is depicted on the web. Data were collected from seven comprehensive search engines: AltaVista, Excite, Infoseek, Lycos, Magellan, Opentext, and Yahoo!. This data collection process led to the realization that the overlap between the search engines is quite small [30.14]. Today, we have only a few comprehensive search engines, and in the Western world, Google is most used, but we should keep in mind that Google does not and cannot cover everything. Studies on the overlap between search engines cannot be conducted anymore, because of the vast amount of information and because the search engines limit the number of results that they provide. In 1997 (time of data collection) altogether 6681 web pages were found containing the search term `Erdos`. As of May, 2017, Google reports that it located about 1 830 000 results, Bing reports *only* 319 000, Yandex 3 million results, and Baidu seemingly does not report the number of search results.

Bar-Ilan and *Peritz* [30.15] carried out an 8-year longitudinal study starting in 1998, using the search phrase `informetric OR informetrics`, where the query was run once a year, except for 2000 and 2001. Two data collection methods were used: search engine results and revisiting previously located web pages containing one of the search terms and located in a previous year. As pointed out before, the web is not static, new pages are created, old ones can get removed or updated (the search term does not appear anymore on the page) or moved to a new URL. In 1998, 866 pages were located, and by 2006 this number had increased 33-fold to 28 914 pages. Out of the 866 pages, only 165 pages (19%) still existed in 2006 and contained one of the search terms. The search engines used for data collection were AltaVista, Excite, HotBot, Infoseek, Lycos, and NorthernLight (all defunct now). The search engine scenery has changed considerably during the years, and in the last two years the data collection was from Google, Exalead, Teoma (Ask), and Yahoo!. Brent Payne's photostream on Flickr has nice screenshots of the user interfaces of some of these search engines (start from https://www.flickr.com/photos/brentdpayne/4306540031/in/photostream/). At the last data collection point *tricks* (query chunking) were used to overcome the limitations on the number of results displayed by the search engine, by including/excluding additional search terms [e. g., (`informetrics AND scientometrics`) and (`informetrics AND NOT scientometrics`)], limiting the query by domain or site, by filetype or by date, or a combination of the previous methods. These tactics can be useful also today when collecting large amounts of data from search engines, as was suggested also by *Thelwall* [30.16]. However, search engines, especially Google, do not like extensive data collection, and they often lock out the user from searching for a few hours and even for a whole day. A detailed methodology on how to conduct such longitudinal studies on the web appears in [30.17].

Other longitudinal studies that collected data for more than a year include the one conducted by *Koehler* [30.18] for six years that monitored a fixed set of 361 pages, the study by *Gomes* and *Silva* [30.19]—a 3-year study of the Portuguese national web, and of *Baeza-Yates* and *Poblete* [30.20] that followed the changes in the Chilean web for three years.

30.5 Search Engine Reliability and Validity

Snyder and *Rosenbaum* [30.21] identified problems with the reliability of the number of results reported by search engines. They compared the results from the then existing search engines with capability of searching for links to a specific domain. There were two such search engines at the time, HotBot and AltaVista. They showed that there are differences not only in the number of reported links, but also in the ratios, and had serious reservations about the use of data collected from web search engines for research purposes. Currently link searches are not available anymore, however the number of pages in each domain is still retrievable.

Table 30.1 shows the results retrieved on May 6, 2017 from Google and Bing for the generic top-level domains and for a few country top-level domains, English speaking and non-English speaking, questioning the validity of the reported numbers and/or the coverage of the search engines.

The longitudinal studies conducted by Bar-Ilan and Peritz, mentioned before, led to the realization that not only is the web dynamic, but so is search engines' coverage of the web. Pages indexed at one point in time might be excluded from the index a month later and reappear two months later and might disappear and reappear again. There can be several explanations for this behavior: search engines refresh their databases either periodically or continuously. If they do it periodically (which was done most probably by some of the search engines in the 1990s), they recrawl from scratch and since the storage space of a search engine is finite they may reach or not reach a given page. Such behavior was demonstrated by *Bar-Ilan* [30.22] for the search engine Excite. Other reasons for disappearance/reappearance could be that the page was temporarily not available at the time the search engine tried to visit it or other considerations by the search engine. *Bar-Ilan* [30.22] demonstrated monthly fluctuations, while in another paper [30.23], daily fluctuations were observed for 20 queries tracked for ten days. In this study two search engines were studied, HotBot and Snap, where both were powered by the Inktomi database, and in addition to the daily fluctuations in the results, there were considerable differences between the number of results reported by the search engines, that were two different interfaces to the same database. Currently, Bing powers Yahoo!'s search results and there are differences in the number of results reported by the two search engines (to be more precise, by the two search interfaces). On May 6, 2017, Yahoo! search reported about 200 000 results

Table 30.1 Sizes of generic top-level domains as reported by Google and Bing (May 6, 2017)

Top-level domain	Google	Bing
.com	25 270 000 000	27 800 000 000
.org	4 520 000 000	1 360 000 000
.edu	610 000 000	106 000 000
.net	1 300 000 000	1 880 000 000
.gov	1 280 000 000	107 000 000
.mil	83 000 000	10 400 000
.uk (United Kingdom)	1 560 000 000	123 000 000
.ca (Canada)	956 000 000	151 000 000
.au (Australia)	723 000 000	206 000 000
.nz New Zealand)	204 000 000	56 800 000
.es (Spain)	445 000 000	81 400 000
.fr (France)	1 250 000 000	154 000 000
.de (Germany)	1 690 000 000	427 000 000
.il (Israel)	113 000 000	41 700 000
.cn (China)	203 000 000	97 800 000
.ru (Russia)	442 000 000	96 900 000
.br (Brazil)	566 000 000	157 000 000
.za (South Africa)	181 000 000	3 370 000

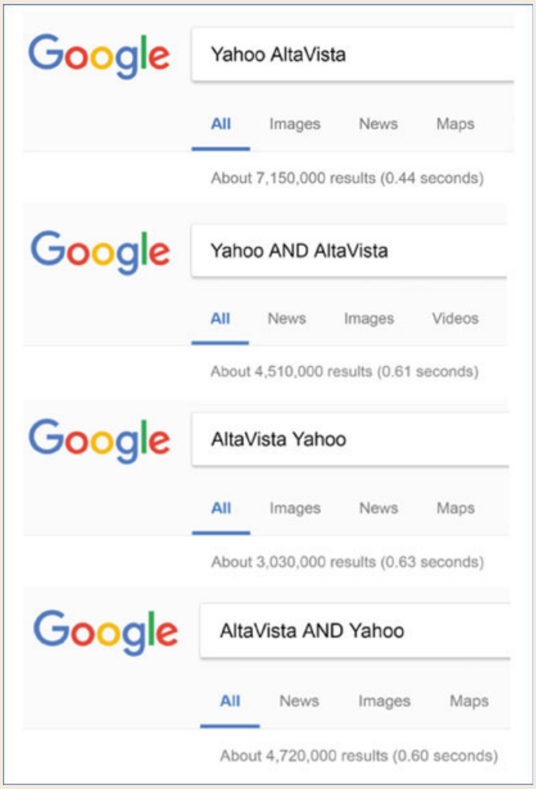

Fig. 30.1 Google search results with and without AND

and Bing reported about 429 000 results for the query `altmetrics`. Thus, one must be aware of reliability issues when using the number of results reported by search engines.

Other studies showed [30.24, 25] that for some unknown reason, search engines do not retrieve all the pages indexed by them. At that time the number of results to a query was small, thus such studies were plausible. However, the techniques applied by Bar-Ilan, pulling all search results from several search engines and checking whether the URLs not retrieved by the given search engine, but retrieved by others are in the given search engine's database, cannot be applied anymore because the number of results for an intelligent query exceeds the number of search results the search engine is willing to display, although for very specific queries the query chunking method, mentioned above, might be applicable.

Another issue regarding reliability is that search engines are not doing well in math. *Ingwersen* [30.7] noted that for the search engine AltaVista, the number of results for a query `A and B` is not identical to the number of results for a query `B and A`. Google is not better, as was shown in [30.25], and in a very recent test conducted on December 18, 2017, using http://google.com (Figs. 30.1 and 30.2). The queries were run within 10 min. The Boolean operator AND does not appear in the current help sheet of Google [30.5], it is supposed to be assumed, however when running the query with and without the AND operator, entirely different results are received as can be seen in Fig. 30.1. Among the inconsistencies is the huge difference between the results for `AltaVista AND Yahoo` versus `Yahoo AND AltaVista` (Fig. 30.1). Google also fails in the `A AND B` versus the `B AND A` test, irrespective of the use of the AND operator, and the NOT operator (- in Google). The Venn diagram in Fig. 30.3, clearly shows the impossibility of the reported number of results for the queries. Of course, Google has a good excuse, the numbers are only estimates, however these estimates do not make sense. A more plausible explanation is that these query operators are rarely used, and thus search engines do not need to make an effort to make the numbers consistent. Users rarely go beyond the first 10

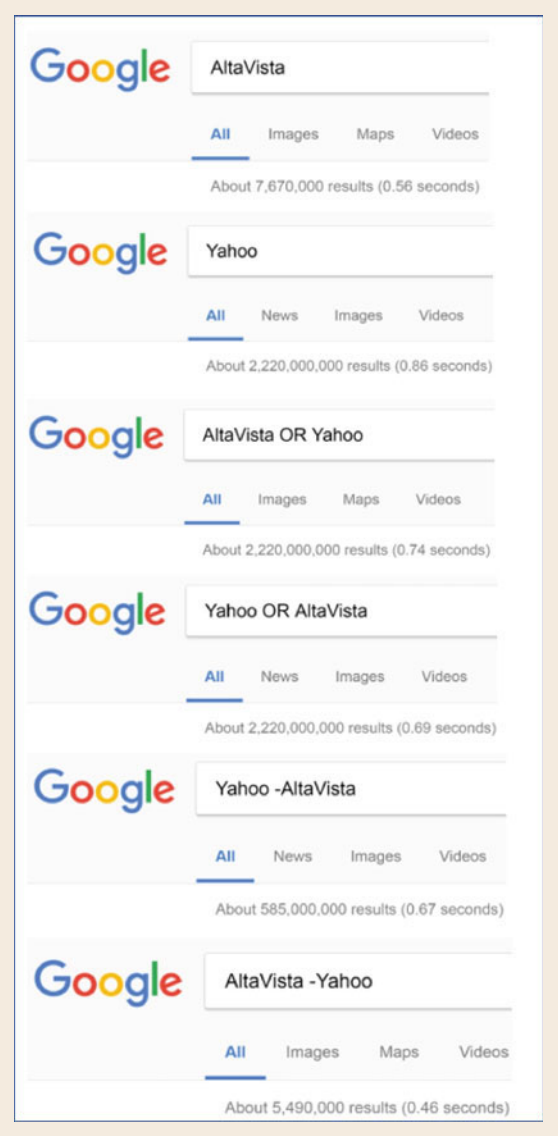

Fig. 30.2 Inconsistencies in the number of search results

or 20 search results [30.26], and do not care whether there are ten thousand or ten million results for a given query.

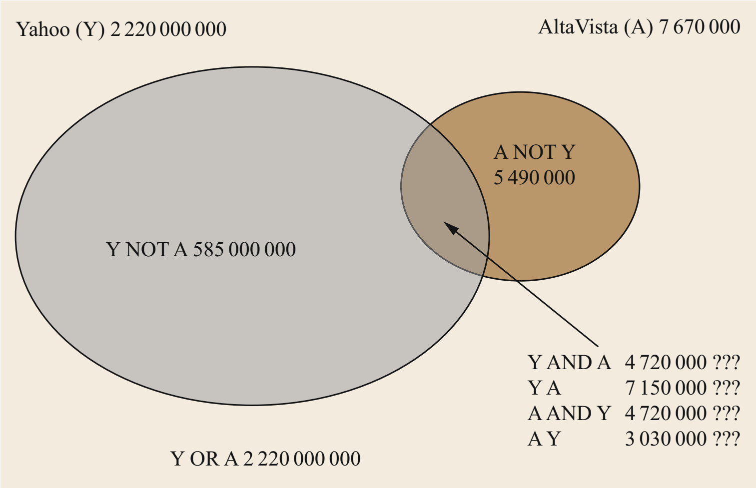

Fig. 30.3 Venn diagram of the number of search results reported for searches combining the query terms `AltaVista` and `Yahoo`

30.6 Data Cleansing

As seen above, a lot of problems in the data collection stage have been identified. These should be clearly identified in web-based studies and listed in the limitations. Steps can be taken in trying to overcome this problem by trying to cleanse the data. *Wikipedia* [30.27] defines data cleansing as

> the process of detecting and correcting (or removing) corrupt or inaccurate records from a record set, table, or database and refers to identifying incomplete, incorrect, inaccurate or irrelevant parts of the data and then replacing, modifying, or deleting the dirty or coarse data.

Data cleansing is an essential step for data collection not only from the web but from other sources (like commercial databases) as well. The major difference is that the web is an uncontrolled environment, thus data cleansing is an absolute must. It is a time-consuming and iterative process, that includes deduplication (especially when data are collected from several sources), identifying outliers and deciding how to handle them, resolving inconsistencies, and correcting obvious mistakes [30.28, 29].

30.7 Link Analysis

Snyder and *Rosenbaum* [30.21] were the first to study linkage between domains, and as a test case they showed links between and within generic top-level domains. *Thelwall* [30.9] suggested that top-level domains are too coarse, and that academic domains tend to be older and better linked than commercial ones. He took his own advice and concentrated on studying the linkage between university domains mainly in the UK. In several countries academic websites have a special subdomain, like .edu in the US or .ac.uk in the UK. First, because in a previous paper [30.9] he showed that the coverage of the then existing search engines was not satisfactory, he built his own "web impact factor crawler" [30.30]. The homepage of the university website was the starting point for the crawl to cover the whole website by following links. While crawling the website, all links were collected. This was done systematically for six universities at first and was conducted twice to prove the reliability of the data. The crawler encountered several obstacles, and sometimes manual intervention was needed to overcome them, and the collected data also had to be cleansed. Thelwall, like *Smith* [30.8] could not find a relationship between the research ranking of the university and its WIF, which is understandable because many links (even external links) are not research related. The crawler is an alternative to information retrieval from search engines, but it needs computational sources, technical capabilities that are not readily available to all researchers. It should be noted, that Mike Thelwall developed several data collection tools from the web, and keeps them updated, and most importantly these tools are freely available for use by researchers. The tools have a common interface, now called *Webometric Analyst*, and can be accessed at http://lexiurl.wlv.ac.uk/. The crawler, *SocSciBot* is also freely available from http://socscibot.wlv.ac.uk/.

Thelwall extended his initial, proof-of-concept paper, and extensively studied links between UK universities and managed to disprove initial findings [30.8, 9] that there is no relationship between conventional academic measures and WIF, by modifying the definition of the WIF and filtering out links that were not research related [30.31]. The process of categorizing links was very time consuming and somewhat subjective. The method using the crawler was compared to data collection using AltaVista. The findings were that AltaVista found more links between the university websites than the specially designed crawler and there was a strong and significant correlation between the WIFs calculated based on the two methods. It was also claimed that AltaVista was reliable, in contrast with previous findings [30.21], which can easily be explained by improvements and increased coverage of AltaVista over the years.

At first only links between universities were counted, but later the inlinks were extended to other inlink sources (.edu, .ac.uk, and .uk). The external WIF was further modified by replacing the denominator: instead of the size of the university website, the number of full time equivalent (FTE) research staff was used. Using this modified WIF strong correlations were found between the WIF and the research assessment scores from the RAE (the old UK research assessment exercise, now replaced by REF—research excellence framework) [30.32]. *Thelwall* defined additional WIFs based not on links to individual web pages but to directories or to domains, called range metrics [30.33, 34], and studied the effects of geographic distances [30.35] utilizing the link crawler developed by him. Other link analysis studies, like linguistic characteristics of linking within a set of European countries [30.36] or studying the linkage between Asia-Pacific university websites [30.37] were carried out using AltaVista's search features. A large number of additional studies on link analysis were carried out by *Mike Thelwall* and his students and collaborators, as documented on his website (http://www.scit.wlv.ac.uk/~cm1993/mtpublications.html#LinkAnalysisMethods) and summarized in his books on link analysis [30.38] and on webometrics [30.39].

A different data collection method is to explore colinks instead of direct links between entities. In this process a set of target entities are identified, and pages that link to pairs of target websites are retrieved using search engines. Such a study of Canadian universities was conducted by *Liwen Vaughan* [30.40]. In this study, Yahoo! search was used to retrieve colink data. Yahoo bought both AltaVista and AlltheWeb in 2003, and used to have extensive capabilities for retrieving inlinks and colinks.

Unfortunately, there are no commercial search engines anymore that allow retrieving links to websites, and thus alternative, but less comprehensive techniques were developed to assess the web visibility of web sites or web pages, e. g., URL citations (where the URL of the linked web page explicitly appears on the linking page) [30.41] or linked title mentions [30.42]. The link title mentions method first uses a search engine to retrieve pages that mention the name of the target website, and then using the previously mentioned *Webometric Analyst* automatically checks whether there is a link to the target website on the page.

Clearly, counting links from/to websites is not sufficient. One must try to understand the reasons for linking. *Kim* [30.43] interviewed researchers on why they inserted hyperlinks into their electronic publications, and identified three major motivations: scholarly, social, and technological. Although interviews are highly useful, they are also time consuming. An alternative technique is trying to deduce from the context of the link the reason for creating it. *Wilkinson* et al. [30.44], using a sample of about 400 pages from UK universities linking to other universities, created a typology of reasons to link, including teaching materials, information for students, research partners, research support, research reference, recreational, e-journals, and similar department. *Bar-Ilan* [30.45] claimed that, to attempt to understand the motivation for linking in the academic context, one must consider the properties of the source and the target pages, the properties and context of the link, including the relationship between the source and target page. The entries in the codebook were derived from the literature and from a small sample of linkage data between Israeli universities, and then successfully applied to a larger sample of nearly 600 pages.

Besides analyzing links to and between academic institutions, the linking structure of other types of entities was also explored. Vaughan et al. found relationships between inlink counts to commercial sites and their business performance measures. In 2004, she [30.46] studied American and Canadian IT companies. The data collection steps for such a study are clearly described, starting with selecting companies for which financial information is available and that have a presence on the web. Web data were collected from multiple search engines to minimize possible bias. Significant correlations were found between inlink counts and business performance indicators. Later colink data was used to explore similarities between companies [30.47]. Commercial companies in the same field are competitors and have no incentive to link to each other, thus third-party sites are needed to map the positions of different companies in the field. This study, like [30.40], used Yahoo! search for data collection. In order to understand the reasons for linking to commercial websites, a classification scheme was designed, and a content and context analysis of the linking websites was carried out [30.48]. As for academic inlink studies [30.44, 45], presenting numbers and relationships is not sufficient, and quantitative studies should be supplemented by qualitative ones.

Leydesdorff and *Curran* [30.49] and *Stuart* and *Thelwall* [30.50] explored university–government–industry links. In the first study the data source was AltaVista and it concentrated on Brazil and the Netherlands. In the second paper, the UK West Midland automobile industry was chosen. In this study, Stuart and Thelwall utilized the Google search API (not existent anymore). Although Mike Thelwall had his own crawler, it was not used because commercial sites often let in the crawlers of the well-known search engines, but not academic crawlers. By 2006, Google could extract links not only from html files but also from Word or PDF files. Stuart and Thelwall used query modifiers that were available at the time of the study but are not available anymore, and instead of actual links (Google never had good means for reporting inlinks to a site), the URL citation method [30.41] was applied. They were able to create meaningful visualizations of the connections between the websites from the data collected. They concluded that URL citations only partially match real-world relationships.

30.8 Bibliometric Citations Versus Web References

In an early paper, *Bar-Ilan* [30.23] showed that the web is a rich source of metadata on scholarly publications on the web. While searching for the appearance of the term `informetrics`, she found that about 40% pages included references to scholarly publications. The number of times authors, journals, and publications appeared in the retrieved web pages was calculated. This can be seen as a forerunner of altmetric counts on social media platforms, indicating visibility of publications. The coverage of the references (metadata) found on the web was compared to several commercial databases. There was a 75% overlap between WoS articles published after 1995 with the term informetrics in the title of the journal article and the metadata retrieved from the web. *Vaughan* and *Shaw* [30.51] further explored this issue on a much larger data set. They quoted Tom Wilson's post in 2002 on the SIGMETRICS discussion list [30.51, p. 1313]:

> I looked at a couple of my own papers and counted the SSCI citations and then searched for mentions of the papers on the Web—the results left me wondering whether the reliance on citation indexing as a measure of performance is now past its sell by date.

Eugene Garfield replied to this message:

> I suppose that some day the people who run google and other search engines will figure out a way to separate true research citations from mere mentions of names, but in the meantime it is really not defensible to compare information retrieval via WoS or STN or Dialog of ePsyche or whatever, to searches using google or other search engines over the Internet. That is why I don't waste my time trying to do so.

Vaughan and Shaw were challenged by Garfield's reply, and retrieved articles published in 1992 and 1997 in library and information science (LIS) journals indexed by WoS, recorded the number of citations on WoS and the number of mentions on the web by 2002. Web data were retrieved using Google (Google Scholar did not exist at the time). The average correlations between WoS citations and web citations was around 0.6 for the 1997 data set, the correlations were significant for more than 60% of the journals. In a later study, they explored web mentions (called web citations) in biology, genetics, medicine, and multidisciplinary sciences [30.52] and found significant correlations between web and WoS citations. Google search was used to retrieve data, where the query was the title of the article as a phrase search and the results retrieved were manually checked and classified.

30.9 Google Scholar

The year 2004 was another milestone in data collection from the web for informetric purposes. Two new citation databases, Google Scholar and Scopus were both launched, ending the hegemony of the Web of Science. Google Scholar was launched in beta, gathering information on scientific publications from the web, from libraries and publishers, and provided citation counts and links to the documents, some behind a paywall and others freely accessible. Unlike the commercial citation databases, Google Scholar was (and is) free to use by everyone. It also uses Google's technology to suggest corrections of typos and spelling mistakes.

The initial response of the scientific community was quite mixed. *Peter Jacsó*, in a number of papers, emphasized the shortcomings of Google Scholar [30.53, 54]. In an early paper, he mainly criticized the coverage, in the paper from 2008 he took a closer look and found inaccuracies in author names, and publication dates. On the positive side, he mentioned the improved coverage of journals, the inclusion of books, impressive geographic and language coverage and (partial) coverage of digital repositories. Others criticized Google Scholar's lack of transparency about its coverage both in terms of the list of journals covered and the document types included, a definition or explanation of what are the characteristics of scholarly documents to be included in the index, lack of information on the update frequency and the ranking of search results (at the beginning most of the time the results were ordered in descending order of citations) [30.55–57]. A good summary of Google Scholar's shortcomings appears in [30.58].

One of the common methods for evaluating a bibliographic or bibliometric database is by comparing it to other similar databases in terms of coverage, freshness, accuracy, and reliability. The obvious choice is to compare Google Scholar to the Web of Science and Scopus. *Jacsó* [30.59] did this, and clearly favored the Web of Science. *Bauer* and *Bakkalbasi* [30.60] also compared the three citation databases on JASIST articles for the years 1985 and 2000. They found that Web of Science and Scopus reported similar citation counts for the articles published in 2000, and Google Scholar reported significantly higher citation counts. This result increased interest in Google Scholar and further comparison studied were conducted.

Besides citation counts, coverage is a major issue, and can also be studied by comparing Google Scholar to other databases. *Neuhaus* et al. [30.61] compared Google Scholar to 47 other databases/publishers by drawing 50 random article titles from each database and testing whether they were indexed by Google Scholar. The lowest coverage was in humanities (10%), followed by the social sciences (39%). *Neuhaus* et al. [30.61] tested article coverage, whereas *Oppenheim* and *Norris* [30.62] were interested both in journal title coverage and article coverage of WoS, Scopus, Google Scholar, and CSA Illumina. A random sample of 380 journal titles was drawn from the list of journal titles submitted to the UK 2001 research assessment exercise to 13 subject areas (units of assessment) covering the social sciences. A further random sample of 306 articles appearing in the sampled journals were tested. Their conclusion was that Scopus had best coverage. *Schultz* [30.58] conducted ten searches (topic, journal, and author searches) in parallel on PubMed and Google Scholar, and found that Google Scholar returned more results, including grey literature, but the overlap with PubMed was small. The lack of controlled vocabulary in Google Scholar was listed as a serious obstacle for complex searches. The coverage of Compendex was compared to that of Google Scholar in engineering with a decade by decade comparison, starting with the 1950s [30.63]. The authors found that Google Scholar's coverage increased by publication year to around 90% from the 1990s onwards. The data collection method for this study was to run eight topic searches and to select 20 random articles from each decade for each of the searches.

Kousha and *Thelwall* [30.64] compared web/URL citations (described above) with WoS and Google Scholar citations on a sample of Open Access articles in several science and social science fields. Significant and strong correlations were found between WoS citations and web/URL citations. Google Scholar citation counts were higher than WoS citation counts in the social sciences and in computer science, probably because for these disciplines journals are not necessarily the primary publication venue. Books and book chapters are important for the social sciences and proceedings for computer science and these are not covered (or covered only partially) by WoS.

Another major study [30.55] considered the publications of 25 LIS faculty members and explored the citations to their work on WoS, Scopus, and Google Scholar, examining more than 10 000 citing documents and checking whether these actually cited the target article. They found that Google Scholar excelled in its coverage of proceedings and non-English journals. Their recommendation was to use all three citation databases if the aim is a comprehensive assessment of scholarly impact. Their main conclusion was that even though Google Scholar had much better coverage of proceedings papers, it does not influence the rankings of the scholars, and the effort to add data from Google

Scholar is very high. Hence, WoS together with Scopus are sufficient for ranking LIS researchers.

They complained about the amount of work they invested in the study: 100 hours on WoS, 200 on Scopus, and 3000 (!) on Google Scholar. Data from WoS and Scopus were retrieved manually and data from Google Scholar was *harvested*. Data from all three sources were checked and cleansed—I assume this was the most time-consuming part, but even so 3000 hours seems a lot. Data were collected in March 2006, and the manuscript was submitted in mid-October 2006, which means 180 days between data collection and submission or 16.7 hours daily spent on data collection and cleansing of results retrieved by Google Scholar.

Google Scholar is quite unfriendly for data collection. Luckily the problem was partially solved by Anne-Wil Harzing, who released the first version of *Publish or Perish* in 2007 [30.65]. This software organizes and reranks retrieved items according to the number of citations, and provides metrics, including total cites, h-index, and g-index. In the most recent version *Publish or Perish* also covers Google Scholar Citation Profiles and yearly citation counts of the profiled author. The output can be saved in various formats, most notably for further analysis as comma-separated values (CSV) or Excel, but different citation styles are supported as well. See [30.66] for a 10-year history of Publish and Perish. This is an indispensable tool for retrieval and basic analysis of data from Google Scholar.

This tool was used in 2008 to study author and journal impact as reflected on Google Scholar [30.57] for 20 top journals in management. Strong and significant correlations were found between the JIF and the three measures derived from Google Scholar by *Publish or Perish*: h-index, g-index, and citations per paper. A follow-up paper [30.67] further advocated the use of Google Scholar's h-index for journals over the JIF. They provided supporting evidence from 838 journals in economics and business.

In contrast, *Bornmann* et al. [30.68] compared citation counts reported by WoS, Scopus, Google Scholar, and Chemical Abstracts for 1837 articles submitted to Angewandte Chemie International Edition (accepted or rejected and published elsewhere later). They found the three fee-based services provided very similar results, however large differences were observed between the fee-based sources and Google Scholar, indicating the lack of convergent validity of Google Scholar.

Database coverage is a major factor both for the number of publications and for citations, because the database is aware only of citations from publications that are indexed by the database. The h-index [30.69] is a function of both the number of publications and the number of citations—thus the h-index calculation depends on the data source, as was shown by *Bar-Ilan* [30.70] for 40 highly cited Israeli scientists listed in the HCR (highly cited researchers) database (2001 version—http://hcr.stateofinnovation.com/page/archives) and three Israeli Nobel prize winners. The data, especially from Google Scholar, were cleansed extensively, but such a process was needed for Scopus and WoS as well. The h-indices based on Scopus and WoS were similar. In a few cases the Google Scholar-based h-index was lower than the other two h-indices, but for computer science and mathematics, for almost all scientists the Google Scholar based h-index was more than 70% higher. *Meho* and *Rogers* [30.71] computed the h-index of 22 highly cited researchers, based on WoS, Scopus, and Google Scholar. The h-index based on Google Scholar was always higher than the h-index based on the other two sources (by 59% on average).

Google Scholar has since matured, as can be seen from a study by *Anne-Wil Harzing* [30.72] of 20 Nobel prize winners in chemistry, economics, medicine, and physics. The results were stable over time, and Google Scholar had good coverage of the Nobel prize winners' publications. A follow-up study [30.73] supported these findings. Longitudinal studies are of importance as they provide information on the growth and stability of the database.

In a recent large-scale study [30.74], Google Scholar was compared to Scopus, in terms of coverage, number of citations, and indexing speed. Two journals from each of six disciplines were chosen. One hundred top-cited articles published in the 12 journals between 2010–2014 were selected. Data on the 1200 selected articles were collected in 2015. Correlations of citation counts were high and significant. Except for one journal in chemistry, citation counts on Google Scholar were higher than on Scopus. Duplication due to multiple versions was observed in less than 2% of the cases.

Google Scholar, like the other citation databases, not only reports the number of citations, but also links to the citing documents. Since there were complaints about nonexisting, "phantom" citations [30.75], *Bar-Ilan* [30.76] examined all the citing documents reported by Google Scholar to the book *Introduction to Informetrics* by Leo Egghe and Ronald Rousseau. Rather surprisingly, in less than 2% of the cases the same citing URL appeared twice (double counting) and less than 7% were content duplicates (the same citing source at different URLs). After duplicate removal, all citing documents were checked for the existence of a reference to *Introduction of Informetrics*. More than 85% of the citations were genuine. This was only a case study examining 358 citing documents, but the findings on the accuracy of Google Scholar did not support complaints by *Jacsó* [30.75] or by

Meho and *Yang* [30.55]. One of the possible reasons is that Google Scholar had improved considerably over time.

Despite the cold welcome Google Scholar received at first, it has greatly improved over time. However, this does not mean that it cannot be manipulated, as was shown by *Delgado López-Cózar* et al. [30.77]. They created and uploaded six documents by a fake author, Marco Pantani-Contador, that were linked from an institutional web page. All six documents referenced all the publications of the research group. The documents were picked up by Google Scholar and resulted in an increase of 649 citations for the three authors and an average increase of 2.3 in their h-indices. Four of the *publications* of the nonexistent Pantani-Contador are still indexed by Google Scholar (GS) as of May 18, 2017, and are picked up from the supplementary material to the article describing the experiment, as legitimate publications (Fig. 30.4), even though the paper reports that after the announcement of the results of the experiment [30.77, p. 451]:

> Google erased all traces from our false fictitious researcher Pantani-Contador as well as the GS citations profiles of the authors of this article, which were kept in quarantine for some weeks without notifying the authors at any time and then cleaned and made publicly available.

A quick test of one of the papers in the reference list of the papers *published* by the nonexistent Pantani-Contador, "Strategic knowledge maps of the techno-scientific network" [30.78], was cited by 14 publications, including three of the four *publications* of Pantani-Contador appearing in Fig. 30.4 (Fig. 30.5). Another article, "State of the library and information science blogosphere after social networks boom: A metric approach" referenced by Pantani-Contador, was cited 32 times including five citations from the fake publications (four of them from the four Pantani-Contador *publications* still indexed by Google Scholar, and the fifth from the supplementary materials to [30.77] which contains the six fake publications). Thus, the research group lead by Emilio Delgado López-Cózar still profits from the fake experiment that took place more than four years ago.

It should be noted that as of December 2017 the fulltext of the fake articles is no longer available from Google Scholar, but they still count as citations to the above-mentioned articles. The fulltext of the fake articles is accessible from https://zenodo.org/record/1043395#.WjjCbmdG2Uk.

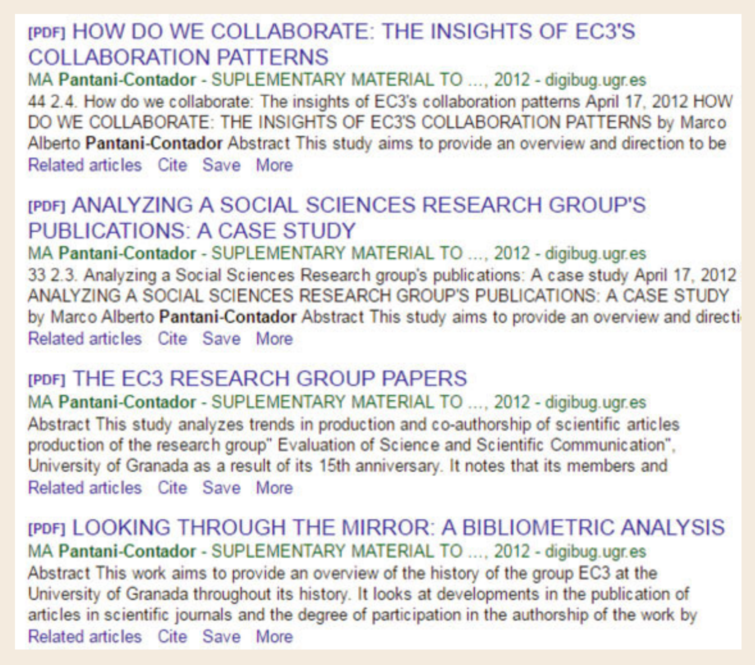

Fig. 30.4 Google Scholar continues to index fake publications, including the four above

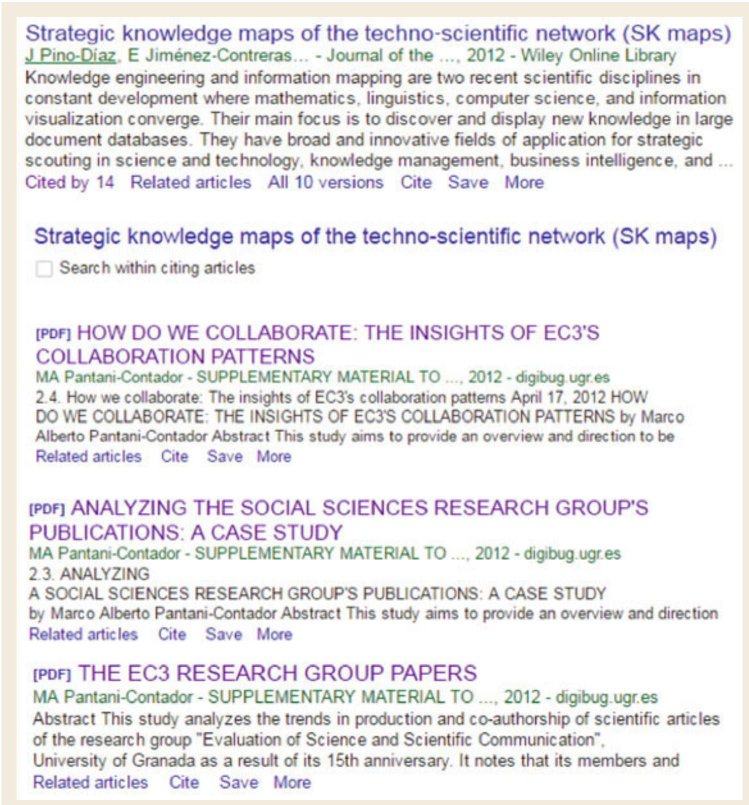

Fig. 30.5 Fake publications that continue to count as legitimate citations in Google Scholar

30.10 Additional Google Sources

An additional data source, Google Books, first named Google Print, was launched in 2002 and renamed Google Books in 2005 [30.79]. Its primary aim is to search the full text of books and magazines. Google digitizes and OCRs books by partnering with publishers and major libraries that allow Google to do that. Although Web of Science has its Book Citation Index and Scopus also indexes some books, their coverage is very poor, compared to Google Books. Google Scholar provides citation counts to books, but probably not from books. Citations to books can also be extracted from the Web of Science (using the *cited reference search*) and from Scopus (using the *view secondary documents link*), however these are not straightforward processes.

In Google Scholar, one can simply search for the book title, or for a topic, and in the search results relevant books with citation counts will appear [30.76]. The opposite direction, extracting references in books to scholarly publications has also been explored by *Kayvan Kousha* and *Mike Thelwall* [30.80], where they manually entered the titles of more than 1900 journal articles into the Google Books search box. The search results contain books that cite the given article, but also retrieve nonsense results. At first, I was very glad to see that the book search for `Which h-index`, published in 2008 retrieved about 428 results. On the first and second result pages most of the results seemed relevant, but by the fifth page my suspicions grew, as books from the 1960s and 1970s were retrieved, even though the concept of the h-index was introduced only in 2005 [30.69] and the article published in 2006. Actually, it would have been an honor to be cited by Eugene Garfield or by Derek De Solla Price. On the seventh page after 62 results, I was informed that no books contain the phrase (Fig. 30.6). The search was carried out on 19 December 2017. To overcome this problem, *Kousha* and *Thelwall* [30.81] developed an automatic method to retrieve and clean citations from books to books, a method that can be applied to searching for citations to articles from books as well and is part of the *Webometric Analyst* tool set, mentioned before.

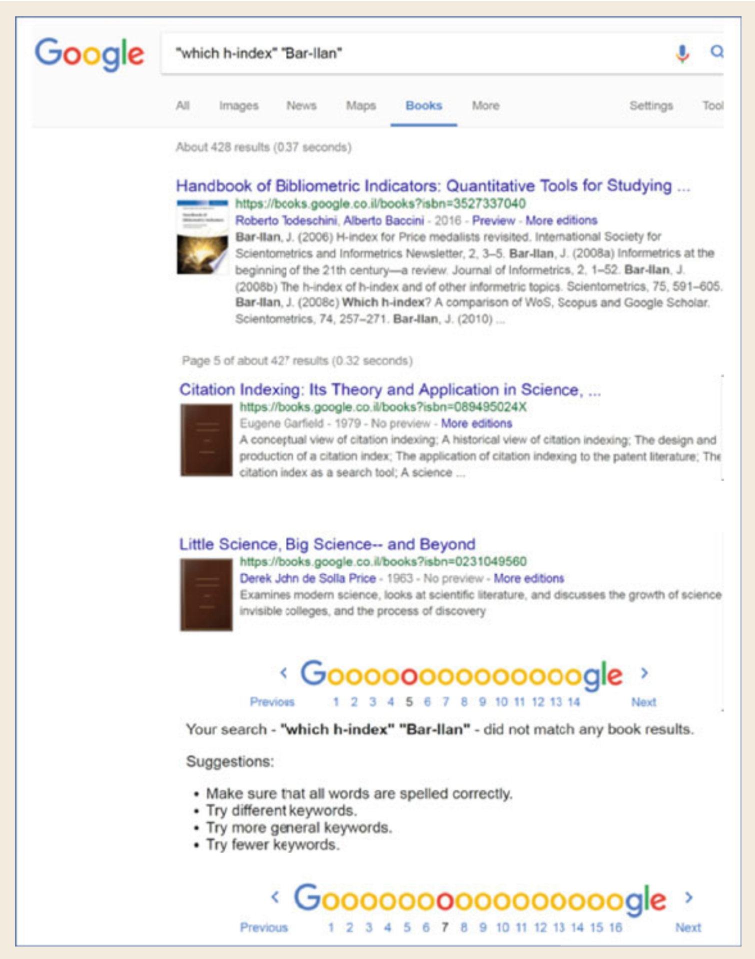

Fig. 30.6 Problems with the accuracy of Google Books citation matches

Google Scholar Citation Profiles were introduced in 2011. This tool allows researchers to set up a profile and to showcase their scholarly publications. Publications of the researcher are pulled from Google Scholar and citation counts are continuously updated. The researcher can correct the profile, delete publications that were not authored by her, and add missing ones. This tool is very popular and many institutions require faculty to setup such a profile. When setting up the profile, the researchers are asked about their affiliation. Google Scholar created institutional profiles from these data, and the Cybermetrics Lab, led by Isidro Aguillo, produces a ranking of universities based on the top Citation Profiles of researchers from the institutions. This ranking is called *Transparent Ranking* (http://www.webometrics.info/en/node/169).

Currently Google Scholar provides tools that can be utilized for research assessment. We already described Google Scholar Citation Profiles, which can be utilized in individual assessments and can be used for ranking universities. Another tool, Google Citation Metrics, launched in 2012, ranks journals according to their 5-year h-index (h-index of publications in the last five years). Each comprehensive citation database provides slightly different measures for journals: WoS's main journal measure is the Journal Impact Factor and Scopus now promotes its new measure CiteScore, however there are additional measures, like the 5-year impact factor, the eigenfactor and the article influence measure provided by WoS, and the SJR (SCImago Journal Rank) and SNIP (Source Normalized Impact per Paper) of Scopus. Scopus and Google Scholar offer their journal indicators freely, while the Journal Citation Report is accessible only to subscribers. In spite of the heavy criticism against using the impact factor for assessing individual articles (DORA Declaration [30.82], Leiden Manifesto [30.83]) it continues to have a central position in research evaluations.

The h5-index of Google Scholar has a different flavor, as can be seen by comparing the top five journals

Table 30.2 Rankings by different journal indicators

Journal	Rank—GS	Rank—IF	Rank—CiteScore
Nature	1	9	60
New England Journal of Medicine	2	2	91
Science	3	16	80
Lancet	4	4	243
Cell	5	27	17
CA—A Cancer Journal for Clinicians	NA	1	1
Nature Reviews Drug Discovery	99	3	168
Nature Biotechnology	36	5	97
Chemical Reviews	13	12	2
Annual Review of Immunology	NA	14	3
Chemical Society Reviews	6	18	5
Annual Review of Astronomy and Astrophysics	NA	10	5

ranked by impact factor (IF), h5-index, and CiteScore. Table 30.2 displays rankings published for 2015, and the differences between the most-used ranking in each database speak for themselves. Google Scholar ranks only the top 100 journals, it covers The *Annual Review of Immunology* and *CA—A Cancer Journal for Clinicians*, but their h5-indexes are lower than those in the top 100, while the *Annual Review of Astronomy and Astrophysics* is not listed at all. So far little research has been done on Google Scholar Metrics [30.77, 84, 85].

30.11 Microsoft Academic

A competitor of Google Scholar is Microsoft Academic Search. It was launched in 2006, but its development ceased and it stopped being updated in 2012. It was redesigned and relaunched in 2016 as Microsoft Academic. It is not mature enough yet, but has potential. Since it was relaunched just recently, its accuracy, coverage, and data retrieval capabilities have not been explored. This an area for future research. In July 2017 version 2.0 was launched, which seems to be a big improvement. *Harzing* and *Alakagnas* [30.86] are optimistic about the future of the relaunched Microsoft Academic. *Publish or Perish* provides an interface to download metadata from Microsoft Academic.

30.12 Subject Specific and Institutional Repositories

Subject-specific repositories like arXiv, SSRN, RePec, and PubMed Central are also a rich source for data collection and analysis, especially if they provide methods or APIs for large-scale data collection. These subject-specific repositories contain preprints (submitted for peer review), postprints (as accepted by the journal, after peer review and revision, but typically not in the journal format), and also the paper in its final format (depending on publisher permission). Postprints are especially useful for journals with long publication delays or items published in proceedings that are not online. In such cases, both the final published item and the version in the repository can accumulate citations. Early citations are directed to the repository version, but later citations may target the version on the publisher's site or the repository. It should be noted that publishers are aware of publication delays and often upload articles not yet assigned to a journal issue in an area called *early view*, but these articles are typically behind a paywall, whereas articles uploaded to repositories as pre- or postprints (depending on what the publisher allows), are green open access items with full text availability. arXiv, RePEc, and PubMed Central have APIs. *Webometric Analyst* has an interface that allows the downloading of metadata from arXiv. *Davis* and *Fromerth* [30.87] showed that depositing in arXiv gives citation advantage to the deposited articles in mathematics, while *Henk Moed* [30.88] analyzed the condensed matter section of arXiv and reached the conclusion that "ArXiv accelerates citations due to the fact that ArXiv makes papers available earlier" [30.88, p. 2047]. *Larivière* et al. [30.89] conducted an extensive comparison of arXiv and WoS, and found that 64% of the submissions on arXiv could be matched to publications in WoS. Citations from WoS to arXiv preprints were also explored. *Li* et al. [30.90] studied citations from documents indexed in Scopus to arXiv, SSRN, RePec, and PubMed Central and concluded that if a published version exists, it serves as the preferred citation target.

30.13 Altmetrics

Altmetrics are the newest addition to the metrics soup. The term was introduced in 2010 in the Altmetrics Manifesto [30.91]. The basic idea was to extend the notion of scientific impact by capturing data from the social media platforms and counting the number of relevant events [30.92]. Altmetrics events accumulate much faster than citations, and so can serve as early signals of impact. Of course, this is not always the case, because a catchy title or a controversial topic might result in a lot of likes, shares, comments, discussion, without any long-lasting impact.

Currently, the most heavily studied altmetric platforms are Mendeley and Twitter, probably because of their coverage. Mendeley and Twitter have APIs; data can be collected either directly from the APIs or by using *Webometric Analyst*. There are open source applications both in R and in Python for retrieving data using the APIs. Another option for Twitter is to request data from Altmetric.com, currently the major aggregator collecting altmetric signals of scholarly output.

Mendeley is a free online reference manager launched in 2007. When a user saves an item to her Mendeley library, she is counted as a *reader* of the item. Mendeley aggregates these reader counts and displays the number of readers of the scholarly publication. Thus, readership counts can be compared to citations. Most studies report Spearman correlations of about 0.5 between Mendeley readership counts and citation counts—showing that they are related but also different [30.93–98]. Mendeley users include authors who cite scholarly publications, but also read things that they do not cite. In addition, many users are students or other persons interested in science who have no intention to publish in scholarly venues. One should also take into account that not everything that is downloaded is read.

Twitter users are even more diverse including the general public, journal editors, and publishers who use Twitter in order to increase the visibility of their publications. *Thelwall* et al. [30.99] received data from Altmetric.com on publications that have PubMed IDs, and have at least one nonzero metric from the 11 sources covered at the time of the study by the data provider. Altmetric.com currently tracks 17 types of altmetric sources [30.100]. The aim of the study was to test whether articles with higher altmetric counts are cited more than articles with lower or nonexisting altmetric counts per altmetric. Statistically significant relationships were found between WoS citations and a number of altmetric scores, including Twitter. Because of the low coverage of the other altmetrics, only this relationship was classified as meaningful. It should be noted that as of mid-2016, Altmetric.com also tracks citations from Scopus, which should ease the process of matching citations and altmetric counts. Another more recent development is that Elsevier bought PlumX, a competitor of Altmetric, and thus it is not clear whether the collaboration between Altmetric and Scopus (owned by Elsevier) will continue. Currently, Scopus displays Mendeley readership counts for each item and additional altmetrics tracked by Altmetric.com.

Another large-scale study on tweets and citations in the biomedical literature [30.101] showed that Twitter coverage was low, and the correlation between citation counts from WoS and Twitter counts was also low. *Costas* et al. [30.102] explored the coverage of different altmetrics (Mendeley excluded) on a large data set derived from WoS. Findings show that the coverage of Twitter was highest (13%). Correlations with citation counts were low (below 0.25 for all citation measures tested), even for Twitter. For a comparison between tweets and Mendeley readers see [30.95].

It should be noted that different altmetrics reflect different aspects of *impact*. Mendeley reader counts and Reddit reflect usage, tweets probably show general interest, and other social media platforms (e.g., postpublication peer-review sites, blogs, Facebook, and academic social media sites, like ResearchGate and Academia.edu) allow for commenting and discussion. Studies were and are being conducted to explore the value of the different altmetric sources (e.g., scientific blogs [30.103]; F1000Prime [30.104, 105]; ResearchGate [30.106, 107]; Academia.edu [30.108]). As a result of an initiative of Springer-Nature and Altmetric, Bookmetrix was developed which tracks "citations, online mentions, book reviews and downloads" [30.109] both at the book- and the book-chapter level. It currently covers Springer books only, but hopefully wider coverage will be provided in the future. The metrics for each book are displayed, but access to the Bookmetrix platform is currently limited to Springer staff only. The metrics of Bookmetrix are especially useful for evaluations in the social sciences and the humanities, where in many areas traditional metrics have little value.

The Altmetrics Manifesto [30.91] also calls for measuring scholarly outputs besides articles, for example data reuse and the use of software tools. Infrastructure for measuring data reuse is being developed by DataCite, primarily by assigning DOIs (digital object identifiers) to data sets and developing a metadata schema for accurate identification of resources. Data sharing and reuse are not the norm yet [30.110], but they are encouraged by open science initiatives [30.111].

An increasing number of publishers release usage data. PLoS (Public Library of Science) was probably the first to publish article-level metrics (ALM)—see [30.112]. The idea is to be diverse and multifaceted. PLoS ALM have three central goals: to assess interest in the article before it receives citations, to incorporate both academic and social metrics, and to allow a longitudinal view of the various signals. The metrics are grouped into categories [30.113]: viewed, saved, cited, recommended, and discussed. PLoS ALMs can be accessed through the PLoS API.

The major shortcoming of altmetric research at this point in time is that altmetrics provide counts of things without a clear meaning. Hopefully in the future we will have a better understanding, using qualitative methods together with quantitative ones. We must keep in mind that "not everything that counts can be counted, and not everything that can be counted counts" (a saying attributed to Albert Einstein).

30.14 A Wish-List for Future Data Collection from the Web

To sum up, I list the most important features that would enhance current data collection methods in my opinion:

- Transparency: This is a major problem, especially since the owners of the data are commercial companies. Examples of problems related to this aspect are: not knowing what is exactly covered by Google Scholar or the public Twitter API that samples somehow 10% of the data.
- Coverage: This issue was emphasized throughout the chapter, by comparing the number results reported by Google and Bing, low coverage of several altmetrics in general, and in the humanities especially (it is not easy or maybe even impossible to improve this situation, but I can still include it in my wish-list). The major point is that highly visible scholarly outputs are easily identifiable, and we need measures to assess items with medium or low visibility. We need measures that have good coverage if not of science as a whole, at least for the specific subject area being evaluated.
- Reliability and validity: In some cases there are huge fluctuations in the reported counts within a short period of time or inconsistencies in the reported number of results. This should be clearly avoided. Another aspect of reliability is continued availability of the information (this again is a wish that probably cannot be fulfilled, since platforms and tools change or even disappear over time). Validity is partially in the hands of the researcher. One has to be convinced that the data collected are the best possible data to answer the research questions.
- Search features and APIs: Please, bring the inlink operators back, and improve search on social media websites! Provide APIs to access data, and remove limitations (like maximum 1000 results displayed). Improve the precision and the recall of the retrieved data. This will result in less time spent on data cleansing. Improve handling of special characters that are problematic in several databases. Data quality of scholarly output can be improved by the use of unique identifiers (e.g., DOI, ORCiD).
- Provide access to web data and search engine logfiles: This again is easier said than done, because privacy issues are involved, and the interests of the commercial companies owning the data.
- Usage data: Publishers, aggregators, and repositories, please release more usage data.

Most of these points are not new, see for example [30.83, 114–117] for similar and additional recommendations.

To end the chapter on a positive note, research achievements in quantitative informetrics are quite remarkable, there are new developments and a growing interest. Researchers in the field have been able to overcome the difficulties and limitations in data collection and data cleansing by devising innovative methods and techniques. New and exciting research opportunities are ahead of us both in terms of techniques and methods (data science) and in terms of incentives (open science initiatives).

Judit Bar-Ilan

Information Science
Bar-Ilan University
Ramat Gan, Israel
judit.bar-ilan@biu.ac.il

Judit Bar-Ilan is a Professor at the Department of Information Science of Bar-Ilan University (Israel). She received her PhD in Computer Science from the Hebrew University of Jerusalem. She started her research on information science in the mid-1990s at the School of Library, Archive and Information Studies of the Hebrew University of Jerusalem. She moved to Bar-Ilan University in 2002. Her major areas of interest are informetrics and information retrieval.

31. Web Citation Indicators for Wider Impact Assessment of Articles

Kayvan Kousha

There are many ways in which academic articles can be used outside research contexts for teaching, culture, medical practice, business, policy making, or knowledge communication. Articles that have significant wider benefits may therefore be undervalued if they are assessed through conventional citation indicators and sources (e. g., the Web of Science (WoS) and Scopus). A range of online document genres and sources may help to evaluate these broader impacts of articles, including academic syllabi, textbooks, clinical trials or guidelines, patents, encyclopedia articles, and grey literature publications. Web citations can be used as a quantitative impact indicator for monitoring the wider impact of articles, especially in the arts, humanities, and social sciences where many research outputs have value beyond academia. This article reviews literature about the web citation analysis of articles and explains different methods to capture web citations from a range of online sources via commercial search engines. The applications and limitations of web citation analysis for wider impact assessment of articles are discussed, in addition to practical advice for data gathering. New web citation indicators can help research evaluation peer review and citation analysis by giving additional information about the wider benefits of published research when a type of impact (e. g., teaching, commercial, or clinical impact) is required to be assessed by authors, research funders, or evaluators in addition to their academic research impact.

31.1 Web as a Citation Source

Citation indicators derived from the Web of Science (WoS) and Scopus are often used to support research impact assessment for academic publications [31.1]. Nevertheless, formal citations from journal articles and conference papers are unlikely to be useful for monitoring the wider impacts of research. Alternative sources of citations may help research evaluations when the published research is cited in nonacademic publications (e. g., clinical trials or patents) or when an article's journal is not indexed by common citation databases (e. g., non-WoS journals). Alternative sources of citations may aid research evaluation exercises, where "all kinds of social, economic and cultural benefits and impacts beyond academia" need to be measured [31.2, p. 4]. Some scientometricians have recommended that indicators beyond bibliometrics [31.3, 4] and nonstan-

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_31

dard publications [31.5] are needed to examine all types of research impacts. This is because some research that has a significant intellectual impact may be undervalued if assessed through conventional citation indicators and databases. For instance, some scientific articles might be extensively used for teaching, clinical practice, technology transfer, policy making, or knowledge dissemination without being cited in academic publications.

There have been early initiatives to extract citations from web documents as part of the webometrics research area to develop alternative quantitative indicators for impact assessment (for reviews see: [31.6–8]). In a pioneering pair of studies, *Vaughan* and *Shaw* [31.9, 10] applied the term *web citation* to refer to citations that can be identified by searching for bibliographic information from an article, such as its title, author(s), journal name, or publication year, via commercial search engines. The assumption is that counting mentions of research in online sources can reflect the level of interest in scientific, scholarly related, educational, or cultural contexts. Web citations could be more useful in the arts and humanities than science, where scholarly outputs may have teaching, cultural, artistic, economic, or social influence rather than primarily academic impact, and because the coverage of current citation databases is insufficient for citation analyses of humanities research [31.11, 12]. Most previous web citation studies have examined online data sources to identify the broader benefits of academic outputs [31.13] and some web impact indicators have been proposed to assess wider benefits of funded scientific research [31.14–16].

The term *web citations* in this chapter refers to online mentions of scientific articles. Web citation indicators are different from social media metrics (known as altmetrics), which incorporate bookmarks, comments, views, downloads, and ratings from *social media* sites, such as Mendeley, CiteULike, LinkedIn, Twitter, and Facebook [31.17]. Both altmetrics and web citations are alternative indicators that may be called upon when the wider impacts of academic research are assessed. There have been several literature reviews and books about webometrics [31.6, 8, 18] and web citation indicators [31.13, 19, 20]. This chapter emphasizes web indicators for *articles* and their publishing journal, and summarizes what is known about new online sources and document genres (e. g., encyclopedia articles, grey literature publications, clinical sources, and news stories), search techniques, and disciplinary differences. Some of the web citation indicators introduced in this chapter, such as Google Books, syllabus and Wikipedia citations, can also be used for the impact assessment of books (Chap. 27).

31.2 Sources of Web Citations: Websites and Document Genres

This section introduces a range of types of website (e. g., blogs, Wikipedia) and document genres (e. g., syllabi, presentations) that may cite academic research. Their citations may be especially relevant when evaluators, funders, or scholars want to assess research impact beyond academia. Citations from these sources or genres may be identified with search engine queries or, in some cases, Application Programming Interface (API) queries, and the process can be automated to a large extent with free software.

There are four generic limitations with using the web for research evaluation purposes. First, not everything is online and so impact may occur without being recorded on the web. Second, it is likely that a biased fraction of impacts is recorded on the web. For example, impacts occurring in developing nations and for people that do not routinely publish online are likely to be underrepresented or absent. Third, commercial search engines do not index the entire web and so it is impossible to guarantee that all web citations to a document will be found. Thus, when using any type of web citation, researchers need to provide evidence that the results are meaningful. Finally, most web citation counts can be manipulated and so cannot be used if stakeholders are aware in advance that they will be used. This does not prevent formative applications and use for evaluations when the methods are unknown to stakeholders [31.21]. These limitations are discussed in more detail in the limitations section below.

This section lists the main types of web citation and a later section covers one of the ways (correlation tests) in which the validity of web indicators can be assessed.

31.2.1 Citations from the General Web

It is possible to identify citations to academic publications from the web using manual or automatic citation searches. Extra manual checks are often necessary to remove irrelevant matches, however.

General Web Citations

Commercial search engines (e. g., Google and Bing) can be used to manually or automatically locate mentions of academic articles from the web and this may reflect the overall interest in articles, at least as reflected online. *Bar-Ilan* [31.22] argued that the web is a free data source that can be used for bibliometric research. She searched the terms 'informetrics' and 'informetric' in major web search engines to identify the contexts in which they were used, finding that the web can locate relevant information not found in commercial bibliographic databases. *Vaughan* and *Shaw* [31.9] found that the web contains citations outside conventional citation indexes that can be identified online through searching with the bibliographic information of publications (see an example below). Nevertheless, the practical limitation of general web citation searches is that not all web citations are indicators of academic impact and web-extracted citations may be from library lists, tables of contents, current awareness databases, publishers' websites, or authors' CVs, which cannot be considered as evidence of scholarly impact. For example, there is evidence that only a third of general web citations from Google ($n = 854$) to library and information science journal articles were from references in other publications [31.9] and a follow-up study across four science subject areas (biology, genetics, medicine, and multidisciplinary science) found that 30% of web citations reflected intellectual impact, including citations from papers and from class reading lists [31.10]. Another study classified sources of 1577 web citations to open access journals from biology, physics, chemistry, and computing, finding a quarter of citations were from references of other publications [31.23]. These studies suggest that most general web citations could be mentioned for noncitation reasons (e.g., navigational), making this indicator less useful for intellectual impact assessment of articles. Nevertheless, general web citation searches could be more useful as evidence of impact for individual articles when searches are limited to a specific file type or website.

```
Jha "Chronic kidney disease:
Global dimension and
perspectives," Lancet 2013
```

URL Citations

URL citations of online publications have also been suggested as an alternative to web citations [31.24]. Although one advantage of URL citations over general web citations is that URLs are unique, giving less false matches than searching for articles by name, URLs of online articles might change over time and some journals may have multiple links to the same article in different formats (e.g., PDF or HTML). Moreover, some journals may use DOIs instead of URLs for directing users to articles and some authors may not mention URLs of online articles in their references, making URL citations less useful for impact assessment of research. Below is an example of a URL citation search for an article published in an open access journal, *Educational Technology & Society*.

```
https://www.j-ets.net/ETS/
journals/12_1/11.pdf
```

31.2.2 Citations from Specific Document Types

Web citation searches can be limited to specific document file types or specific internet domains to generate more targeted searches than general web citation queries.

Document Citations

Many papers, dissertations, and reports are available in Portable Document Format (PDF) or Microsoft Word format [31.25] and citations from these file formats may be more useful than general web citation searches for impact assessment [31.26]. Web citations from PDF, Microsoft Word (DOC and DOCX), or other document formats such as Rich Text Format (RTF) or PostScript (PS) can be counted using the *filetype:* search command in Google manual searches or automatically via the Bing API (see the examples below). For an inclusive web citation search from all document types, queries should be combined using the OR operator (Sect. 31.5), although the Google OR operator does not always work properly [31.27]. Document web citation searches are useful when evidence of the wider impact of research is required from online grey literature such as reports, white papers, or newsletters [31.28]. However, document web citation searches may retrieve many false matches from CVs in PDF or Microsoft Word format. It may also retrieve citations from the duplicate self-archived citing papers from authors' websites or different digital libraries (e.g., ResearchGate, Academia.edu, arXiv.org) and so manual checking of results may be necessary. Moreover, it seems unlikely that document web citation searches give more effective results than Google Scholar manual citation searches. In the absence of Google Scholar automatic searches for large-scale analyses, document citation web searches seem to be the only practical method to automatically estimate citations to articles from PDF or Microsoft Word format documents, unless Microsoft Academic can be used (see below).

```
Zhu "Prostate cancer in East
Asia: Evolving trend over the
last decade" 2015 filetype:pdf
```

volume and failure to rescue
for pancreatic surgery" 2015
filetype:doc
```

```
Shinozuka "Statistical analysis
of fragility curves" 2000
filetype:docx
```

Limiting a document type web citation search to a specific internet domain using the site: command is useful when web citations are required to be collected from academic (e. g., .edu, ac.uk, ac.jp), government (e. g., .gov), or national web domains (e. g., .fr, .de, or .ca), as shown in examples below (see also the grey literature citation section below):

```
Hainmueller Hopkins "Public
attitudes toward immigration"
"Annual Review of Political
Science" 2014 filetype:pdf
site:edu
```

```
Harper "Economic and social
implications of aging societies"
"Science" 2014 filetype:pdf
site:ca
```

31.2.3 Presentation Citations

There are many searchable academic presentations online in Microsoft PowerPoint format (.ppt and .pptx). Some scholars cite articles in their research or teaching presentation slides for conferences, seminars, or lectures. Citations from presentations could be more useful in conference-based fields, where presentations are important for disseminating scientific results [31.29]. Presentations for teaching or seminars may instead reflect the educational value of the cited research. Moreover, many scholars may not include references in their presentations, may not share their presentations online, or may publish them in PDF or Microsoft Word formats. Citations from presentations can be manually or automatically identified through searching for articles in presentation files and adding filetype:ppt or filetype:pptx to each query, as shown in the example below. It is important to combine web citation results from both ppt and pptx because they may give different matches (e. g., the second example below).

```
Liben-Nowell Kleinberg "The
link-prediction problem for
social networks" filetype:ppt
```

```
Kasimati "Economic aspects and
the Summer Olympics: A review of
related research" filetype:pptx
```

Another source of presentation citations is the SlideShare (slideshare.net) website, which is a specialized platform to share presentations (see an example below), although other scientific repositories, such as Figshare.org also include academic presentations [31.30]. A content analysis of SlideShare documents citing academic articles showed that most (64%) were academic publications (e. g., journal articles) rather than slides, making it less unique for presentation citation analysis [31.31].

```
Møller "Breast cancer survival
in England, Norway and Sweden:
a population-based comparison"
site:slideshare.net
```

Syllabus Citations

Course syllabi or reading lists are key documents for teaching and learning. University lecturers or teaching staff list academic publications in syllabi that are required or recommended for students to read. Mentions of publications in academic course syllabi or reading lists may reflect the educational benefits of the works listed [31.32]. Syllabus citations could help to estimate the educational value of teaching materials, such as textbooks and monographs. For instance, a study found that a third of about 14 000 Scopus-indexed monographs had at least one academic syllabus mention [31.33]. Syllabus citations can also be used to assess the teaching utility of academic articles. It is possible to locate syllabus citations through manual searches for academic papers in fully searchable syllabi that have been published online, although this requires extensive manual checking to filter out irrelevant matches. For instance, the bibliographic information of articles can be searched for in conjunction with the phrases `course description` or `syllabus` to identify syllabi that mention the articles searched for.

```
Harnad "Scholarly skywriting and
the prepublication continuum
of scientific inquiry" "course
description" site:edu
```

```
Gollin "The Lewis model:
A 60-year retrospective" syllabus
site:edu
```

To help identify academic research with high educational impact from university websites, a method has been developed to automatically search for mentions of articles in online academic course syllabi and filter out false matches, limiting search results to a list of over 24 600 university websites to help remove search matches originating from nonacademic sites. This method includes any search results from second-level academic domains, such as Australia (.edu.au/), Malaysia (.edu.my/), or Taiwan (.edu.tw/), as well as individual universities without specific academic domains, such as in Canada, France, and Germany [31.33].

There are also specialized educational websites that can be searched to assess the teaching benefits of research articles. One example in medical science is Radiopaedia.org, which provides radiology images and additional references related to them for educational purposes.

```
Angouras "Bovine aortic arch:
normal variant or a marker of
aortopathy?" Cardiology 2012
site:radiopaedia.org
```

31.2.4 Citations from High-Value Websites

Some important websites cite scientific articles for a specific purpose, including encyclopedia articles, clinical trials, or guidelines sites, and websites containing policy or planning documents, annual reports, science blogs or news. It is possible to use the `site:` command at the end of web citation queries to restrict the search results to a specific website and identify only citations from the given site.

Encyclopedia Citations

Citations from general or specialized encyclopedia entries to journal articles may reflect scientific, social, or cultural knowledge transfer to the wider public. Wikipedia citations, for instance, occur in scientific, educational, societal, and cultural contexts within encyclopedia entries (e.g., popular science, biographies, art, entertainment, history, and geography). To search for citations in Wikipedia articles with Google or Bing, bibliographic information from the articles should be combined with the wikipedia.org/wiki/ command (see an example below). Nevertheless, for a large-scale systematic analysis to identify Wikipedia citations Bing API searches should be used (see also the Web citation searching section). There is strong evidence that citations from Wikipedia articles are useful to assess the wider impacts of textbooks and monographs—a third of English monographs had at least one citation from Wikipedia [31.34]. Wikipedia citations can also be used for the wider impact assessment of articles, especially in the arts and humanities. As an example, the article below published in *Film History: An International Journal* had received over 50 Wikipedia citations without being cited in Scopus (as of April 2017).

```
Pierce "Forgotten faces: Why some
of our cinema heritage is part of
the public domain"
"Film History: An
International Journal" 2007
site:en.wikipedia.org
```

About 5% of the articles published by the Public Library of Science (PLoS) have been cited in Wikipedia [31.35] and a large-scale study of 302 328 Scopus articles published during 2005–2012 across multiple fields found that Wikipedia citations to articles were more frequent in History (11%) and in Music, Visual Arts and Performing Arts, Political Science (7%) than in Computer Science (1.4%) and Surgery (2%) [31.34].

Wikipedia citation searches can be restricted to entries in different languages by adding the language codes (see https://en.wikipedia.org/wiki/List_of_Wikipedias) to the site: command, such as for Spanish (es.wikipedia.org/wiki), Italian (it.wikipedia.org/wiki), or Persian (fa.wikipedia.org/wiki). For instance, the French article below had received two citations from French Wikipedia entries but none from English Wikipedia articles (see below). Nevertheless, because references in Wikipedia articles can be edited by any registered user, citations from Wikipedia can be manipulated or inflated [31.36]. Moreover, very few science articles are cited by Wikipedia, suggesting that Wikipedia citations could be most useful in the arts and humanities and perhaps some social science disciplines.

```
Messaoudi "Frontière du fractal
de Rauzy et système de numération
complexe" "Acta Arithmetica" 2000
site:fr.wikipedia.org/wiki/
```

In contrast to Wikipedia, there is a range of specialized and peer-reviewed online encyclopedias with quality-control mechanisms, such as Scholarpedia (scholarpedia.org) within the fields of mathematics and sciences (e.g., physical, biological, and behavioral sciences), Encyclopedia of Laser Physics and Technology (rp-photonics.com/encyclopedia.html), Stanford Encyclopedia of Philosophy (plato.stanford.edu), or The

A.D.A.M. Medical Encyclopedia (medlineplus.gov/ency) as shown in the examples below.

site:plato.stanford.edu
```

Medical Citations

Clinical trials and medical guidelines are important components of the process of improving healthcare in society in terms of diagnosis, health care and treatment of clinical problems [31.37]. It is possible to manually or automatically search for citations to medical research in some clinical trials and guideline websites (see also the Web citation searching section below). Web citation extraction methods have been used to count citations to medical journal articles from clinical guidelines from the *National Institute of Health and Clinical Excellence (NICE)* in the UK [31.38], clinical trials in ClinicalTrials.gov [31.39], and clinical drug information from the AHFS DI Essentials in Drugs.com [31.40]. These studies found that articles referenced in clinical publications tended to be more highly cited than comparable articles that were not cited in clinical documents. This suggests that articles with clinical practice value tend to attract more citations from other academic publications.

```

```

There are other national clinical guidelines databases that may be used to assess the overall clinical influence or benefits of research such as Australian National Health and Medical Research Council clinical practice guidelines [31.41], Canadian Clinical Practice Guidelines [31.42], or Scottish Intercollegiate Guidelines Network [31.43].

Grey Literature Citations

Many national or international organizations produce grey literature in the form of annual reports, regulations, statistics, white papers, and government publications or policy documents. Citations from these can point to nonacademic types of impacts. Most of the grey literature is not published by academic or commercial publishers and hence not indexed in citation databases. Because of difficulties accessing grey literature, the *Grey Literature Report* (www.greylit.org/) from the New York Academy of Medicine has attempted to catalogue thousands of medical grey literature publications from many organizations, institutions, and medical centers around the world. Some of these sources are fully searchable by commercial search engines and can be found for web citation analysis. This includes in medicine and healthcare the World Health Organization (WHO), the Joint United Nations Programme on HIV/AIDS (UNAIDS), and the International Diabetes Federation, in environmental science the United Nations Environment Programme (UNEP) and the International Union for Conservation of Nature, in agriculture the Food and Agriculture Organization (FAO) and the International Food Policy Research Institute or in publications, reports, or statistics documents from the European Union. These organizations publish many publications, such as annual reports, white papers, regulations, statistics, guidelines, or government documents, that can be used for the wider impact assessment of research. Nevertheless, less than 0.5% of "policy-related documents" had at least one citation to WoS-indexed articles based on Altmetric data [31.44]. Below are some examples of web citation searches limited to PDF files in websites publishing grey literature.

```

Kumar "Antibiotic uptake by
plants from soil fertilized with
animal manure" site:eu
```

General web searches in huge websites such as WHO may also return results from CVs, library lists, or even formal publications such as published books, monographs, or journal articles, requiring extensive manual checks to identify correct grey literature citations. For instance, the query below retrieves one citation from an open access article published in Bulletin of the World Health Organization which is also indexed by both WoS and Scopus databases. Hence, it is important to exclude citations from these publications (e.g., http://www.who.int/bulletin) or to identify URL addresses associated with grey literature publications (e.g., http://apps.who.int/iris/) to avoid counting citations from journals or books instead of grey literature publications. However, some websites may use similar URLs for publishing their books, journals, or grey literature publications online, making web citation extraction more problematic.

```
Noor "A spatial national health
facility database for public
health sector planning in Kenya
in 2008" "Int J Health Geogr"
2009 site:who.int
```

ResearchGate Citations

ResearchGate can be used to identify early citations to articles from other uploaded publications. Each article in ResearchGate has a profile page, showing how many citations it has received from other documents in ResearchGate. DOIs of articles can be searched for in Bing or Google with a query that combines site:researchgate.net/publication with article information (e.g., title, publication year, journal name) to locate article pages in ResearchGate (see below). There is empirical evidence that ResearchGate citations are more numerous than both WoS and Scopus for recently published library and information science articles, but are less common than Google Scholar citations [31.45]. For instance, the query below locates five citations to an article published in 2016 ("Estimating open access mandate effectiveness: The MELIBEA score.") from uploaded preprints in ResearchGate without being cited either in WoS or Scopus (as of 24th of April 2017). Nevertheless, ResearchGate citations can be manipulated or inflated by uploading fake or nonpeer reviewed publications and an automatic method to extract ResearchGate citations for a large-scale study is likely to be problematic [31.45].

```

```

Blog Citations

Many science blogs disseminate and discuss scientific issues, such as those indexed in *ScienceBlogs.com, ResearchBlogging.org, blogs.nature.com*, and *blogs.plos.org*. Scholars may cite other research in their blog posts to support their claims, discussions, or reviews [31.46, 47]. There is evidence that science blog citations to other articles can show the wider impact of scientific articles [31.48, 49] and articles blogged in ResearchBlogging.org in the year of publication tended to receive more citations than other articles in the same journal [31.49]. Blog citations can be gathered by commercial search engines, although they may include links to other publications instead of cited references and sometimes mention research just for current awareness. Below is an example of a web citation search for a citation to an article from the ScienceBlogs website.

```

31.2.5 Citations from Digital Libraries and Online Citation Indexes

Google Scholar Citations

Google Scholar systematically extracts citations from a huge number of scientific journals from many publishers, as well as conference papers, preprints and postprints of articles, dissertations, and other scholarly documents. Google Scholar citation counts are often substantially greater than those from conventional citation indexes [31.18, 50, 51], although this varies across subject areas [31.52]. Despite possible manipulation [31.53, 54], Google Scholar is useful for extracting and analyzing citations for impact assessment of articles [31.55]. Google Scholar is a better source of early citation impact evidence for new articles than WoS and Scopus because it takes longer for articles to be indexed by traditional citation indexes [31.45]. Although Google Scholar does not support automatic citation counting for a large-scale research evaluation of articles, the *Publish or Perish* software can be used for individual assessment of researchers and journals based on Google Scholar citation counts [31.56].

Google Books Citations

Books and monographs are important academic outputs and book citations can reflect a different type of impact compared with citations from journal articles [31.57]. Citations from scientific books to research articles presumably reflect a type of scientific impact. However, citations in books that are primarily written for teaching, such as textbooks for undergraduates, reflect educational impact instead. In some fields, such as history, arts, and literature, citations from books to academic articles may reflect cultural value. Because WoS and Scopus index a small number of books from selected academic publishers, citation indicators from them could be unrepresentative [31.58, 59]. Google Books seems to be a useful citation source because it contains millions of fully searchable books. In literature Google books citations to academic articles were twice as common as WoS citations but they were less numerous in library and information science (31%). They are more common in the arts, humanities, and social sciences than in the sciences [31.60]. Although it is possible to manually search for bibliographic information of articles in Google Books main search interface and to identify correct citations to articles (see an example below), this seems to be impractical for a large-scale impact assessment exercise. In response, a method has been constructed to automatically generate web citation queries for books (e.g., from WoS, Scopus, or other standard book sources) and search for citations to them via the Google Books API. Additional options are provided to filter out false matches from raw Google Books results such as book reviews, bibliographies, and book advertisement to identify correct citation matches with relatively high accuracy and coverage [31.13]. A Google Books API query may take the following form, which can also be submitted to the Google Books web interface.

```
Van Djik Hacker "The digital
divide as a complex and dynamic
phenomenon" "Information Society"
2003
```

Google Patents Citations

Citations from patents to academic publications may reflect the technological value of research [31.61, 62]. Google Patents covers a large collection of searchable patents from the multiple patent offices including the United States Patent and Trademark Office (USPTO) since 1790 and the European Patent Office (EPO) since 1978 as well as patents from the World Intellectual Property Organization (WIPO), Canada, China, and Germany. Hence, the Google Patents website can be a useful source of citations to scientific articles in patent references. To generate Google Patent searches, article bibliographic information should be combined with the `site:google.com/patents` command to restrict the results to the Google Patents website (see example below). Although Google Patents citation searches can be conducted manually through Google, the Bing API can be used to automatically submit the queries instead. In some fields with a patenting culture, such as Biomedical Engineering, Biotechnology, and Pharmacology & Pharmaceutics, patent citations are numerous enough to help assess the commercial value of academic articles [31.63].

```
Lagasse "Purified hematopoietic
stem cells can differentiate
into hepatocytes in vivo"
"Nature Medicine" 2000
site:google.com/patents
```

Microsoft Academic Citations

Like Google Scholar, Microsoft Academic indexes millions of scholarly publications, providing citation counts for them. Unlike Google Scholar, the new version of Microsoft Academic allows a limited number of automatic searches per month which is useful for large-scale bibliometric analysis of articles [31.64]. Several recent studies have shown that Microsoft Academic finds similar numbers of citations or slightly more than Scopus and WoS [31.65–67] and finds substantially more citations for recently-published or in press articles [31.68, 69]. Because Microsoft Academic has faster citation indexing than conventional citation indexes and wide coverage of e-print archives [31.64, 70], it seems to be the most useful automatic tool for monitoring the early citation impact of in press or recently published articles.

Other Digital Libraries

Open access repositories such as *CogPrints* or *bioRxiv* can also be used to extract citations from preprints, postprints, or working papers. However, documents in these archives may also be indexed by Google Scholar or by conventional citation indexes after they have been formally published and hence web citations from these digital libraries may not be very useful for wider impact assessment of articles.

```

31.3 Web Citation Indicators for Journals

There have been efforts to use web citation indicators for journals rather than individual articles, motivated by journal impact factors. Web citation indicators can be derived for journals by calculating the average number of web citations to articles published in a journal during a year, irrespective of the publication year of the citing web page. This could then be compared with the Journal Impact Factor (JIF) or Scopus journal metrics. There is some empirical evidence about the value of web citation indicators for journal impact assessment. The average number of general web citations to journal articles highly correlates with JIFs for library and information science [31.10] and four science fields (Vaughan & Shaw, 2005), suggesting that web citations could also be useful for assessing the impact of journals. There is also evidence that counts of citations from Wikipedia to journal articles significantly correlate with JIFs [31.71].

It is reasonable to examine the web citation impact of journals based upon relevant online sources that cite them. For example, articles published in the journal *Expert Opinion on Therapeutic Patents* (Taylor & Francis Group) or *Drug Development Research* (Wiley) may attract many citations from patents (both with over 100 citations). Similarly, articles in clinical medicine journals such as *Clinical Infectious Diseases* or *Journal of Clinical Oncology* may receive many citations from clinical trials or guidelines and articles published in *Journal of Medical Biography* or *British Journal for the History of Science* may be widely used in encyclopedia articles to provide historical background information.

Online news stories are another source of web citations, where research findings with general interest or relevance for the public may be reported [31.72, 73]. Since journalists rarely mention article titles and authors in their news stories, web citation analysis seems to be not useful for individual article impact assessment purposes. Nevertheless, several studies have shown that most news stories name journals as their sources [31.74–76]. Mentions of journals can be captured through searching for journal names in searchable news websites (e. g., bbc.co.uk, cnn.com, and reuters.com) or newspapers (e. g., The Guardian or The Independent). For short generic journal names (e. g., Science and Nature) the term *journal* needs to be added before or after their names to reduce false matches during web citation searches. Nevertheless, software is required to extract journal citations from the matching news stories [31.77].

```

31.4 Types of Web Citation Impacts

Some web citation indicators can reflect a different type of impact to that of traditional citations such as educational, cultural, clinical treatment, commercial, knowledge dissemination, public awareness, and policy. These types of intellectual impacts are helpful for assessing the wider influence or benefits of academic articles, although collecting web citations is generally much more difficult than using traditional citation databases (see also below limitations of web citation analysis). Scholars may believe that their academic outputs have wider impacts rather than, or in addition to, research impact. For instance, some academic articles may be frequently mentioned in academic course syllabi or textbooks for their educational benefits or receive relatively many citations in medical clinical records because of their value in healthcare and patient treatments. Other articles may be cited in patents by inventors for their commercial or technological values or cited in annual reports or regulations by organizations or governments to support their arguments about policy changes. Table 31.1 summarizes different types of intellectual impacts from web citation sources and their application for the impact assessment of articles.

Table 31.1 Type of web citation indicators from different online sources and their limitations and potential use for impact assessment of articles

Web source	Web citation source	Impact type	Limitations	Overall usefulness (Poor/Fair/Good)	Citation overlap with WoS/Scopus
General web	All academic or nonacademic web sites and publications	General web impact	• Possible manipulation of citations • Many false matches and navigational citations • Needs extensive manual checks • Includes diverse impact types	Poor	To some extent
Document files	Online PDF or Microsoft Word (.doc or docx) documents	General web impact	• Possible manipulation of citations • Needs manual check of results • Less effective than Google Scholar citations	Fair	To some extent
Presentations	Online presentations (.ppt or pptx)	Educational; Scholarly	• Possible manipulation of citations • Needs manual checks of results • Missing presentations in other formats (e. g., PDF), many academic presentations are not searchable by search engines	Fair	Not at all
Syllabi	Online searchable academic course syllabi or reading lists	Educational	• Needs manual checks of results, although software can help filtering nonsyllabus matches • Many academic syllabi are not searchable online	Good	Not at all
Encyclopedias	Online searchable encyclopedias	Scholarly; educational; cultural; arts and history	• Possible manipulation of citations for editable encyclopedias (e. g., Wikipedia), although this is less likely for peer-reviewed online encyclopedias (e. g., Stanford Encyclopedia of Philosophy)	Good	Not at all
Clinical practices	Online searchable clinical guidelines or trails	Health care and treatment	• Many clinical practise documents are not searchable online	Good	Not at all
Grey literature	Digitized reports, statistics, regulations, guidelines, and policy documents	Policy making; educational; economic; legislative	• May need manual checks of results • Searches may include false matches from online CVs or journals or bulletins published by organizations • Many grey literature publications are not searchable online	Good	Not at all
ResearchGate	Uploaded publications (e. g., preprints or postprints of articles)	Scholarly; early impact	• Possible manipulation of citations • Automatic citation searches of large numbers of articles may not be possible	Fair	To a great extent
Blogs	Science blog posts	Scholarly; public engagement	• Possible manipulation of citations • May need manual checks of results	Fair	Not at all
Google Scholar	Citations from a large number of scholarly documents	Scholarly; Early impact	• Possible manipulation of citations • Needs manual checks of results • Automatic citation searches of many articles may not possible	Good	To a great extent
Google Books	Citations from a large number of digitized books	Scholarly; educational	• Needs manual checks of results based on live searches, although software can filter out false matches	Good	Very little
Google Patents	Citations from a large number of digitized patents	Commercial; technological	• Needs manual checks of results • Most articles are not cited by patents and patent citations could be helpful in some fields (e. g., biomedical engineering)	Good	Not at all

31.5 Web Citation Searching

In this section, heuristics for conducting effective web searches are discussed. These involve counting the number of times that an article is cited in online documents. Searches need to have an acceptable level of accuracy and coverage to be useful for any given task. This includes 1) generating appropriate web citation queries from article bibliographic information and 2) submitting the queries to a search engine to locate citations.

Although it is possible to manually generate queries and use the Google or Bing web search interfaces to identify web citations for a few articles, for a large data set free software can be used to automate web citation searches. Web citation queries can be generated and searched automatically through the free Webometric Analyst software (http://lexiurl.wlv.ac.uk, see also [31.20]). This software can construct web citation queries for different web sources (e. g., Google Patents, Wikipedia, syllabi, PowerPoint, Blogs, or document file types) from a set of WoS or Scopus data. To generate queries using Webometric Analyst, article bibliographic information should be in plain text (tab delimited) Unicode format. The software automatically searches the queries generated in Bing through the Bing web search API. Users need to register for the Bing Search API key and enter it in Webometric Analyst prior to running searches, allowing 1000 free searches per month for up to three months. For a large-scale research evaluation exercise involving many articles and multiple queries, users need to purchase extra API transactions to automatically collect the web citation data (https://azure.microsoft.com/en-us/pricing/details/cognitive-services/search-api/web/). Webometric Analyst also supports automatic query building and locating citations in digitized books via Google Books API [31.78] in addition to the automatic searching and filtering options to identify academic syllabus citations [31.33].

Web citation queries can be generated by combining the last name of the first author, phrase searches for the article title and journal name, and the publication year. Any bibliographic database listing articles in a standard format, such as WoS, Scopus Medline, Compendex, or ERIC, can be used to generate web citation queries in this way. It is recommended that each query contains the last names of the first (up to) three authors in order to reduce false matches. For an article with more than three authors, sometimes the first author's names plus 'et al.' might be mentioned in the reference lists and so including all authors' names in the queries may considerably reduce the number of correct web citation matches. Below is an example of a journal article cited in a Wikipedia entry mentioning only the first author of a publication with six authors.

```
White, Howard D., et al.
"Libcitations: A measure
for comparative assessment
of book publications in the
humanities and social sciences."
Journal of the American Society
for Information Science and
Technology 60.6 (2009):
1083-1096.
```

For articles with very short or general titles (e. g., *When less is more* or *Developing an HIV vaccine*), it is necessary to add extra bibliographic information to the queries such as journal names to prevent retrieving too many false matches. Nevertheless, a practical problem is that depending on academic citation styles, journal names may be mentioned in full (e. g., *Journal of Cancer Clinical Trials* in APA (American Psychological Association) or Harvard citation styles) or in abbreviated format (e. g., *J Cancer Clin Trials* in Vancouver or NLM (National Library of Medicine) styles) in the reference lists of publications. Hence, journal names in the web citation queries should be used carefully. Abbreviated journal titles are more frequently used within medical or physical sciences than social sciences. For instance, the Google search of query *LANCET INFECT DIS site:clinicaltrials.gov* retrieved 204 results from online clinical trials, whereas no result was found using the full journal name *('Lancet Infectious Diseases" site:clinicaltrials.gov*). Different abbreviations might be used for a single journal in the cited references of publications such as *N. Engl. J. Med.* (ISO Abbreviation) or *NEW ENGL J MED* (JCR Abbreviation) for *The New England Journal of Medicine*. Thus, for a comprehensive web citation search of articles with short or common titles, it is important to conduct two or three separate queries at the same time covering full and abbreviated journal names and to combine the results using the OR operator or the vertical bar "|" in Webometric Analyst Bing automatic search (see an example below and [31.20]). The vertical bar in Webometric Analyst instructs it to submit two searches and combine the results, avoiding potential problems due to inadequate processing of OR queries by search engines. One advantage of searching abbreviated journal names (Drug Dev. Res. or DRUG DEVELOP RES) over full journal names with very generic titles ("Drug Development Research") is that they return much fewer false matches, particularly from large fully searchable databases such as Google Books or Google Patents, especially in subject areas where abbreviated journal names are used in the references (e. g., NLM, AMA, or Vancouver). Both WoS and Scopus provide full and abbreviated journal names in their export files that can be used for this purpose.

ENGL J MED" 2016
```

Although the most common method to locate web citations from web documents is through manual or automatic searches in commercial search engines, the contents of some websites may not be well indexed by search engines and hence web citation extraction might not be useful. In this case, it might be possible to extract citations from web documents through a free crawler such as SocSciBot, (http://socscibot.wlv.ac.uk). This needs a list of URLs and another specific program to capture citations from downloaded pages such as from ResearchGate, ClinicalTrials.gov, or Drugs.com (see the Services tab in the free Webometric Analyst software). Several studies have used this method for citation analysis instead of searching for articles via Bing or Google [31.39, 40, 45].

31.6 Correlations Between Web Citation Indicators and Citation Counts for Academic Articles

There is empirical evidence that some web citation indicators for academic articles positively correlate with counts of citations from traditional citation databases. Correlation tests have been used to assess the degree of similarity between web citation indicators and traditional citations and to examine whether a similar type of citation impact from different scholarly sources (e. g., books, patents, encyclopedia articles, and course syllabi) can be observed from either WoS or Scopus citations. A strong correlation would suggest that the two data sources reflect similar types of academic research impact, while a weak correlation suggests that they reflect different types of intellectual impact or that at least one is affected by random or spurious influences. Several early investigations found that general web or URL citations to journal articles correlate significantly and positively with counts of citations from journal articles across multiple subject areas, suggesting that both could be in some way reflecting a similar type of intellectual impact. The average number of Google web citations to journal articles correlated significantly with JIFs for library and information science in 1998 (0.59) and 1999 (0.43) [31.10]. Stronger associations were found in biology (0.72), genetics (0.68), medicine (0.74), and multidisciplinary journals (0.79) [31.10]. Another study also found significant Spearman correlations between WoS and Google web citation counts for open access journal articles across four science and four social science disciplines (except psychology), ranging from 0.70 in computer science and 0.52 in sociology to 0.26 in biology and 0.29 in chemistry [31.79]. These investigations gave initial evidence that web citations could be useful for assessing the impact of journal articles.

Google Scholar citations have the highest positive correlations with WoS or Scopus citation counts and Google Scholar commonly retrieves more citations to individual articles than WoS and Scopus [31.50, 79–82]. A study of 2675 recently published library and information science articles (2016–March 2017) found higher correlations between Google Scholar and ResearchGate citations (0.732) than between Google Scholar with either WoS (0.582) or Scopus (0.624), suggesting that both online databases reflect early citations in a similar way [31.45].

Spearman correlations between WoS and Google Books citations are high in computer science (0.71; perhaps because conference proceedings were indexed as books), philosophy (0.65), linguistics (0.61), psychology (0.59), and social science (0.48) [31.60]. Nevertheless, correlations between conventional citations and other web citation indicators are low, and so not all web indicators are useful for scholarly impact evaluation, although they may be useful to identify wider impacts of research. For instance, Spearmen correlations between syllabus mentions and WoS citations to 1987 journal articles in library and information science are low but significant (0.23) [31.32] and weak but positive significant correlations were found between Google Patent and Scopus citations to over 322 000 articles in 16 science and engineering fields. The correlations were highest in Biomedical Engineering (0.36) and lowest in Industrial & Manufacturing Engineering (0.05) [31.63]. There were also significant, but low, Spearman correlations between Scopus and Wikipedia citations to over 300 000 articles across multiple fields (e. g., ranging from 0.105 in social sciences to 0.179 in science subject areas), suggesting that Wikipedia citations do not directly reflect academic research impact [31.34] and similarly an investigation found a weak correlation (0.201) between blog citations and WoS citations to 13 300 articles in medicine and biological sciences [31.48].

31.7 Limitations of Web Citation Analysis

Using the web for informetric research is much more challenging than traditional citation analysis [31.83]. For web citation analysis, software is usually needed for data collection and running many searches via Bing API keys can be expensive. Although Google Scholar generally locates more citations than Scopus or WoS, it does not allow automatic data collection. Microsoft Academic seems to be a suitable alternative, however. Coverage of searches, incorrect matches, and possible manipulation of online citations are other limitations for web impact assessment of articles.

31.7.1 Coverage

Search engines only report web citations from the part of the web that they crawl [31.84, 85]. For example, many academic course reading lists or syllabi are not indexed by commercial search engines. Moreover, Google probably covers more of the web than Bing [31.86], which is a limitation for web citation analyses with Bing, especially for PDF or PowerPoint files. Some websites may only be indexed by one search engine. For instance, only Google returns web citation results from The Munich Personal RePEc Archive (https://mpra.ub.uni-muenchen.de/) which includes about 40 000 preprints and postprints of articles and working papers in the field of economics (see an example below). Another limitation of web citation searches, and especially for journal-level impact assessment, is that commercial search engines such as Google and Bing return a maximum of 1000 results per query, although this seems to be less problematic for monitoring the web citation impact of individual articles.

```
Bonanno "Intensity of competition
and the choice between product
and process innovations"
site:mpra.ub.uni-muenchen.de
```

31.7.2 False Matches

Web citation searches may return false matches and this is more common for articles with general or short titles (e. g., "*Introduction to American literature*" or "*Negative certainty*"), especially in conjunction with common author names (e. g., Schmidt, Jones, or Yan) and generic journal names (e. g., *Nature*, *Science*, *Alcohol*, or *Appetite*). Sometimes there is no practical method to exclude irrelevant citation matches from web citation results. Reporting absolute citation counts for such cases could be problematic and hence it is necessary to manually check a sample of web citation results, especially those with extreme web citation counts. For instance, searching a query `Pennisi "Making waves" Science 2004` in Google retrieves several false citation matches in PDF files in the sense of not citing the correct article because the citation information of the article had been captured elsewhere within the references (see Fig. 31.1).

Most unwanted matches from web citation searches in the general web are likely to be due to capturing mentions of articles in noncitation contexts such as online CVs, journal tables of contents, library lists, and publisher websites [31.10, 23]. For Google Books citations, manual searches may give many irrelevant results and it is necessary to conduct manual checking to identify correct citation matches. For instance, some citations in digitized books in Google Books may occur in book reviews, bibliographies, advertisements, and abstracting and indexing volumes. Similarly, it is very difficult to identify correct academic syllabus citations through manual checking of web citation results for large research evaluation exercises, although this is possible for small numbers of articles from individual authors or departments. Methods have been designed to automatically filter false matches from both the Google Books [31.78] and academic syllabi citation searches [31.33] with relatively high accuracy (over 90%). However, the filtering mechanisms used are only applicable to English language books and syllabi, and may miss many relevant results in other languages, requiring additional filtering rules to identify correct web citations for different languages.

31.7.3 Duplicate Results

Web citation searches may return duplicate matches from multiple versions of the same publication, such

Pennisi, E. (2004). Bonemaking protein shapes beaks of Darwin's finches. *Science* **305**, 1383.
Phippard, D. J., Weber-Hall, S. J., Sharpe, P. T., Naylor, M. S., Jayatalake, H., Maas. R., Woo, I., Roberts-Ciark, D., Francis-West, P. H., Liu, Y. H., Maxson, R., Hili, R. E., and Dale, T. C. (1996). Regulation of Msx-1. Msx-2, Bmp-2 and Bmp-4 during foetal and postnatal mammary gland development. *Development* **122**, 2729–2737.
Plikus, M., and Chuong, C.-M. (2004). Making waves with hairs. *J. Invest. Dermatol.* **122**, VII–IX.

Fig. 31.1 An example of a false citation match from Google web citation search result as PDF or HTML versions of articles or preprints/postprints of articles shared by different authors in different platforms such as their CVs, academic social websites or repositories. Duplicate citation counting may also occur during Google Patent citation searches from different patent versions (e. g., submitted, revised, and accepted, see [31.63]) as well as through Wikipedia citation searches from articles in different languages with the same contents (e. g., entries translated from one language to other languages, see [31.34]). Hence, it is important to filter out identical citing documents based on their titles. Moreover, sometimes grey literature citation searches based on limiting the results to a specific website may also retrieve citations from journals or bulletins published by governments or organizations that are indexed by conventional citation indexes. Similarly, most citations from SlideShare documents seem to be published journal articles or conference papers rather than presentations. Duplicate citations with traditional citation indexes should not be considered as evidence of wider research impact, although it might be very difficult to identify these cases during systematic data collection.

31.7.4 Manipulation

Web citations can be manipulated or inflated by users to increase citation statistics by generating fake documents with references to be indexed by Google, Google Scholar or Bing or by manipulating citations in Wikipedia entries, or other public web documents. Nevertheless, the risk is much lower for Google Books, Google Patents, academic course syllabi and clinical trials from approved sources because apparently they cannot easily be manipulated by users.

31.7.5 Diverse Types of Impacts

In contrast to the scholarly impact reflected by citations from refereed journal articles, some web citation indicators reflect types of impacts that are difficult to characterize or that may depend on the discipline of the cited article. Google Books or Wikipedia citations to articles may represent scientific, teaching, or cultural impacts. For example, the article "Outcome of symptoms of dizziness in a general practice community sample" published in the journal *Family Practice* has been mostly cited in medical textbooks (e. g., Oxford Textbook of Primary Medical Care) in addition to some scientific books (e. g., "Neuro-Otology"). Citations to articles from patents may also be used for different reasons, such as the commercial benefits of research or other impacts in theoretical contexts (e. g., "Polycaprolactone (PCL) is a polymer used for implantable/injectable drug delivery systems for medical implants"). Similarly, articles may be cited in presentations for research (conference slides) or teaching (lecture slides). To assess the type of impacts in a given context, a content analysis of the citations or citing sources should be carried out. This can be very time consuming, expensive, and the results can also be somewhat subjective.

31.8 Conclusions

Citation analysis is commonly used to evaluate the research impact of scientific articles based on counting citations mainly from journal articles and conference papers indexed by WoS or Scopus. In this chapter, a range of web citation indicators has been introduced to help monitor the impact of academic articles from online books, patents, clinical trials, encyclopedia articles, grey literature publications, and academic syllabi. These web indicators may give some useful quantitative information about the wider impacts of articles outside conventional citation indicators or assist human judgements about the contributions of articles. Web citation indicators can also provide additional information for research funders and evaluators to identify successful research based upon educational, cultural, commercial, or societal impacts.

Google Scholar seems to be useful for the early scholarly impact assessment of articles across different subject areas from a wide range of publications in different languages. Google Books citations from textbooks, monographs, edited books, and reports seems to be useful in the arts, humanities, and social sciences. Google Patents citations can help to identify articles with commercially or technologically relevant benefits in some areas, especially in engineering fields. Microsoft Academic seems to be the most useful web-based automatic tool for assessing the citation impact of articles for large-scale analyses, especially when it is important to know the impacts of preprints or recently published articles (e. g., 1–2 years after publication or peer review). Citations from academic course reading lists can reveal the educational value of published articles and citations from encyclopedia articles can reflect the value of articles for knowledge communication to the wider public. In medical and health care sciences, clinical publications can be used to assess clinical benefits of articles such as for the treatment of patients. There is a range of digitized grey literature publications such as annual reports, guidelines, regulations, statistics, and government publications that may be used as citation evidence for the wider impacts of articles on national or international policies or strategies. News stories citing journals could also be useful to examine which scientific journals or academic subjects are most frequently of interest to the public.

There is evidence that different web citation indicators significantly correlate (but with low to medium strength) with counts of citations from journal articles at the article level and in some cases at the journal level, indicating that web citations are not random and have similarities with traditional citation counts. Google Scholar and Google Books citations have the highest correlations with traditional citation counts because they contain citations from academic publications. There are low but significant correlations between WoS/Scopus citations to articles and other web citation indicators such as syllabus and encyclopedia citations, which reflect wider benefits of research such as teaching or cultural value. Hence, some web citation indicators may be more useful in the arts and humanities and social science, where broader publication types and scholarly related outputs such as textbooks, encyclopedia articles, and course reading lists can also help to identify the value of published articles.

Although some web citation indicators may contain errors and can be manipulated, they may still be used to support peer review or WoS/Scopus citation counts, especially in subject areas where peer review is more subjective (e. g., humanities) and WoS/Scopus citations are rare or not useful to assess wider impact of academic articles. In science and medicine, some authors may claim that a particular type of web indicator such as citations in digitized books, clinical trials, or patents, more realistically reflect the value of their research than WoS/Scopus citations. Hence, it is important to identify web indicators that reflect broader impacts of research. For instance, articles about novel solar cell or smartphone technologies are more likely to receive citations in patents than in course syllabi. Similarly, articles with clinical contributions may attract more citations in clinical documents than general encyclopedias or articles about the history of films, music, or literature may relatively receive more citations in educational sources than policy documents. Moreover, some web citation indicators should be used cautiously for recently published articles because in some subject areas such as the arts and humanities and social sciences research takes a longer time to be cited than science and medicine. This also depends on citing sources like patents and books where they need more time to be published than articles and blog posts.

Finally, there are many subject-oriented websites that can be used for wider impact assessment of articles in specific academic subject areas in addition to the general web sources introduced in this chapter. Hence, it is important to identify potential relevant websites, such as digital libraries, repositories, online encyclopedias, and key organizations publishing grey literature publications in the relevant fields. If this could be achieved in accordance with the nature of different subject areas, then web citation indicators could more comprehensively reflect the wider impacts of academic publications.

Kayvan Kousha

Statistical Cybermetrics Research Group
University of Wolverhampton
Wolverhampton, UK
k.kousha@wlv.ac.uk

Dr. Kayvan Kousha is a researcher in the Statistical Cybermetrics Research Group at the University of Wolverhampton, UK. His research contribution has been mainly in the development of novel methods for extracting and analyzing web citations for wider impact assessment of research. He has published over 50 journal articles and 20 conference papers about online citations such as digitized books, patents, encyclopedia articles, clinical documents, and course syllabi.

32. Usage Bibliometrics as a Tool to Measure Research Activity

Edwin A. Henneken, Michael J. Kurtz

Measures for research activity and impact have become integral ingredients in the assessment of a wide range of entities (individual researchers, organizations, institutions, regions, disciplines). Traditional bibliometric indicators, like publication- and citation-based indicators, provide an essential part of this picture, but cannot describe the complete picture. Since reading scholarly publications is an essential part of the research lifecycle, it is only natural to introduce measures for this activity in attempts to quantify the efficiency, productivity and impact of an entity. Citations and reads are significantly different signals, so taken together, they provide a more complete picture of research activity. Most scholarly publications are now accessed online, making the study of reads and read patterns possible. Clickstream logs allow us to follow information access by the entire research community in real time. Publication and citation datasets just reflect activity by authors. In addition, download statistics, derived from these clickstreams, will help us identify publications with significant impact, but which do not attract many citations. Clickstream signals are arguably more complex than, say, citation signals. For one, they are a superposition of different classes of readers. Systematic downloads by crawlers also contaminate the signal, as does random browsing behavior. We will discuss the complexities associated with clickstream data and how, with proper filtering, statistically significant relations and conclusions can be inferred from download statistics. We will describe how download statistics can be used to describe research activity at different levels of aggregation, ranging from organizations to countries. These statistics show a strong correlation with socioeconomic indicators, like the gross domestic product (GDP). A comparison will be made with traditional bibliometric indicators. Since we will be using clickstream data from the Astrophysics Data System (ADS), we will argue that astronomy is representative for more general trends.

32.1 Previous Studies and Scope

The standard indicators to measure the quality and quantity of scholarly research are funds expended, number of papers published, and number of citations to those papers and measures derived from these citations. Since the turn of the century a fourth key indicator for research assessment has arisen: measures of the use of the (now almost exclusively) digital research documents. The concept of *research documents* represents a more general class of expressions of research than *scholarly publications*, because it contains anything that may get published during research. This study is confined to scholarly publications, that is articles in scholarly journals. Scholarly research can be represented by identifying a *research cycle*; research consists of activity expended in the various stages of this cycle (illustrated in Fig. 32.1). We assume that taking the publication stage of the research cycle as a proxy will sufficiently represent *research activity*. Also, from a practical point of view, the publication stage is the only stage in this cycle that allows for clearly quantifiable metrics. Therefore we focus on usage of scholarly publications.

The use of this usage information is in its infancy. The leading assessments of the quality and quantity of

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_32

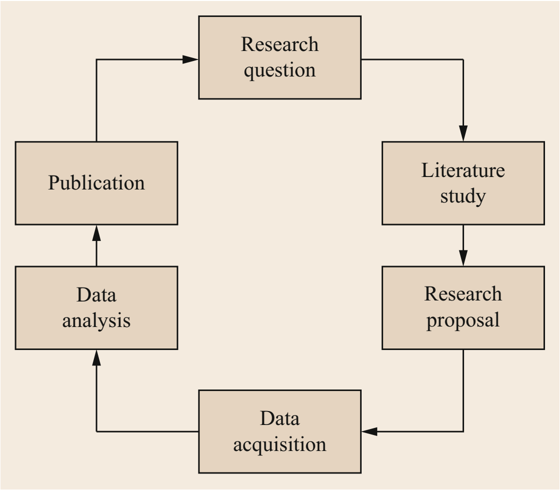

Fig. 32.1 Graphical representation of the research cycle

research on a country basis (Science & Engineering Indicator [32.1], for a given year), a university basis (Times Higher Education [32.2] or ARWU [32.3] ranking, for a given year), or on a journal basis (Impact Factor [32.4], Eigenfactor [32.5, 6] or Source Normalized Impact per Paper [32.7], for a given year) do not use usage information. The only widespread use of digital download records is by librarians making purchase decisions, aided by the COUNTER [32.8] standard for a given year, continuing their practice from the print era.

Since the first obsolescence function based on digital downloads was published 20 years ago [32.9] there has been an avalanche of work on the nature of digital download information. The review by *Kurtz* and *Bollen* [32.10] contains 171 references; more recent work with extensive discussions and bibliographies include [32.11–18]. Download information is now commonly found on article pages on journal websites and on various aggregator websites. Perhaps the most influential of these are the article download counts for a given year by the SSRN (formerly known as Social Science Research Network).

Before usage information can be widely used in making practical decisions some obvious problems need to be addressed. Just as the most popular wine, novel, or politician is not necessarily the best one, pure usage counts of scholarly article downloads may not be an accurate measure of research activity.

Users of scholarly research articles can be crudely divided into four categories [32.10, 11]: researchers, practitioners, students, and the general public. It is not uncommon that researchers represent just a small fraction of the total use. The number of healthcare practitioners dwarfs the number of medical researchers, for example. Students [32.19] use the scholarly literature very differently from researchers. In astronomy the number of interested lay people exceeds the number of research astronomers by a factor of perhaps 10 000; the number of serious amateur astronomers is about 100 times the number of researchers, while the number of citizen scientists on a single astronomy project, Galaxy Zoo, is a factor of ten larger than the world total of researchers in astronomy [32.20]. All these groups can and do access and read the scholarly literature. However, just the user class of researchers contribute to usage corresponding to research activity.

In this paper we use download measures to assess the quantity and to some degree quality of astronomy research, with the expectation that the techniques will also prove useful in other fields. We are aided in this by the fact that there are few professional astronomers who are not researchers; there is no such thing as applied astronomy. This simplifies the task compared with a field such as medicine, where a majority of professionals are not researchers. There are two different aspects to download measures: who is downloading and what is downloaded. Both are quantifiable signals and we will use both of them in our analysis. In order to get meaningful results, measures for both aspects are essential.

To some degree, research activity is related to economic trends. In previous publications we have explored relationships between economic indicators and research-related indicators [32.21–24]. This present paper substantially expands on the download analysis in these publications and shows that the data used in this analysis are consistent with the conclusions from these earlier studies.

32.2 Definition of Terminology

Use and usage are terms that seem to have a range of different meanings in the literature on bibliometrics. Other terms often encountered are *hits*, *clicks*, *reads* and *downloads*. Used as a measure, usage reflects aspects of user interaction with a digital service, in this case the Smithsonian/NASA Astrophysics Data System (ADS). During a session, users typically access different types of information by clicking on the appropriate links. In this study, we restrict ourselves to *downloads*, which is defined as clicking on a link that will take a user to the full text version of an article (either stored locally on an ADS server or stored externally). In the presentation and discussion of our results, we will use the terms *downloads* and *usage*, but they will both refer to the act of getting to the full article text.

The terms listed in Table 32.1 will be used frequently in the description of data (among others) and are particularly important with respect to creating and interpreting data. Hence, it's important to define them.

The data in this study have been derived from the usage logs of the ADS. These usage logs contain the user interactions with the user interface, recording the nature of the interaction (the type of information being requested), the time of this interaction (the date and time in Eastern Standard Time, EST), the identifier associated with the user and the IP address of the source requesting the information. The originating country of a request is derived from the hostname of the request, which in turn is derived from the IP address. In the mapping from hostname to country, we associated the top level domains *.net*, *.edu*, *.gov* and *.mil* with the USA.

When logging user interactions with the ADS, we attempt to filter out robots based on our knowledge of so-called *User Agents* and origin IP addresses of these requests. Since these robot requests are mostly for metadata, missed robot requests in our filtering will not contaminate our data, because we are focusing our study on downloads. Figure 32.1 shows the number of users in various categories over the period of our analysis (2005–2015). The line representing the *remainder* in this diagram represents situations like computers in libraries. In an earlier study [32.24] we observed that the median of the number of reads for frequent users is fairly constant at a value of about 21 reads per month. Since this number includes more than downloads, we decided to take 100 downloads per year as the lower boundary for the frequency interval associated with *frequent users*. Usage data for frequent users suggests a reads to download ratio of between 2 and 3. A second argument indicating that our choice of the definition for frequent users is meaningful is illustrated by the number of frequent users when restricted to downloads of publications from the main astronomy journals (line with open triangles in Fig. 32.2). This restriction will underestimate the number of research astronomers, so it is a lower limit. In the period 2005–2015, the total number of members of the International Astronomical Union (IAU) grows from around 9000 in 2005 to around 12 000 in 2015, represented by the dashed line. We only have actual IAU membership numbers for the period of 2008–2015. The fact that this line is bounded by the two lines representing both types of frequent users is a strong indication that our definition of frequent user can be interpreted as a representative definition.

Figure 32.1 also characterizes the type of signal we are looking at in this study. We will be looking at the access of full texts (*downloads*) by frequent users, which is roughly two orders of magnitude smaller than the total access. Also, as shown in an earlier study (Fig. 3 in [32.24]), the readership pattern of frequent users is significantly different from that of incidental users. Figure 32.2 indicates that the class of frequent users of the ADS exceeds the number of professional astronomers, the excess mostly likely consisting of physicists and engineers. Since most professional astronomers are using the ADS on a daily basis, it makes sense to focus on the field of astronomy in our analysis, because this will result in signals that can be regarded as truly representative for the entire field.

Why do we focus on the downloads by frequent users? Essentially because all authors are ADS users, but not all ADS users are authors. A comparison of the obsolescence functions of reads and citations makes this abundantly clear. Figure 32.3 (taken from [32.24]) illustrates this fact. From the ADS usage logs for January and February of 2008, we display the usage by frequent users of the ADS with those coming in from Google Scholar (representing incidental users) and compare these signals with citation rates and total citations. This analysis has been restricted to publications from the main astronomy journals. The fact that the relative use for frequent users follows the citation rate, rather than total citations, as function of publication year illustrates why we should focus on usage by frequent users. Citations, by their very nature, are deliberate and by using usage by frequent users, we expect to distill a signal that is expected to represent actions by authors with the least amount of noise. Note that

Table 32.1 Definition of frequently used terms

Term	Definition
Entity	A group of people generating publications, which can be identified through queries in the ADS, and whose interaction with the ADS can be easily identified in the usage logs. The following examples come to mind: country, institute/organization
Frequent user	This is an ADS user identified from the usage logs as one with at least 100, but no more than 1000, downloads per year. The reason for the upper limit is the fact that there are download sessions that cannot be associated with one particular individual (like computers in libraries)
Main astronomy journals	The Astrophysical Journal, The Astrophysical Journal Letters, The Astrophysical Journal Supplement Series, The Astronomical Journal, Monthly Notices of the Royal Astronomical Society, Astronomy & Astrophysics

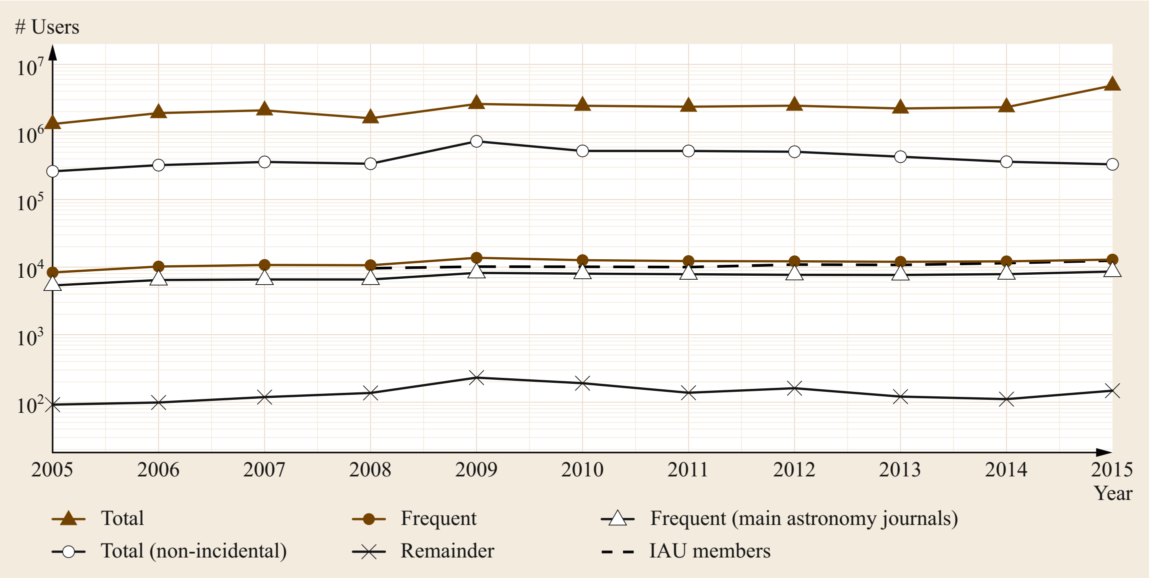

Fig. 32.2 The number of ADS users during the period of analysis, based on the number of yearly downloads. The line with *solid triangles* shows the total number of users for each year, the line with *open circles* shows the total number of users who downloaded at least one publication (this excludes those users who just look at an abstract), the line with *solid circles* shows the number of users who accessed the full text of between 100 and 1000 publications per year and the line with *crosses* represents the remainder. The line with *open triangles* shows the number of users who accessed the full text in the main astronomy journals of between 100 and 1000 publications per year. The *dashed line* represents the total number of IAU members

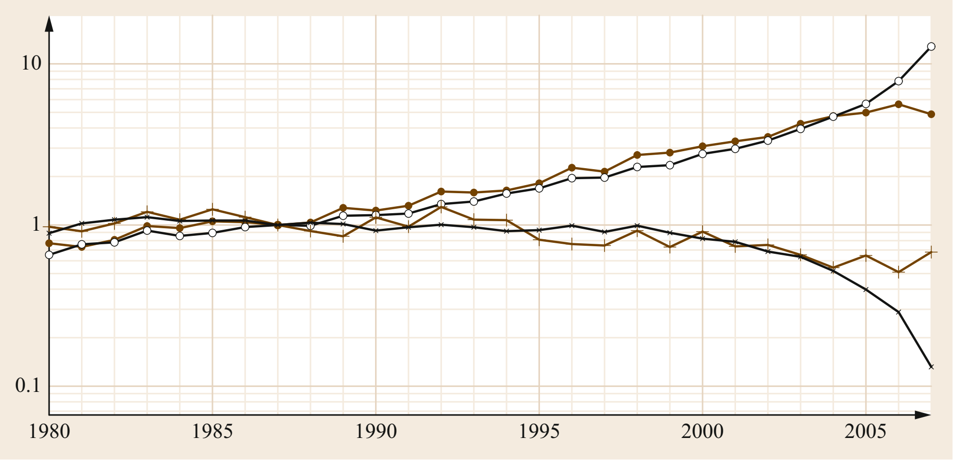

Fig. 32.3 Comparison of readership patterns from ADS and Google Scholar queries, as observed in the ADS access logs. The line marked with *open circles* shows the readership use by people using the ADS search engine. The line marked with + corresponds with the readership use by people who used the Google Scholar engine. The line marked with *solid circles* shows the citation rate of the articles, while the line marked with x represents their total number of citations

an additional interpretation of Fig. 32.3 is that Google Scholar does not provide results that researchers are looking for.

The other component of research activity considered in our study consists of the scholarly publications generated by entities analyzed. For each year in the period analyzed, a bibliography is compiled for any given entity using the query capabilities of the beta version of the ADS, codenamed *Bumblebee* (http://ui.adsabs.harvard.edu). The main reason for using this version of

Table 32.2 Overview of publication numbers for the start and end of the period, for a number of entities

Entity	Total		Refereed		Main astronomy	
	2005	2015	2005	2015	2005	2015
Yale	677	1130	502	945	79	194
Princeton	1479	2338	1157	1603	195	264
CfA	2541	1950	713	1061	497	824
NOAO	283	251	232	246	218	238
Canada	5785	9055	4209	6494	395	893
The Netherlands	3444	6120	2697	4169	442	841
Argentina	899	1376	793	1062	85	139
India	3484	9278	3190	6927	153	339

the ADS, rather than the older version, ADS *Classic*, is the fact that it supports a rich query language, allowing queries that involve affiliation information. With a couple of exceptions, the bibliographies were determined with the following query:

```
aff: "<affiliation string>"
year: 2005-2015
```

We used the application programming interface (API) of ADS *Bumblebee* (https://github.com/adsabs/adsabs-dev-api) to generate the bibliographies with metadata identifying the publication, the affiliation of the authors and the refereed status of the publication, indicating whether it is a refereed or nonrefereed publication. The few exceptions to this approach are those for which the ADS already contains a curated bibliography in its database, in which case the query just needed to retrieve those entries from this bibliography for the year range considered. Table 32.2 shows an overview of publication number for the start and end of the period, for a number of entities (with a wide range in size).

We will work with a dataset with maximum homogeneity by restricting both usage data and publication data to the main astronomy journals. This way we can be assured that all necessary metadata will be available for article selection.

32.3 Usage and Research Activity

One of the products of research activity is the generation of scholarly publications. It seems reasonable to assume that, as part of the preparation process, publications are read and may get added to the bibliographies of future publications. Since the ADS is the main literature discovery tool in astronomy, we assume that the publications read during this preparation process are found using the ADS. This model implies a number of questions:

1. Is there a correlation between the publications generated by an entity and the ADS usage by people associated with that entity?
2. Assuming that at least a fraction of downloaded papers will get cited in the publications generated, is there enough signal to detect that relationship?

In addition to the question of whether there is a correlation between downloads and number of publications, we also should look into the similarity of both sets. If our assumption is true that people download publications that serve as foundations for their publications, you would expect an overlap between the two sets. This leads to a third question:

3. How similar are the set of publications cited by the publications generated by an entity and the publications downloaded by people associated with that entity?

Before exploring these questions, we need to address the relationship between the actors in the usage and research activities. In the section on the data, we looked at usage data and publication data as separate quantities, but since the ADS lies at the center of both, we expect some common sense correlations. For the authors associated with a given entity, especially when they are the first author, we expect them to be among the frequent ADS users for that entity. This should be particularly true when we restrict ourselves to publications downloaded by the frequent ADS users associated with that entity. For example, given all the papers published in one of the main astronomy journals in 2005, where one of the authors is

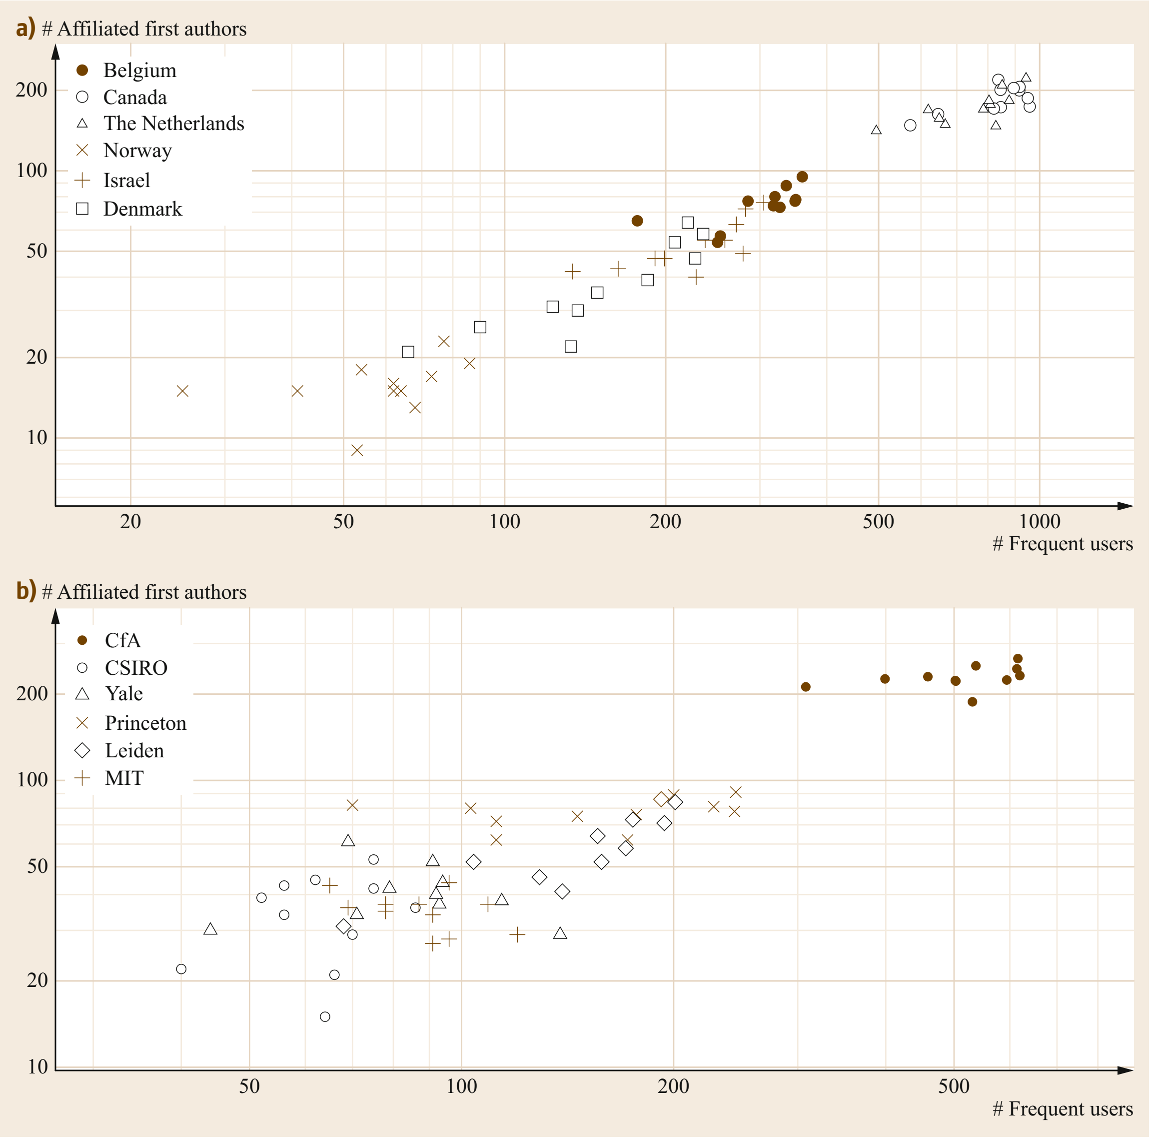

Fig. 32.4a,b Relationship between the number of frequent users and the number of affiliated first authors for a number of entities. Every data point corresponds with one year for the entity displayed. **(a)** Countries. **(b)** Institutes

affiliated with an institute in Belgium, what is the correlation between number of authors who appeared as first author in this set and the number of frequent users from Belgium in 2005? Figure 32.4 shows this relationship for a number of countries and institutes.

For countries, we also expect a significant correlation between the number of affiliated first authors and the number of national members of the IAU. This is shown in Fig. 32.5.

Figures 32.4 and 32.5 show that our data is consistent with common sense expectations: there is a significant overlap between the population downloading publications on a regular basis and publishing articles in main astronomy journals.

Next, we will explore the relationship between downloads and generated publications for a range of entities. As before, we will focus our analysis on frequent users and publications from the main astronomy journals. Figure 32.6 shows the numbers of downloads by frequent users of main astronomy papers recently published versus the number of main astronomy papers where one of the authors is affiliated with the entity under consideration.

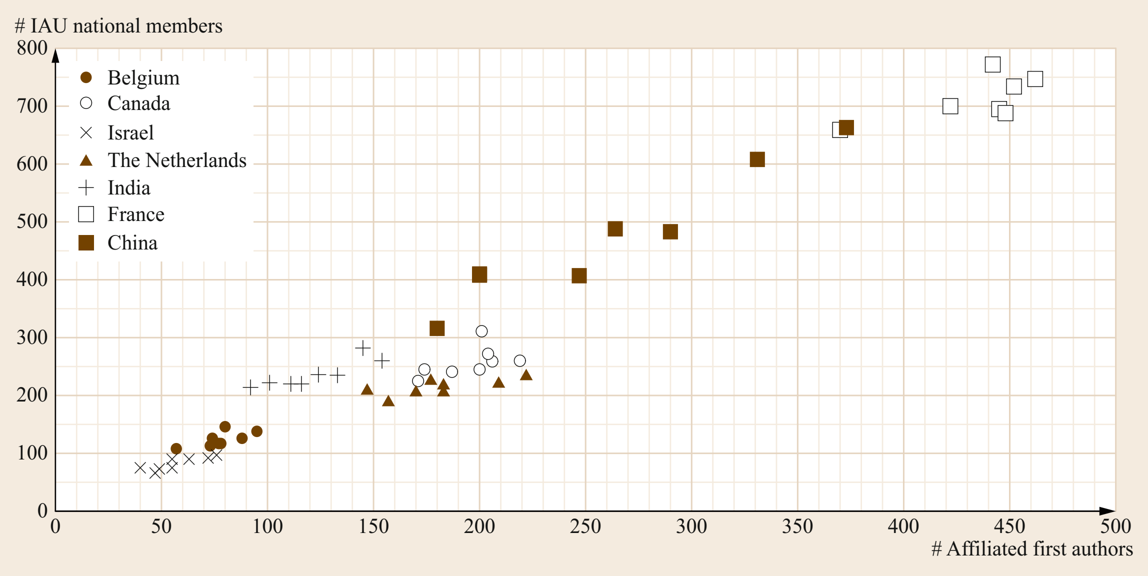

Fig. 32.5 Relationship between the number of affiliated first authors for a number of countries and the number of national members of the IAU. Every point represents a year in the period 2008–2015 (no IAU data was available prior to 2008)

The correlation between download and publication numbers has a scalar character. It does not provide any insight into the similarity of the downloaded and published articles. This is an aspect we can explore in a number of ways. Table 32.3 shows the quantities that will be used to explore the similarity between downloaded publications and those cited in a given year Y for a specific entity E.

Every publication has a publication year. Figure 32.7 shows a number of relationships based on publication year. One signal we have observed is, for a given year and entity, the set of downloaded publications in the main astronomy journals, by frequent users, with a publication year in the interval starting in 1980 and ending in the year under consideration. For this signal we derive the following two quantities. First, for each year in the range of publications years, the number of downloaded publications, normalized by the total number of publications in that set. The other quantity is the number of unique publications with a given publication year, normalized by the total number of publications in the main astronomy journals for that year. We derive the same quantities for another signal: all papers from the main astronomy journals and a publication year in the same range, cited by the publications in the bibliography for the entity in the year under consideration. Figure 32.7 shows the results for The Netherlands (E) in 2015 (Y).

Finally, we consider similarity on the most granular level: using individual publications as the data in the comparison. Assuming that researchers, affiliated with an entity, actually read the publications (at least to a nonnegligible degree) they cite in their scholarly papers, you would expect an overlap in those citations and the publications downloaded by frequent users from that same entity. The critical assumption here is that the ADS is used to get to the full text (either hosted locally on the ADS servers or external to the ADS). For both sets of publications, we have lists of identifiers, uniquely associated with publications. We will use these identifiers in our analysis. For a given entity in a given year, the main astronomy papers cited in the first-authored papers are compared with the downloaded main astronomy papers by frequent users, associated with the same entity. We will consider the similarity measured by the fraction of overlap between the two sets. Figure 32.8 shows results for a number of countries.

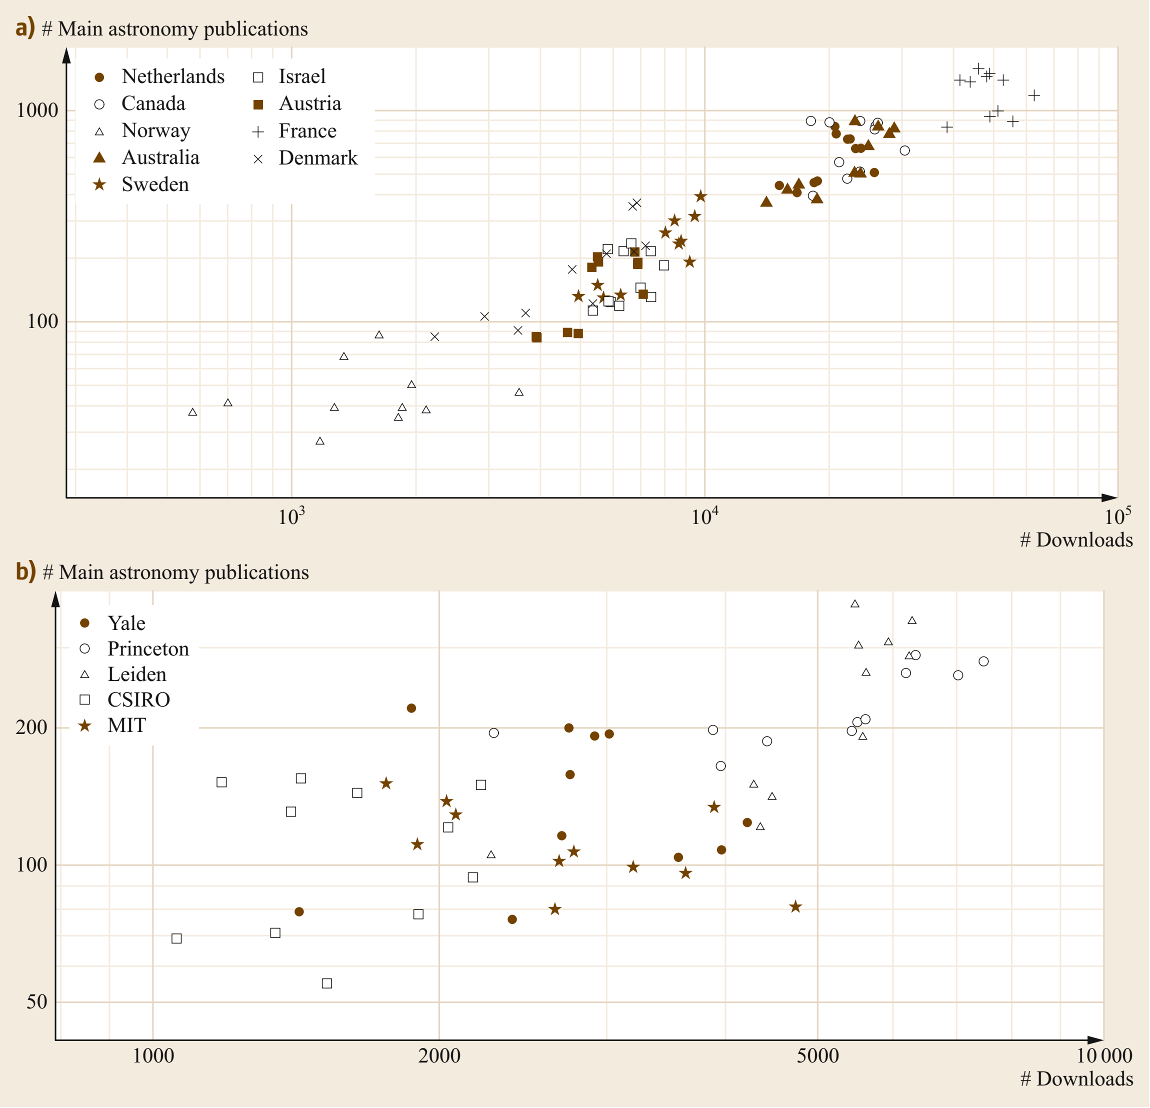

Fig. 32.6a,b Number of downloads by frequent users of main astronomy papers recently published versus the number of main astronomy papers where one of the authors is affiliated with the entity under consideration. Every point represents a year in the period 2005–2015. **(a)** Relationship for countries. **(b)** Relationship for institutes

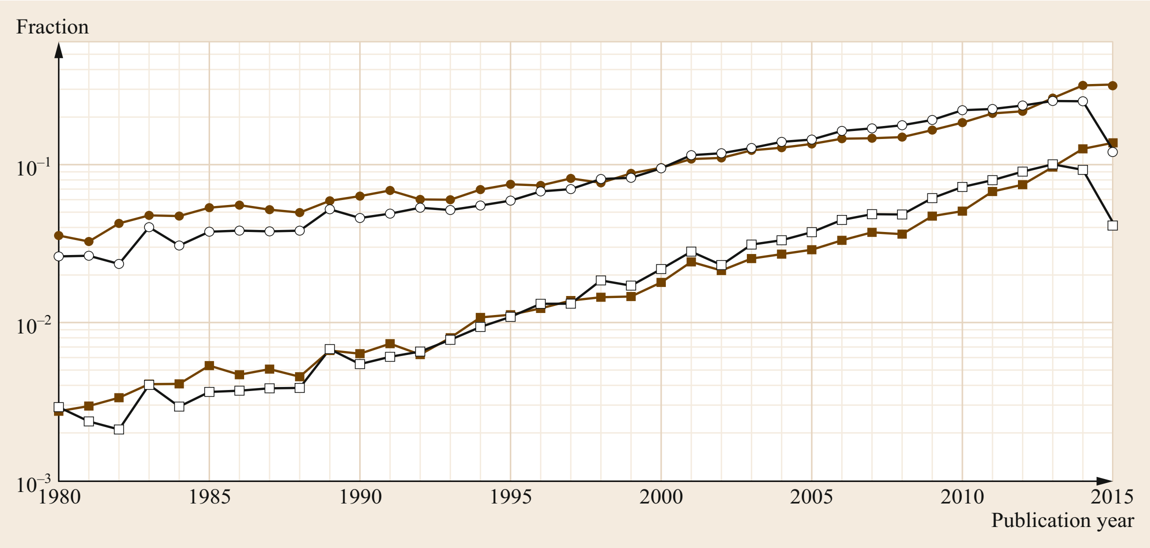

Fig. 32.7 For The Netherlands (entity) and the year 2015, this figure compares the distribution of publication years, in the range of 1980 through 2015, in the lists of downloaded main astronomy publications by frequent users and those cited by main astronomy publications in that year. The lines with *open* and *closed circles* show the fraction of unique publications in the citation (*open*) and download (*closed*) lists. The lines with *squares* show the normalized publication numbers in the citation (*open*) and download (*closed*) lists

Table 32.3 Definition of quantities used to explore the similarity between downloaded publications and those cited in a given year Y for a specific entity E

R^Y(E)	Publications in main astronomy journals downloaded by frequent users associated with E
P^Y(E)	Publications in main astronomy journals where the first author is affiliated with E
C^Y(E)	All publications in main astronomy journals cited by the publications in P^Y(E)

32.4 Traditional Indicators

Bibliometrics is an example of a discipline that provides tools for quantifying research output and its impact. As mentioned before, we assume that research output, in the form of publications, can be regarded as a proxy for research activity. In this context, bibliometrics provides a suite of measures that can be seen as research metrics. These bibliometric measures are used to quantify a degree of research output. Traditionally, citations are used as fundamental building blocks for these measures. There are many citation-based research productivity measures, ranging from straightforward ones, like total citations, to complex indicators, like the Tori indicator [32.25]. The one thing they have in common is that, in fact, they are a measure for impact, rather than a direct measure for research activity. Of course, without research activity, there is nothing to cite, so in this sense they are an indirect measure for research activity. Even when e-prints from a repository like arXiv.org are used in conjunction with these measures, they do not provide the immediate

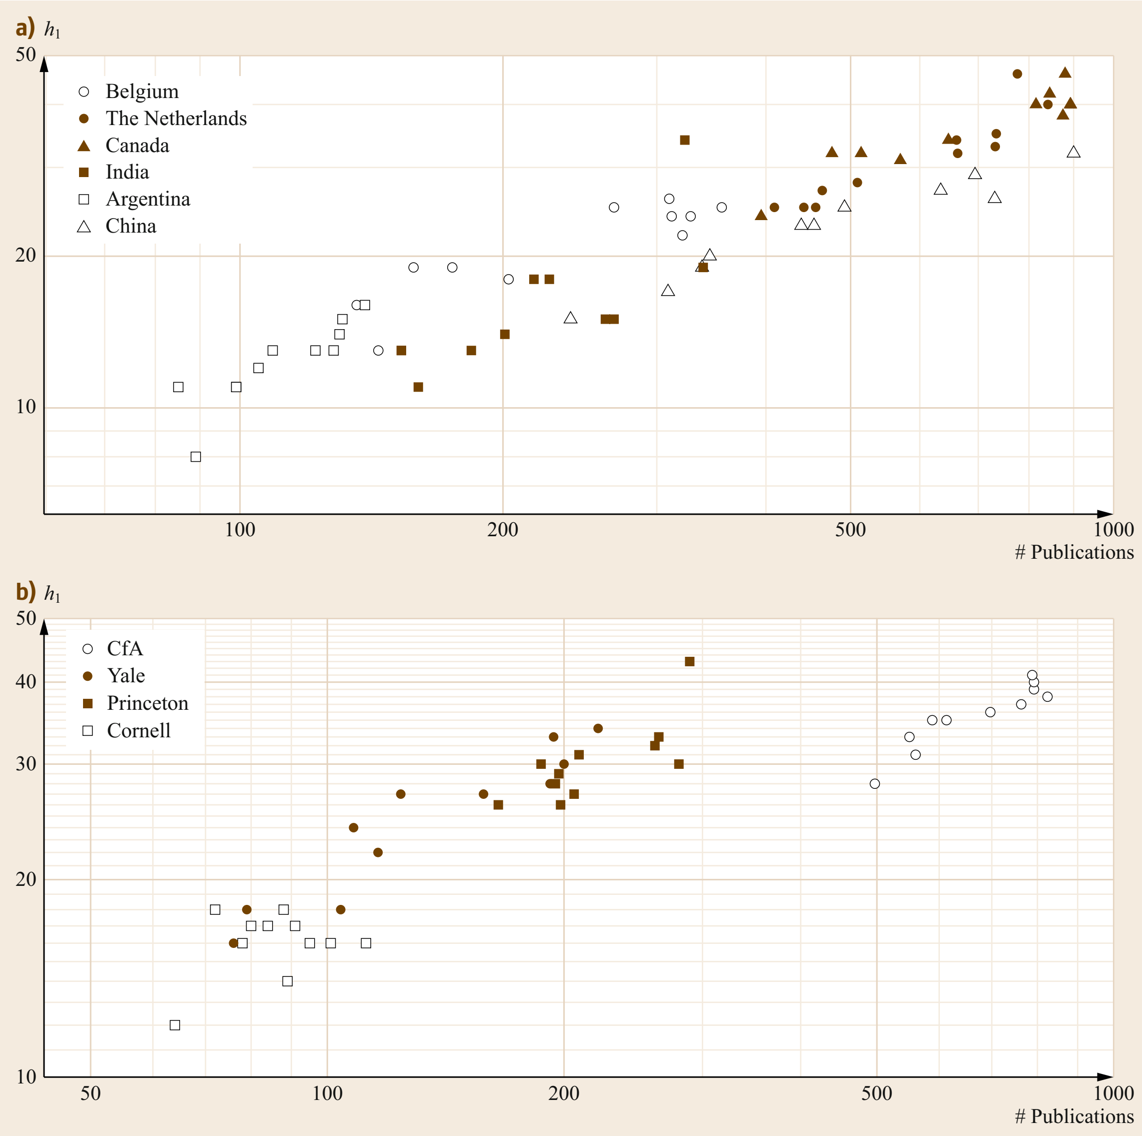

Fig. 32.9a,b The number of publications in the main astronomy journals associated with an entity compared to the h-index for these publication in the next year. **(a)** Countries. **(b)** Institutes

sense of research activity that usage-based measures provide. By comparing citation-based measures with those based on usage, you look at more than just research activity. This comparison also involves research quality.

With the correlation found between usage (in the form of downloads by frequent users) and publications, you would expect significant correlations with citation-based indicators. The act of publishing generates citations. In Fig. 32.9 we explore the relationship between the number of publications (in the main astronomy journals) generated for an entity in a year and the value of the h-index, for these publications, in the next year.

32.5 Discussion

Our selection of data for the analysis put forward in this publication has been guided by the following observation: while citation is a deliberate, public act, usage is private act, with a wide range of types. Citations are solely generated by authors, while usage is not solely the result of actions by authors. Taking publications as a measure for research activity, we necessarily need to focus on usage patterns associated with ADS users who are most likely to be authors. Because we have unique identifiers associated with users, we are able to do this. Figure 32.2 illustrates that, with a proper definition of usage frequency, a class of users can be delineated that strongly correlates with the size of professional researchers. With lower and upper boundaries set to 100 and 1000 downloads per year, over the period covered by this paper (2005–2015), the number of frequent users closely resembles the number of IAU members for the period with available data (2008–2015). For a number of entities, we determined the set of publications in the main astronomy journals where one of the authors has an affiliation associated with that entity. From these sets, we created subsets where the first author is affiliated with a particular entity. For each year in our period of analysis, we compared the number of first, affiliated authors with the number of frequent users for that entity. This comparison shows a very strong correlation for countries and a strong correlation for institutes, but definitely more spread. Examples of sources that contribute to spread are the fact that not all frequent users are authors and time lapses inherent to the act of publishing (particularly relevant for publications early and late in each year). In countries with multiple institutes, especially those with higher numbers of frequent users and authors, spread is less because of an averaging effect. In the case of countries, Fig. 32.5 compares the number of affiliated first authors with the number of national IAU members, for the period 2008–2015. Affiliated first authors can be visiting scholars from another country or simply not be a member of the IAU. Also, not all national IAU members are active authors. Nevertheless, Fig. 32.5 shows a strong correlation between both numbers. Taken together, Figs. 32.2, 32.4 and 32.5 make a strong case for being able to trust that the class of frequent users, derived from the ADS usage logs, sufficiently represents those scholars that generate research activity in the form of publications, for a given entity.

In the next stage, we compare the signals, at various levels of granularity, generated by the two populations we have defined: authors affiliated with an entity and frequent users associated with that entity. The author-centric data consists of publications generated in a particular year (and the publications cited in their respective bibliographies) and the data for the frequent users consists of lists of publications downloaded by them in a particular year. In both cases, publications are identified by a unique entity. At the least granular level, we compare just numbers, specifically the number of publications from the main astronomy journals, downloaded by a frequent user associated with an entity, and the number of main astronomy publications where one of the authors is affiliated with that entity. Figure 32.6 shows that the correlation is the strongest for countries. As noted before, there are the effects of missed data at the start and end of each year, but the effect of this gets dampened on the scale of a country. The smaller amounts of data on the level of institutes results in a larger amount of scatter. At best, the results in Fig. 32.6 show that there is a relationship in the mean. By comparing scalar quantities we have removed any information on what actually is downloaded and published.

Ideally, authors should read every publication that they intend to cite in the paper they are writing. However, this is unlikely to be true [32.26]. The question is whether this is true enough. Assuming that the populations of frequent users sufficiently represent authors, we still expect a lot of scatter on the detailed level of actual downloaded publications. Publications are downloaded that for various reasons do not get cited or get cited in a paper which appears in the next year. Figure 32.7 explores relationships at a more granular level, but not yet at the most granular level of using individual publications in comparisons. Figure 32.7 was constructed by using one particular aspect of article metadata: the publication year. With the publication year we examine the similarity in obsolescence functions for cited and downloaded publications. We explored these quantities for one particular entity and year, but the results were found to hold true for a wide range of either. The similarity of the obsolescence functions indicates that the correlation found earlier, in the least granular level, is still present at the more granular level of using the publication years of individual articles.

Before going to the level of individual publications, there is at least one additional approach for comparing the results for both populations. This approach would give an estimate for the similarity in subject matter between the published publications and those downloaded by frequent users, for example by using a clustering algorithm (like k-means or Louvain clustering based on keywords). We will not consider this approach in this publication, but it may be a subject for a future publication.

Finally, we explore the similarity between downloaded publications and the cited papers, for a range of entities. We selected the most straightforward comparison: calculating the fraction of overlap between both sets. Figure 32.8 shows the results for a number of entities. Would these fractions have been significantly smaller if the downloads had been a random selection of publications from the main astronomy journals? Figure 32.10 shows results for a number of entities. Every *random* value is the average of ten samples.

For both countries and institutes we find moderate, yet significant similarities between main astronomy publications, downloaded by frequent users and the main astronomy publications cited in the publications for a given entity and year. We wouldn't expect this similarity to be more than modest because of the reasons we mentioned earlier.

Is there a relation with traditional bibliometric measures? It is difficult to use traditional bibliometric measures to quantify research activity, in particular if you are interested in a measure that is very close, temporally, to when the research is actually happening. For any measure based on citations, the articles will have to have been published and available long enough to accumulate a reasonable amount of citations. By considering citations as a measure, you are immediately attaching a quality assessment to your analysis. A usage-based measure, like the READ10 indicator [32.22], based on current reads of publications, is an alternative, but it is still an impact measure. This does not mean that there is nothing to compare. Given the fact that most of these traditional measures are citation-based, any relationship is indirect and circumstantial at best. We have shown that download activity correlates with publication numbers. Publications result in citations. Taking

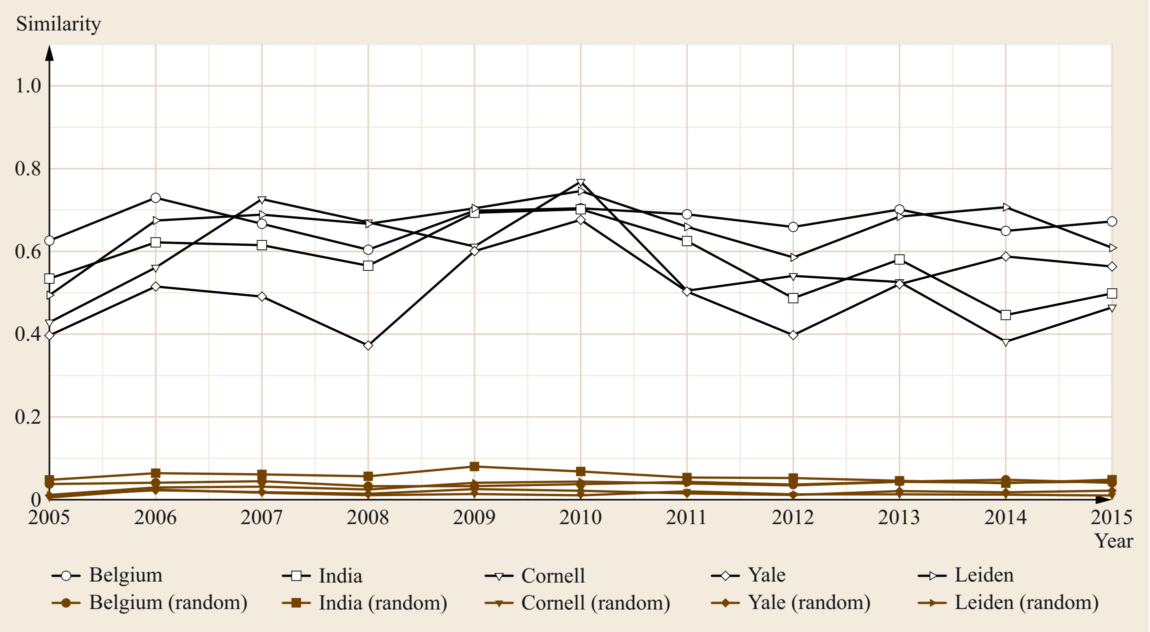

Fig. 32.10 The fraction of overlap between the sets of main astronomy papers cited in the first-authored papers are compared and the downloaded main astronomy papers by frequent users, associated with the same entity are shown. Lines with *open symbols* show the actual data and lines with corresponding *solid symbols* show the results if the downloads had been random

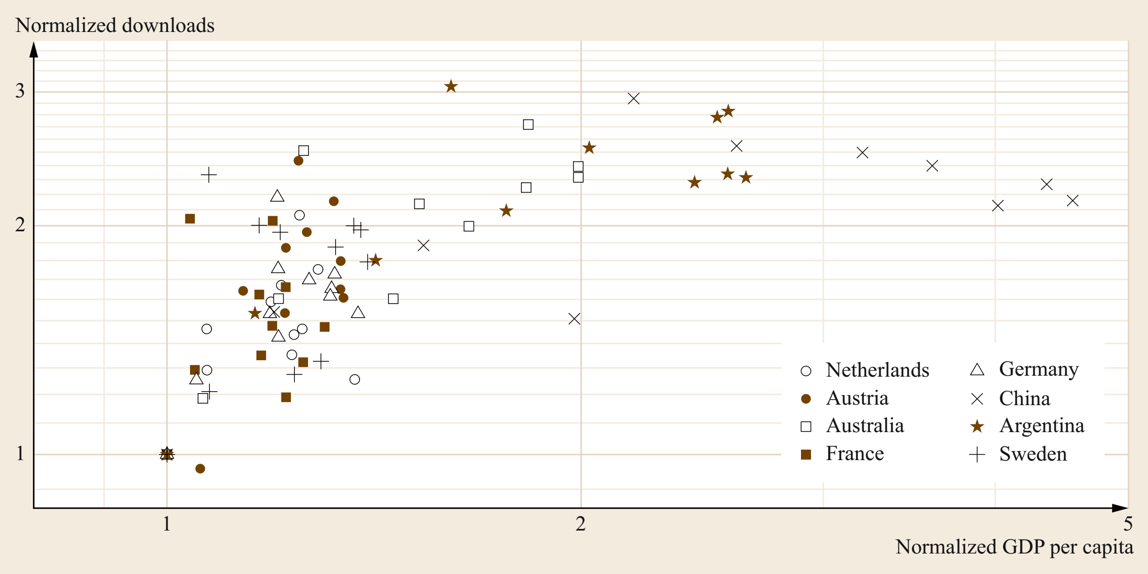

Fig. 32.11 GDP per capita (current USD) versus number of downloads by frequent users. Both quantities have been normalized by their values in 2005. Every point corresponds to a year in the range 2005–2015

into account that there is a lag for citations to accumulate, there may be a correlation between current downloads and a citation-based indicator *later* (say, the following year). The results in Fig. 32.9 show this to be a correct assumption. *Kurtz* et al. [32.22] showed the relation between downloads of an author's work and citations to that work, both on an individual author basis, and summed over research institutes.

Eichhorn et al. [32.21] first showed the relation between the number of times individuals in a country download an astronomy article and the GDP of that country, and in an earlier publication we showed a relationship between general usage and the GDP per capita for a range of geographic regions [32.24]. We found that growth in GDP per capita in general translates to an increase in ADS usage. Is there a similar trend for just downloads by frequent users? Figure 32.11 indicates that, with a few exceptions, an increase in GDP per capita results in an increase of downloads by frequent users, implying increased research activity. An exception is China, where it seems that research activity does not keep up with the explosive economic growth.

Kurtz et al. [32.23] showed that the number of downloads in a country is proportional to that country's GDP squared divided by it population. In that publication, they also showed that that the number of downloads by researchers of astronomy articles better predicts the mean of the number of articles published and the citations of those articles—all measured as fractions of the world total.

32.6 Concluding Remarks

When a researcher cites a publication in an article, it is a public, deliberate act. The only room for interpretation is the sentiment of the citation. From a process point of view, because of this deliberate nature, there is no noise component in the citation signal. This cannot be said for the process of usage. For any entity where some level of scholarly research is performed, literature discovery is an essential ingredient in the research lifecycle. However, this is a process with many components, depending on the goal of the literature search. All of this activity, for all entities on all levels, comes together for a service provider like the ADS. Somewhere, buried in the millions of yearly interactions with the service, are the signals that represent the act of gathering the necessary literature for producing scholarly articles. Although *research activity* consists of many components that do not involve literature search and writing, we feel that the act of generating scholarly articles is a measure that is a good proxy for research activity. Key to being able to find these signals is the ability to associate sessions with individuals. It is not sufficient to use IP addresses to identify sessions. For one, researchers are mobile and some institutes proxy their requests through one single host. We noted the presence of library computers in Fig. 32.2 and how these result in usage of multiple users end up being indistinguishable. For usage information to have any use, either for bibliometric analysis or to enhance the discovery experience of a service, a lot of meaningless systematic (e. g., robots) and random (e. g., incidental users entering through Google) signals need to be removed. We showed the dramatic difference in orders of magnitude between incidental use and the use by people who use the ADS professionally. When thinking about a very specific class of researchers, namely authors, it is important that all authors use the ADS, but that not all users (even frequent users) are authors. Going back to our original question of quantifying research activity, this emphasizes the need for being able to properly identify these frequent users. In this study we showed that for the ADS we can identify a class of frequent users and that there is convincing evidence that these users represent the population of active researchers (and even authors) in astronomy. Having identified these frequent users for various entities and having constructed bibliographies for these entities for the time period of 2005–2015, we have shown that there is a significant correlation between the number of frequent users and first, affiliated authors for a range of entities. For countries we also showed a correlation between the number of first, affiliated authors and the number of national IAU members. Based on this evidence we argue that the class of frequent users represents the authors making use of the ADS while in the process of writing scholarly articles. For the main astronomy journals, the download activity by these frequent users correlates with publications on multiple levels of granularity. This correlation is stronger for countries than for institutes. Our conclusion is that download activity for main astronomy journals represents research activity. Even though we did not show this explicitly, we feel that this observation can be extended to refereed literature in general. The research cycle is a process common to many disciplines, and producing scholarly publications is always part of this cycle. Since all authors in astronomy are also users of the ADS and always use the ADS in their research, we feel that our results, presented in this paper, are of a more general nature and not just an indicator of trends in astronomy.

Is it meaningful to consider rankings of entities based on usage-based indicators? Making meaningful comparisons using citation-based indicators is already a complicated issue [32.18], so doing this using data that is intrinsically more noisy is going to be very hard indeed and probably even meaningless in a practical sense.

mkurtz@cfa.harvard.edu

Michael Kurtz is an astronomer and computer scientist at the Harvard-Smithsonian Center for Astrophysics in Cambridge, Massachusetts. Kurtz is the author or co-author of over 300 technical articles and abstracts on subjects ranging from cosmology and extra-galactic astronomy to data reduction and archiving techniques to information systems and text retrieval algorithms. He is the project scientist for the Smithsonian/NASA Astrophysics Data System.

33. Online Indicators for Non-Standard Academic Outputs

Mike Thelwall

This chapter reviews webometric, altmetric, and other online indicators for the impact of nonstandard academic outputs, such as software, data, presentations, images, videos, blogs, and grey literature. Although the main outputs of academics are journal articles in science and the social sciences, and monographs, chapters, or edited books to some extent in the arts and humanities, many scholars also produce other primary research outputs. For nonstandard outputs, it is important to provide evidence to justify a claim for a type of impact and online indicators may help with this. Using the web, academics may obtain data to present as evidence for a specific impact claim. The research reviewed in this chapter describes the types of evidence that can be gathered, the nature of the claims that can be made, and methods to collect and process the raw data. The chapter concludes by discussing the limitations of online data and summarizing recommendations for interpreting impact evidence.

33.1 Non-Standard Academic Outputs

Although most scientometric evaluations of researchers are restricted to journal articles, there are many other valid academic outputs. In the humanities, monographs are more important than journal articles and edited books are also valued [33.1, 2]. Similarly, conferences can be more important than journals in engineering-related fields, and performances, exhibitions, and individual works of art are key academic outputs in the arts. Thus, in some fields, journal articles are secondary or irrelevant. Even in disciplines where the traditional journal-based publishing model dominates, individual scholars may legitimately focus on other outputs and activities that make important contributions to the wider goals of science, such as patents, educational resources, software, data, and websites as well as public outreach blogs, videos, and presentations. It is important that these are not ignored or undervalued in research evaluations because this would narrow the focus of science and isolate it from its wider societal goals. It would also make science less efficient if communal activities like data and software sharing were inadvertently discouraged.

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_33

Given that it is essential to recognize the value of nonstandard academic outputs, quantitative indicators are needed to support this. In practice, nonstandard outputs are probably evaluated informally without the aid of systematic data in appointment, tenure, and promotion decisions. If an academic's blog or software is well-known in their field then this might be enough to ensure that this contribution is valued when she applies for promotion. Similarly, an appointment committee may notice a list of media engagements on an applicant's curriculum vitae (CV) and informally estimate the value of this contribution by the length of the list and the prestige of the sources mentioned. Nevertheless, many critical decisions are made by senior committees that are not field experts and might find it difficult to evaluate nonstandard contributions to research. Moreover, most academics do not produce high-profile work, making the exact value of their outputs difficult to determine, even for subject experts. Thus, there is a need to obtain quantitative data to help the evaluation of nonstandard outputs.

One former EU (European Union) project took a researcher-centered approach to evaluations and argued that scholars should produce a portfolio of evidence of their outputs, achievements, and capabilities [33.3, 4]. Within this portfolio, individuals could list their outputs and any available quantitative impact evidence. The heart of their claim for value would be a narrative statement that refers to this evidence. This sets the quantitative evidence of a researcher's achievements in the context of the value that they believe that it has. One researcher might present 1000 website visits as evidence of substantial success for a blog aimed at field experts, whereas another might claim 100 000 visits as similarly powerful evidence of success for a blog aimed at science education for school pupils. The ACUMEN portfolio requirement for the researcher to marshal their evidence and make a claim for the value of their work formalizes the more standard process of job applicants submitting a cover letter and CV. The portfolio approach also foregrounds the importance of data to support claims.

Nonstandard outputs are prominently evaluated in the UK research excellence framework (REF) national research evaluations [33.5, 6]. As part of the 2014 evaluation, UK academics selected four outputs to represent their best work 2008–2013. Whilst most chose journal articles, monographs were common in the humanities and a range of different artistic outputs in arts subjects. In both cases the outputs were evaluated by subject experts' judgements of their significance, rigor and impact, without the aid of metrics. In contrast, REF2014 also required submitting departments to construct impact case studies, which were narratives describing how some of the department's previous research had made an impact outside of academia [33.7]. These narratives were expected to provide evidence of impact and this could take the form of qualitative support or quantitative data from any source. The impact case studies provide many examples of how ad hoc quantitative data can be used to support impact claims. The following extracts illustrate this:

- Claim: "Ulinka Rublack's research focuses on the history of Renaissance dress. Her work has enhanced public awareness that social groups beyond courtly elites created fashion in the past. It led to a re-creation of one of the most significant outfits recorded in the wardrobe of a sixteenth-century accountant." [33.8] Evidence example: "Cambridge University Website article on Rublack's research and the reconstruction, launched 1 May 2013, shared 2051 times, tweeted 253 times, taken up as top item on website http://medievalists.net" [33.8]
- "[Breeze's] research into rich donors in the UK has impacted on the policies of both governmental and non-governmental bodies." [33.9] Evidence example: "Breeze has 2250 followers on her @UKCPhilanthropy Twitter account, and has tweeted 1306 times (as at 24/10/13)." [33.9]
- "The 10 min Puzzle podcast series seeks to engage lay audiences with some of the central puzzles driving contemporary research in analytic philosophy. As of September 19th, 2013, there had been over 63 000 downloads." [33.10]
- "Visual analytics is a powerful method for understanding large and complex datasets that makes information accessible to non-statistically trained users. The Non-linearity and Complexity Research Group (NCRG) developed several fundamental algorithms and brought them to users by developing interactive software tools (e. g., Netlab pattern analysis toolbox in 2002 (more than 40 000 downloads))." [33.11]
- "Dr Katharina Hall's blog Mrs Peabody Investigates (http://mrspeabodyinvestigates.wordpress.com/; henceforth MPI) has been fostering public debate on German, European and international crime fiction since January 2011. Beneficiaries include readers, authors, translators, publishers, critics and bloggers in 130 countries. With over 220 000 hits and 2500 comments, MPI has been featured on BBC Radio 4 and is linked to by BBC Online, crime blogs, and publisher/author websites (C10). Providing a distinctive service of academically-informed reviews of high-quality crime fiction, MPI

is regarded in the industry as *a ground-breaking blog that is transforming readers' understanding and appreciation of international crime* (The Times crime-fiction critic)." [33.12]

- "In collaboration with film-maker Brady Haran we have developed the YouTube channel *60 Symbols* to present topics related to research in physics to the wider public. Since the 2009 launch of *60 Symbols* we have posted 212 videos, which have amassed 21.2 M views, over 200 k comments, over 266 k subscribers and a content approval rating of 99.4%, placing *60 Symbols* in the top 0.01% of all YouTube channels." [33.13]

Of course, there are many academic contributions that cannot be easily quantified. For example, the REF impact case study, *Preventing disease through promotion of handwashing with soap* (HWWS), makes the hugely impressive claim [33.14]:

> [Val] Curtis has spearheaded an effective alliance of industry with organisations like the World Bank, USAID and UNICEF to promote good hygiene. This means that millions of people around the world have now been exposed to HWWS promotion programmes. In the last decade, diarrhoea deaths in under 5 s have steadily fallen from 1.2 to 0.85 m per year, and while some of the credit must go to economic development and improved clinical treatment, some is undoubtedly due to the promotion of better hand hygiene based on Curtis' research.

The concrete claim *has spearheaded* is clearly one that is difficult to provide quantitative data to support and the impact data provided covers the work of the *alliance* rather than the individual researcher. In this case, and probably most others, it is not possible to quantify individual contributions by academics.

The ACUMEN portfolio and REF case study examples to some extent circumvent a major difficulty in using quantitative data for nonstandard research outputs. Because such outputs are nonstandard, with varied purposes as well as different forms and intended audiences, it is difficult to benchmark the results or to normalize them in any way [33.15]. In consequence, it can be unclear whether an indicator value represents high or low impact. There is no equivalent to the field-normalized citation count indicators for journal articles, where values above 1 indicate impact above the world average for the field and year examined [33.16]. There is not a simple solution to this problem for most of the output types discussed here. A fundamental issue in this context is that whilst journal articles address very broadly similar-sized audiences (other scholars in the same field), nonstandard outputs could be intended to reach a small audience, such as other specialist scholars, or a very large audience, such as members of the public interested in science. It would be unfair to directly compare indicators for outputs designed for such different-sized audiences.

The lack of field normalization for typical nonstandard outputs makes it more natural to evaluate them individually rather than through a group average. Effective normalization is needed for group averages to make sense. Thus, for example, it would not be helpful to report the average visitor count for all blogs produced by a university, whereas the visitor counts of each individual blog alongside information about its purpose and intended target audience could be useful.

This chapter discusses webometric, altmetric, and other methods to evaluate a range of nonstandard academic outputs. Webometric methods refer to techniques to extract impact evidence from the web in general [33.17]. In contrast, altmetric methods are restricted to data from social websites [33.18, 19], although the term seems to now be used to encompass all online indicators. Social web data is typically easier to obtain and more plentiful but is not always better than webometric data. This chapter extends a previous literature review of this topic [33.20] with updated and wider coverage. It also includes evaluations of websites, as researched within the field of webometrics. It does not cover all academics' activities. It excludes most awareness-raising activities, such as tweeting, maintaining a personal home page, or engaging on ResearchGate or Academia (http://www.academia.edu). Whilst these are all important activities, they are rarely the primary outputs of scholars.

33.2 Core Concepts

All online indicators need to be collected and evaluated before they can be used with confidence. These are discussed here to support future sections on specific indicators.

33.2.1 Indicator Creation

An impact indicator for a nonstandard output is a number that is expected to associate with the impact of the output. For example, the viewer count of a scientific YouTube video might be used as an impact indicator because, whatever type of impact the video has, the more people watch it, the more impact of that type it is likely to generate.

Some nonstandard outputs have natural and easily accessible indicators, such as the view count visible on YouTube video pages. In this case, if an indicator is needed for a single output then it can be looked up in the hosting website. If indicator values are needed for large collections of outputs, including for testing, evaluation or benchmarking purposes, then an automatic process is needed to gather the numbers. Data collection for informetric purposes is discussed in another chapter but the basics are also covered here.

For websites like YouTube with an application programming interface (API), it can be possible to automatically gather indicator values through a computer program. An API is a set of facilities within a website that allows computer programs to automatically access some or all the website content. Using an API, a researcher could feed a program with a list of nonstandard outputs and then it would download their scores. At the time of writing, the free software Webometric Analyst (http://lexiurl.wlv.ac.uk) could use the YouTube API to gather usage data for YouTube videos, the Twitter API to gather retweet and follower count data for individual users, the Mendeley API to count the registered Mendeley readers of any type of document, and the Google Books API to count citations from books. The Altmetric API (https://api.altmetric.com/) can also be used to download impact information from a variety of sources for individual outputs. It is mainly restricted to items with a digital object identifier (DOI), which most nonstandard outputs do not have. For websites with an API that is not supported by any currently existing software for academic purposes, a user would need to create a new program for their task. This is a straightforward task for an experienced programmer.

Most websites do not have an API, making it more difficult to extract data automatically. Examples at the time of writing include ResearchGate and Academia.edu. For sites without an API the main alternative strategy is to use a web crawler and/or page scraper software to automatically extract relevant data. A web crawler is a computer program that can be fed with one or more URLs (uniform resource locators) and then downloads them, perhaps also recursively following the hyperlinks in the downloaded pages (typically to other pages in the same website). After downloading the pages, the indicator data can be automatically extracted from the pages using a custom-written program, called a page scraper, which can either be part of the web crawler or a separate utility. The free web crawler SocSciBot (http://socscibot.wlv.ac.uk) is an example of a general-purpose crawler that can download either entire websites or collections of pages within a website. It is paired with Webometric Analyst, which incorporates page scrapers for many different websites. At the time of writing, the combination of these two programs (i. e., first downloading with SocSciBot, then page scraping with Webometric Analyst) could be used to systematically extract indicator values from ResearchGate, Academia.edu, SlideShare, DataDryad.org, Google Code, and FigShare (see the *Webometric Analyst Services* menu). When using a web crawler, it is important not to overload the targeted website by crawling it too quickly or by ignoring a request not to crawl it [33.21]. Damaging an academic website in this way would be a serious problem. Ethical behavior of this nature is designed into SocSciBot and most web crawlers to ensure that no damage is inadvertently done.

Many repositories and individual outputs have no accessible indicators. For example, the mainly physics repository arXiv does not report download or view counts. Similarly, if researchers post a report to their own institutional website then they may not have access to any usage statistics for it. For these outputs, it may still be possible to gather online citation data by counting how often they have been mentioned on the web. If some uses of an artifact mention it online, counting web citations (i. e., the number of web pages mentioning it) is a reasonable way to generate a simple impact indicator. For individual outputs, the easiest way to achieve this is to Google their titles and then manually check the results for accuracy to get an estimate of the number of online mentions. This underestimates the number of online citations because commercial search engines do not reach or report the entire web for various reasons [33.5, 22–26] and have internationally biased coverage [33.27] but this underestimate may still give an idea of the order of magnitude of the number of results. It also allows comparisons between different outputs or sets of outputs.

It is possible to automatically gather data from search engines on the number of web citations for scholarly outputs using the Bing search API. Thus, to count the number of web citations for each one of many outputs (e. g., grey literature, presentations), appropriate Bing queries can be automatically submitted. The program Webometric Analyst incorporates code to interact with the Bing API. This includes procedures to create appropriate web citation queries for sets of documents as well as to submit them to Bing and summarize the results [33.28]. The initial step, converting the output information into Bing queries, typically uses the first words of the title as a phrase search and then adds the first author last name and the publication year. This is based upon the assumption that when an output is cited in any web page, its title, publication year, and first main author are likely to be mentioned. This is clearly an oversimplification because, for instance, news stories rarely give much information about research that they mention. Nevertheless, it is a simple way to construct searches. Whilst the Google custom search is not designed to provide a general search service (http://developers.google.com/custom-search/), it is possible to adapt it for this and so Bing is not the only choice for automatic queries.

For citation indicators (e. g., citations to grey literature or theses), Scopus or the Web of Science (WoS) may give citation counts but online alternatives, such as Mendeley [33.29], Google Scholar [33.30], Microsoft Academic [33.31, 32], or ResearchGate [33.33] may give earlier evidence of impact.

In summary, for individual outputs, impact evidence may sometimes be obtained from the download data or other usage statistics in the hosting website and, if this is not available, then search engine queries could be used to obtain (an underestimate of) the number of pages mentioning the output. In contrast, for groups of outputs, usage statistics may be obtained automatically from the hosting website API, if it has one, or from using a crawler and page scraper if not. For websites not reporting usage data, web citation counts can instead be obtained by submitting automated searches to Bing with queries designed to match web pages mentioning the outputs.

33.2.2 Indicator Robustness

Almost all online indicators for nonstandard outputs are not robust in the sense that they can be easily spammed, both deliberately and accidentally. Most of these indicators are derived from usage data, which is easy to manipulate. In the simplest case, a person may repeatedly download their own resources and a computer scientist may even write a program to repeatedly download their outputs. Some websites take steps to avoid such manipulation but it seems likely that a resourceful person could circumvent most protection measures. Accidental manipulation may take the form of uses of an output for spurious reasons. For example, a statistician may use a dataset to illustrate a statistical technique to a large class of students, asking them all to download the dataset to try out the method themselves. This would inflate the download count of the dataset and give a misleading impression of its intrinsic value.

The same is true for web citation data: someone could create many artificial web pages citing their outputs to inflate web citation counts. Thus, almost none of the data sources for nonstandard outputs are safe against manipulation. This means that these indicators should either not be used for formal evaluations or evaluators should be cautious when interpreting them. This caution could take the form of considering whether the indicators are credible in the context of other available information. For instance, an evaluator reading a researcher's claim to have created a blog with a million views might reject this evidence after visiting the blog and finding it to be poor and unlikely to have attracted much attention. In contrast, another blog might have a similar claim accepted as credible if it was clearly interesting and professional and its author had attracted a lot of media attention.

As an aside, because of the potential to manipulate most web data, Altmetric.com at the time of writing only uses data that could be tracked to its originator in its main altmetrics. For example, it includes tweet counts and reports each individual tweet but does not report Mendeley reader counts within its main outputs because they cannot be tracked to the individual readers through the Mendeley API.

The main current exceptions in terms of robust indicators for nonstandard outputs are citations to books from book citation indexes (see Chap. 27), and citations in the Clarivate Analytics Data Citation Index (DCI). The latter is an exception because the data citations originate from a (mainly) peer reviewed source: academic journal articles indexed in the Web of Science. This makes them much more difficult to manipulate and therefore reasonably credible. These exceptions use (mainly) traditional citation indexes rather than online indicators.

Given the problems with a lack of robustness for most indicators for nonstandard outputs, should they be used at all? It seems reasonable to exploit them in situations where manipulation is unlikely or pointless, such as for self-evaluations or formative evaluations [33.34], and when they can be supported by other sources of information so that an evaluator can make a judgement about their credibility. In this context, it seems desirable that for formal evaluations, indicators that could be spammed should be accompanied by an honesty declaration to state that they have not been deliberately manipulated. This would both raise awareness amongst evaluators of the possibility for manipulation and raise the stakes for those that would be prepared to dishonestly manipulate their data.

33.2.3 Indicator Evaluation

Systematic scientometric assessments of indicators for nonstandard outputs are needed to give evaluators confidence in them, even in the absence of manipulation. For citations to journal articles, a standard approach is to compare the rank order or quality categories assigned to a set of documents by citation counts with the same information produced by a set of subject experts [33.35, 36]. This uses peer review as the gold standard against which citation-based indictors should be judged. Such evaluations are rare because of the time and expense needed for subject expert judgements. There are a few exceptions, such as public evaluations of biomedical research in the F1000 website [33.37].

Citation counts are the main source of evidence used for alternative indicators for journal articles. Most evaluations have assessed the strength of the correlation with citation counts because citation counts have already been validated against peer judgements in many fields. Correlations with citation counts are therefore an indirect method of assessing value. Paradoxically, most alternative indicators are valued for their ability to highlight a different type of impact to that of citations but a positive correlation at least demonstrates that the alternative indicator is nonrandom and related in some way to scholarly activity [33.38]. Alternative methods, such as content analyses of random samples, can be used to identify the *type* of impact reflected by the indicator. Content analysis involves human judges assessing a set of texts to categorize them into coherent and relevant groups [33.39]. Content analysis and other human checking can reveal whether a potential impact indicator is reflecting a desired type of impact rather than spam [33.40, 41].

The situation is different for nonstandard output indicators because these typically do not have citation counts in Scopus or the Web of Science and so correlations with traditional citation counts cannot be calculated. Moreover, even nonstandard outputs of the same type (e. g., videos) have many different audiences and purposes and so are not homogeneous enough in impact type for a correlation test to be meaningful, even when citation data is available. Thus, systematic evaluations of nonstandard output indicators are difficult to achieve. In practice, as in the REF case study examples above, indicators are probably evaluated separately and informally for each individual output rather than collectively as a theoretical exercise.

33.3 Research Outputs for Applications

Scholars produce artifacts, such as data and software, that are designed to be exploited by others for future research or applications. Important designs or ideas may also be patented to protect their commercial value if they are used for future research. There may be associated journal articles describing these outputs but, if not, then developing impact indicators would help to give recognition to the creators.

33.3.1 Data

Projects may produce data as a natural part of their research and then publish articles that evaluate that data. Sharing the data produced would have several advantages, including some that are field-specific [33.42]. First, the analysis of the work could be checked for accuracy (reproducibility is a desired goal for science: [33.43]. Second, the data could be reanalyzed to check if the results are dependent on the analysis methods chosen (method triangulation). Third, the data could be used for other purposes, such as meta-analyses of multiple papers, or aggregated with other data for a different type of investigation.

In the past, few researchers shared their data [33.44] but there are now increasingly many incentives and funder/journal mandates to promote data sharing [33.45]. There are many free or cheap digital repositories for this purpose and an organization, DataCite, that assigns DOIs or other identifiers to data to make it easier to cite [33.46, 47]. Data sharing can have drawbacks for researchers, such as the time needed to format a dataset in a way that is suitable for sharing and the risk that other researchers will publish a study on the data that its creators had intended to do [33.48, 49]. Most researchers would be willing to use others' data, in principle, however [33.50]. For these reasons, it is important to reward researchers for data sharing by allowing them to have suitable acknowledgements of their work, such as in the form of citations or download counts. Whilst there is some evidence that sharing data associated with an article may help to attract citations to the paper [33.51], this may not be a direct enough incentive.

Although not an online indictor in the sense of the current chapter, the Clarivate Analytics DCI systematically indexes data from a large set of academic repositories and counts citations to that data from the scholarly documents that it indexes [33.52]. Its coverage is international and multidisciplinary [33.53]. It therefore gives a large and systematic source of citation counts for data that has been indexed in one of the repositories that it covers. It has broad coverage but seems to be dominated by life sciences research [33.53, 54], presumably because of extensive and systematic data sharing in this area.

Despite the large coverage of the Web of Science, about 85–89% of DCI datasets have received no citations but more recent datasets are a little more likely to be cited than older ones [33.55–57]. This may have occurred because it has become more usual to cite data used, or data re-use has become more common. Whatever the reason, most datasets will probably remain uncited in the long term but there is nevertheless still an opportunity to recognize the minority of particularly useful datasets through their citation counts. In some specific fields, however, including crystallography and genomics, data citation has become common [33.57] and appears to be central to progress [33.58].

Although citation counts are more robust, a more natural method with which to investigate the impact of data is through downloads. Each download could represent a use of the data even though few uses eventually result in a DCI citation [33.59–61]. For example, the data could be re-used for education and training [33.62]. Low positive correlations between data downloads and citations to the article originating the data suggest that a paper's data has a value that is to a large extent independent of the paper that produced it, at least for the Dryad repository [33.60]. Repositories often report download counts for their datasets that can be used as impact evidence for more typical datasets that are not in the 15% that attract DCI citations. For example, the average (geometric mean) number of downloads of datasets in FigShare is at least 11 for all subject areas as investigated in one study [33.61]. Evidence of sharing, viewing, or interacting with data may also be useful [33.63].

33.3.2 Software

Computer programs are sets of instructions for a computer to complete tasks. Software can be written in many different languages, including Java, Python, C, and Visual Basic. It can also consist of scripts to run in a software environment to draw upon and extend its existing functionality, such as Excel, Matlab, or R. Computer programs are used in research for a variety of reasons, including web data collection (e. g., web crawlers), data collection from elsewhere (e. g., movement trackers in smartphones), and data analysis. Programs can be general purpose and multifunctional (e. g., the visualization software Gephi), targeted at a field-specific task (e. g., VOSViewer for bibliometric network construction and visualization), or may complete a single task, such as a small R script to fit a hooked power law to a set of citation counts.

Software sharing can be valuable because programs can be time consuming to create and the researcher that shares software can save the time of others who would have to recreate it otherwise. Software sharing can also aid scientific quality control by allowing others to check the work presented in a publication. There are three types of software sharing. The most common type is probably to post the finished program in a repository or on its own website for others to download. Programmers may also post the source code of the program online (open source software) so that others can modify it, if necessary. Finally, a program can be shared interactively by posting it to a collaborative working environment, such as Google Code, GitHub or SourceForge, so that other programmers can collaborate on developing the code [33.64]. High-profile examples of collaboratively developed open source software include Linux, Open Office, and the web browser Mozilla [33.65]. There are many less well-known programs that are the primary work of individual academics or research groups and are in code-sharing sites. A high-profile hybrid example is the statistical software R that has a common core but can be extended by installing *packages* with additional functionality, many created by researchers [33.66].

Although there are many academic studies of the mechanics of software sharing, few have assessed whether it is reasonable to use indicators to evaluate the usefulness of the product itself. One exception found that download counts for Scopus-cited software in Google Code correlated weakly with Scopus citation counts. The low correlation was due to some code with apparently little academic value being widely used outside of academia. Unsurprisingly, software was typically downloaded many times more often than it was cited and one program had over a million downloads but only one Scopus citation [33.67]. Thus, the potential audience for a program as well as its added value to the user must be considered when evaluating software download counts. A complex and unique program may have enormous value to a few researchers that would otherwise not be able to conduct a type of research, whereas another program might be widely downloaded by the public despite the existence of similar programs from other sources, or for a trivial usage.

In addition to special-purpose software websites and ad hoc places online, code can also be stored in some general-purpose academic and other repositories. The general repository FigShare includes software as a resource type and code deposited in the site seems to have been viewed an average of at least 40 times in all research fields, with the cross-field average being 45 [33.61].

33.3.3 Patents and Products

Some scientists produce ideas or products of patentable commercial value [33.68]. Patents are documents that confer the legal right to protect an invention. They are recognized as valid research outputs in some national research assessment systems, such as that of the UK [33.69], Denmark and Italy, and the publication of a patent can be taken as an indicator of potentially useful research [33.70]. Universities may publish patents to safeguard the discoveries of their academics and so counts of patents are sometimes used as indicators of innovation or commercially relevant innovation. At the level of individual academics, the value of their patents can also be assessed financially or with the aid of citations from other patents, from scientific literature, or generally on the web. Patents can also be used to map areas of technology [33.71] and commercial technology transfer [33.72], underlining their value as indicators of commercial innovation. Patents are covered in other chapters of this book.

33.4 Multimedia Outputs

Scholars may communicate through rich visual or auditory media, including performances. The purpose may be to educate (in the pedagogical sense), inform (targeting the public or a professional audience), entertain, or culturally enrich. Some multimedia outputs are also a form of research data (e. g., diagnostic medical images, video records of animal behaviors). This section includes artistic performances even though they are not usually multimedia.

33.4.1 Presentations

Scientists routinely give presentations as part of their research. These include seminars to their own university or other institutions, talks at professional or trade conferences, and public lectures. A growing form of presentation is the video made to be posted online for later watching [33.73]. Some journals now encourage authors to record explanations of their work to post alongside the published paper in the journal website.

Scholarly presentations can be influential, but their impact is rarely tracked. Conference presentations in computing, computational linguistics, and some engineering-related fields are a partial exception [33.74, 75] because the impact of the conference proceedings paper associated with a talk can be tracked and used as primary evidence of the value of the content of the associated talk. Similarly, presentations that are associated with journal articles can also have their value subsumed into that of the article. Nevertheless, some types of research are unlikely to be eventually published in a journal [33.76] and therefore the conference presentation slides may be the main record of the information contained in them, and the only chance for the authors to track the impact of their work. This is the case for some business research areas, where PowerPoint presentations are an important outlet for scholarly knowledge [33.77].

It is increasingly common for live talks to be recorded and posted online as a video or slides with audio. The impact of scholarly videos is discussed in a different section. Presenters can also share their slides with the audience and for wider future use by posting them online. This could be on their personal website, on the conference website, or in a specialist presentation-sharing site like SlideShare [33.78]. This has created the potential to record, report and assess the impact of online presentations, as well as to use the citations from them as a new source of impact evidence for other documents [33.79].

Only one study so far seems to have explicitly assessed methods to evaluate the impact of online presentations other than videos. SlideShare is perhaps the most prominent free repository of online presentations. Although any type of presentation can be uploaded, SlideShare is owned by LinkedIn and is branded for use by the professional community, rather than scholars or educators. About 70% of recent SlideShare content consists of presentations (rather than just sets of images, for example). About 10% are of academic origin (2% associated with conferences), with the humanities, social science, business, and computing topics dominating in comparison to natural/life science, engineering, and medicine. Only a tiny minority of SlideShare presentations are cited by Scopus (by 2016, there were a total of 4436 such citations) and so there is little value in using formal citation analyses on them. Nevertheless, individual researchers could use the number of downloads per document, which averages about ten, as evidence of their presentation's impact [33.80].

33.4.2 Videos

Many academic videos are recordings of talks or lectures given to students and conferences that serve as a reminder or as an alternative means of accessing the content for people that were unable to attend. At the other extreme, some are professionally scripted, created, and edited films for online dissemination. The intended audiences for such videos might be a narrow set of scholars (e. g., for a video demonstrating specialist software or a method), a specific nonacademic group (e. g., entertaining science outreach videos aimed at school pupils), or the public.

Considering only YouTube videos that have been cited at least once in Scopus, the uses of videos vary greatly by field, but they seem to be most valuable in the arts and social sciences. The ability of a video to show a performance or film is an obvious advantage in comparison to the written word or still images. Scientific videos can also usefully demonstrate experimental procedures or surgery that would be more difficult to express in words [33.81].

As for most nonstandard academic outputs, interpreting the value of a video or set of videos is difficult because the different potential audience sizes make benchmarking or field normalization difficult. This issue is exacerbated for videos posted to general sites like YouTube, where the competitors include commercially produced popular content, such as music videos and television shows [33.82]. The task is easiest for outputs that are designed to attract a large audience because their creators would not need to explain in as much detail why the audience numbers demonstrated substantial impact—the large numbers would speak for themselves. For initiatives that produce large sets of videos, hybrid indicators have been proposed that combine the quantity of videos produced with their downloads [33.83] or Like counts and other data [33.84]. This is probably not useful in an academic context because more fine-grained information is needed to help interpret the meaning of the data.

The TED (Technology, Entertainment, Design) initiative and TED talks website are a partial exception to the difficulty of benchmarking scholarly videos:

> TED began in 1984 as a conference where Technology, Entertainment and Design converged, and today covers almost all topics—from science to business to global issues—in more than 110 languages (http://www.ted.com).

TED talks are disseminated in YouTube and the TED website, with the total number of views exceeding a billion [33.85]. A large proportion of its talks are by academics but all target a general audience and have a similar style and production input. It is therefore reasonable to benchmark the viewer figures for them against other videos from the same site to get useful impact evidence. This benchmarking should be against other videos from the same field (and of the same age) because there are broad disciplinary differences in popularity [33.85]. Of course, only a small minority of academics ever give a TED talk, and just being invited to give one is an indicator of prestige and potential public interest [33.86], although those invited seem to be a gender-, country-, and institution-biased subset of academics [33.87]. TED talks attract interactions in the form of comments from viewers, often in the form of substantial discussions, and the content of these may form a source of additional qualitative evidence about the impact of a presenter's work [33.88].

33.4.3 Images

Pictures are central to some visual arts-based scholarship and can also be useful to convey scientific information visually through graphs. In some areas of science, photographs can also be important to convey naturally visual information, such as the appearance of species, solar objects, and disease symptoms. In some of these cases the image is the scholarly output, not only in the obvious case of visual art, but also in health contexts. For instance, the *New England Journal of Medicine* accepts submissions that are images with extended captions [33.89]. Images can also be useful for science communication because visual information can be more easily communicated and is perhaps intrinsically more interesting [33.90]. Thus, for example, NASA's (National Aeronautics and Space Administration's) astronomy picture of the day archive (http://apod.nasa.gov/apod/) is a popular collection of images that seems to be widely used in schools (Fig. 33.1).

The impact of individual images within scientific articles and books does not need to be assessed separately, but there is still a need to evaluate the impact of individual images and image collections that are separate academic outputs. If these images are hosted in a standard media-sharing site, such as Flickr, then their impact can usually be assessed with the download or

Fig. 33.1 A free NASA image of Sam the monkey, recovered after a 1959 flight in an experimental spacecraft. Engaging images aid public science communication

viewing statistics provided by that site [33.91]. Like most other indicators discussed in this chapter, these would be hard to benchmark or field normalize and so it would be difficult to use them as fine-grained impact indicators.

One impact indicator is specific to images and not applicable to any other type of academic output: copying. Images that are freely shared can have their impact assessed by counting how many copies of them have been found online. Thus, a successful image would be one that could be found in many different websites and perhaps also employed for multiple different purposes, from illustrating an academic or educational article to being part of a book cover [33.92–94]. It is possible to find such image copies with Google image search and TinEye searches for image copies (i. e., search by image). Current image searching is not restricted to identical copies of an image but can also find similar images and versions that have been modified by having text added, being cropped or resized [33.93]. It does not seem to be possible to automate image searching, however, making it difficult to achieve for large collections of images and hard to gather data for benchmarking purposes. Analyzing the web pages hosting the image copies can also give useful information about the types of uses found for each image [33.94].

33.4.4 Artistic Outputs and Performances

Many artists do not write journal articles or monographs but instead produce other creative outputs, such as plays, acting, sculptures, choreography, or musical performances. For instance, *performance as research* is accepted within the arts [33.95], although it seems to be far from universal [33.96]. In the UK REF 2014, for example, artifacts, exhibitions, performances, compositions, designs, and visual media were treated as equivalent to journal articles [33.69]. A sample valid output from a high-scoring University of Manchester submission is the performance portfolio, *Reflecting on environmental change through site-based performance*, involving *Site-specific performances, in open air locations* in *Bradford* and *Bristol* [33.97]. One exhibition, part of the successful REF submission of the Courtauld Institute of Art, was *Devotion by Design: Italian Altarpieces before 1500* at the National Gallery. The context provided with this submission included:

> Devotion by design investigated ways in which altarpieces can be re-displayed to emphasise their original contexts despite being framed, literally and figuratively, by modern institutions. Additionally the exhibition presented research findings on the materiality and construction of these artefacts. [33.98]

The heterogeneity of artistic outputs makes the production of systematic data for evaluations difficult and even undesirable [33.99]. This issue is tackled by guidelines for evaluating funded arts and humanities research projects in the UK that emphasize a multiple methods approach [33.100]. Any kind of standardization of indicators can be undesirable because of the varied means through which art can influence people, sometimes in very personal and long-term ways [33.101]. Nevertheless, it seems reasonable to use an ad hoc range of methods to help evaluate artistic outputs. For example, a performance of a play might be assessed with the aid of audience numbers, contextual information about the nature of the audience (e. g., regular theater-goers versus new attendees), and the depth of the engagement with, and reaction to, the event. This information may be obtainable from questionnaires and a few in-depth interviews as well as (for larger performances) published press and academic reviews. Thus, the goal of arts evaluations may be to collect ad hoc data to help assess whether the work has had the intended effect [33.99].

Some artistic outputs can also be assessed with the aid of prestige-based indicators, such as the importance of the hosting gallery or theater or the awarding of national or international prizes relevant to the genre.

33.5 Websites

Websites may be created by academics to communicate with other scholars or the public (e. g., blogs). They may also be substantial engineering tasks to create a useful resource (e. g., digital archives).

33.5.1 Academic Websites

Researchers sometimes produce websites as an important means of communicating their ideas to a specific audience. In the UK REF 2014, websites were accepted as valid outputs, equivalent to journal articles [33.69], although both were subject to peer review for quality assessment. The work of individual scholars, research groups, departments, and institutions can also be promoted by their official websites and so a simple all-encompassing way to attempt to assess the overall impact would be to assess the popularity of the website. This basic idea led to the creation of the web impact factor (WIF), which is the number of hyperlinks pointing to a website divided by the number of pages in the website [33.102, 103]. This mimicked the Journal Impact Factor. Since hyperlinks to university websites are created for primarily academic-related reasons (including education), this seems to be a reasonable general indicator of scholarly impact [33.104–106].

It was easy to calculate this indicator for any website in the early years of the web using the hyperlink search commands of the search engines AltaVista, Microsoft Live Search and Yahoo!, but these have all now disappeared. The WIF was problematic because it penalized websites for creating many pages. If the denominator was replaced by a measure of the size of an institution then this produced a better indicator that correlated overall with the quality and amount of research produced by the institution [33.107]. Nevertheless, additional information is needed to help investigate the meaning of the link counts [33.108] so that the type of impact (if any) that they reflect can be identified.

There are several methods to assess the impact of a website other than the number of hyperlinks pointing to it. The most obvious is the number of visitors but this information is not generally shared by website owners. A practical alternative for large sites is the traffic volume ranking of Alexa.com [33.109], which gives an idea of a website's visitor traffic. It is only useful for large websites and cannot be used for subdomains of websites, such as for most individual departments and research groups. It is also possible to gather hyperlinks from part of the web, such as all universities in a single country, with a web crawler [33.107] but this is impractical for the whole web or very large websites. A practical alternative is the URL citation [33.110, 111]. This is a mention of the URL of one website in another. Thus, instead of counting the number of hyperlinks to a website, it is possible to count the number of times the website URL has been mentioned. This can be achieved by a simple search engine query. For example, to find pages mentioning any URL from the University of Wolverhampton (http://www.wlv.ac.uk/) the following Bing or Google query would work:

```
"wlv.ac.uk"
```

The query can be modified by adding an extra term to exclude pages from the University website, since these self-citations depend mainly on the size of the site.

```
"wlv.ac.uk" -site:wlv.ac.uk
```

This approach has the advantage that the data can be automatically gathered using search engine queries in Bing, such as via the Webometric Analyst free software, but the disadvantage is that there are far fewer URL citations than hyperlinks. For large websites, Bing queries return only a small fraction of the URL citations. This fraction is produced by a complex algorithm [33.24] and so the results need to be treated very cautiously. Partial solutions to the latter problem are possible by varying the search parameters to gain additional results previously hidden by Bing, either by varying the search market of a query [33.112] or by adding refining terms to generate derivative queries [33.113].

The problem that websites are typically cited by hyperlink or by name rather than by URL can be circumvented by querying Bing for mentions of the name of an organization rather than its website URL. This does not work well because many organizations have similar or derivative names and so name searches are not unique. The linked title mention method circumvents this problem through a two-stage approach, first searching for mentions of a website and then checking that the matching pages also contain a hyperlink to the relevant website [33.114].

In summary, it is possible to assess the overall impact of organizational websites as a method to assess their overall influence, combining that of their academics' standard and nonstandard outputs as well as their educational and other influences.

It may also be useful to evaluate academic-related websites on a smaller scale, such as at the level of departments, for formative evaluations or assessments of research areas. Investigations of research areas through their groups can help to identify patterns of development of new fields, as well as the relationship between key academic and nonacademic actors, at least online [33.115]. Moreover, whilst departmental or research group websites may not be often worth evaluating systematically as part of an assessment, an exception could be made when the research group's primary outputs are all nonstandard, such as in performance-based arts research areas and for institutes that generate resources to serve local industry, such as for some maritime research groups.

The websites or home pages of individual scholars could also be evaluated using URL citation counts or linked web mentions, but this again is presumably only useful in the case where an academic's reputation is their primary value and they do not have specific tangible outputs that can have their impacts assessed. Online impact assessment may be used in a formative mode to seek systematic gender, nationality, and other biases in online recognition, however [33.116]. This type of evaluation is difficult to conduct fairly because there are substantial differences in the extent to which academics engage with the web and social web [33.117, 118].

33.5.2 Digital Repositories

Digital repositories are important in some areas of scholarship. Whilst some commercial repositories have long been essential, such as newspaper archives, there have been many initiatives to digitize images, documents, maps, and other artifacts both as a means of preserving them and to reach a wide audience. Examples include the Lives of the First World War archive of photographs, letters, and other digital artifacts (livesofthefirstworldwar.org), the Internet Archive's moving image archive (archive.org/details/movies), and the British Library's historical British Newspaper Archive (http://www.britishnewspaperarchive.co.uk). Some universities, such as the UK's University for the Creative Arts (http://www.research.ucreative.ac.uk), also have specialist digital archives to record or document artistic outputs, including performances [33.119]. Digital repositories can be substantial outputs produced by teams of academics, librarians, and computer scientists and may even be their primary outputs over a period of years during the development phase.

Whilst a logical way to assess the value of a digital repository is by counting visitors or downloads, they are often too important to employ such a basic indicator [33.120]. Moreover, usage information is insufficient due to the lack of benchmarking data because usage data is rarely shared by repositories. Because of these problems a suite of methods has been recommended for evaluations. This should include usage data but also web citation data (e.g., URL citations) because these can be benchmarked against comparable repositories, if any. Interviews with end users, log file analysis, and content analyses of URL citations are recommended to get more detailed insights into the nature and depth of the value generated by each repository [33.121, 122]. Web citation data on comparable repositories can point to types of uses that are possible for the repository being evaluated, even if they are not occurring for it—in other words, missed opportunities [33.123]. Additional resource-specific methods may also be possible in some cases, such as reverse image lookup to find copies of images shared from image archives [33.94].

Fine-grained web server log file analyses may be helpful to discover more about a repository's visitors. Each user of a website must supply information about their location to the web server to communicate with it and this is routinely logged for monitoring purposes. Analyzing such web server log files can then reveal the origins of the visitors in broad terms, such as whether they are likely to be accessing from academic, governmental, personal, or commercial premises. Aggregating this information can point to the sectors of society in which a repository has the most impact, in addition to geographic information, such as country of origin [33.124]. This information is imperfect because a person's location does not necessarily reflect their activity type—such as people working from home—but can give deeper insights than simple usage data. This is helpful even for infrastructures that get extensively cited in formal academic publications because it can point to otherwise overlooked user groups [33.125].

Despite the proposals discussed above, it is easy to overlook the benefits of a repository for unknown user groups. Thus, there is an ongoing need to develop methods to give insights into the value of digital repositories—and other expensive research infrastructures [33.120].

33.5.3 Blogs

Blogs are simple websites that center on a collection of separate posts that are displayed in reverse chronological order. Many scholars maintain a blog to discuss aspects of their research. Whilst in many cases blogs are secondary outputs, some are widely read and reliably disseminate information to a large audience. Important blogs include The Impact Blog of the London School of Economics [33.126], which contains content mainly about social sciences research impact that has been authored by many different scholars, and *DC's Improbable Science*, a blog created by a single biochemist that claims over three million views and includes many discussions on science, including many attacks on bibliometrics and altmetrics [33.127]. If a blog is an important output of a scholar or group of scholars, then it would be useful to be able to evaluate its impact with the help of appropriate indicators.

Research blogs typically discuss published research and often focus on new journal articles that seem to be important, such as due to publication in a prestigious journal [33.128]. Their role is not just to discuss and evaluate research but also to translate it for a lay audience or nonspecialist researchers, particularly in the life sciences [33.129–132]. Blogs may reach a wider audience than the articles reviewed [33.133] because of these goals.

Although there is much research about blogs [33.134], there do not seem to have been systematic studies of blog impact, other than individual case studies [33.135]. The logical choice for a blog impact indicator is the number of visitors or the number of page views. One UK REF case study reported [33.136]:

> An outreach campaign has communicated SCCS's (School of Contemporary Chinese Studies) economic research to a broader audience. Yao's blog [h], first launched in April 2010 by Beijing-based finance and economics publication Caijing, has now attracted more than a million hits.

And from another [33.137]:

> Butterworth's *Life and Physics* blog [] attracts a sustained average of about 50 000 unique visitors a month, with peaks of around 20 000 a day for key posts at key times.

Thus, despite the absence of benchmarks and supporting scientometric research, simple blog indicators are being used to help demonstrate the impact of blogs as nonstandard research outputs.

33.6 Documentary Outputs

Whilst journal articles, conference papers, and books are discussed elsewhere in this volume and may naturally be evaluated with traditional citation indexes, grey literature and dissertations are important in some fields. Grey literature may target nonacademic audiences and so it is natural to seek online evidence of its impact. Dissertations may be important in the humanities when a thesis is not subsequently published as a monograph.

33.6.1 Grey Literature

The term grey literature refers to documents that are informally circulated online or offline rather than as an officially published book or as part of an edited volume, academic journal, or other recognized publication venue. Many grey literature documents are freely shared online in the form of PDF or Microsoft Word documents although they may also exist as web pages.

Grey literature is extensively cited in health research, including technical reports prepared by international organizations like the United Nations [33.138]. Traditional citation analyses can be conducted on grey literature, although the citation counts are not likely to be high. Google Scholar is an appropriate tool for this because it also indexes some grey literature [33.139], but perhaps not all [33.140]. Microsoft Academic is an alternative that allows automatic data collection [33.141]. Nevertheless, most technical reports of this type are not aimed at scholars and so academic citation counts would give a misleading impression of their level of uptake. In veterinary medicine, citations to the grey literature are common, accounting for about 6% of all journal article references (this figure includes conference papers as grey literature, accounting for half of the 6%), although the proportion varies substantially by specialism [33.142]. Excluding conference papers, most of the grey literature originated from governmental or commercial organizations. Research reports are also important in a policy context. A survey of senior UK civil servants found that they accessed academic expertise from these more often than from journal articles, books, or any other publication type [33.143].

Grey literature is an important output of some research organizations. A study of the outputs of a marine advisory body found that two thirds of its Web of Science citations were to its reports rather than its monographs and journal articles [33.144]. This shows that traditional citation analysis can give nontrivial results for some types of grey literature. In medicine and some other areas of research it is important to publish unsuccessful studies or those without statistically significant findings to ensure that future meta analyses and systematic reviews have findings that are unduly influenced by publication bias [33.145, 146].

Informally published documents can be posted anywhere on the web but scientific repositories offer enhanced visibility and long-term preservation. The preprint archive arXiv [33.147], for instance, contains many otherwise unpublished documents, as do RePEc (Research Papers in Economics; economics) and SSRN (Social Science Research Network; social sciences). Although these are discipline-based they still attract citations from outside of their home discipline [33.148] and can therefore be used for the wider dissemination of research. Whilst some reports in archives are rejected journal articles, others are research reports that were not designed for peer review. Unlike for arXiv, grey literature posted to FigShare has associated usage statistics within the site [33.61] that can be used to track impact. RePEc (Research Papers in Economics) has an extensive suite of statistics, including the h-index and others aggregated at the level of authors (and institutions) in addition to paper-level statistics. Author-level indicators with RePEc data are imperfect [33.149], for example due to missing citations, and so RePEc indicators should be used cautiously. RePEc also includes measures to detect and exclude manipulation and so its data is probably more robust than that of most other repositories [33.150]. At the time of writing, for each uploaded paper, SSRN (Social Science Research Network) provided the number of downloads and abstract views as well as the rank within the repository based on the download count (for an alternative ranking, [33.151]). Thus, if authors wish to track the impact of their informally published reports, then it would help to deposit them in a place that tracks their usage.

An alternative strategy, and a method to obtain deeper insights into the use of grey literature, is the Web impact report (WIRe) [33.152]. This includes a range of types of online impact evidence for a collection of grey literature and benchmarks it against similar sets produced by other organizations. The basic method to identify online impact evidence is a web citation search. This is a commercial search engine query for each document by name and author to identify how often it has been cited online. The use of web searches rather than Scopus of WoS citations stems from the assumption that much grey literature targets wider audiences than publishing academics. Thus, Googling with the query below would match web pages mentioning the NatPaCT leaflet *Ten Steps to SMART objectives*.

```
"Ten Steps to SMART objectives
natpact"
```

The query below is an improvement by excluding self-citations.

```
"Ten Steps to SMART objectives
natpact" -site:natpact.info
```

This gives a simple web citation count for each document. The citing URLs can then be broken down by top-level domain (TLD) and the national TLDs (e. g., .uk, .de) would give evidence of international spread. A parallel content analysis of the citing pages is recommended to give deeper evidence about who was using the grey literature documents and how they were using it. The use of web citations from search engines is limited by the partial web coverage of search engines, as discussed above, but also because grey literature documents may be cited informally online. Informal citations may omit the author, shorten the document name, or even just describe it as a report from a given organization.

33.6.2 Dissertations

The PhD thesis is a nonstandard academic output in the sense discussed here, although produced by most academics at the start of their careers. The thesis is a book-like document (see the chapter on book impact assessment) and theses may contain material that is not otherwise published. Although science PhDs may attempt to publish their key findings in journal articles, humanities scholars may turn their dissertations into monographs, and some countries require PhDs to be published as books (e. g., by university presses), it still seems likely that this is not the general rule. Thus, especially for junior scholars, it may be useful to attempt to assess the impact of their dissertations. The increasingly common institutional requirement to publish dissertations electronically online [33.153] help evaluations by publicizing them online and simplifying access.

The quality of dissertations or the success of the scholars that produced them may be outputs for the main supervisors [33.154]. Whilst numbers of successful PhD supervisions are already seen as valid outputs in some research assessment exercises (e. g., New Zealand, UK), academics may list individual students supervised in their CVs for more fine-grained evidence. Evidence from library and information science suggests that successful doctoral student mentoring is a dimension of scholarship that is not well reflected by citation counts and is therefore valuable to assess separately [33.155].

The primary audience of most dissertations is probably other scholars from the same field, rather than any section of the wider public. Dissertations are long documents that need to satisfy examiners and are likely to be complex and difficult for nonspecialists to read. Thus, traditional citation counts are the logical choice of indicator for theses. Nevertheless, the similarity between theses and books and the scholarly connection in some fields [33.156, 157] suggest that citations from books (via Google Books, Scopus, or WoS) should be obtained in addition to citations from journal articles, if possible. The ProQuest dissertation database gives an additional source of impact evidence for the theses indexed in it. It originates from the USA but has international coverage and tracks the usage of the dissertation in its collection [33.158].

33.7 Reputation

An important aspect of a scholar's profile is their reputation inside and outside of academia. This can be thought of as a nonstandard output of their scholarly work. The h-index is an obvious (but flawed) reputation indicator, and is covered in another chapter.

Reputation can be assessed informally or with the aid of a CV that lists ad hoc indicators of prestige. These may include invitations to give talks and keynote presentations, as well as editorial positions and awards [33.159, 160]. Invitations can apply to all levels of achievement. Even a PhD student might get asked to talk to a departmental seminar, for instance. Depending on the field of scholarship, an academic might be asked to exhibit their work in a prestigious venue, accept a valued national training role, speak on radio or television, or give evidence to a parliamentary select committee. Scholars may also apply for prestigious roles, such as association president or committee chair.

Reputation could also be assessed by counting links to an academic's home page or by measuring their followers in sites that they use. This would be unfair for sites like Twitter, that often combine social and informational elements [33.161]. Whilst Academia.edu and ResearchGate are both natural places to evaluate reputation [33.162], not all academics use these sites with some disciplines being more active users than others and newer articles being more likely to be registered [33.163]. The usage and reputation scores in these academic sites probably reflect use of the site to a large extent, rather than overall reputation [33.164]. There is evidence of ResearchGate scores for individuals primarily reflecting activity within the site rather than external evidence of success, for example [33.165–167]. Like Twitter, these sites can merge personal and professional interactions [33.165, 168]. Nevertheless, reputation in Academica.edu seems to be primarily driven by academic rather than personal factors [33.169], although more evidence is needed to confirm this and it might change over time as the users and uses of the site evolve. At the institutional level, ResearchGate scores seem to reflect university rankings from other sources, although there are big national differences in uptake for the site [33.170].

Influence is like reputation because an influential academic would presumably have a good reputation and a highly regarded scholar would have the potential to be influential. There has been much research to develop methods to assess influence in social media [33.171], for example as reflected in the likelihood that someone's tweets get extensively retweeted. Although this type of influence does not seem to be widely recognized as a useful academic contribution, it may be a useful indicator of reputation. Thus, academics in the future might like to quantify their (relevant) social media influence to claim an online reputation. A similar concept is *authority* in the sense of being a recognized source of information on a given topic. This too can be quantified online [33.172].

One study analyzed speaking fees charged by some scholars, finding (indirect) evidence that this is a reasonable indicator of their reputation outside of academia and that this is probably not directly influenced by their reputation inside academia [33.86]. Thus, speaking fees could be an indicator of the societal reputation of scholars, although only for the minority that charge them, and this information is not available online.

A more general way to assess the reputation of individual academics is to count how often they have been mentioned on the web, perhaps filtering out self-mentions from their host institutions and publications [33.173]. Depending on the scholar, such online mentions may include media coverage, conference presentations, and invited talks. The main drawback is that human names are rarely unique and so extensive manual filtering would be needed for most individuals and searching the web for mentions of some scholars, such as any of the computer scientists called Michael Jackson, would be very difficult. Nevertheless, in some arts and humanities fields, reputation is the main (intangible) output of some scholars and so counts of web mentions could help in their evaluations.

33.8 Summary: The Importance of Context

As should be evident from the different sections of this chapter, the many different types of output produced by scholars can make contributions either directly to scholarship or to the wider goals of science, including infrastructure and outreach or dissemination activities. Some are the main products of the scholars concerned and without effective ways to evaluate their contribution to academia the researchers are likely to be undervalued and marginalized within science. Currently, most of these activities are probably evaluated only through peer judgement in appointment, promotion, and funding decisions and it would be helpful to be able to provide some form of supporting quantitative data.

Quantitative indicators to support evaluations of nonstandard academic outputs rarely include traditional citation counts because most of the outputs discussed here are not likely to be cited in the academic literature. The main exception is the dissertation, and, to some extent the grey literature, but there is also an increasing move to encourage the formal citation of datasets and software. For most other types of output, usage data, when available, or web citation counts (i. e., counts of how often they have been mentioned online) are reasonable substitutes. They can also be additional sources of evidence for artifacts that are traditionally cited by revealing nonacademic uses that generate web citations.

Except for dissertations, interpreting the numbers generated by web citation or usage data is difficult. The variety of types of output, audience size, and intended purpose make it hard to benchmark scores to judge them high or low unless the numbers are extreme enough for this to be self-evident. An important issue here (discussed explicitly for UK REF case studies) is that both depth and breadth of engagement are desirable [33.174], so the exact number of uses may not reveal the amount of impact. A resource could be used by many people for trivial purposes or extensively by a small group of specialists that rely upon it for their work. Thus, in most cases the solution is to provide context to the numbers. The most natural way to do this—and again often evident in REF impact case studies and recommended in the ACUMEN portfolio—is to include a narrative that makes an explicit claim for a type of impact and then uses multiple sources of quantitative and qualitative evidence to back up that claim.

A generic problem for most online indicators is that they are easily manipulated, either accidentally or deliberately, and are therefore difficult to rely upon in formal evaluations. Thus, if they are reported for formal evaluations (e. g., end of project reports), then evaluators should not take them at face value but should critically analyze their reliability and look for multiple sources of evidence (as mentioned above) and their own common sense to cross-check and assess the credibility of any claim. Honesty declarations may also help.

For high-value resources, such as digital repositories or grey literature collections that are major outputs from an organization, it may be feasible to go further than gathering numbers by using complementary approaches, such as a human content analysis of citing sources or user interviews and questionnaires to get deeper insights into the users and uses. This may take the form of using a formal digital toolkit or an ad hoc collection of discipline-specific [33.23] or appropriate generic methods.

As a final warning, although the use of indicators for nonstandard outputs is a positive step towards recognizing diverse contributions to academia, there are informal contributions that are too difficult to quantify in practice, such as informal mentoring [33.175] and any systematic use of indicators should be aware of the likelihood of introducing biases, including probably gender biases, against those who conduct activities with impacts that are difficult to record.

Despite the studies discussed here, evaluating nonstandard outputs is an under-researched area within scientometrics and in the increasing culture of evaluating academics for their scholarly activities the lack of adequate research risks a situation in which researchers may avoid types of activity for which they will not be recognized. This has been alleviated to some extent in the UK by the mandatory REF impact case studies [33.176], which almost require research groups to engage outside academia and to consider nonstandard outputs, but it is nevertheless a potential threat to the smooth working of science on a global scale.

34. Information Technology-Based Patent Retrieval Models

Carson Leung, Wookey Lee, Justin Jongsu Song

This chapter presents information technology (IT) based patent retrieval models. It first compares and contrasts information retrieval (IR) with patent retrieval, and highlights their key differences. For instance, IR can be considered as a precision-oriented retrieval, whereas patent retrieval can be considered as a recall-oriented retrieval. The chapter then describes the boolean retrieval model, which was designed for IR but can be used for patent retrieval. To facilitate effective patent retrieval, a basic patent retrieval model is presented. With this model, representative keyword terms are extracted from the user query and are ranked according to their importance so that top-*k* relevant patents can be retrieved with irrelevant patents eliminated. Moreover, the chapter also presents some enhancements and extensions to the basic patent retrieval model, which include incorporation of relevance feedback, estimation of the importance of keyword terms, text preprocessing of patent documents, and handling of patent category frequency. In addition, two dynamic patent retrieval models are also described. These two models perform interactive patent retrieval via dispersion or accumulation to dynamically rank the patents. Experimental results with real-life datasets show that the models presented in this chapter outperformed many conventional search systems with respect to time and cost. While this chapter focuses on the theoretical aspects of IT based patent retrieval models which are of interest to IT specialists, practical illustrative examples in the chapter demonstrate the empirical aspects of patent retrieval models which are helpful to IT practitioners.

34.1 Patent Retrieval Versus Information Retrieval

With scientific and technological advances, *intellectual property* (IP) has attracted worldwide attention from both qualitative and quantitative points of view. Data are of such a large scale that practitioners face unprecedented challenges collect and analyze the IP information which is relevant to their daily tasks. As science and technology indicators, *patents* have played crucial roles to defend and protect the IP of inventors for their individual innovations and/or innovations in high-tech corporations, institutes, organizations and traditional industries. This is noticeably apparent through the tremendously increasing number of patent activities in recent years. For example, according to the United States Patent and Trademark Office (USPTO) [34.1], more than 576 000 patents were filed in calendar year 2012, which was approximately 160% greater than the number in 2002. The number further increased to near 630 000 filed patents in calendar year 2015, which included more than 589 000 utility patent applications (with US origin and foreign origin), more than 39 000 design patent applications, and more than 1000 plant patent applications (Fig. 34.1). This number is expected to be higher for the current calendar year. Moreover, the number of patents filed to other offices—such as the Canadian Intellectual Property Office (CIPO), the European Patent Office (EPO), the Japan Patent Office (JPO), the Korean Intellectual Property Office (KIPO), and the State Intellectual Property Office (SIPO) of China—also keeps growing.

With this increasing number of patents stored in databases, it becomes almost infeasible for a patent examiner to identify all the relevant patents without utilizing a special methodological power. In addition, as the patent portfolio grows, knowledge discovery in patent databases also becomes imperative. Moreover, these patent databases are very useful in many aspects. For instance, they can be used for measurement of technological performance such as science and technology indicators for performance assessment in research and development (R&D). Hence, quantitative methods, statistics and indicators built upon patent data that are relevant for studies of R&D systems are in demand.

Currently, most of those who search patents do so by applying one of the following techniques:

- A self-classification code system for a domestic domain
- The International Patent Classification (IPC) rule [34.2].

However, these search techniques have severe limitations in obtaining desirable searching outputs. For instance, prevailing patent search engines usually include too many unrelated results. Consequently, with high volumes of unrelated results, patent experts have to spend lots of time on manually refining the results.

Generally, there are fundamental differences between patent search and general information retrieval (IR) [34.3]. In high-level abstract terms, general IR can be considered as a *precision-oriented retrieval*, which focuses more on precision than recall. In contrast, patent search can be considered as a *recall-oriented retrieval*, which focuses more on recall than precision.

Note that *precision* measures the fraction of retrieved instances that are relevant

$$\text{Precision} = \frac{\text{Relevant retrieved instances}}{\text{Retrieved instances}} . \tag{34.1}$$

Precision is sometimes known as *positive predictive value* (PPV), which is the fraction of true positives (TPs) among all *outcome positives* including TPs and

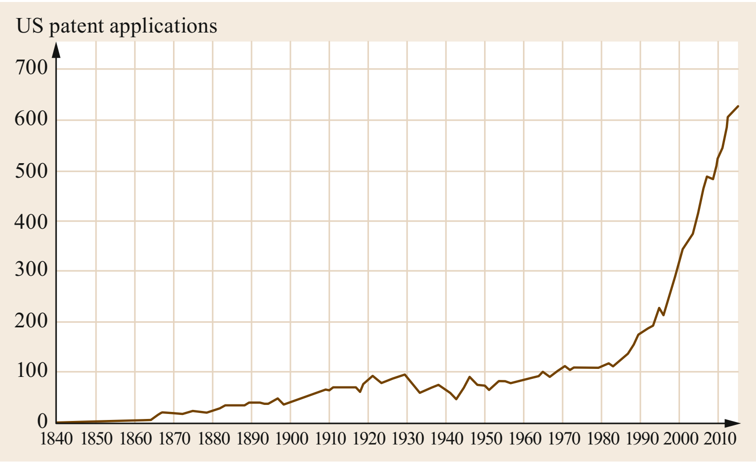

Fig. 34.1 Annual US patent statistics: Annual sum (in thousands) of all utility patent applications with US origin and foreign origin, design patent applications, and plant patent applications for the period 1840–2015 based on the USPTO statistics (after [34.1])

false positives (FPs)

$$\mathrm{PPV} = \frac{\mathrm{TPs}}{\mathrm{TPs} + \mathrm{FPs}} , \quad (34.2)$$

where outcome positives (i. e., TPs + FPs) are instances that are identified as *positive* outcomes regardless of whether they are correctly identified as positives (i. e., TPs) or incorrectly identified as positives (i. e., FPs). In other words, a FP is a *false alarm* or *Type-I error*. In the context of general retrieval:

1. Outcome positives are retrieved instances
2. TPs are relevant retrieved instances
3. FPs are irrelevant retrieved instances.

In contrast, *recall* measures the fraction of relevant instances that are retrieved

$$\mathrm{Recall} = \frac{\text{Relevant retrieved instances}}{\text{Relevant instances}} . \quad (34.3)$$

Recall is sometimes known as *sensitivity* or *true positive rate* (TPR), which is the fraction of TPs among all *condition positives* including TPs and false negatives (FNs)

$$\mathrm{TPR} = \frac{\mathrm{TPs}}{\mathrm{TPs} + \mathrm{FNs}} , \quad (34.4)$$

where condition positives (i. e., TPs + FNs) are instances with positive conditions regardless whether they are positive instances that are correctly identified (i. e., TPs) or positive instances that are incorrectly rejected/ignored (i. e., FNs). In other words, a FN is a *miss* or *Type-II error*. In the context of general retrieval:

1. Condition positives are relevant instances
2. TPs are retrieved relevant instances
3. FNs are missed/ignored relevant instances.

The purpose of a patent search is different from general IR. A conventional *general IR* from the news or the web aims to achieve high precision. For instance, when conducting a news search or a web search, users are keen on finding the answer to their query as quickly as possible and within the top-ranked list. Otherwise, they reformulate the query. In other words, users want to find one or a few relevant documents at the top of the ranked list that satisfy their need. In contrast, a *patent search*—or recall-oriented retrieval in general—aims to achieve high recall. For instance, when conducting a patent search, patent examiners need to work through the ranked list to identify all relevant patents before they stop and reformulate the query. Similarly, when conducting a legal search, lawyers or legal officers need to work through a ranked list to find every piece of evidence related to the case at hand from the documents that are under legal holds before they stop and reformulate the query. In similar situations, scientists do not want to miss any important prior works related to their ongoing research, so they examine the ranked list to find all relevant works before they stop and reformulate the query. In these three instances, users of recall-oriented retrieval such as patent search are professional experts in the field of search, and they want to find all possible relevant documents within a ranked list. In other words, users are keen on finding as many as possible, if not all of, the relevant documents that satisfy their needs. In real life, a patent examiner typically checks hundreds to thousands of documents in the result list to locate all possible relevant documents [34.4]. Finding relevant documents at the top of the list remains a desirable feature in recall-oriented retrieval, because this may reduce the retrieval effort. However, the key objective is to retrieve all the relevant documents while trying to minimize the number of documents to be checked.

The most frequently used measures for general IR search assessment are *precision* and *recall*, as defined in (34.1) and (34.3), respectively. In an extreme case, to achieve high precision (at a price of low recall), a system could retrieve a single relevant instance without attempting to retrieve some or all relevant instances. This leads to a precision value of 1 but a very low recall value, especially when the number of relevant instances is high. To elaborate, let $d_1, \ldots, d_n$ be n relevant instances. Without loss of generality, let d_1 be the only relevant instance retrieved by the system. Then, the precision value of this search is $1/1 = 1$ according to (34.1), but the corresponding recall value according to (34.3) is $1/n$ which becomes very low for a high number n of relevant instances. Hence, such a high-precision (but low-recall) system is suitable for real-life applications in which users just want to retrieve a relevant instance satisfying the user queries.

However, there are many other real-life applications in which users want to retrieve as many relevant instances as possible that satisfy the user queries. An example of such applications is patent search, which calls for high-recall systems. In an extreme case, to achieve high recall (at a price of low precision), a system could retrieve all instances without attempting to distinguish which ones are relevant and which ones are not. This leads to a recall value of 1 but a very low precision, especially when the number of retrieved instances is high. To elaborate, let $d_1, \ldots, d_n$ be n instances retrieved by the system. Without loss of generality, let $d_1, \ldots, d_q$ be q relevant retrieved instances (where $q \leq n$). If the system retrieves all q relevant instances together with additional $(n - q)$ irrelevant instances, then the recall value of this search is $q/q = 1$ according to (34.3), but the corresponding precision value according to (34.1) is q/n which becomes very low for a high number n (where $q \ll n$) of retrieved instances. A potential problem of using such a high-recall (but low-precision) system is that it may retrieve numerous instances, out of which many are irrelevant. These irrelevant retrieved instances are considered as *noise*. The noise may force users to spend lots of time on refining the search or on finding relevant instances from a haystack of irrelevant instances.

To assess a retrieval system that does not go to these extreme cases and maintains a good balance of both precision and recall, an *F-score* (F_1) can be used for a fixed number of retrieved documents [34.5]

$$F_1 = \frac{2 \times \text{precision} \times \text{recall}}{\text{precision} + \text{recall}} . \tag{34.5}$$

As the F_1 score is designed for classification tasks rather than recall-oriented retrieval in general (or patent search in particular), the same recall value—and thus the same F_1 score—may be obtained when retrieving n documents from two systems in which relevant documents are retrieved in one system earlier than another. For example, suppose there are 11 relevant instances. System 1 retrieves seven instances out of which the first three are relevant; system 2 also retrieves seven instances out of which the last three are relevant. Then, the recall value and F_1 score for system 1 are $3/11$ and

$$\frac{2 \times \frac{3}{7} \times \frac{3}{11}}{\frac{3}{7} + \frac{3}{11}} = \frac{1}{3}$$

respectively, which yield the same recall value and F_1 score for system 2.

As an enhancement, when assessing recall-oriented retrieval or patent search, more emphasis should be focused on the *recall* value. Hence, F-score can be modified to measure a weighted combination of *average precision* (AP) [34.6] and recall. The AP is the mean of the precision values after each relevant instance is retrieved

$$AP = \frac{\sum_k P(k)}{\text{Relevant retrieved instances}} , \tag{34.6}$$

where $P(k)$ is the precision for *k relevant instances*. It measures the precision at r, denoted as $P@r$, where r is the rank of k-th relevant retrieved instance: $P@r = k/r$, which indicates that k of the r retrieved instances are relevant. In other words, $P(k)$ captures the minimum number of instances that need to be retrieved in order to obtain k relevant instances

$$P(k) = \frac{k \text{ relevant retrieved instances}}{\min \#\text{retrieved instances for } k \text{ relevant ones}} . \tag{34.7}$$

For example, suppose system 1 retrieves seven instances, out of which the first three are relevant. Then, the AP for system 1 is

$$\frac{\frac{1}{1} + \frac{2}{2} + \frac{3}{3}}{3} = 1 ,$$

because the first relevant instance is obtained after retrieving one instance, the first two relevant instances are obtained after retrieving two instances, and the first three relevant instances are obtained after retrieving three instances. In contrast, suppose system 2 also retrieves seven instances, out of which the last three are relevant. Then, the AP for system 2 is lower than that for system 1. Specifically, the AP for system 2 is

$$\frac{\frac{1}{5} + \frac{2}{6} + \frac{3}{7}}{3} = \frac{101}{315} < \frac{1}{3} ,$$

because the first relevant instance is obtained after retrieving five instances, the first two relevant instances are obtained after retrieving six instances, and the first three relevant instances are obtained after retrieving seven instances.

With the definition of AP, the computation of F-score can be modified as follows

$$F'_\beta = \frac{(1+\beta) \times \text{AP} \times \text{recall}}{\beta \times \text{AP} + \text{recall}} , \tag{34.8}$$

where β is the weight of recall to precision. With the computation of F'_β score, two systems that retrieve the same relevant documents would give the same recall value and F_1 score. However, the system that retrieves relevant documents earlier would give a higher F'_β score (where $\beta > 1$) than the one that retrieves relevant documents later. For example, suppose there are 11 relevant instances. System 1 retrieves seven instances out of which the first three are relevant; system 2 also retrieves seven instances out of which the last three are relevant. Then, the recall value and F_1 score for system 1 are $3/11$ and

$$\frac{2 \times \frac{3}{7} \times \frac{3}{11}}{\frac{3}{7} + \frac{3}{11}} = \frac{1}{3}$$

respectively, which are the same recall value and F_1 score for system 2. However, the AP for system 1 is

$$\frac{\frac{1}{1} + \frac{2}{2} + \frac{3}{3}}{3} = 1 ,$$

which is higher than the AP for system 2 with a value of

$$\frac{\frac{1}{5} + \frac{2}{6} + \frac{3}{7}}{3} = \frac{101}{315} < \frac{1}{3} .$$

Thus, the F'_β score for system 1 is higher than that for system 2 (where $\beta > 1$).

34.2 Boolean Retrieval Model

Patent retrieval is one of the main activities carried out in patent offices. It checks the novelty of patent applications for the filed inventions. For many years, the boolean search has been a common approach used for finding relevant patents and documents that can invalidate the novelty of a patent application. Although this approach is very exhaustive and time consuming, interactive boolean search remains the search technique preferred by patent examiners because it is reproducible [34.4]. Here, *reproducibility* of patent retrieval means that the retrieval system will always give the same results for the same query each time. Having reproducible retrieval results is an essential criterion for patent examiners to defend their decisions about the novelty of patents.

To elaborate, as the boolean search is reproducible, it gives the same results for the same query—even when irrelevant documents are added to the document collection. Of course, the search may give a different result when relevant documents are added to the document collection. Note that a reproducible search is different from a probabilistic search, which may give a different result even when irrelevant documents are added to the document collection.

34.2.1 Extended Boolean Retrieval Model

Many existing patent retrieval systems originate from the boolean model [34.4, 7–9], which returns all the patent documents if any search keyword in the query is included. The query can be extended by applying boolean operators (e. g., AND, OR, NOT) on the keywords in the query. As an addition to the patent retrieval systems like USPTO, several quantifiers—such as AND, OR, NEAR, and NOT—are added to form an *extended boolean model*. On the one hand, the search results are reduced when the query is restrained with AND operators (i. e., when the number of AND operators is increased in the query). On the other hand, the search results are increased when the query is relaxed with OR operators (i. e., when the number of OR operators is increased in the query).

Moreover, although both the boolean retrieval model and its extended boolean retrieval model are commonly used for both IR and patent retrieval due to their reproducibility, they can be time-consuming. For precision-oriented tasks like IR, as the focus is on retrieving the top few relevant results, the high runtime complexity may not be a big concern. However, it becomes a big concern for recall-oriented tasks like patent searches because the focus is on retrieving all relevant results. Hence, it is desirable to have a model designed for (recall-oriented) patent retrieval, which focuses on retrieving all relevant patents.

34.3 Basic Patent Retrieval Model

When the number of searched patents increases, the amount of both valid data (i. e., relevant patents) and noise data (i. e., irrelevant patents) examined by the boolean retrieval model also increases. Consequently, it may take a lot of time to eliminate the noise from the valid candidate set. Knowing that the number of patents to be searched can be reduced once the recall is satisfied, the amount of noise data can be eliminated, and thus the possibility of losing valid data can also be reduced. So, noise elimination has become important for any patent retrieval model [34.10]. This section describes key phases of a basic patent retrieval model that finds the top-k valid answers (i. e., relevant patents) and eliminates noise (i. e., irrelevant patents).

34.3.1 Extraction of Representative Terms

As patent search queries consist of many keywords (e. g., hundreds of terms) and need thorough investigation of the results, a patent search usually takes much more time than a conventional general IR search from the web. A key success factor for a patent search relies on the selection of good search keywords. The keyword selection phase identifies the importance of the terms on which a proper weight needs to be assigned. One way to extract representative keyword terms is to model the term distribution of a patent query. By doing so, a detailed representation of the patent query can be obtained.

34.3.2 Ranking of Extracted Terms Based on Term Frequency

After extracting the representative keyword terms from the user query and a collection D of patent documents, the next phase is to rank these terms according to their importance. In the context of patent search, the quality of a search is influenced by the distribution of keyword terms. Note that there are two kinds of distribution for keyword terms:

- Absolute distribution
- Relative distribution.

The *term frequency* (tf) of a keyword t_i in a patent document d_j measures the absolute or relative word count $\mathrm{tf}(t_i, d_j)$ of t_i in d_j. It can be obtained by using keyword term measurements like the *term frequency-inverse document frequency* (TF-IDF). More specifically, the *absolute* term frequency of a keyword t_i in a patent document d_j measures the word count $\mathrm{tf}(t_i, d_j)$ of t_i in d_j, whereas the *relative* term frequency of a keyword t_i in a document d_j measures the ratio of the word count of t_i in d_j to the total number of words in d_j, i. e.,

$$\frac{\mathrm{tf}(t_i, d_j)}{\sum_{t_h} \mathrm{tf}(t_h, d_j)} .$$

Consider a set $D = \{d_1, d_2, \ldots, d_n\}$ of n patent documents. Any document $d_j = \{t_1, t_2, \ldots, t_m\}$ of these n documents contains m keyword terms (where $1 \le j \le n$). Then, the keyword weight distribution $\mathrm{KWD}(d_j)$ of a document d_j (where $1 \le j \le n$ documents in D), which is the distribution among the fully-qualified keywords from d_j, is defined as a product of the keyword weights $\mathrm{KW}(t_i, d_j)$ for all m terms in document d_j

$$\mathrm{KWD}(d_j) = \prod_{i=1}^{m} \mathrm{KW}(t_i, d_j) , \tag{34.9}$$

where $1 \le i \le m$ terms in d_j. Here, the keyword weight $\mathrm{KW}(t_i, d_j)$—which is also known as *cardinality*—of a term t_i contained in a document d_j can be computed as follows

$$\mathrm{KW}(t_i, d_j) = \frac{1}{1 + \mathrm{e}^{-\frac{\mathrm{tf}(t_i, d_j)}{10}}} , \tag{34.10}$$

such that (a) $1 \le i \le m$ terms in d_j and (b) $1 \le j \le n$ documents in D. Note that, in order not to weight too heavily on the term frequency of keyword term t_i, a sigmoid function $f(x) = 1/(1 + \mathrm{e}^{-x})$ can be used (where $x \ge 0$).

Based on the definition of keyword weight $\mathrm{KW}(t_i, d_j)$ in (34.10), when keyword term t_i appears very rarely in document d_j (i. e., a very low $\mathrm{tf}(t_i, d_j)$), the corresponding keyword weight $\mathrm{KW}(t_i, d_j)$ approaches $1/(1 + 1) = 0.5$. On the other hand, when keyword term t_i appears very frequently in d_j (i. e., a very high $\mathrm{tf}(t_i, d_j)$), the corresponding keyword weight $\mathrm{KW}(t_i, d_j)$ approaches $1/(1 + 0) = 1$. Hence, the range of $\mathrm{KW}(t_i, d_j)$ is in the range of $[0.5, 1]$.

Then, since keyword weight distribution $\mathrm{KWD}(d_j)$ is defined in (34.9) as the product of $\mathrm{KW}(t_i, d_j)$ over all m terms in a document d_j, the value of $\mathrm{KWD}(d_j)$ can range from $(0.5)^m$ to 1^m. When keyword term t_i appears very rarely in d_j (i. e., a very low $\mathrm{tf}(t_i, d_j)$) for many of the m terms (where $1 \le i \le m$), the corresponding $\mathrm{KWD}(d_j)$ approaches $(0.5)^m$, which approximately converges to 0 for a very large number m of keyword terms. On the other hand, when keyword term t_i appears very frequently in d_j (i. e., a very high $\mathrm{tf}(t_i, d_j)$) for many of the m keyword terms, the corresponding $\mathrm{KWD}(d_j)$ approaches $1^m = 1$. Hence, the range of $\mathrm{KWD}(d_j)$ is approximately $(0, 1]$.

34.3.3 Retrieval of Top-k Answers with Elimination of Noise by the Patent Threshold Algorithm (Patent TA)

After extracting the representative keyword terms and ranking these extracted terms based on their keyword weight distribution (which shows the importance of the keyword terms), the next phase is to retrieve the top-k answers (i. e., relevant instances) to user query q while eliminating noise (i. e., irrelevant instances). Specifically, for m keyword terms in n documents, a total of m lists are created. A list L_i of length n is created for each keyword t_i for $1 \le i \le m$. The j-th entry (where $1 \le j \le n$) in the list L_i captures the keyword weight $\mathrm{KW}(t_i, d_j)$ of t_i in document d_j. Entries in each list are then sorted in descending order of their keyword weights.

The patent retrieval process starts with the top entry in each of these m sorted lists (i. e., the highest keyword weight of each t_i for $1 \le i \le m$). Set a new threshold τ for the patent retrieval and noise elimination process to be the lowest keyword weight among the m keyword weights at the tops of these lists. For each document d_y appearing at the top of these lists find its lowest keyword weight within d_y (i. e., $\min_{1 \le i \le m} \mathrm{KW}(t_i, d_y)$). If such a lowest keyword weight in d_y meets or exceeds τ (i. e., $\min_{1 \le i \le m} \mathrm{KW}(t_i, d_y) \ge \tau$) implying that all m keyword weights within d_y meet or exceed τ (i. e., $\mathrm{KW}(t_i, d_y) \ge \tau$ for all $i \in [1, m]$), then d_y is chosen as one of the top-k answers to user query q. Otherwise, keep such a lowest keyword weight in d_y for future consideration, and continue with the next keyword weight on each of the m sorted lists.

Afterwards, set a new threshold τ for the patent retrieval and noise elimination process to be the lowest keyword weight among these m keyword weights (i. e., second highest keyword weights on these m lists). For each document d_y appearing at the new top of these lists, find its lowest keyword weight within d_y. If such a lowest keyword weight in d_y meets or exceeds τ, then d_y

is chosen as one of the top-k answers to user query q. Otherwise, repeat this process until all top-k answers are found and returned to the user. This patent retrieval process is called the *patent threshold algorithm* (*patent TA*). A benefit of using this patent TA is that it can find the top-k answers without examining the entire $m \times n$ list entries.

34.3.4 An Illustrative Example of the Basic Patent Retrieval Model

As an illustrative example, consider a practical situation where the user would like to search patents about service robots for vacuum cleaning. Table 34.1 shows the keyword term frequencies based on $m = 2$ keyword terms (`service robot`, `vacuum cleaning`) extracted from $n = 4$ sample documents (d_1, d_2, d_3 and d_4). Here, keyword term t_1 = `service robot` appears 80, 60, 30 and 40 times in d_1, d_2, d_3 and d_4, respectively—i. e., $\mathrm{tf}(t_1, d_1) = 80$, $\mathrm{tf}(t_1, d_2) = 60$, $\mathrm{tf}(t_1, d_3) = 30$ and $\mathrm{tf}(t_1, d_4) = 40$. Keyword term t_2 = `vacuum cleaning` appears 70, 50, 90 and 20 times in d_1, d_2, d_3 and d_4, respectively. Hence, keyword weights of these two terms in the four documents can be computed using (34.10). For instance,

$$\begin{aligned}
&\mathrm{KW}(t_1, d_1) = 0.9997\,, && \mathrm{KW}(t_1, d_2) = 0.9975\,,\\
&\mathrm{KW}(t_1, d_3) = 0.9526\,, && \mathrm{KW}(t_1, d_4) = 0.9820\,,\\
&\mathrm{KW}(t_2, d_1) = 0.9991\,, && \mathrm{KW}(t_2, d_2) = 0.9933\,,\\
&\mathrm{KW}(t_2, d_3) = 0.9999\,, \quad \text{and} && \mathrm{KW}(t_2, d_4) = 0.8808\,,
\end{aligned}$$

as shown in Table 34.2.

Table 34.1 Sample keyword term frequencies for a patent search on `service robots for vacuum cleaning` with the basic patent retrieval model

$\mathrm{tf}(t_i, d_j)$	t_1 = `service robot`	t_2 = `vacuum cleaning`
Document d_1	80	70
Document d_2	60	50
Document d_3	30	90
Document d_4	40	20

Table 34.2 Keyword weights for the sample keyword term frequencies in Table 34.1 for a patent search on `service robots for vacuum cleaning` with the basic patent retrieval model

$\mathrm{KW}(t_i, d_j)$	t_1 = `service robot`	t_2 = `vacuum cleaning`
Document d_1	0.9997	0.9991
Document d_2	0.9975	0.9933
Document d_3	0.9526	0.9999
Document d_4	0.9820	0.8808

To retrieve the top-2 answers (i. e., top-2 patent documents) with noise elimination, documents are ranked in descending order of their keyword weights. Specifically, the sorted list L_1 for keyword term t_1 contains $\langle d_1, 0.9997\rangle$, $\langle d_2, 0.9975\rangle$, $\langle d_4, 0.9820\rangle$, then $\langle d_3, 0.9526\rangle$. Similarly, the sorted list L_2 for keyword term t_2 contains $\langle d_3, 0.9999\rangle$, $\langle d_1, 0.9991\rangle$, $\langle d_2, 0.9933\rangle$, then $\langle d_4, 0.8808\rangle$. Set a threshold τ to be 0.9997, which is the minimum of $\mathrm{KW}(t_1, d_1) = 0.9997$ and $\mathrm{KW}(t_2, d_3) = 0.9999$. For documents (i. e., d_1 and d_3) appearing at the top of these two lists L_1 and L_2, their corresponding lowest keyword weights $\mathrm{KW}(t_2, d_1) = 0.9991$ and $\mathrm{KW}(t_1, d_3) = 0.9526$ are found. As neither of these two weights meets or exceeds $\tau = 0.9997$, they are kept for future consideration.

Then, continue the patent retrieval process with the next entry on each of these two sorted lists, i. e., $\langle d_2, 0.9975\rangle$ on L_1 and $\langle d_1, 0.9991\rangle$ on L_2. Update τ to be 0.9975, which is the minimum of these two weights. The lowest keyword weight in d_2 is $\mathrm{KW}(t_2, d_2) = 0.9933$. Recall that the lowest keyword weight in d_1 (i. e., $\mathrm{KW}(t_2, d_1) = 0.9991$) was found earlier. Consequently, the current top-2 lowest keyword weights become $\mathrm{KW}(t_2, d_1) = 0.9991$ and $\mathrm{KW}(t_2, d_2) = 0.9933$ because $\mathrm{KW}(t_1, d_3) = 0.9526$ possesses a lower weight than these top-2 lowest keyword weights. Note that, as $\mathrm{KW}(t_2, d_1) = 0.9991 \geq \tau = 0.9975$, d_1 is returned as one of the top-2 answers. On the other hand, as $\mathrm{KW}(t_2, d_2) = 0.9933$ does not meet or exceed τ, it is kept for future consideration.

In a similar fashion, the next entries on these two sorted lists are $\langle d_4, 0.9820\rangle$ on L_1 and $\langle d_2, 0.9933\rangle$ on L_2. Update τ to be 0.9820, which is the minimum of these two weights. The lowest keyword weight in d_4 is $\mathrm{KW}(t_2, d_4) = 0.8808$. Recall that the lowest keyword weight in d_2 (i. e., $\mathrm{KW}(t_2, d_2) = 0.9933$) was found earlier. Consequently, the current top-2 lowest keyword weights remain $\mathrm{KW}(t_2, d_1) = 0.9991$ and $\mathrm{KW}(t_2, d_2) = 0.9933$ because $\mathrm{KW}(t_2, d_4)$ possesses a lower weight than these top-2 lowest keyword weights. Note that, as $\mathrm{KW}(t_2, d_2) = 0.9933 \geq \tau = 0.9820$, d_2 is returned by the basic patent retrieval model. This completes the patent retrieval process with top-2 answers (namely, d_1 and d_2) returned to the user.

34.3.5 Summary

This basic model retrieves the top-k valid answers with noise elimination (i. e., retrieving top-k relevant patents with the elimination of irrelevant patents) by first extracting representative keyword terms from user patent-query q and the target patent collection D.

These terms are then ranked according to the keyword weight distribution (KWD), which is computed based on term frequency $\mathrm{tf}(t_i, d_j)$ of a keyword t_i in a patent document d_j. Afterwards, top-k answers to user query q can then be found by using the top-k patent threshold algorithm (patent TA), which can be considered as an adaptation of the threshold algorithm [34.11] designed for general IR. As patent TA was designed specifically for patent retrieval, it efficiently retrieves the top-k patents while eliminating noise (i. e., removing irrelevant instances).

34.4 Enhancements and Extensions to the Basic Patent Retrieval Model

While the basic model described in Sect. 34.3 retrieves the top-k patents with noise elimination, such a model can be further enhanced and extended. This section describes some of these enhancements and extensions.

34.4.1 Relevance Feedback

Recall from Sect. 34.3.1 that the first phase of the basic patent retrieval model is to extract representative keyword terms. Given a patent database (e. g., the USPTO patent database), an enhancement to the basic patent retrieval model is to take a sample, from which representative keyword terms (and appropriate features) are extracted to form an initial query vector $\boldsymbol{q}_{\text{init}}$. Ideally, such an initial query vector $\boldsymbol{q}_{\text{init}}$ should be formed in a way that maximizes the similarities of relevant documents while minimizing the similarities of irrelevant documents. Let D_{R} be a set of relevant documents, and let D_{I} be a set of irrelevant documents. Then, $\boldsymbol{q}_{\text{init}}$ should be formed as follows [34.12]

$$\boldsymbol{q}_{\text{init}} = \arg\max_{\boldsymbol{q}} \left(\mathrm{sim}(\boldsymbol{q}, D_{\text{R}}) - \mathrm{sim}(\boldsymbol{q}, D_{\text{I}})\right) , \quad (34.11)$$

where sim() can be any function that measures similarity. A commonly used similarity function is *cosine similarity*, under which the optimal query vector $\boldsymbol{q}_{\text{opt}}$ for separating the relevant and irrelevant patent documents can be derived as follows

$$\boldsymbol{q}_{\text{opt}} = \frac{\sum_{\boldsymbol{d}_j \in D_{\text{R}}} \boldsymbol{d}_j}{|D_{\text{R}}|} - \frac{\sum_{\boldsymbol{d}_j \in D_{\text{I}}} \boldsymbol{d}_j}{|D_{\text{I}}|} , \quad (34.12)$$

which means that the optimal query is the vector difference between the centroids of the relevant and irrelevant patent documents [34.13]. Unfortunately, complete knowledge of D_{R} and D_{I} may not always be available in practice.

Instead, a practical enhancement is to incorporate *relevance feedback* (e. g., some partial knowledge of known relevant and irrelevant documents). A well-known relevance feedback mechanism is the Rocchio model [34.14]. With this mechanism, a suboptimal query $\boldsymbol{q}_{\text{s}}$ can be computed as follows

$$\boldsymbol{q}_{\text{s}} = \alpha \boldsymbol{q}_{\text{init}} + \beta \frac{\sum_{\boldsymbol{d}_j \in D_{\text{KR}}} \boldsymbol{d}_j}{|D_{\text{KR}}|} + \gamma \frac{\sum_{\boldsymbol{d}_j \in D_{\text{KI}}} \boldsymbol{d}_j}{|D_{\text{KI}}|} , \quad (34.13)$$

where (a) D_{KR} and D_{KI} are sets of *known* relevant and irrelevant patent documents, respectively, whereas (b) α, β and γ are weights attached to each term.

34.4.2 Estimation of the Importance of Keyword Terms

In addition to incorporating relevance feedback, another enhancement is to bridge the vocabulary gap between the underlying information for a user patent-query q and the target patent collection D by setting up a unigram model of a query's language θ_q to *estimate the importance of each keyword term* t_i according to a weighted log-likelihood based approach [34.15]

$$P(t_i|q) = P(t_i|\theta_q) \log\left(\frac{P(t_i|\theta_q)}{P(t_i|\theta_D)}\right) . \quad (34.14)$$

Here, the maximum likelihood estimate $P(t_i|\theta_q)$ is a weight for a query term $t_i \in q$, which is defined as follows

$$P(t_i|\theta_q) = (1-\lambda) P_{\text{ML}}(t_i|d_j) + \lambda P_{\text{ML}}(t_i|D) , \quad (34.15)$$

such that:

- $0 \le \lambda \le 1$
- The maximum likelihood estimate $P_{\text{ML}}(t_i|d_j)$ of the query term t_i in a patent document d_j is calculated as follows

  $$P_{\text{ML}}(t_i|d_j) = \frac{\mathrm{tf}(t_i, d_j)}{\sum_{t_h} \mathrm{tf}(t_h, d_j)} , \quad (34.16)$$

  for $\mathrm{tf}(t_i, d_j)$ denotes the *term frequency* of t_i in d_j, which can be obtained by using keyword term measurements like the *term frequency-inverse document frequency* (*TF-IDF*)

- The maximum likelihood estimate $P_{\text{ML}}(t_i|D)$ of the query term t_i in a collection D of documents (where $D = \{d_j|1 \le j \le n\}$) is calculated as follows

$$P_{\text{ML}}(t_i|D) = \frac{\text{tf}(t_i, D)}{\sum_{t_h} \text{tf}(t_h, D)} . \quad (34.17)$$

Equation (34.14) captures the *Kullback–Leibler* divergence [34.15] between the document language model θ_{q} and the collection language model θ_D. Those terms with high similarity to θ_q and θ_D are favorable. Moreover, such an estimate $P(t_i|q)$ in the equation can be normalized by a normalization factor

$$\frac{1}{\sum_{t_i \in q} P(t_i|q)} .$$

34.4.3 Patent Text Preprocessing

Recall from Sect. 34.3.2 that the second phase of the basic patent retrieval model is to rank keyword terms in the patent documents. Hence, an extension to the basic patent retrieval model is to perform *text preprocessing* on these patent documents. The main purpose of this extension is for cleaning and preprocessing the patent documents for further analysis. Preprocessing involves the following tasks:

- *Syntax tagging*, which uses an English part-of-speech (POS) tagger (e. g., log-linear POS tagger [34.16]) to distinguish words and terms in sentences based on their syntactic or morphological features
- *Word stemming*, which reduces inflected (or derived) words to their word stem, base or root form (i. e., generally a written word form) so that only nouns (including singular or collective nouns, singular proper nouns, plural nouns, and plural proper nouns) and verbs (including verbs in base form, past tense, gerunds or present participles, past participles, as well as non-third person singular present and third person singular present verbs) are reserved
- *Stop-word elimination*, which removes irrelevant but extremely common words (e. g., a, on, which, zero).

34.4.4 Ranking of Terms Based on Category Frequency

In general, patent documents can be gathered from a variety of sources, such as the Canadian Intellectual Property Office (CIPO), the European Patent Office (EPO), the Japan Patent Office (JPO), the Korean Intellectual Property Office (KIPO), the State Intellectual Property Office (SIPO) of China, as well as the United States Patent and Trademark Office (USPTO). For instance, patent documents can be collected from target patent databases such as the USPTO database. The group-level labels of the International Patent Classification (IPC) codes are tagged for the basic attributes of the indexing vocabulary. For each of the group-level labels, a certain number of patent documents can be gathered for further analysis. Let $D = \{d_1, d_2, \ldots, d_n\}$ be the set of n patent documents (where n is the total number of documents in D). Let c_h be a group-level category code (which is the main group in the IPC hierarchy); let $C = \{c_1, c_2, \ldots, c_p\}$ be the set of group-level category codes within the IPC hierarchy, where p is the total number of category codes in the IPC hierarchy. Then, the set $D(c_h)$ of documents in a category code c_h includes all the documents belonging to category code c_h, i. e., $D(c_h) = \{d_j \in c_h\}$. For example, if category code c_1 includes document d_1, then $D(c_1) = \{d_1\}$. Similarly, if category code c_2 includes documents d_2 and d_3, then $D(c_2) = \{d_2, d_3\}$.

Recall from Sect. 34.3.2 that representative keyword terms extracted from the user query q and a collection D of patent documents are ranked based on the term frequency $\text{tf}(t_i, d_j)$ of a keyword t_i in a patent document d_j. Due to the variety of sources for patent documents, an extension to the basic patent retrieval model is the ability to rank patent documents based on category frequency—more specifically, based on the frequency of a keyword t_i in patent documents belonging to a group-level category code c_h within the IPC hierarchy. These frequencies of patent documents can be represented in a matrix form—specifically, in a (document $\times$ IPC category)-matrix $\mathbf{W}^{d \times c}$, which can be computed as a matrix product of a (document $\times$ term)-matrix $\mathbf{W}^{d \times t}$ with a (term $\times$ IPC category)-matrix $\mathbf{W}^{t \times c}$.

Step 1. Construction of a (Document × Term)-Matrix

To build a (document $\times$ term)-matrix $\mathbf{W}^{d \times t}$, let $T = \{t_1, t_2, \ldots, t_m\}$ be a set of distinctive keyword terms extracted from the patent documents, where (a) t_i is a keyword term in T and (b) m is the total number of keyword terms in T. Generally, an IPC category covers a certain number of documents, and each document consists of multiple terms. A set of terms contained in a document d_j is denoted as $T(d_j) = \{t_i|t_i \in d_j\}$. Moreover, let $\text{tf}_{j,i} = \text{tf}(t_i, d_j)$ represent the frequency of term t_i in document d_j. For example, if five terms t_1, t_1, t_2, t_4 and t_5 (i. e., with duplicated t_1) appear in document d_1, then $T(d_1) = \{t_1, t_2, t_4, t_5\}$ and $\text{tf}_{1,1} = 2$, $\text{tf}_{1,2} = 1$, $\text{tf}_{1,4} = 1$ and $\text{tf}_{1,5} = 1$.

Then, let $T(c_h) = \{T(d_j)|d_j \in c_h\}$ represent the set of terms belonging to the documents in IPC category code c_h. When using the traditional *vector space model* (VSM) built for retrieval, documents are represented as vectors of terms. The score of each attribute in the vector can be calculated by the following *term frequency-inverse document frequency* (*TF-IDF*) formula [34.17], which says that the weight factor TF-IDF can be calculated as a product of TF and IDF

$$\text{TF-IDF}(t_i, d_j, D) = \text{tf}(t_i, d_j) \times \text{idf}(t_i, D)\,, \tag{34.18}$$

where $\text{idf}(t_i, D)$ is commonly defined as follows

$$\text{idf}(t_i, D) = \log\left(\frac{n}{n_i}\right). \tag{34.19}$$

Here, (a) $n = |\{d_j \in D\}|$ is the total number of documents in D, and (b) the IDF weight $n_i = |\{d_j \in D | t_i \in d_j\}|$ is number of documents in D containing the term t_i. Thus, each weight factor $\text{TF-IDF}(t_j, d_j, D) = w_{j,i}^{d\times t}$ can be represented as an entry or element in a (document $\times$ term)-matrix $\mathbf{W}^{d\times t}$ with $n \times m$ entries capturing the weights of m distinctive keyword terms on n patent documents. In other words,

$$\mathbf{W}^{d\times t} = \left[w_{j,i}^{d\times t}\right]_{n\times m}\,, \tag{34.20}$$

where

$$w_{j,i}^{d\times t} = \text{tf}_{j,i} \times \log\left(\frac{n}{n_i}\right). \tag{34.21}$$

Step 2. Construction of a (IPC Category × Term)-Matrix Based on Patent Category Frequency

Inspired by the concept of *term frequency-inverse corpus frequency* (TF-ICF) [34.18] as a term weighting scheme for clustering dynamic data streams, the TF-IDF formula in (34.18) and (34.21) can be extended into the *term frequency-inverse patent category frequency* (TF-IPCF) for measuring the weight $w_{h,i}^{c\times t}$ of a term t_i of a category c_h as follows

$$w_{h,i}^{c\times t} = \frac{\sum_{d_j \in D(c_h)} \frac{\text{tf}_{j,i}}{\max_{t_l \in T(d_j)} \text{tf}_{j,l}}}{|D(c_h)|} \log\left(\frac{p}{p_i}\right), \tag{34.22}$$

where:

- $\max_{t_l \in T(d_j)} \text{tf}_{j,l}$ is the maximum frequency over all terms in document d_j, which is used to standardize the term frequency in a document so as to avoid the influence of varied document sizes
- $\sum_{d_j \in D(c_h)} \text{tf}_{j,i} / (\max_{t_l \in T(d_j)} \text{tf}_{j,l})$ measures the normalized term frequency in category c_h
- $|D(c_h)|$ is the number of documents in category c_h, which is used to standardize the TF value so as to avoid the bias caused by different numbers of documents contained in a category
- $\log(p/p_i)$ calculates the IPCF value for term t_i, where (a) p is the total number of categories and (b) p_i is the number of categories in which the percentage of documents containing term t_i that meets or exceeds a specific threshold. The setting of this threshold can be used to treat those infrequent terms as noise.

Advantages of using TF-IPCF in the extended patent retrieval model (when compared to TF-IDF used in the basic patent retrieval model) include the following:

- TF-IPCF reduces the bias caused by varied document length
- TF-IPCF reduces the bias due to the different numbers of documents contained in a category
- TF-IPCF remedies the bias caused when a term appears in almost every category (which may happen when a category contains many documents).

After calculating the weight $w_{h,i}^{c\times t}$ for every term t_i of a category c_h, the corresponding row vector $\boldsymbol{c}_h$ in the (IPC category $\times$ term)-matrix $\mathbf{W}^{c\times t}$ can be generated. In other words,

$$\boldsymbol{c}_h = \left[w_{h,1}^{c\times t}, w_{h,2}^{c\times t}, \ldots, w_{h,m}^{c\times t}\right]_{1\times m}\,, \tag{34.23}$$

which captures the weight $w_{h,i}^{c\times t}$ of each of the m keyword terms in $T(c_h)$ where $T(c_h) = \{T(d_j) | d_j \in c_h\}$. Here, the weight $w_{h,i}^{c\times t}$ can be calculated as per (34.22).

Consequently, an (IPC category $\times$ term)-matrix $\mathbf{W}^{c\times t}$ can be represented as a $p \times m$ matrix capturing the weights of m distinctive keyword terms on patent documents belonging to p patent categories, as follows

$$\mathbf{W}^{c\times t} = \left[w_{h,i}^{c\times t}\right]_{p\times m}\,, \tag{34.24}$$

$$= [\boldsymbol{c}_h]_{p\times 1}\,, \tag{34.25}$$

$$= \begin{bmatrix} \boldsymbol{c}_1 \\ \boldsymbol{c}_2 \\ \vdots \\ \boldsymbol{c}_p \end{bmatrix}, \tag{34.26}$$

$$= \begin{bmatrix} w_{1,1}^{c\times t} & w_{1,2}^{c\times t} & \cdots & w_{1,m}^{c\times t} \\ w_{2,1}^{c\times t} & w_{2,2}^{c\times t} & \cdots & w_{2,m}^{c\times t} \\ \vdots & \vdots & \ddots & \vdots \\ w_{p,1}^{c\times t} & w_{p,2}^{c\times t} & \cdots & w_{p,m}^{c\times t} \end{bmatrix}. \tag{34.27}$$

As a further enhancement, the size of this matrix can be reduced. Specifically, by using a filtering process to discover distinctive terms, the discrimination power of a term can be computed through a term distribution, which in turn is computed by using a term standard deviation among categories. During this filtering process, the terms with lower standard deviations—which indicate weaker discriminative capability among categories—are removed. Here, the standard deviation is used as the discrimination recognition threshold because it is a simple way to calculate the variation among attributes. The standard deviation $\rho(t_i)$ of a term t_i among categories can be calculated as follow

$$\rho(t_i) = \sqrt{\frac{1}{p}\sum_{h=1}^{p}\left(w_{h,i}^{c\times t} - \overline{w}_i^t\right)^2}\,, \tag{34.28}$$

where $\overline{w}_i^t$ is the average (i. e., the mean) of $w_{h,i}^{c\times t}$ over all p categories $c_1,\ldots,c_p$. A term t_i with a smaller standard deviation is observed to have weaker discriminative ability between categories, and vice versa. The distinctive term can be an index term in the indexing vocabulary. Through this filtering process, the (IPC category $\times$ term)-matrix can shrink in size.

Step 3. Construction of a (Document × IPC category)-Matrix

Recall that, in step 1, the (document $\times$ term)-matrix $\mathbf{W}^{d\times t} = [w_{j,i}^{d\times t}]_{n\times m}$ with $n\times m$ entries for capturing the weights of m distinct keyword terms on n patent documents was constructed with every weight value $w_{j,i}^{d\times t}$ calculated by the traditional TF-IDF formula in (34.21). Similarly, in Step 2, the (IPC category $\times$ term)-matrix $\mathbf{W}^{c\times t} = [w_{h,i}^{c\times t}]_{p\times m}$ with $p\times m$ entries for capturing the weights of m distinct keyword terms on patent documents belonging to p IPC patent categories was constructed with every weight value $w_{h,i}^{c\times t}$ calculated by the TF-IPCF formula in (34.22).

By taking the transpose of $\mathbf{W}^{c\times t}$, a (term $\times$ IPC category)-matrix $\mathbf{W}^{t\times c} = [w_{i,h}^{t\times c}]_{m\times p}$ with $m\times p$ entries for capturing the weights of m distinct keyword terms on patent documents belonging to p IPC patent categories can be obtained

$$\mathbf{W}^{t\times c} = (\mathbf{W}^{c\times t})^{\mathrm{T}}\,. \tag{34.29}$$

Consequently, in the current step (i. e., Step 3), a (document $\times$ IPC category)-matrix $\mathbf{W}^{d\times c} = [w_{j,h}^{d\times c}]_{n\times p}$ with $n\times p$ entries for capturing the weights of distinct keyword terms on n patent documents belonging to p IPC patent categories can be constructed by performing matrix multiplication on the matrices $\mathbf{W}^{d\times t}$ and $\mathbf{W}^{t\times c}$ as follows

$$\mathbf{W}^{d\times c} = \mathbf{W}^{d\times t}\times\mathbf{W}^{t\times c}\,, \tag{34.30}$$

$$= \mathbf{W}^{d\times t}\times(\mathbf{W}^{c\times t})^{\mathrm{T}}\,. \tag{34.31}$$

34.4.5 Extension of the Patent Threshold Algorithm for Handling IPC Category

Recall from Sect. 34.3.3 that the third phase of the basic patent retrieval model is to use the patent threshold algorithm (patent TA) to retrieve the top-k relevant patent documents based on the weight $w^{d\times t}$ of m distinct keyword terms on n patent documents. With the availability of the weight $w^{d\times c}$ of m distinct keyword terms on patent documents belonging to p IPC patent categories, the patent TA can be extended to the top-k relevant patent documents based on the weight $w^{d\times c}$.

To elaborate, the extended patent TA starts with the top element in each of these p sorted vectors (i. e., the highest weight of each c_h for $1\le h\le p$). Set a new threshold τ for the patent retrieval and noise elimination process to be the lowest weight among the p weights at the front of these vectors (i. e., the top row in the resulting matrix). For each document d_y appearing at the front of these vectors, find its lowest weight within d_j (i. e., $\min_{1\le h\le p} w_{j,h}^{d\times c}$). If such a lowest weight in d_j meets or exceeds τ (i. e., $\min_{1\le h\le p} w_{j,h}^{d\times c}\ge\tau$) implying that all p weights within d_j meet or exceed τ (i. e., $w_{j,h}^{d\times c}\ge\tau$ for all $h\in[1,p]$), then d_j is chosen as one of the top-k answers to user query q. Otherwise, keep such a lowest weight in d_j for future consideration, and continue with the next row of the matrix. Afterwards, set a new threshold τ for the patent retrieval and noise elimination process to be the lowest weight among these p weights (in this second row of the matrix). For each document d_j appearing in this row, find its lowest weight within d_j. If such a lowest weight in d_j meets or exceeds τ, then d_j is chosen as one of the top-k answers to user query q. Otherwise, repeat this process until all top-k answers are found and returned to the user. This patent retrieval process is called the *extended patent TA*.

Please note that retrieving the top-k answers with this extended patent TA is similar to doing so with the patent TA used in the basic model (described in Sect. 34.3.3). As such, a benefit of using this model for patent retrieval is that it can find top-k answers without examining the entire $n\times p$ matrix space. Moreover, since $\mathbf{W}^{d\times c}$ is in a matrix form, the number of vectors to be examined by this model during the patent retrieval process can be reduced by using IPC category-based *singular value decomposition* (SVD) which identifies the more relevant documents and categories.

34.4.6 An Illustrative Example of the Enhanced or Extended Patent Retrieval Model

As an illustrative example, consider a practical situation where the user would like to search patents about service robots for vacuum cleaning. Let $C = \{c_1, c_2\}$ be a set of group-level category codes within the International Patent Classification (IPC) hierarchy such that:

- c_1 covers keyword term

  $t_1 =$ `service robot`,
  $t_2 =$ `entertainment robot`,
  $t_3 =$ `industrial robot`,
  $t_4 =$ `juggling robot`, and
  $t_5 =$ `military robot`;

  whereas
- c_2 covers keyword term $t_6 =$ `vacuum cleaning` and other keyword terms for related household chores.

Consider the following matrix $\mathbf{W}^{d\times c}$ that captures the above keyword terms in $p = 2$ categories extracted from $n = 4$ documents

$$\mathbf{W}^{d\times c} = \begin{bmatrix} 0.9998 & 0.9997 \\ 0.9991 & 0.9975 \\ 0.9820 & 0.9999 \\ 0.9933 & 0.9526 \end{bmatrix}.$$

To retrieve the top-2 answers with noise elimination, documents are ranked in descending order of their weights for each category, resulting in the following two sorted vectors

$$\boldsymbol{L}_1 = \begin{bmatrix} d_1 \\ d_2 \\ d_4 \\ d_3 \end{bmatrix} \text{ and } \boldsymbol{L}_2 = \begin{bmatrix} d_3 \\ d_1 \\ d_2 \\ d_4 \end{bmatrix}.$$

Then, set a threshold τ to be 0.9998, which is the minimum of $w_{d_1,c_1} = 0.9998$ and $w_{d_3,c_2} = 0.9999$. For documents (i. e., d_1 and d_3) appearing at the top of these two vectors L_1 and L_2, their corresponding lowest weights $\min_h w_{d_1,c_h} = 0.9997$ and $\min_h w_{d_3,c_h} = 0.9820$ are found. As neither of these two weights meets or exceeds $\tau = 0.9998$, they are kept for future consideration.

Next, continue the patent retrieval process with the next element on each of these two sorted vectors (i. e., d_2 on $\boldsymbol{L}_1$ and d_1 on $\boldsymbol{L}_2$). Update τ to be 0.9991, which is the minimum of the two weights $w_{d_2,c_1} = 0.9991$ and $w_{d_1,c_2} = 0.9997$. The lowest weight in d_2 is $\min_h w_{d_2,c_h} = 0.9975$. Recall that the lowest weight in d_1 (i. e., $\min_h w_{d_1,c_h} = 0.9997$) was found earlier. Consequently, the current top-2 lowest weights become $\min_h w_{d_1,c_h} = 0.9997$ and $\min_h w_{d_2,c_h} = 0.9975$ because $\min_h w_{d_3,c_h} = 0.9820$ possesses a lower weight than these top-2 lowest weights. Note that, on the one hand, as $\min_h w_{d_1,c_h} = 0.9997 \geq \tau = 0.9991$, d_1 is returned as one of the top-2 answers. On the other hand, as $\min_h w_{d_2,c_h} = 0.9975$ does not meet or exceed τ, it is kept for future consideration.

In a similar fashion, the next elements on each of these two sorted vectors are d_4 on $\boldsymbol{L}_1$ and d_2 on $\boldsymbol{L}_2$. Update τ to be 0.9933, which is the minimum of the two weights $w_{d_4,c_1} = 0.9933$ and $w_{d_2,c_2} = 0.9975$. The lowest weight in d_4 is $\min_h w_{d_4,c_h} = 0.9526$. Recall that the lowest weight in d_2 (i. e., $\min_h w_{d_2,c_h} = 0.9975$) was found earlier. Consequently, the current top-2 lowest keyword weights remain $\min_h w_{d_1,c_h} = 0.9997$ and $\min_h w_{d_2,c_h} = 0.9975$ because $\min_h w_{d_4,c_h} = 0.9526$ possesses a lower weight than these top-2 lowest weights. Note that, as $\min_h w_{d_2,c_h} = 0.9975 \geq \tau = 0.9933$, d_2 is returned by the patent retrieval model. This completes the patent retrieval process with top-2 answers (namely, d_1 and d_2) returned to the user.

As illustrated in our examples, which are consistent with some empirical results [34.12], the patent retrieval model usually leads to higher recall and/or checks fewer irrelevant patent documents than traditional approaches such as the boolean model for retrieving patents from the USPTO patent database. To elaborate, the *recall for k retrieved documents*—denoted as $R(k)$, which measures the recall after retrieving k relevant documents—for the patent retrieval model keeps improving and $R(k)$ for traditional approaches increases only slightly (or remains the same) when k increases. As a result, the gap between the two keeps widening when k increases, showing the benefits of applying the patent retrieval model. Moreover, to achieve a certain recall target (say, an 80% recall), the boolean model patent retrieval described in Sect. 34.2 checked 1800 patent documents, but the patent retrieval model described in this section only checked 650 patent documents, when searching for 58 relevant patents.

34.4.7 Summary

By incorporating the enhancements and extensions described in this section, the resulting model can retrieve the top-k patents with noise elimination by first extracting appropriate features of a sample taken from the patent database to form an initial query vector, which is then modified after incorporating relevance feedback (e. g., partial knowledge of known relevant and irrelevant patent documents). Then, the importance of keyword terms from the resulting query vector can be estimated. Regarding the patent documents, they can be preprocessed by syntax tagging, word stemming, and stop-word elimination. Moreover, weights are assigned to keyword terms in documents belonging to different categories based on the term frequency-inverse document frequency (TF-IDF) formula (34.21) and term frequency-inverse patent category frequency (TF-IPCF) formula (34.22) for capturing the TF-IDF and the TF-IPCF. The resulting (document × IPC category)-matrix is formed by multiplying its corresponding (document × term)-matrix and the transpose of the (IPC category × term)-matrix (34.31). Documents in the vectors that form the resulting matrix are ranked in non-ascending order of their weights. The top-k answers to the user query can then be found by using the top-k extended patent TA.

34.5 Dynamic Patent Retrieval Models

Recall that, in both the basic patent retrieval model and its enhancements described in Sect. 34.3 and 34.4, documents were ranked in descending order of their weights and patent TA (or extended patent TA) was used to retrieve the top-k answers to a user query using this ranked list containing keyword terms. As alternatives to the patent TA or extended patent TA, two dynamic patent retrieval models [34.19] can be used to retrieve the top-k answers. These two models are:

- Dispersion for dynamic ranking (DDR)
- Accumulation for dynamic ranking (ADR)

34.5.1 Dispersion for Dynamic Ranking

The idea behind the *dispersion for dynamic ranking* (*DDR*) model [34.19] is that, in the process of retrieving the top-k patent documents, if the first patent document in the ranked list is irrelevant, the furthest document (say, d_j) will be checked in the next iteration. Here, various distance measures—such as cosine distance $\mathrm{dist}(d_x, d_y)$ between two patent documents d_x and d_y—can be used

$$\mathrm{dist}(d_x, d_y) = 1 - \mathrm{sim}(d_x, d_y)\ , \tag{34.32}$$

where $\mathrm{sim}(d_x, d_y)$ measures the cosine similarity between the vectors $\boldsymbol{d}_x$ and $\boldsymbol{d}_y$ representing two patent documents d_x and d_y, which is defined as follows

$$\mathrm{sim}(d_x, d_y) = \frac{\boldsymbol{d}_x \cdot \boldsymbol{d}_y}{||\boldsymbol{d}_x||_2\, ||\boldsymbol{d}_y||_2}\ . \tag{34.33}$$

Hence, by substituting (34.33) into (34.32), the resulting equation can be written as follows

$$\mathrm{dist}(d_x, d_y) = 1 - \frac{\boldsymbol{d}_x \cdot \boldsymbol{d}_y}{||\boldsymbol{d}_x||_2\, ||\boldsymbol{d}_y||_2}\ . \tag{34.34}$$

Let d_j be the document furthest from the first irrelevant patent document in the ranked list. If d_j happens to be relevant, then its most similar document (i. e., the nearest document) among the unchecked patents will be considered in the following iteration. The remaining iterations can be executed in a similar matter. In other words, for each iteration, if a currently checked patent document is relevant, then retrieve its nearest document (i. e., the most similar one). Otherwise, retrieve its furthest document (i. e., the least similar one from the current document). The DDR terminates when it finds all of the top-k answers.

34.5.2 An Illustrative Example of Dispersion for Dynamic Ranking

As an illustrative example, consider a ranked list of eight patent documents $\{d_1, d_2, \ldots, d_8\}$ such that documents d_1–d_6 are irrelevant and only d_7–d_8 are relevant. See Fig. 34.2 for the location of these documents in multi-dimensional vector space. To find the top-2 relevant patent documents, DDR starts with d_1, which is irrelevant. Then, DDR checks document d_2 (which is the furthest from d_1, i. e., $\arg\max_j \mathrm{dist}(d_j, d_1) = 2$) and finds that d_2 is also irrelevant. Afterwards, DDR checks and finds irrelevant document d_3 (which is the furthest from d_2) and its furthest (but irrelevant) document d_4. DDR checks document d_8 (which is the furthest from d_4, i. e., $\arg\max_j\, dist(d_j, d_4) = 8$) next and finds that d_8 turns out to be relevant. After returning d_8 as a top-1 relevant patent document, DDR checks document d_7 (which is the nearest to d_8) and finds that d_7 is also relevant. DDR then stops because it finds all top-2 relevant patent documents d_8 and d_7 (after checking four irrelevant documents d_1, d_2, d_3 and d_4).

34.5.3 Accumulation for Dynamic Ranking

The idea behind the *accumulation for dynamic ranking* (*ADR*) model [34.19] is very similar to that of the DDR, except that the vector accumulated values are used. More specifically, when finding the next patent document, ADR considers the document that is furthest from the cumulative mean value of the checked irrelevant documents (DDR considers the document that is furthest from the most recently checked irrelevant document). In

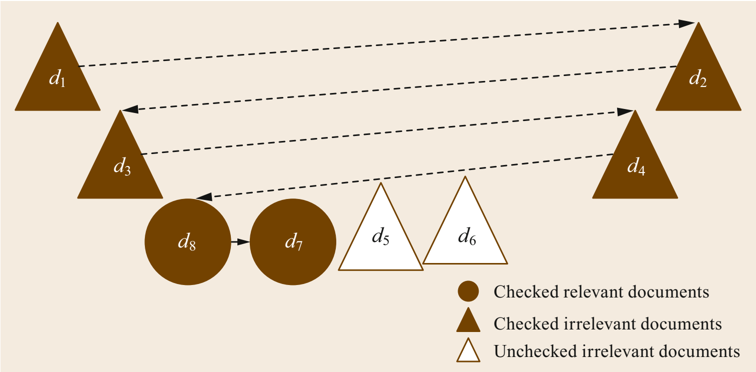

Fig. 34.2 Illustrative example on applying DDR to patent documents

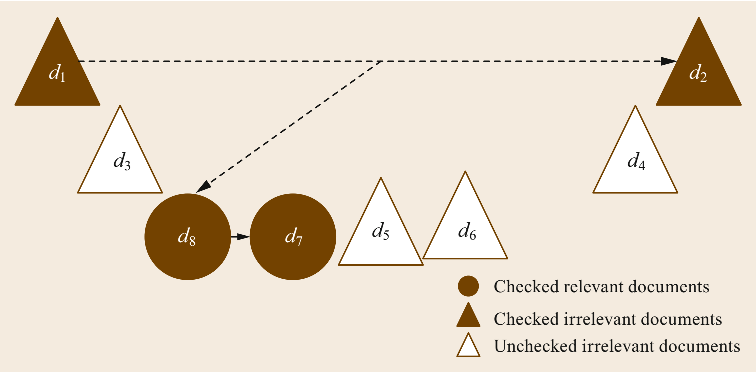

Fig. 34.3 Illustrative example on applying ADR to patent documents

other words, for each iteration, if a currently checked patent document is relevant, then retrieve its nearest document (i. e., the most similar one). Otherwise, retrieve the document that is furthest from the *vector average* among all previously checked irrelevant documents. The ADR terminates when it finds all top-k answers.

34.5.4 An Illustrative Example of Accumulation for Dynamic Ranking

As an illustrative example, consider a ranked list of eight patent documents $\{d_1, d_2, \ldots, d_8\}$ such that documents d_1–d_6 are irrelevant and only d_7–d_8 are relevant. See Fig. 34.3 for the location of these documents in multi-dimensional vector space. To find the top-2 relevant patent documents, ADR starts with d_1, which is irrelevant. Then, ADR checks document d_2 (which is the furthest from d_1, i. e., $\arg\max_j \mathrm{dist}(d_j, \mathrm{avg}(\{d_1\})) = 2$) and finds that d_2 is also irrelevant. Afterwards, ADR checks document d_8 (which is the furthest from the cumulative mean between d_1 and d_2, i. e., $\arg\max_j \mathrm{dist}(d_j, \mathrm{avg}(\{d_1, d_2\})) = 8$) and finds that d_8 turns out to be relevant. After returning d_8 as a top-1 relevant patent document, ADR checks document d_7 (which is the nearest to d_8) and finds that d_7 is also relevant. ADR then stops because it finds all top-2 relevant patent documents d_8 and d_7 (after checking only two irrelevant documents d_1 and d_2).

34.5.5 Summary

This section describes both the dispersion for dynamic ranking (DDR) and the accumulation for dynamic ranking (ADR) as alternatives to the patent TA (or its extended patent TA). Both DDR and ADR consider weights in all dimensions (rather than just the highest and lowest weights as in the patent TA and extended patent TA). Moreover, the consideration of jumping to the furthest document in both DDR and ADR helps reduce the likelihood of checking a sequences of similar irrelevant documents in traditional approaches such as clustering-based geometrical structure retrieval [34.20].

As illustrated in our examples, which are consistent with some empirical results [34.19], ADR usually checks fewer irrelevant patent documents than DDR when finding the top-k relevant patent documents. For instance, to achieve a 100% recall (i. e., to retrieve all relevant patent documents) in a patent search, traditional approaches checked 400 patent documents whereas DDR and ADR checked only 230 patent documents and 80 patent documents, respectively.

34.6 Conclusions

This chapter focuses on information technology (IT) based patent retrieval models. It first highlighted some key differences between patent retrieval and general information retrieval (IR). For instance, patent retrieval is recall-oriented, whereas general IR is precision-oriented. In terms of the search space and time, patent search usually requires longer search time than general IR because (a) patent search queries usually contain more keyword terms than general IR search queries and (b) patent documents are usually longer and more complex than web or news articles searched by general IR. Many existing patent retrieval systems use the boolean model, which was designed for IR. Hence, to facilitate effective patent search, a basic model that was designed for patent retrieval was described. It finds the top-*k* relevant patent documents with no irrelevant documents being returned. The model first extracts representative keyword terms from the user query, then ranks the patent documents containing these keyword terms by assigning weights based on term frequency-inverse document frequency (TF-IDF), and finally returns the top-*k* answers to the user query. Such a model can be enhanced and extended in different aspects:

1. First, the user query can be enhanced by:
   a) Taking a sample and extracting representative terms from the sample
   b) Incorporating relevance feedback about partial knowledge on relevant and irrelevant documents
   c) Estimating the importance of keyword terms.
2. Second, patent documents can be cleaned up by text preprocessing tasks like syntax tagging, word stemming, and stop-word elimination.
3. Third, the ranking of the patent documents can be enhanced by taking into account the international patent classification (IPC) categories.

Hence, patent documents containing the keyword terms belonging to any of these categories can be ranked according to the weights assigned based on the term frequency-inverse patent category frequency (TF-IPCF). The resulting ranked lists of patent documents can be represented as a matrix or a collection of vectors. Moreover, in this chapter, four different top-*k* patent retrieval algorithms were described:

1. Patent threshold algorithm (patent TA) that handles TF-IDF
2. Extended patent TA that handles TF-IPCF
3. Dispersion for dynamic ranking (DDR)
4. Accumulation for dynamic ranking (ADR).

When using these four algorithms in the basic patent retrieval model or its extensions, the top-*k* answers to a user query can be retrieved efficiently with noise elimination, i. e., patent documents that are relevant to keyword terms in the user query can be retrieved efficiently without returning any irrelevant patent documents.

35. The Role of the Patent Attorney in the Filing Process

Rainer Frietsch, Peter Neuhäusler

The role of the legal representative in patent filing processes is, so far, under-explored in patent statistics. This chapter addresses the question of the role and the impact of the patent attorney in the filing process. One of the core assumptions is that more experienced attorneys have more in-depth knowledge of the intricacies of the patent system and, thus, are more likely to pursue more elaborate and successful filing strategies.

The results show a high concentration of attorneys and filing action in absolute as well as in relative terms in some countries, namely Germany and the UK, and numbers worth mentioning also in other larger applicant countries like France, Italy, Sweden, or the Netherlands. Explanations for this biased distribution in Europe are language advantages in the case of the UK (and also Ireland) and geographical proximity to the European Patent Office (EPO), as well as economies of scale in the case of Germany.

The experience of the representative has a considerable impact on the outcome. Multivariate analyses suggest that the (financial) resource endowment is a decisive factor in the hiring of patent attorneys. It was shown that the patents of more experienced representatives were significantly more often withdrawn (but neither refused nor granted with a higher probability), and they were less often opposed than the ones by less experienced attorneys.

35.1 Starting Points

In the past 20 years, the patent system underwent a considerable change in what applicants/assignees expect from it and how they use it. Though still being important, the pure protection mechanism lost relevance compared to the more strategic aspects like blocking competitors or signaling to the capital market [35.1]. Though strategies are people's reactions to the expectations on future developments, the role of a certain group of people, namely patent attorneys, has mainly been disregarded in the literature and is—in consequence—rather under-explored so far. People are involved in the production, drafting, and especially decision making on patents. Consequently, there is a human factor in the patenting process that plays a crucial role. The applicant's representative and the patent examiner are usually in direct contact and communicate on the different stages of filing a patent. The examiner provides the applicant (or his representative) with information on the application and might make suggestions or even requests to the representative, who, on the other hand, is able to react to this in one way or another. In other words, patenting is a process where negotiations play a major role.

Patents are a vested right for a limited time, which applicants are granted. Patents are essential to secure the investment in research and development (R&D) and in the technological progress, especially in innovation-oriented countries. Applicants are granted this right in exchange for the disclosure of their technology/process. Furthermore, patents have to fulfill several formal criteria, among them novelty and inventive steps, which are both examined by professionals in the particular field. The formulation of patent applications is a sophisticated and challenging task, mostly fulfilled

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_35

by professionals—patent attorneys—who then take responsibility of (in most cases) massive investments in R&D to be protected. A patent application is not just a simple matter of filling in a form. The way from filing to the granted patent is a long one and is full of obstacles and traps. All this makes the patent attorney—or more, generally speaking, the representative—a very important person within this process. High qualifications, broad experience, and a number of other characteristics are mandatory, or at least helpful, for a successful patent application.

For the representation at the EPO there are clear rules and regulations on who might undertake this legal act on behalf of the patent applicant. Article 134 of the European Patent Convention (EPC) deals with the question of who could act as a representative of the patent owner [35.2]. This can only be done by a natural person and a national of one of the 38 EPC member states, who has a place of business within the member states and has passed the European qualifying examination. These are so-called European patent attorneys. In addition, any legal practitioner entitled to represent patent owners in patent matters in any of the EPC member states might also be able to act as a representative at the EPO. So, any national patent attorney could also act on behalf of the patent applicant.

In addition to legal practitioners (lawyers/attorneys), a patent applicant who has their place of business—this means either headquarters or a subsidiary organized as its own legal entity—within the EPC member states might also file a patent without appointing a legal practitioner. Even non-residential entities who have their place of business outside the territory of the EPC might file an application on their own account, but then need to appoint a legal practitioner in the further course of the process.

In the guide for applicants [35.3] the EPO strongly recommends appointing a professional legal representative, especially to keep the probability of a successful application high. Different to the US, where individual applicants who act pro-se, i. e., on their own, get support and even consultancy from the examiner; such a special rule does not exist at the EPO. So, if an individual fails to fulfil his/her requirements of the process, the filing procedure might end, and the patent be rejected without any benefit of doubt. In the US, the applicant might even get some support and consultancy on how to reformulate some claims or change the scope of the patent to keep the process running. However, also in Europe a communication between the examiner and the applicant (or his representative) occurs. The applicant might derive some useful information on how to refine his application, but there is no formal support for unexperienced applicants.

The majority of patent applications are filed by a professional legal representative, who can either be internal—so, directly employed by the patent applicant—or external. Especially small and medium-sized enterprises (SMEs)or at least small applicants (applicants with only few patent applications) might choose external representatives, whereas larger enterprises and larger applicants might be able to sport their own patent attorney or even their own legal department with more than one attorney. However, in reality, large multinational enterprises with their own legal departments employ both internal and external representatives, depending on the workload and the sensitivity of the particular application. It is often the case that a number of different legal practitioners are involved in a single patent filing procedure. Even within the patent system there is plenty of room for specialization. One person might be an expert in drafting the text, another one even in writing the claims, a third one in corresponding with the office, and another one being the best to act at the court of appeals in the case of opposition or in law suits when already granted patents are under attack. For licensing and contracting yet another legal representative might enter the scene. In fact, also in most smaller law firms and certainly in larger ones, a patent application is usually teamwork, where prior art searches, correspondence, process management, fee payment, etc., are done by a team of people. Nevertheless, in the patent application, only one person is mentioned as having to fulfill the criteria of Article 134 mentioned above. This particular person named on the patent as a representative is the scope of this analysis.

Once the decision to hire a lawyer was made, one might employ an experienced or a less experienced attorney. Larger companies might even employ internal legal staff and then have the choice between an internal and an external representative. Of course, applicants who frequently file patents might prefer to have permanent staff that is familiar with the technologies, the strategies, and the habits of the company. Less frequently or irregularly filing assignees might not have these options, or their lawyers might not only do patents but also fulfill other legal duties. At least, they might not have the same opportunity to gain experience in patenting. The same holds for external representatives, who might be specialized in patenting, filing hundreds of patents per year. Others might also be representatives for other legal issues, therefore filing less patents per year and also having less experience with patents. It is necessary to register with the U.S. Patent and Trademark Office (USPTO) to be allowed to act in front of the USPTO. The same holds for the EPO, where it takes about 3 years of training to become a European patent attorney. In sum, the individual skills and experience of the lawyer and the law firm, as well as the framework conditions might have an impact on the outcome of the filing.

The costs of filing patents is in most cases defined by the procedural costs of the endeavor, where processing fees at the patent offices are calculable and straightforward and are, therefore, often used to assess the overall costs of a patent application. However, they are only a part of these overall costs. The costs for the services of the patent attorney, for translation, for prior art searches, etc., are also considerable and make patents a costly thing [35.4, 5]. It becomes even more costly—though hard to predict—when law suits or infringements are involved. Moreover, this holds for both parties of law suits or infringements. This is why the resource endowment is often discussed as a crucial factor for pursuing one's own patent rights. Further, the resource endowment might also extend to the legal representative, where a *better* one might be more costly than the *average* one, and this might have an impact on the outcome of the filing process.

The role of the legal representative in this procedure is a so far an under-explored research question in patent statistics. This chapter addresses the question of the role and the impact of the patent attorney on the filing process. One of the core assumptions is that more experienced attorneys have more in-depth knowledge of the intricacies of the patent system and, thus, are more likely to pursue more elaborate filing strategies.

This chapter has the following structure. A brief literature review on the scarce empirical and theoretical evidence describes the framework conditions under which the role and the impact of the attorney on the filing outcome are analyzed. Next, the dataset to describe the structures is introduced, and a descriptive statistical section is followed by the discussion of the multivariate empirical results. A final section summarizes and concludes.

35.2 Literature Review and Regulations

The importance and the role of the patent attorney has been mentioned in several publications [35.6–9], but the empirical evidence that examines this impact is scarce, and quantitative empirical evidence hardly exists. One of the few papers that contains empirical evidence was presented by *Somaya* et al. [35.10], who stress the skills and competencies of the attorneys in the patent process or in drafting patents.

Macdonald and *Lefang* [35.11] have a rather skeptical perspective on the role of the patent attorney in producing innovations. However, already two decades ago they saw an increasing role of the representative for the invention activity. The reasons were an increasing importance of the patent system in general, as well as tacit knowledge within the system that was supposed to gain relevance. They conclude that the system, thereby, deviated from its original and social task to help securing innovations.

Li et al. [35.12] stress the potential role of patent attorneys as intermediaries or match-makers for technology transfer in particular in developing countries. They argue that inventors who have the technological expertise often miss competence in commercialization and in identifying partners for collaboration. On the other hand, companies in need of technologies often lack the knowledge of what is technologically possible and what already exists. In the discussion of *Li* et al. [35.12], the patent attorneys are seen to close this gap and act as match-makers in these kinds of situations. However, what they neglect in their line of argumentation is that not seldom companies are suffering from the not invented here (NIH) syndrome, which means that they are unable to absorb or even accept technologies from outside the company [35.13–15]. In addition, not seldom the technological solutions suggested by individual inventors or public research is of no direct use but requires additional investments in development activities to get them ready for the market, to adapt them to the requirements of the interested company, and to enable their upscaling for mass production.

One of the few papers that examines the impact of the attorney on the outcome of filings was published by *Gaudry* [35.16], who analyzed the difference between attorney representation and pro-se applicants at the USPTO. She found considerable differences not only in the success rate of the application as such, but also in terms of the number and broadness of claims. Pro-se applicants do not fully exploit the possibilities of the system, and it appears that several of them abandon the process unintentionally due to a lack of experience with the legal issues and the procedures.

A paper published by *Koller* and *Ebersberger* [35.17] uses the experience of patent attorneys, measured in years since their examination at the EPO or as a cumulated number of previously represented patents, to analyze their impact on the filing outcome. They measure the outcome as the duration from application to grant, as well as the number of forward citations received. They, indeed, find a positive relation between experience and time to grant and also the number of forward citations, which is an indication of patent quality in their eyes. However, what they are not able to take into account in their models is the intentional or strategic use of the legal status [35.1, 18]. In some cases, a withdrawal or even a refusal is sufficient to achieve one's goals. In other words, not all patents that are not granted are of no or low value, whereas also not all patents that are granted are of any value at all [35.19]. Moreover, it could very well be that experience enables attorneys to act strategically in this way.

A few papers also address the impact of the judges and the courts in case law systems. For example, *Moore* [35.20] starts from the widespread perception of the existence of jury bias in patent trials in favor of individuals and in disfavor of corporations. She, indeed, finds empirical evidence for the existence of such a bias as individuals win 78% (companies win 22%, respectively) of cases in a jury trial, while they only win 47% in trials decided by a judge [35.20, p. 82]:

> Asymmetries in resources, stakes, and information, differences in risk preferences, concern over adjudicator bias, behavioral science, and repeat-player economies all suggest a difference in the pool of cases litigated by individuals as opposed to the pool litigated by corporations.

This leads her to conclude that there is a selection bias at play at the same time when cases are tried. Corporations might only try the solid ones, while individuals might not be able to assess this in advance. She even finds empirical evidence for the statement that individuals do not file fewer law suits because they are more selective and more risk averse, but because their patents are—on average—not as strong as the ones held by larger parties. She explains this by the affection of the individual for her own invention. In addition, she refers to anecdotal evidence and argues that individuals who are not afraid of trouble might be more willing to file weak law suits. On the other hand, larger parties might use their resources to file litigations against smaller, less resource-equipped patentees and tear them down or reach a settlement simply by the power of their resources.

Reitzig and *Wagner* [35.21] derive from a number of interviews that external patent attorneys are—due to possible economies of scale—more efficient in filing patents. However, in the case of litigation, internal attorneys are more efficient and effective according to their findings.

Apart from patents, the fact that the attorney—or to be more precise: her/his ability and experience—has an impact on the outcome of legal procedures was shown in several papers. For example, *Abrams* and *Yoon* [35.22] use felony cases randomly assigned to attorneys to show that experience matters—and that this experience is not equally distributed among attorneys [35.22, p. 1146]:

> In civil cases, higher-ability plaintiff attorneys are more likely to win, and garner larger damage awards for their clients; higher-ability defense attorneys are more likely to avoid a finding of liability for their clients, or at least minimize the size of the damage award

Also *Szmer* et al. [35.23] take the capabilities and experience of the lawyer into account when they analyze Supreme Court decisions in Canada. They find that litigation experience and team size have an impact on the performance.

35.3 Basic Research Questions

The analytical potential of our dataset regarding patent attorneys has many dimensions (the data will be presented below), so in this chapter, we restrict ourselves to some basic questions as the existing literature does not provide satisfying answers even to these basic questions. Does the experience of the patent attorney differ by applicant type (small and midsize enterprise, large enterprise, university, public research, or individual inventor)? Does the experience of the patent attorney have a significant impact on the legal status of a patent? Additional questions, could be, whether more experienced attorneys achieve more valuable patents or are hired to process more valuable patents (measured by forward citations, according to International Patent Classification (IPC) classes, or claims)? Are patents drafted by experienced attorneys opposed less often? Finally, the question of all questions in this context is—and where we will be able to also only deliver a few indications—whether more experienced attorneys are more capable of strategic patenting than less experienced colleagues?

35.3.1 Data

This chapter uses a dataset of more than 1.8 million patent applications filed at the EPO between 1990 and 2010—we had data up to 2012, but the Patent Cooperation Treaty (PCT) filings of the last 2 years had not yet entered the regional phase at the EPO by then. However, for country comparisons, we use only data from the latest available year, while we use data of the whole period for the multivariate analyses. The data was extracted from PATSTAT, also known as the EPO Worldwide Patent Statistical Database, which contains mainly bibliographic information extracted from the INPADOC (International Patent Documentation) database that is used by the patent examiners of the EPO and which covers patent filings at more than 80 offices worldwide [35.24, 25]. The database is run on an Oracle SQL Server, which offers high potential to calculate and introduce additional indicators. Next to standard data, our database also contains the information on the size [35.26] and type of the assignee, so if it is an SME, a large enterprise, a university, a public research organization, or an independent inventor. Assignee types have also been identified by the K.U. Leuven [35.27–29], which can be added to PATSTAT as well. However, this data was not used here, as the most relevant information on the size of the applicant is not available. We, therefore, used our own definition of applicant types, which, however, is only available for nine countries.

Furthermore, the PATSTAT database was enriched and matched with additional information, like the WIPO (World Intellectual Property Organization) classification on technological fields [35.30]. In addition, for the sake of this paper, the PRS-data was included, which contains the legal status of the patent filings. This data source offers information for several patent offices if a patent is granted, refused, withdrawn, pending, or if the granted patents are maintained. Another product of the EPO that is essential in the context of this paper is the *ESPACE Bulletin*, where the name and address of the legal representatives—covered in addition to several other information already available in PATSTAT—was extracted and added to our database. After the extraction, the data was processed, and each law firm received an individual ID as did each patent lawyer. As many patents only contain information on the law firm, and the individual lawyer/representative is not always mentioned, the coverage of this latter variable is much lower than that of the law firm. Therefore, we restrict our analyses on law firms in this chapter.

In some cases—especially large enterprises—the legal department, an IPR (intellectual property rights) subsidiary and/or individual persons were named. They were then directly coded as internal representatives. In cases where no representative was mentioned at all, they were coded separately, but also treated as if they were internal representatives.

The experience of the law firm or the individual lawyer in a particular year was calculated as the cumulated number of EPO patent filings up to that particular year, starting in 1978, when the EPO started its business. It was calculated this way as this is system immanent information. One could argue that the law firms and lawyers might file patents outside the EPO and, thereby, also gain experience, for example, in drafting a patent or negotiating with the office. However, as the analysis is restricted to EPO patent applications, the experience within the system seems to be a legitimate and appropriate perspective.

Experience increases over time. It does so as a matter of fact and as a matter of the construction of this indicator, which is defined as the cumulated number of filings over time. It is reasonable to assume decreasing marginal effects of individual filings on the additional experience. In other words, the first and the second patent filing might add much more to the overall experience of a law firm or an individual lawyer, while the 101st or the 1001st filing will add much less. To take this effect of decreasing marginal effects into account, the logarithm of the cumulated number of filings is used instead of the absolute number. However, there is still the problem of strictly increasing experience over time due to the construction of the variable, which might have an effect on the estimations. Moreover, even if the time is controlled by using the information on the filing year, there is a specific impact due to the fact that the total number of filings and, therefore, the level of additional experience are not constant over the years. While the number of filings was much lower in the 1980s, they steeply increased in the second half of the 1990s and—more or less—stabilized on a higher level in the 2000s [35.1, 31, 32]. To cope with this, the individual experience of a law firm or a lawyer, respectively, could be benchmarked against the average experience level across all actors in the patent system in that particular year. This indicator could be characterized as a relative experience level in a particular year, but independent of time effects. However, for the sake of simplicity, and as the overall results allow the same conclusions, we restrict our empirical analyses to the former variable and use the logarithm of the cumulated number of patent filings as the indication for experience here.

35.4 Descriptive Results

All the representatives are located in one of the EPC member states. However, we restrict our focus to EU-28 member countries here. The total and relative numbers (in relation to the number of inhabitants to control for size) vary considerably between countries. Focusing on the year 2010, where we have complete data including PCT filings that already entered the regional phase at the EPO, the numbers of representatives in the member countries vary considerably between almost 2400 in the case of Germany and none at all in the case of Malta (Fig. 35.1a). We count about 1300 representatives in the year 2010 in the UK and about 570 in France, which ranks third. In total, we were able to identify 6286 different representatives in the year 2010.

The ranking changes completely when size effects of the countries are taken into account by relating the number of representatives to the countries' population (Fig. 35.1b). In this perspective, Luxembourg ranks first with almost 40, followed by Germany with 29. The Scandinavian countries Sweden and Denmark are slightly ahead of the UK, all of them having more than 20 attorneys per 1 000 000 inhabitants. Countries like Austria, France, Ireland, or Italy reach numbers between 5 and 10.

In this section, we start with the analysis of the average number of patents previously filed by the representatives—calculated as the accumulated number of patent filings for each representative (Fig. 35.2). One factor influencing the experience is the duration of practice. Eastern European countries have a disadvantage here due to the later accession not only to the EU, but also to the EPCT that underlies the EPO. While the EU average of years of practice per representative is 12, that of eastern European countries is much lower, but also Spain or Luxembourg show below average values. There are a couple of countries that are close to this average or even above, namely with the UK, Ireland, and Austria ahead and Germany, Italy, and the Netherlands slightly below.

The shares of most of the countries in the period between 2000 and 2010 are rather stable for most of the countries with slightly increasing trends in Germany

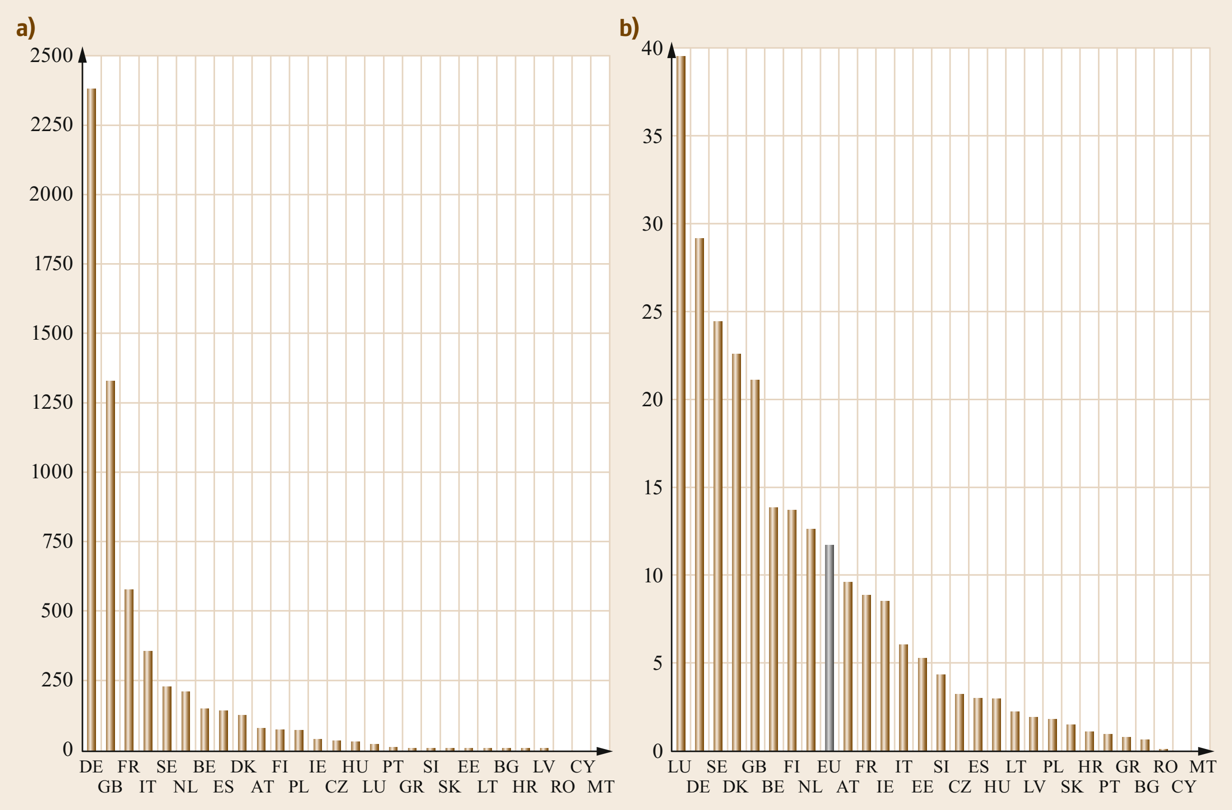

Fig. 35.1a,b Total number of representatives **(a)** and in relation to 1 million inhabitants **(b)** by country of residence of the representative, 2010. Source: EPO-PATSTAT; Fraunhofer ISI calculations

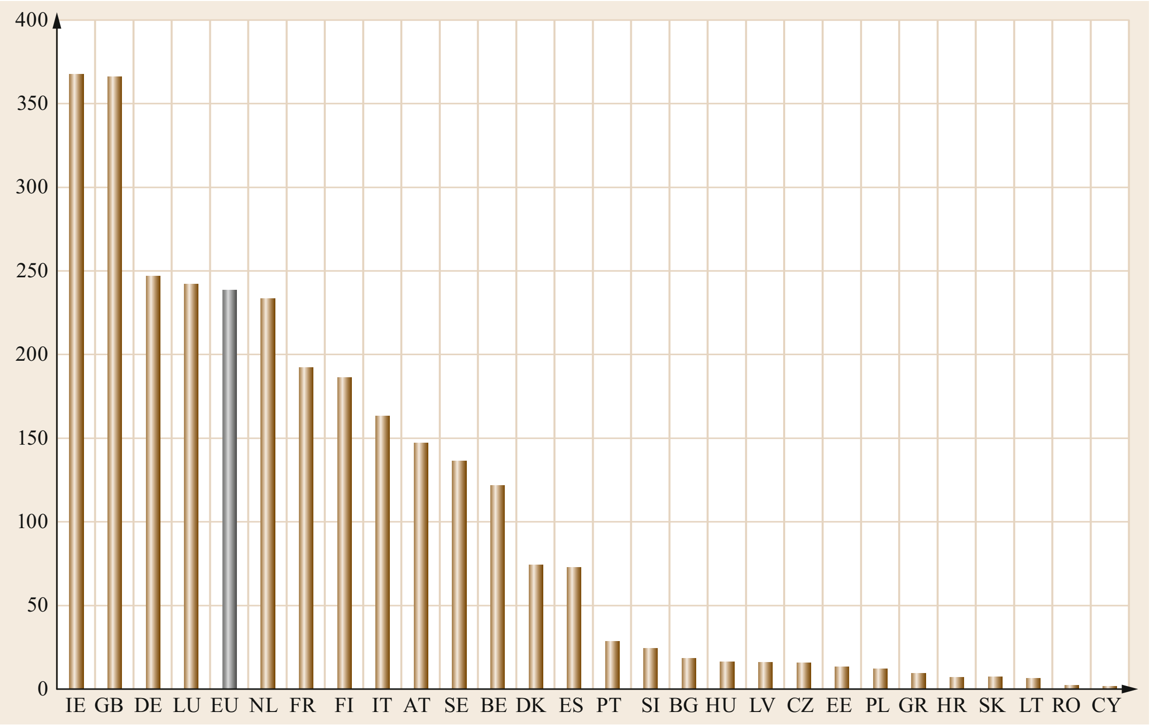

Fig. 35.2 Average experience (cumulated number of filings) of representatives by country, 2010. Source: EPO-PATSTAT; Fraunhofer ISI calculations

and France, but clearly a decreasing trend from 32.4 to 25% in the UK. However, on average, a representative in the UK and in Ireland previously represented almost 370 patents. The numbers for Germany, Luxembourg, and the Netherlands, as well as the EU average accumulate to almost 250, whereas in most other western European countries like France, Finland, and Italy the experience sums up to below 150 patents.

The explanation for these considerable differences is that the high share of the patents processed by UK, Irish, and also by German representatives are filings from non-European applicants, which are subsequent filings to priorities outside Europe. In many cases, these documents are prepared by legal practitioners outside Europe. As these non-European practitioners are not allowed to file patents at the EPO, a corresponding attorney from Europe is necessary to act in between. Essentially, these representatives have much less work, as they often only act as a corresponding representative, so that they can process (in our case simply occur on) many more patents. This is much less work, but also results in less experience in drafting patent applications than if they had to fully prepare them from scratch. Obviously for practical reasons, UK and German representatives are chosen rather frequently by non-European applicants in absolute terms. These practical reasons mainly stem from language issues on the one hand and sheer absolute numbers (availability) on the other hand, but in the end also from experience (economies of scale) as a kind of self-fulfilling process. In relative terms, however, there is a big difference between the UK and the rest of the European countries. As an indication of this, the relation between patents processed by national representatives and the number of EPO filings by applicants from each country is calculated. The most outstanding data can be found in the case of the UK. Representatives from the UK processed about seven times more patents in 2010 than there were filings from UK applicants (Fig. 35.3). The language advantage seems to be the decisive factor here and makes UK law firms the main entry point for US-American applicants—and of course there are also several *European headquarters* of non-European multinational companies in the UK, which is itself partly also a consequence of the language. The effect might be amplified by the fact that the UK industry is not very patent-intensive and, therefore, files rather low numbers of patents per employee [35.32] so that applicants (and filings) from the UK themselves are rather scarce. Inventors from the UK file about 250 patents per one million employments, whereas, for example, inventors from Germany file 770 patents per one million employments [35.33].

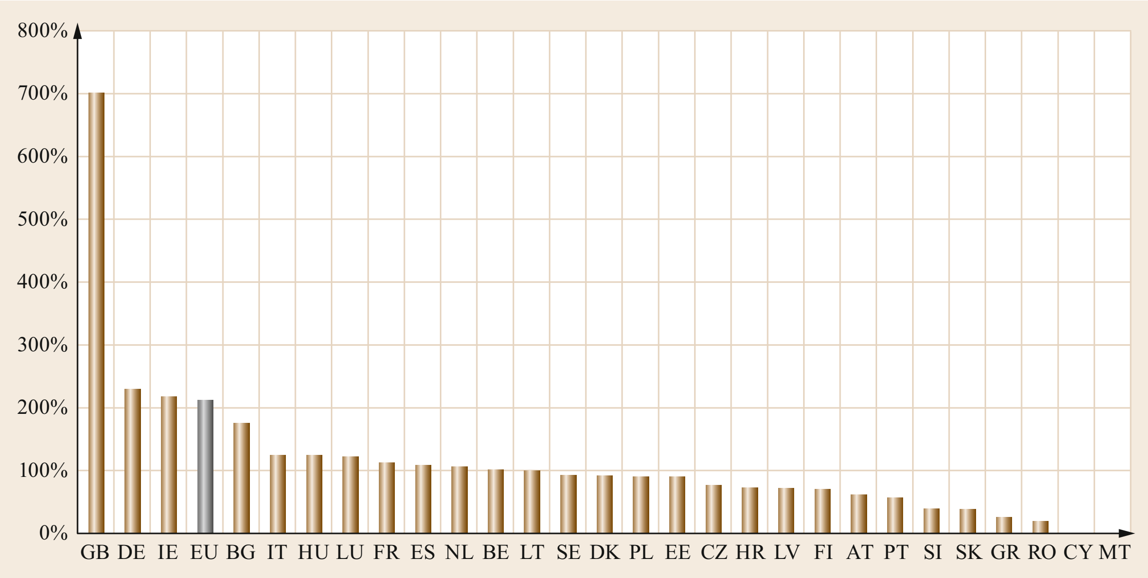

Fig. 35.3 Number of patents processed by representatives in a country as a share of applications from that particular country. The numbers for Bulgaria (and several other smaller countries) should not be over-interpreted. These are based on only 14 patents processed by Bulgarian representatives in 2010). Source: EPO-PATSTAT; Fraunhofer ISI calculations

In Germany and Ireland the relation is more than 2 : 1, with Ireland benefiting from the language advantage as well (including the *European headquarter* effect). Germany is the largest applicant country from Europe at the EPO and files rather high numbers of patents in relation to its work force (patent intensity). It is, therefore, even more remarkable that two times as many patents are processed by German representatives than there are filings by domestic applicants. The explanation for this is—again, in addition to the *European headquarter* effect—simply the large number of law firms, resulting from the proximity to the EPO, but also from the high domestic demand for patent practitioners.

Figure 35.4 provides additional evidence that supports these explanations. Here, a change of the level of analysis from the number of representatives to the number of patents is made. The figure shows the share of patents of three applicant country groups—domestic, other-EU, and countries outside Europe—by the country of residence of the representative.

It can be seen that representatives in the UK, Ireland, Germany but also Bulgaria and Luxembourg process high shares of applications by non-European applicants. Slovenia's and Slovakia's representatives only process patents for domestic applicants. In countries like Finland, Estonia, the Czech Republic, or also Austria, the representatives process high shares of applications by domestic applicants. High shares of filings from applicants located in other European countries can hardly be found. Greece, Hungary, and the Czech Republic, as well as Latvia are exemptions, but with low absolute numbers; 12.4% of the patents processed by Belgian representatives are owned by applicants from other European countries, which is a rather high share compared to most of the other countries. This might be due to the language advantages of Flemish representatives, also processing filings from the Netherlands and Wallonian representatives processing filings from France.

This general finding is further supported by the applicant structure in the countries. German and UK representatives file in about two-thirds of the cases patents for large enterprises. Also, in the Netherlands, Finland, and Sweden rather high shares of larger enterprises' patent filings can be found, which is the result of one or a few very active enterprises in these countries. In France, the shares are similarly high with about 55%. In eastern and southern European countries, on the other hand, there are almost no large enterprises to be found, but higher shares of SME, and often individuals and public research organizations account for shares of around one fourth of all filings. In Greece, for example, half of all filings processed by domestic representatives stem from individuals.

In Belgium and the Netherlands about 40% of patents are represented by internal attorneys—as a reminder: both countries have high shares of large enterprises of more than 50%. Also in Finland or Sweden, the share of internal representatives is close to 30%. In the UK and Germany, this share is about 6.5 and 6.3%, respectively. At least in the case of Germany, this might be somehow surprising, as the share of patent applica-

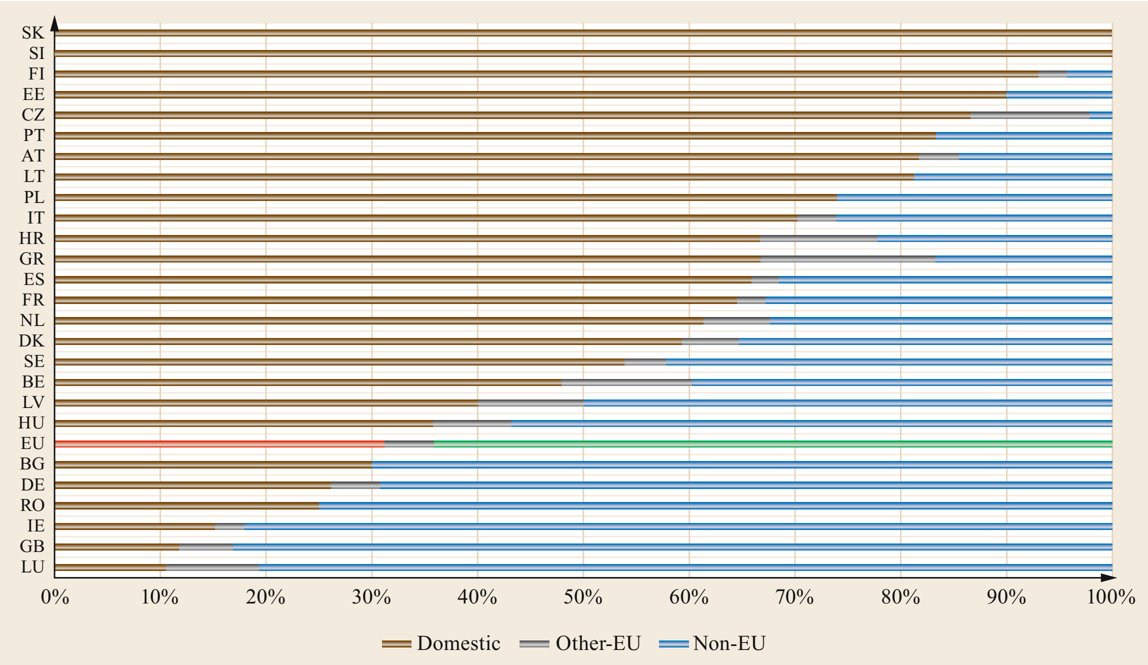

Fig. 35.4 Shares of applicant country groups by country of representative, 2010. Due to low absolute numbers, data for Malta and Cyprus cannot be analyzed. Source: EPO-PATSTAT; Fraunhofer ISI calculations

tions filed by large applicants is rather high [35.26]. As large applicants have a higher probability of employing internal representatives, the expectation for this share might have been higher. One explanation again is that about two-thirds of the patents processed by German representatives are filed by non-European applicants. Another explanation is that there might be a higher division of labor between internal and external representatives, simply due to the fact that German companies have a high absolute output of patent filings, which cannot all fully be processed by internal representatives.

In general, our data suggests that large enterprises employ far more internal representatives than any of the other groups. It is interesting to note, however, that the shares of internal representatives are higher for applications to the EPO by non-EU applicants than by applicants from EU-28 countries. The explanation might be that a number of multinational companies have subsidiaries in Europe, very often with intellectual property (IP) departments or even simply IP management subsidiaries, which then fulfil the criteria of Article 134 of being a resident of the EPC states and/or having its place of business in Europe.

The average number of technological fields per representative in each of the countries of residence of the representative is shown in Fig. 35.5. Representatives from Ireland and the UK cover—on average—more than 25 or more than 20 fields, respectively. This might be seen as another indication of rather high shares of subsequent patents with priorities outside Europe, especially in the US, where representatives from these countries mainly act as corresponding representatives. To act as a corresponding representative it is not absolutely essential to be an expert in the particular technological field. At first sight, however, the result for Germany is in contradiction to this line of argumentation, as the average number of fields is only 13. We found high shares of filings for German representatives originating in non-European countries. Based on these additional insights we might be able to further qualify the above-mentioned result. For Ireland and the UK, the language advantage seems to be the decisive factor for the high shares of non-European filings. For Germany, the language advantage does not really hold, but the proximity to the EPO and the economies of scale, due to a large number of national filings might be attracting factors. This then also results in a higher specialization in terms of the average number of technological fields per representative. In general, Fig. 35.5 shows that representatives in the northern and western innovation-oriented countries seem to be able to cover a larger number of technological fields, whereas—maybe also as a matter of low absolute numbers—representatives in southern and eastern European countries concentrate their technological expertise more.

35.5 Multivariate Results

The descriptive statistics provide an overview of the structures and allow some conclusions on how these structures come into being. However, the question of the role of the patent attorneys (or more precisely of the representatives) in the filing process is not sufficiently addressed by these statistics. In the following, we provide some multivariate analyses based on the data set we have compiled to address these questions.

The first question we analyze addresses whether large enterprises are able to hire more experienced representatives. We will control for some other features like internal versus external representative, time, technology field and country (of applicant).

With classical human capital theory [35.34–40] we assume that individuals can increase their human capital endowment by formal qualification and training, but in addition also simply by their doing, whereby they gain experience. The (labor) market rewards higher human capital endowment by higher (average long-term) income. Usually, when the economic returns on human capital investment are to be estimated in empirical research [35.41, 42], the discussion focuses on formal qualification and takes experience as a kind of control into account. Here, we argue the other way around, as all patent attorneys/representatives should have similar formal qualifications; they differ in their experience, which then is rewarded by the market. We do not, however, have information on the rewards in economic terms, but just assume that this is so. What we can observe in our data, though, is the difference in the experience and the structures of the patent applicants employing these more or less experienced representatives. In addition, and this will be the second part of this multivariate analysis, we can also examine the performance of the representatives, according to their experience and given some structural information on the applicant and the patent.

In Table 35.1 the logarithm of the experience is regressed on the applicant type, the year, a dummy that covers internal versus external representatives, as well as field and applicant countries as control variables. We see that all coefficients are statistically significant, and the model explains about 23.5% of the variance in the data, which is a satisfying level. In the case of applicant type, large enterprises are the benchmark. The representatives hired by individual inventors have the

least experience, followed by representatives of SMEs. Universities, and even more so public research organizations (PROs), employ only slightly less experienced representatives than large enterprises do. On average, internal representatives have slightly less experience, but this might be due to the fact that large numbers of PCT filings entering the European patent system are just to be represented. This is usually not done by internal attorneys—as by definition these companies do not have a subsidiary or branch in Europe. Moreover, even large companies with subsidiaries or branches in Europe might not have legal departments here.

A multinomial logit model (not displayed) restricted to the already processed patents—so essentially excluding still pending patent processes—with the legal status as dependent variable and the experience of the representative as relevant explanatory variable as well as a number of controls shows no significant difference between granted and refused patents. Only the withdrawal rate increases significantly with increasing experience. This could suggest that more experienced representatives act more strategically, given that withdrawals are seen as a—surely imperfect—indication of strategic behavior. It could also well be just an effect of the PCT filings, which add to the experience of some representatives, without requiring the full workload of drafting a patent. This, however, could then also be seen as a kind of strategic behavior. Not all PCTs are strategic patents, but most strategic patents—defined as patents with postponed decision, rather with option values than direct economic values, and in some cases also with more passive or blocking motives—are PCTs. Filings from the US, most of them entering the EPO via the PCT system, have a much lower probability of being granted and, therefore, a higher withdrawal rate than filings from most other countries [35.18].

The impact of the experience of the representative on the probability of being opposed, given that the patent is granted, is displayed in Table 35.2. Indeed, according to these estimations, the experience of the representative mentioned on the patent signifi-

cantly reduces the probability that a patent is opposed. Granted patents that reached the EPO via the PCT route have a higher probability of being opposed, as well as such patents that have a higher number of forward citations. While patents filed by public research organizations are less often opposed than those of large enterprises, patents by SMEs have a higher probability of being opposed, given the model specification we chose here and which reaches a satisfying pseudo R^2 of about 5.4%.

The impact of experience on strategic aspects of patenting can also be found in Table 35.3, where we report the results of a Poisson regression of the number of claims. More experienced representatives file significantly more claims: PCT filings—on average—also have a higher number of claims, and university filings have slightly more claims than those of the applications of large enterprises, while SMEs, public research organizations, and also individual inventor's patents are filed with slightly fewer claims.

35.6 Summarizing Discussion

This chapter tried to address a new line of research in patent analyses, namely the role of the patent attorney/representative in the filing process. The literature, especially the empirical literature, on this issue is rather limited so far, which might in part be a result of limited availability of ready to use data. In consequence, a dataset was generated for EPO patents and their representatives.

The analysis of the structure of representatives at the EPO shows a high concentration in absolute as well as in relative terms in Germany and the UK, with some activity in other larger applicant countries like France, Italy, Sweden, or the Netherlands. As a matter of fact the most experienced representatives are located in Germany and the UK, but this result might be biased due to high numbers of subsequent filings in these countries, originating mainly in the US or also Japan. Explanations for this effect are language advantages in the case of the UK (and also Ireland) and geographical proximity to the EPO as well as economies of scale in the case of Germany.

Large companies are responsible for the majority of the representatives' workload in Germany and the UK, but also in France, the Netherlands, Belgium, or Sweden—of course, mainly because many large and also multinational companies have their headquarters or IPR departments in these countries. The much lower absolute numbers of patents in southern and eastern European countries mainly stem from SMEs, individual inventors, and in some countries—for example, Portugal, Greece, Hungary, or Latvia—also stem from public research organizations or universities, which account for large shares of filings from these countries.

The multivariate analyses suggest that the (financial) resource endowment is a decisive factor in the hiring of patent attorneys. Large enterprises are able to employ the most experienced representatives, while the representatives of individual inventors are the least experienced in our dataset. While the experience has no significant impact on the probability of getting a patent granted or refused, the probability of a withdrawal increases with increasing experience of the representative. This was interpreted as experienced attorneys act more often strategically than their less experienced colleagues. In addition, it was shown that the patents of more experienced representatives were significantly less often opposed than the ones by less experienced attorneys. However, the large number of non-European filings processed in some countries might intervene, but was not separately estimated in this paper. In sum, the results show that it is possible to analyze the role of the patent attorney in the filing process, and that this is a relevant but so far under-explored dimension in the economics of patents field. The experience of the representative has a considerable impact on the outcome.

The role and characteristics of representatives on patent filings as an object of economic research is a topic that is still in its infant stage. Only limited empirical evidence is available so far, and methods and indicators are far from having been established. The analyses and discussions presented in this chapter suggest further distinctions, for example, between first and subsequent filings in future research. A more detailed analysis of internal versus external, as well as registered, European attorneys versus other legal representatives seems a reasonable distinction to be taken into account as well. A fine tuning of the experience measure also seems appropriate. We used the cumulated number of all patent filings being represented by the attorney in the past. A differentiation of the experience accumulation by different kinds of patent applications—here, we mainly argued for a distinction between subsequent PCT filings entering the regional phase versus direct filings at the EPO or at a national office in Europe—could also be worthwhile. In addition, taking into account the size of the law firm or the *organizational knowledge* of a law firm measured by the cumulated number of patents processed by the particular firm (instead of individual representative) could be another dimension to be examined. The rather rudimentary theoretical foundation with some basics of the human capital theory that was mentioned in this chapter deserves further exploration as well.

He studied Social Sciences, majoring in Micro- and Macro-Sociology, Applied Social Research, and Quantitative Methodology at the University of Mannheim and graduated with a diploma in 2008. Peter Neuhäusler was awarded his Doctoral degree in Innovation Economics at the Technical University of Berlin in 2012.

36. Exploiting Images for Patent Search

Ilias Gialampoukidis, Anastasia Moumtzidou, Stefanos Vrochidis, Ioannis Kompatsiaris

Patent offices worldwide receive considerable numbers of patent documents that aim at describing and protecting innovative artifacts, processes, algorithms, and other inventions. These documents apart from the main text description may contain figures, drawings, and diagrams in an effort to better explain the patented object. Two main directions are presented in this chapter; concept-based and content-based patent retrieval. Concept-based search utilizes textual and visual information, fusing them in a classification late fusion stage. Conversely, content-based retrieval is based on the shape/content information from patent images and is therefore based on the visual descriptors that are extracted from binary images. Concepts are extracted using classification techniques, such as support vector machines and random forests. Adaptive hierarchical density histograms serve as binary image retrieval techniques that combine high efficiency and effectiveness, while being compact and therefore capable of dealing with large binary image databases. Given the vast number of images included in patent documents, it is highly significant for the patent experts to be able to examine them in their attempt to understand the patent contents and identify relevant inventions. Therefore, patent experts would benefit greatly from a tool that supports efficient patent image retrieval and extends standard figure browsing and metadata-based retrieval by providing content-based search according to the query-by-example paradigm.

36.1 How Patent Document Analysis Evolved

The number of patent documents describing and protecting innovative artifacts, processes, and other inventions that are submitted to patent offices worldwide is growing steadily, thus necessitating the development of advanced patent search technologies that take into consideration that complexity and the unique features of patents. In this direction, the intellectual property and the information retrieval communities have shown great interest in patent image search, which is expressed with common research activities in relevant conferences (e. g., the *International Retrieval Facility Conference* (IRFC) and *The Conference and Labs of*

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_36

the Evaluation Forum Track on Intellectual Property (CLEF-IP). Although a typical patent document contains multimedia information, the majority of the search engines rely upon text to provide search functionalities so the ideas to be patented are usually described in text format. However, many patents include a drawing section that may contain figures, drawings, diagrams as a means for further describing patented inventions and thus they should be considered in the patent retrieval systems given that images by nature are not affected by the applicant's language and remain intact despite the evolvement of the scientific terminology over the years. As a consequence, an increasing interest in patent image and multimodal search has been shown by the intellectual property and the information retrieval communities. The retrieval functionalities of patent image and multimodal systems should extend beyond figure browsing and metadata-based retrieval to include content-based searches including query-by-example search, image classification, and concept extraction.

This chapter analyzes techniques from document image analysis that are employed for patent preprocessing in order to extract the patent images and retrieve visually similar images using content-based and concept-based techniques. Regarding content-based search, it will discuss applications of image processing and visual feature extraction algorithms such as salient-based (e. g., scale invariant features transform (SIFT) [36.1], speeded-up robust features (SURF) [36.2]) as well as color layout and edge histograms, that capture the global characteristics of images (e. g., colored images, images depicting objects, images with landscapes). Moreover, the chapter presents methods oriented towards capturing features of binary images such as the adaptive hierarchical density histogram (AHDH). Retrieval is performed based on similarity metrics using such features, in an effort to imitate the way humans perceive visual similarity.

Following the trend of modern image retrieval approaches that steadily move towards concept-based image search, we present concept extraction approaches for patent images. Concept extraction techniques involve identifying common characteristics among images that classify them into a specific semantic category or depict a specific concept. Specifically, it involves extracting low-level features from patent images combined with supervised machine learning algorithms, such as support vector machines and random forests (RFs). Aiming to boost the effectiveness in concept extraction, hybrid approaches are applied that consider both textual and visual features.

Bridging the semantic gap in patent document search has also been discussed in [36.3]. Firstly, a text/graphic separation module separates the textual elements from the graphical ones, through an optical character recognition (OCR) engine on the text layer, while the nodes and edges on the graphical layer are analyzed. The vectorial-based approach requires a conversion module that transforms the raw pixel image into a vectorial representation. Query expansion methods have also been used in patent image retrieval [36.4], where *LambdaRank* was employed to improve patent retrieval performance by combining different query expansion methods with different text fields weighting strategies of different resources. Patent query logs have also been exploited in [36.5] to expand the query terms that are used by patent examiners. Patent retrieval systems are also compared in the short review of [36.6], but the evaluation of a patent retrieval system is a challenging task [36.7].

The chapter discusses the results for some indicative patent image feature extraction methods [36.8] that are applied for content-based image retrieval (Sect. 36.4). Concept-based patent retrieval methods are discussed in Sect. 36.5, exploiting the involved visual information, in combination with textual information [36.9–11]. Furthermore, specific use cases and interaction modes are presented [36.12], as introduced in the search requirements (Sect. 36.2), demonstrating the benefits and impact of such technologies to patent examiners and industrial developments. Finally, we discuss limitations from recent research and future directions (Sect. 36.6).

36.2 Patent Search Scenario and Requirements

An example of a mechanical search as described by a professional patent searcher [36.13] is the following: "A dancing shoe with a rotatable heel to allow rapid pivoting about your heel. In a preferred embodiment, the heel should have ball bearings." The patent searcher has to distill the core for this disclosure, which could be used as the basis of the upcoming search. Therefore, for the particular example, the core could be expressed by the following concepts:

- Concept 1: *Dancing shoe*
- Concept 2: *Rotating heel*
- Refined Concept 2: *Rotating heel with ball bearings*.

Afterwards, the patent searcher proceeds by keyword-based search on the aforementioned concepts and classification areas. In many cases, such as the aforementioned example, both the important information and the core are described using figures. Thus, it is evident that the existence of such concepts that describe the figures inside patents (i. e., dancing shoe and rotating heel for this example) would simplify and expedite the search of the patent expert.

To that end, it is required to support concept extraction from images, through the exploitation of the heterogeneous information (textual and visual) per patent (image and figure description). However, the image description is not sufficient for the concept extraction in patent images, since many figures can be associated with misleading or incomplete descriptions (e. g., references to other figures or parts of the patent). Moreover, the automatic mapping of figure captions to the figures themselves is not a trivial task and it can be further complicated in the case of handwritten figure labels that cannot be automatically recognized as labels. Another reason is that many patents (and consequently the included image descriptions) are written in languages that present challenges in translation (e. g., Chinese), and thus patent search can only rely on visual information.

Moreover, a set of requirements regarding the system performance has been reported in [36.10]. Firstly, the system should be on the one hand scalable considering that it needs to cope with vast amounts of content (in the order of millions of patent images), to avoid expensive fusion algorithms, but on the other hand the representations of the patent images should suffice so that the concept detectors can perform satisfactory, i. e., accuracy should be around 85–90% (depending also on the concept characteristics). Secondly, a significant number of concepts that are indicative of the patent images of each international patent classification (IPC) class and subclass have to be defined by patent experts, while manual annotation of relevant examples is required for training the machine learning algorithms, and thirdly, the framework needs to use open technologies and standards, in order to be easily adaptable to the established patent search platforms.

36.3 Feature Extraction

The extraction of features involves a preprocessing stage before generating visual and textual features. The initial document processing stage is required in order to extract all the desired images and subfigures embedded in the document, along with related metadata. The decomposition of each document page of the drawing section of the patent PDF file and the extraction of the figures found in the retrieved pages can be performed using automatic segmentation techniques [36.14].

In the sequel, each image is served into the feature extraction component, where the visual and textual based features are produced.

36.3.1 Visual Features

The extraction of global concepts requires the use of visual features that represent the image in a global manner and which can handle the special features and complexity of patent images. The distinctive characteristic of patent figures is that they are usually black-and-white and that they depict technical information in diagrammatic form. As far as coloring is concerned, until recently all the patent figures included in the patent documents were black-and-white. A few Korean patent publications deviate from the general rule and include color images. Most visual representation features are based on color and texture, which are absent in most patent images, thus we need to apply an algorithm that considers other visual elements, such as geometry and pixel distribution. To this end, we apply the algorithm proposed in [36.8] to extract the adaptive hierarchical density histograms (AHDHs) as visual feature vectors. The AHDH was devised specifically to deal with binary and complex images and the overall feature extraction method can be found in Sect. 36.4.1. The experiments realized using several patent datasets revealed that the AHDH outperforms the other state-of-the-art methods, as presented in [36.8].

36.3.2 Textual Features

In order to exploit the textual descriptions related to each figure in the patent document, the figure captions are processed and textual features are extracted from the patent images. In particular, a bag-of-words (BoW) approach is applied, modeling each figure with a vector. The BoW representation method is a simplifying assumption used in natural language processing and information retrieval, where a text description such as a sentence or a document is represented as an unordered collection of words, without considering grammar and word order. The generation of such a vector requires the definition in advance of a vocabulary that consists of the most frequently used words of this dataset. Then for

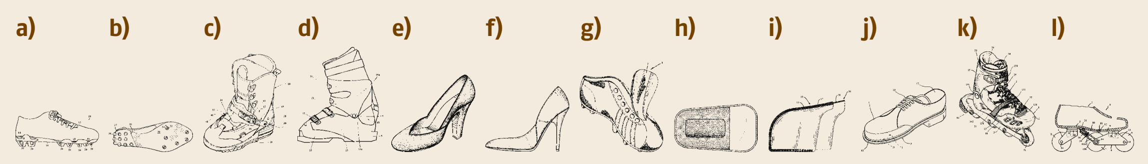

Fig. 36.1a–l Sample of patent images and its associated concepts and description; **(a,b)** cleat, **(c,d)** ski boot, **(e,f)** high heel, **(g,h)** tongue, **(i,j)** toe caps, **(k,l)** roller skate. Reprinted from [36.10], with permission from Elsevier

each word, the term frequency is computed, weighted by inverse document frequency scores (tf-idf) in order to minimize the significance of words appearing too often

$$\text{tf-idf}_{ij} = \frac{n_{id}}{n_d} \log \frac{D}{n_i}\,, \tag{36.1}$$

where n_{id} is the number of occurrences of word i in document d, n_d is the number of words in document d, n_i is the number of occurrences of word i in the whole database, and D is the total number of documents in the database. Apparently, an initial preprocessing on the raw text is required for the removal of stop-words and for stemming the remaining words, using for example Porter's stemming algorithm [36.15].

Several concepts appear in Fig. 36.1; Cleat: A short piece of rubber, metal et cetera, attached to the bottom of a sports shoe used mainly for preventing someone from slipping (a), (b); Ski boot: A specially made boot that fastens onto a ski (c), (d); High heel: Shoes with high heels (e), (f); Tongue: The part of a shoe that lies on top of your foot, under the part where you tie it (g), (h); Toe caps: A reinforced covering of leather or metal for the toe of a shoe or boot (i), (j); Roller skate: A shoe or boot with two or four wheels or casters attached to its sole for skating on hard surfaces (k), (l). All images are manually extracted from around 300 patents belonging to A43B and A63C IPC subclasses, which contain parts of footwear.

36.4 Content-Based Patent Image Retrieval

Content-based image retrieval (CBIR) [36.16] has become one of the most developed fields of computer vision for image retrieval [36.17]. CBIR systems use different types of queries including a query-by-example image, sketch, or region and return relevant images from a given database, by considering textual annotation, media metadata of low-level visual features. CBIR techniques can be applied in several domains, either as standalone implementations supporting queries-by-example, or as complementary modules of an integrated framework that incorporates several retrieval options, such as text and concept search (Sect. 36.5), in order to improve and enhance the results.

CBIR algorithms represent image content with representative feature vectors that employ color, texture, and shape characteristics [36.18]. Although modern technologies generate high-quality color images, there are still many image databases that contain exclusively binary (i. e., black-and-white) images, such as patent images, trademarks, technical drawings, or other specific applications like road signs [36.19], botanical collections [36.20], or medical images [36.21]. The pixels of such images are generated from original black and white documents, which are scanned to gray-scale ones, and then thresholded to the final binary images. Therefore, they contain no color and minimum texture information. As a result, in order to retrieve effectively such images, a content-based binary image analysis technique that considers the image geometric information accurately should be applied [36.22]. The MPEG-7 standard has summarized the required criteria for techniques that measure the similarity between binary images [36.22]: high discrimination capability, invariance to geometric transformations, i. e., rotation, translation and scaling, computational efficiency, robustness to distortion and noise, compactness, generality of the application, and handling large image databases without heavy performance degradation.

However, the aforementioned requirements pose several challenges to binary image retrieval given that many binary images, including technical drawings and patent images, are produced from noisy analog sketches that are exposed both to arbitrary time degradation and content degrading during digitizing. Moreover, it is often the case that binary images are sketches created with a drawing style that is determined exclusively by the creator's preferences and the specific application.

The following section presents the adaptive hierarchical density histogram (AHDH) which employs an adaptive pyramidal decomposition of the image into regions based on the recursive calculation of geometric centroids, and produces a robust binary image descriptor by generating the density histogram of each region.

36.4.1 Adaptive Hierarchical Density Histogram (AHDH)

The algorithm for the generation of AHDH involves two main parts: (a) the region partitioning based on the generation of the adaptive geometric centroids as proposed in [36.23] and (b) the adaptive hierarchical density histogram generation as proposed in [36.8]. Figure 36.2 depicts a schematic view of the algorithm, while Table 36.1 contains the definitions of the most important variables involved in the theoretical analysis of the algorithm.

Binary images are treated as two-dimensional (2-D) planes where the set of shape pixels B is defined. The number of pixels that belong to the shape are defined as N. Before initializing the algorithm, we normalize the pixel coordinates in order to be translation-invariant. Moreover, we define as R_i^l, $i = \{1, 2, \dots, 4^{(l-1)}\}$ the i-th rectangular region of a binary image, which corresponds to the set of black pixels included in the region. Regions are produced progressively, in an iterative manner, by using the following adaptive geometrical centroid estimation algorithm, which leads to the construction of an adaptive asymmetric orthogonal grid that covers the entire (black-and-white) image. Since region partitioning is triggered by an iterative algorithm, l is the number of iteration, or *level*. Each rectangular region R_i^l consists of two main features: first, the number of black pixels N_i^l that lie in it; and second, its area E_i^l.

Table 36.1 Necessary notation

Symbol	Definition
B	The set of black pixels that belong to a binary image
N	The amount of black pixels that belong to a binary image
R_i^l	The i-th region of the l-th level of a binary image
N_i^l	The number of black pixels that belong to the region R_i^l
E_i^l	The area of a region R_i^l
$SR_{i,j}^l$	The j-th subregion of the region R_i^l
$N_{i,j}^l$	The number of black pixels that belong to the region R_i^l
$E_{i,j}^l$	The area of subregion $SR_{i,j}^l$
$d_{i,j}^l$	The density of a subregion $SR_{i,j}^l$ of a region R_i^l
$\hat{d}_{i,j}^l$	The relative density of a subregion $SR_{i,j}^l$ of a region R_i^l
l_{d}:	The minimum level for which a quantized feature is used
w_i	The i-th distribution word that is used for quantization of $\hat{d}_{i,j}^l$
$h(w_i)^l$	The histogram value of the i-th distribution word in the l-th level
L	The lexicon that is formed from all distribution words
FV_l	The density feature of the l-th level that was constructed by the employment of density
$\hat{FV}_l$	The relative density feature of the l-th level that was constructed by the employment of relative density

For each iteration or level l, a region partitioning procedure is applied which involves estimating the geometric centroid of all regions R_i^l produced and the splitting of each region into four subregions $SR_{i,j}^l$, $j =$

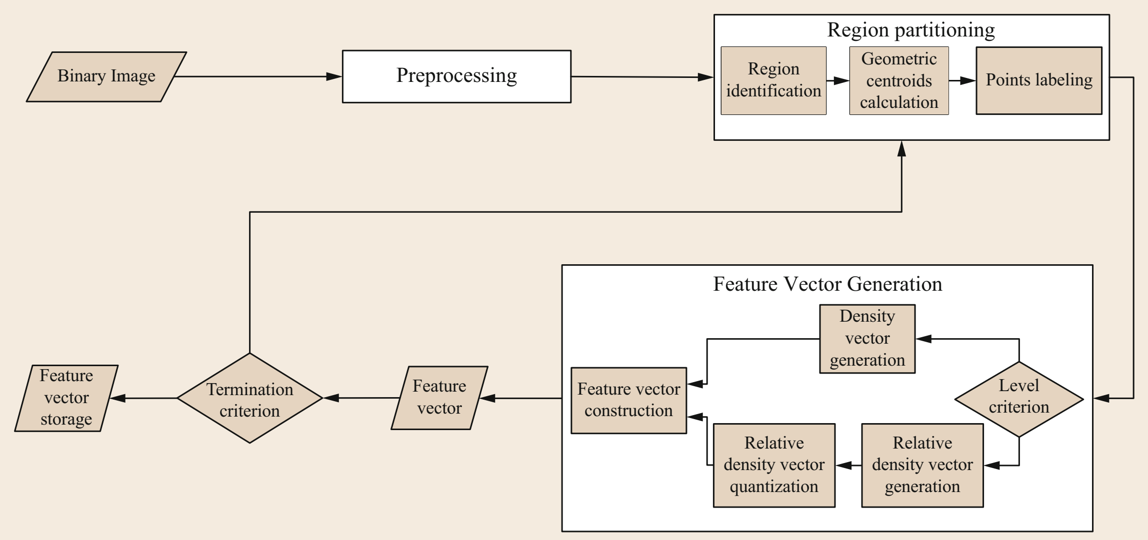

Fig. 36.2 Block diagram for the generation of the adaptive hierarchical density histogram (reprinted from [36.8], with permission from Elsevier)

$\{1, 2, 3, 4\}$ using the geometric centroid as the center. The initial region (i. e., for $l = 1$) is the whole image and for $l > 1$ all regions of level l are the subregions of level $l - 1$. This iterative procedure is terminated when the termination level is reached.

The feature extraction procedure depends on the level value; in *lower* levels, the feature is a vector of the distribution of the N_i^l black pixels into the four subregions, while in *higher* levels a two-class classification of each subregion is employed. The two classes are labeled as *Full* and *Empty* and are defined by the percentage of N_i^l black pixels that lie in the subregion in comparison to the percentage of the region's area E_i^l that belongs to the subregion. The combination of the classes of all four subregions of a region produces a *distribution word*. This *distribution word* histogram is used as the levels feature vector.

In the following section, we will provide some insight regarding the rationale behind the selection of different feature extraction procedures for different level values.

Region Partitioning

Region partitioning is performed using the geometric centroid extraction method that was introduced in [36.24]. Thus, in each level l, a number of 4^{l-1} regions R_i^l has to be processed. We consider a separate Cartesian coordinates system for each region R_i^l, and the equation that captures the geometrical centroid [36.24] of each nonempty region R_i^l is the following

$$x_c = \frac{\sum_{(x,y)\in B_i^l} x}{N_i^l}, \qquad y_c = \frac{\sum_{(x,y)\in B_i^l} y}{N_i^l}. \tag{36.2}$$

N_i^l denotes the amount of black-pixels set B_i^l in the processed region R_i^l, and (x, y) are the pixel coordinates. These centroids partition the image plane into an adaptive hierarchical biased orthogonal grid (Fig. 36.3).

Adaptive Hierarchical Density Histogram Generation

Two different approaches are considered for the construction of the feature vector: (a) density features and (b) quantized relative density features. For levels l less than an experimentally defined level l_d, density features are estimated, while if $l \geq l_d$ quantized relative density features are computed. The features are calculated for all regions at each level and the overall feature vector is updated at each iteration of the algorithm.

Thus, in the l-th level (i. e., after l iterations), 4^{l-1} regions R_i^l are identified, with area E_i^l and N_i^l black pixels. For each of these regions, the centroid estimation results in a partition into four new subregions $SR_{i,j}^l$, $j = \{1, 2, 3, 4\}$ with area $E_{i,j}^l$ and $N_{i,j}^l$ black pixels, where

$$\sum_{j=1}^{4} N_{i,j}^l = N_i^l$$

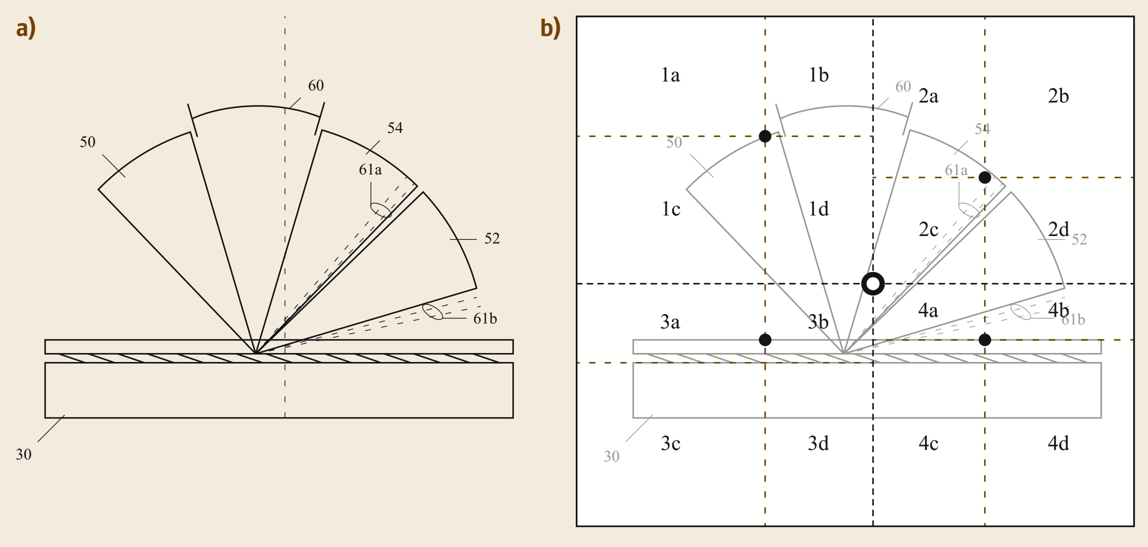

Fig. 36.3 **(a)** Binary figure 15c of patent EP 1 555 563 A2 of the European Patent Office (reprinted from [36.9], with permission from Elsevier). **(b)** First- and second-level centroids and partitions (reprinted from [36.8], with permission from Elsevier). Each subregion is characterized by a number that labels the first-level partition followed by a letter that marks the second-level partitions. It is evident that the iterative geometric centroid procedure generates an adaptive hierarchical biased orthogonal partition

and

$$\sum_{j=1}^{4} E^l_{i,j} = E^l_i \,.$$

Two variables are defined which are the density $d^l_{i,j}$ of a subregion $\mathrm{SR}^l_{i,j}$ of a region R^l_i and the relative density $\hat{d}^l_{i,j}$. Density $d^l_{i,j}$ is defined as the amount of black pixels of a subregion $\mathrm{SR}^l_{i,j}$ divided by N^l_i, while relative density $\hat{d}^l_{i,j}$ as the subregion density compared to the ratio of the subregion area $E^l_{i,j}$ over the region area E^l_i

$$d^l_{i,j} = \frac{N^l_{i,j}}{N^l_i}, \qquad \hat{d}^l_{i,j} = \frac{E^l_i N^l_{i,j}}{N^l_i E^l_{i,j}} \,, \tag{36.3}$$

where $1 \le i \le 4^{l-1}$ and $1 \le j \le 4$. Subsequently a $4^{l-1} \times 4$ feature array FA_l is constructed by the densities of each new subregion.

$$\mathrm{FA}_l = \begin{vmatrix} d^l_{1,1} & d^l_{1,2} & d^l_{1,3} & d^l_{1,4} \\ d^l_{2,1} & d^l_{2,2} & d^l_{2,3} & d^l_{2,4} \\ \cdots & \cdots & \cdots & \cdots \\ d^l_{4^{l-1},1} & d^l_{4^{l-1},2} & d^l_{4^{l-1},3} & d^l_{4^{l-1},4} \end{vmatrix} \,. \tag{36.4}$$

Finally, the FA_l is serialized to form the l-level feature vector FV_l

$$\begin{aligned} \mathrm{FV}_l = \Big\{ & d^l_{1,1}, d^l_{1,2}, d^l_{1,3}, d^l_{1,4}, d^l_{2,1}, d^l_{2,2}, d^l_{2,3}, d^l_{2,4}, \\ & \ldots, d^l_{4^{l-1},1}, d^l_{4^{l-1},2}, d^l_{4^{l-1},3}, d^l_{4^{l-1},4} \Big\} \,. \end{aligned} \tag{36.5}$$

In the same way, the feature vector $\hat{FV}_l$ is constructed, which involves $\hat{d}^l_{i,j}$ instead of $d^l_{i,j}$

$$\begin{aligned} \hat{FV}_l = \Big\{ & \hat{d}^l_{1,1}, \hat{d}^l_{1,2}, \hat{d}^l_{1,3}, \hat{d}^l_{1,4}, \hat{d}^l_{2,1}, \hat{d}^l_{2,2}, \hat{d}^l_{2,3}, \hat{d}^l_{2,4}, \\ & \ldots, \hat{d}^l_{4^{l-1},1}, \hat{d}^l_{4^{l-1},2}, \hat{d}^l_{4^{l-1},3}, \hat{d}^l_{4^{l-1},4} \Big\} \,. \end{aligned} \tag{36.6}$$

The employment of the density or relative density vector is determined by the partition level. Specifically, experiments have shown that the density vector performs best in lower levels. Hence, the feature vector of these levels is simply the serialized density vector of (36.5). Unfortunately, the dimension of the density feature increases exponentially with the number of levels and thus it is not considered appropriate for representation in higher levels. Conversely, in the higher level an image is decomposed into exponentially smaller parts and therefore the information that each feature element contains is rapidly decreasing. In order to overcome those difficulties, we employ a simple density lexicon scheme that reduces descriptor size even for high levels. This quantization process can be applied in either density or relative density vectors (36.6).

Relative Density Vector Quantization

Contrary to centroid vectors, density and relative density vectors may also be (vector) quantized. Thus [36.8] perform vector quantization in relative density vectors.

Subregions $\mathrm{SR}^l_{i,j}$ are labeled as *Full* or *Empty*. Specifically, when

$$\hat{d}^l_{i,j} \ge 1 \,,$$

the subregion is labeled as *Full*, otherwise it is labeled as *Empty*. The motivation behind the use of the Empty and Full labels can be statistically explained. Specifically, when the black pixels of a region R^l_i fall in the four subregions following a uniform random distribution, the expected value of relative density is 1 for every subregion. Consequently, a subregion is labeled *Full* or *Empty* depending on the amount of pixels that lie in its interior compared to the statistically expected value. It should be noted that density vector quantization can not utilize such a statistical measure and the assignment of labels *Full* and *Empty* is fully arbitrary since quantization is controlled by a manually chosen between-classes threshold.

At this stage, a lexicon L of *distribution words* w is defined, which represents the 16 combinations of the 4 Full or Empty subregions of a processed region. Assuming that E corresponds to Empty and F to Full, the lexicon L has the following format

$$\begin{aligned} L &= [EEEE, EEEF, EEFE, \ldots, FFFF] \\ &= [w_0, w_1, w_2, \ldots, w_{15}] \,. \end{aligned} \tag{36.7}$$

However, the valid words that are used are actually 15. *EEEE* or w_0 is a nonvalid word, since, by the definition of relative density the amount of black pixels of a subregion can not be less than the expected value for all four subregions of any region. Therefore, according to the above lexicon, the quantized feature for each level is

$$\hat{FV}_{\mathrm{q},l} = [h(w_1)^l, h(w_2)^l, \ldots, h(w_{15})^l] \,, \tag{36.8}$$

where $h(w_i)^l$ is the normalized histogram, estimated by counting the number of appearances of the respective word, normalized over the total number of subregions in the level l (i. e., $h(w_1)^5$ is the histogram value of the word EEEF in the 5 th level).

Eventually, the newly constructed feature vector is merged with the feature vector that was generated during the previous iterations

$$FV = \left[\mathrm{FV}_1\, \mathrm{FV}_2\, \ldots \mathrm{FV}_{l_\mathrm{d}-1}\, \hat{\mathrm{FV}}_{\mathrm{q},l_\mathrm{d}}\, \hat{\mathrm{FV}}_{\mathrm{q},l_\mathrm{d}+1}\, \ldots \hat{\mathrm{FV}}_{\mathrm{q},l}\right],$$

where l_d, as discussed, is the first level for which quantized relative density features are extracted. When the algorithm is complete, the final FV represents the adaptive hierarchical density histogram of the image and can be used for retrieval purposes.

At this point, we should note that the relative density vectors are employed and quantized only to allow the modeler to reach the deepest levels, where local information about the black pixels topological structure exists. In the upper levels, this is both unnecessary and ineffective, given that the global distribution of black pixels is much better represented by the density vector instead of the knowledge that its relative density vector belongs to a certain class.

36.4.2 AHDH Evaluation in Patent Image Retrieval

A patent image database that includes 2000 binary images has been created in order to evaluate and compare the AHDH method against other methods used in similar cases, including edge orientation autocorrelogram (EOAC)[36.25], triple adjacent segments (tAS) [36.26], and Yang's centroid vector [36.24]. As far as the patent image database is concerned, it contains images extracted from patent documents filed to the European Patent Office [36.27]. These images are usually very complex and cannot be easily segmented into simple shapes, or into connected components with a single contour. Therefore, the contour-based descriptors of [36.25, 28], as well as the technique introduced in [36.29] that requires image partition into filled in regions, are excluded from this comparison. The images used as queries are 120 images randomly selected from the initial database and the number of relevant images found in the database for each query varies from 2 to 73. The AHDH method was tested with $l_\mathrm{d} = 3$ and $l = 10$, while all other methods were implemented with the parameters defined by the corresponding publications.

The precision-recall curves are shown in Fig. 36.4. After a careful observation, we can deduce that for identical recall rates, the AHDH precision rate is at least 20–40% higher than the other techniques, while for identical precision rates, the recall rate is 5–25% better. Table 36.2 contains the maximum F-Score performance values for all methods. Finally, we should note that when recall and precision values are equal (and consequently the F-Score is equal to them), the AHDH method leads to a mutual enhancement of at least 12.7% both for recall and precision values. The above com-

Table 36.2 Performance comparison of AHDH, EOAC [36.25], tAS [36.26], and the centroid vector method proposed in [36.24] for binary image retrieval in a patent image database

Patent image performance comparison			
Method	Recall (%)	Precision (%)	F-Score
AHDH	71.39	67.74	70.13
EOAC	62.97	52.53	59.06
Centroid vector (Yang)	49.82	59.49	52.67
tAS	48.6	53.41	50.1

parison indicates the improved performance of AHDH over the other prominent binary image descriptors.

A query-based experiment has also been conducted [36.8], in which each image example was associated with the 25 most similar images retrieved. For this experiment, 86.9% of the manually annotated near-replicas or similar images were successfully retrieved. Figure 36.5 depicts the query image and the first retrieved images for two cases that involve visual search for technical drawings of circular shape and flowcharts.

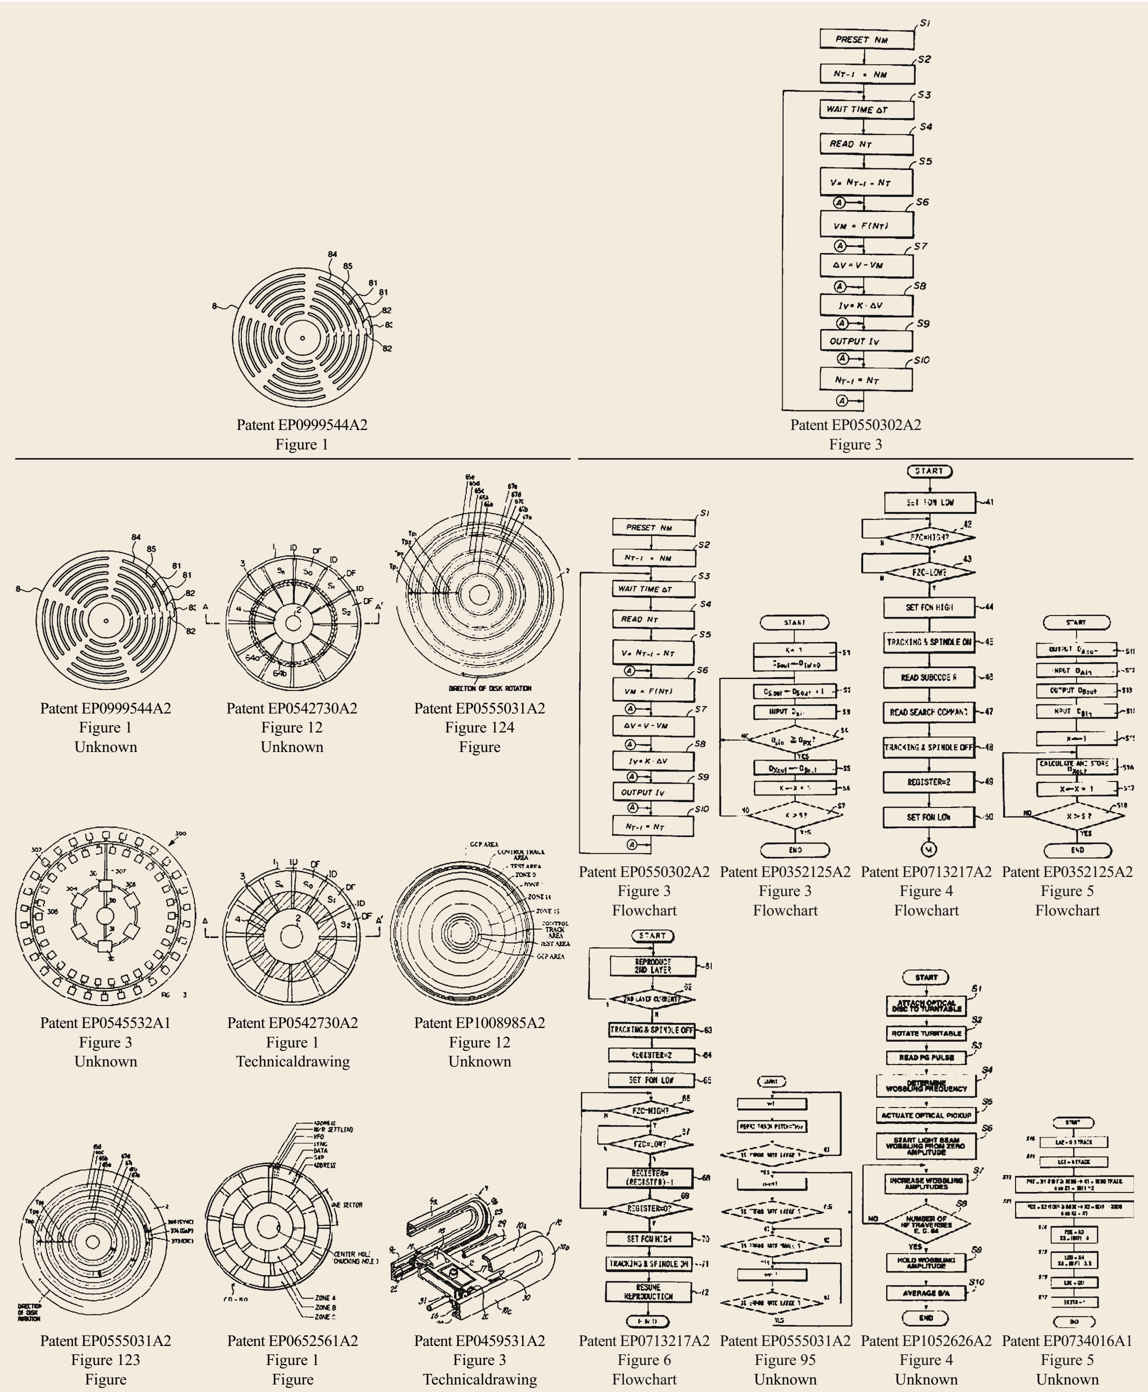

Fig. 36.5 A patent image example and the first nine retrieved similar images for flowcharts and technical drawings

36.5 Concept-Based Patent Image Retrieval

Advanced patent search tools exploit nontextual elements that play a key role in patent search through patent image retrieval. Following the latest challenges in image analysis (semantic indexing, semantic gap), patent image search deals with patent image classification [36.30] and concept extraction [36.10].

The motivation behind the interest in patent concept-based search is revealed by the scenario described earlier in Sect. 36.2, where a patent searcher searches for a dancing shoe that incorporates a rotating heel with ball bearings. The main concepts of the search are recognized by the patent searcher and they may be used as keywords and relevant classification areas. However, it is rather common that the important information is described with figures. In order to deal with such cases, it would be very helpful if the patent searcher could directly retrieve patents that contain figures depicting these concepts. Thus, the integration of concept-based retrieval functionalities in patent search systems would facilitate significantly the tasks of patent searchers.

To address the requirements of Sect. 36.2, a supervised machine learning-based framework has been proposed [36.10, 31], which is based on both visual and textual information [36.30], as illustrated in Fig. 36.6. Specifically, the procedure begins by extracting the patent images and the associated captions. In the sequel, the images and their captions are fed into the feature extraction component, where visual and textual features are obtained. Given that the framework described is based on supervised machine learning techniques, it is essential to have a training dataset for developing the models and a test dataset for evaluating the performance. Thus, the dataset used is manually annotated and split into a training and a test set. It should be noted that when splitting the image/text dataset, the images/text belonging to the same patent are kept together. Then, we train three models for each concept using:

(a) Visual features
(b) Textual features
(c) The results of the previous models (a) and (b).

The latter (c) are used as features to train a hybrid classification model for final results. After observing

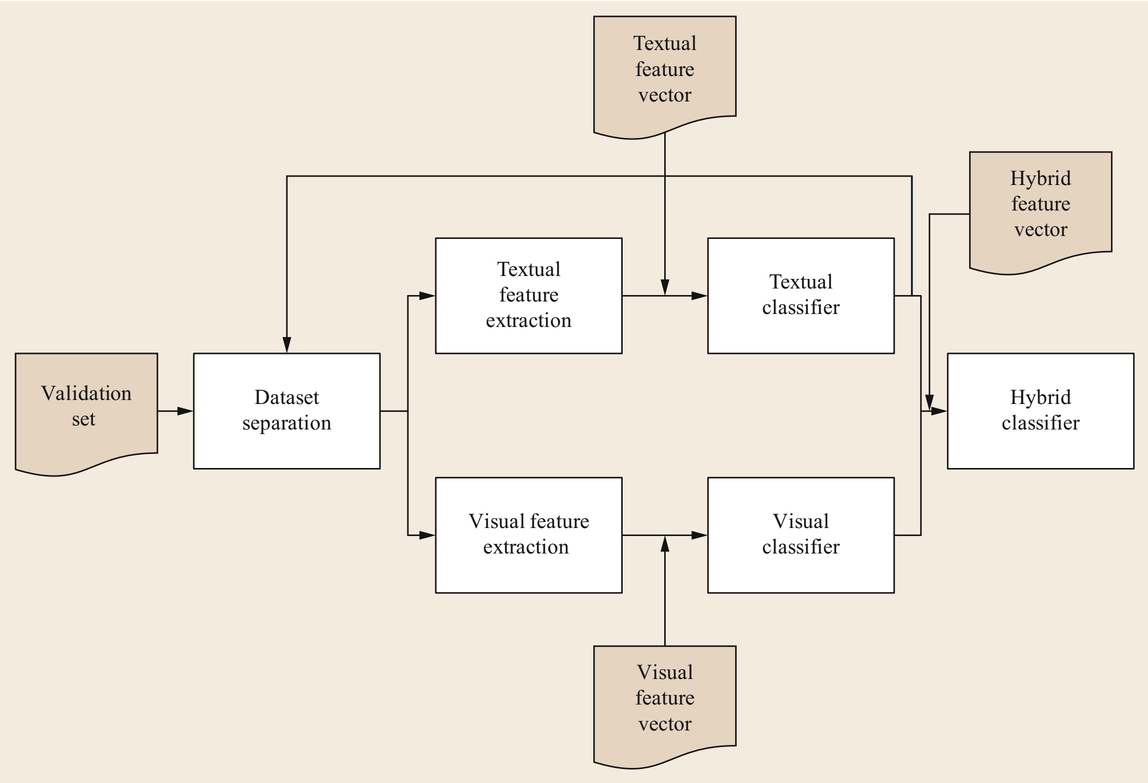

Fig. 36.6 Testing procedure for patent concept extraction to assist the *search-by-concept* functionality, as presented in [36.31]

the figure captions carefully, we discover that a significant number of captions do not provide any description of the figure, but they simply mention that the specific figure depicts another view of another figure (e. g., Fig. 36.2 is the front view of Fig. 36.1). This kind of description is one of the main reasons for retrieving low-quality results in text-based concept extraction [36.10]. Therefore in order to limit the negative impact of such captions, we further split the test set into two sets (i. e., A and B) based on the following rule: the figures that have a description that points to another figure of the same patent belong to set B, while the rest belong to set A. Then, during the testing phase (Fig. 36.6), the figures along with their captions that belong to set A are fed into the textual and visual feature extraction components and their features are used as input to the textual and visual classifiers, respectively. Afterwards, the hybrid classifier provides the final confidence score for each concept. Regarding the images contained in set B, the missing parts of their descriptions are replaced by the results of the textual classifier in a recursive way and this process continues recursively until all the captions of the figures in set B are updated.

36.5.1 Classification Techniques for Concept Extraction in Patent Images

Concept-Extraction Using Support Vector Machines (SVM)

Support vector machines (SVM) are supervised learning models that analyze data and recognize patterns; they have been successfully applied to several classification and regression problems. Specifically, SVM is a discriminative classifier that is formally defined by separating decision hyperplanes. These hyperplanes are constructed in a multidimensional space and aim at separating cases of different class labels.

A simple schematic example is depicted in Fig. 36.7, where the objects belong either to class green stars or red circles. The separating line (i. e., decision hyperplane) defines a boundary on the right side of which all objects are green and to the left of which all objects are red. Thus, any new object that falls to the right is labeled/classified as green, otherwise as red.

At the supervised learning approach of the framework depicted in Fig. 36.6, classification is applied both on the textual and visual features, presented in Sect. 36.3, that describe the patent images. However, other classification techniques have shown that [36.32] can further improve the retrieved results of a patent search scenario. In the following, we present another framework (Fig. 36.8), which also combines textual and visual information from patents, that is able to detect

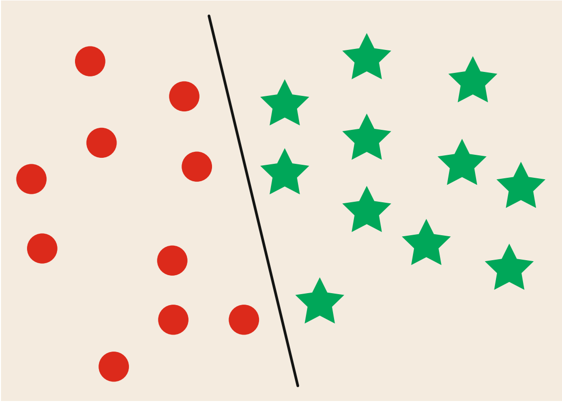

Fig. 36.7 Decision plane which separates the *red circle* class from the *green star* class. Reprinted from [36.10], with permission from Elsevier

outliers to rid our data of unnecessary noise, where the classification is realized with random forests.

Concept-Extraction Using Random Forests (RFs)

Random forests are an ensemble learning method for classification and regression [36.33]. The most prominent characteristic of RFs, which makes them a very popular machine learning algorithm, is their ability to learn multiclass classification problems. RFs operate by constructing a multitude of decision trees at training time. Moreover, RFs operate on two sources of randomness. The first is that each decision tree is grown on a different bootstrap sample drawn randomly from the training data. The second is that at each node split during the construction of a decision tree, a random subset of p variables is selected from the original variable set and the best split based on these p variables is used. When an unknown case arrives, the predictions of all the trees constituting the RF are aggregated using either majority voting for classification or averaging for regression problems. For an RF consisting of N trees, the equation for predicting the class label l of a case y through majority voting is the following

$$l(y) = \operatorname{argmax}_c \left(\sum_{n=1}^{N} I_{h_n}(y) = c \right), \tag{36.9}$$

where I is the indicator function and h_n the n-th tree of the RF.

The RF also provides an internal estimate of its generalization error, by using the out-of-bag (OOB) error estimate. Specifically for each tree that is constructed, 2/3 of the original data instances are used in that particular bootstrap sample, while the remaining instances (OOB data) are classified by the constructed tree and

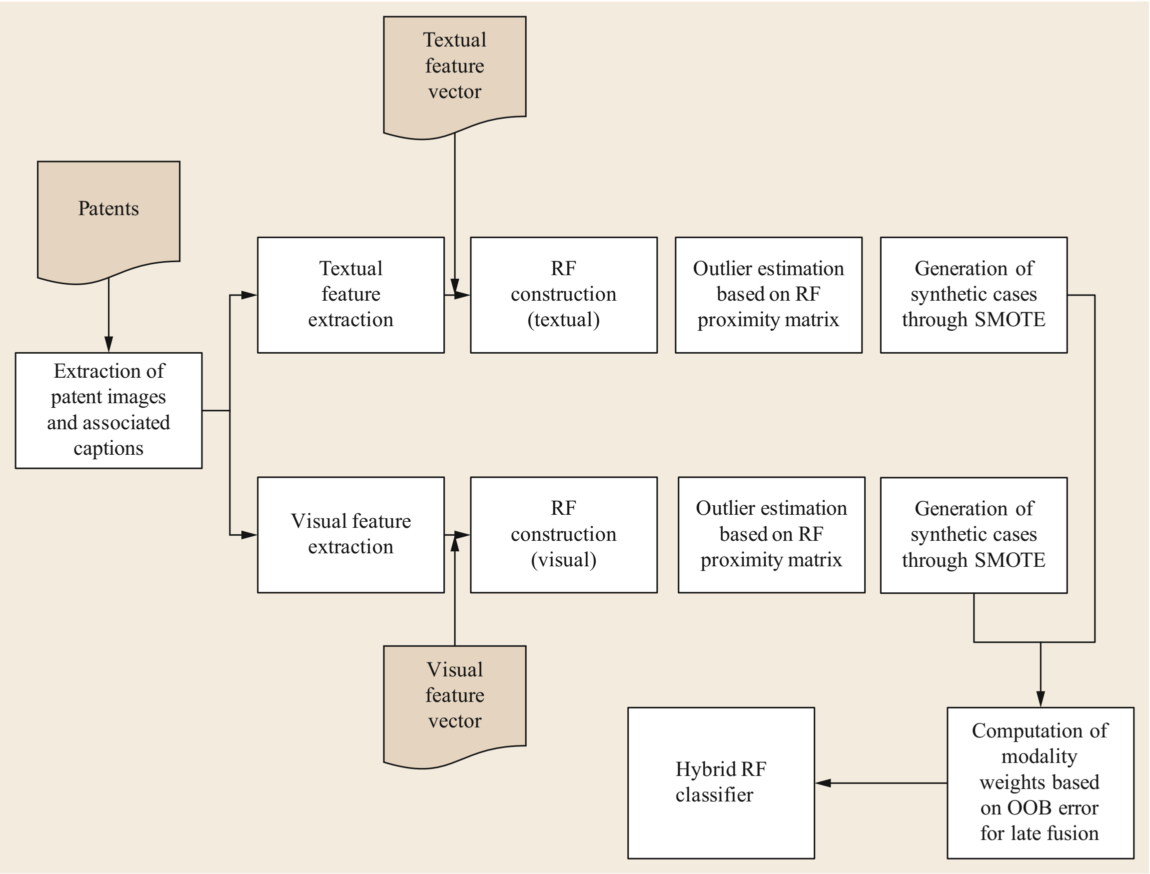

Fig. 36.8 RF multimodal classification for concept extraction in patent images

therefore, used for testing purposes. The OOB error estimate is the averaged prediction error for each training case *y*, using only the trees that do not include *y* in their bootstrap sample. Moreover, the RF has an inherent mechanism for detecting outliers. Within the RF context, instances with very low relevancy to all other instances are considered as outliers [36.33]. Specifically, when an RF is constructed, all the training cases are put down each tree and their proximity matrix is computed, based on whether pairs of cases end up in the same terminal node of a tree. By using this proximity matrix, an outlier measure for each case is derived. The outlier measure of each instance is compared to a specified threshold and if it exceeds it the instance is considered as an outlier. For a more thorough analysis of the core concepts of RFs, see [36.33]. For imbalanced datasets, that is datasets where some of each of the classes are not well represented compared to others, the synthetic minority oversampling technique (SMOTE) is used for constructing efficient classifiers. The basic notion of SMOTE is the synthetic generation of new minority class examples, based on the nearest neighbors of these cases, coupled with the undersampling of the majority class cases. For a more detailed description of the algorithm see [36.34].

The flowchart of the proposed concept extraction and classification framework for the training phase, is depicted in Fig. 36.8. The steps and components of the framework are described as follows.

The first step of the training phase of the framework [36.32] is the extraction of the patent images and the associated caption from the patent documents. In the sequel, the visual and textual features are produced as described in Sect. 36.3. Each modality's features are treated independently, and hence two different feature vectors are formulated. Then the feature vectors from each modality serve as input for the construction of an RF. The detection of outliers is the next step and it is achieved as follows: for each RF, the corresponding dataset's training instances are passed from each tree. If a pair of cases end up in the same terminal node of a tree, their proximity is increased by 1. This is repeated for every pair of cases and all trees in the RF. The final proximity values are calculated by normalizing the computed proximities. Normalization is realized by dividing the proximities values to the number of trees. Thus, if a dataset consists of N cases, an $N \times N$ proximity matrix is derived. From this proximity matrix a measure that indicates the outlierness of each case is computed. Given that the RF algorithm is based on randomization and in order to obtain robust and reliable estimations about potential outliers, it is proposed that the RF construction for the outlier detection and elimination step is repeated several times for each modality and the resulting outlier measure values from the constructed RFs are averaged. The cases that are identified as outliers are eliminated from further processing. The next step targets the problem of imbalanced datasets. As already mentioned the method opted for to solve this issue is the oversampling procedure of SMOTE, which generates in an artificial manner new cases and supplements existing ones. The resulting larger datasets can lead to a better and more efficient RF training. However, we should note that for the particular dataset SMOTE algorithm is solely used for introducing new training instances and not for balancing the dataset given that is balanced by default. According to [36.34], SMOTE oversamples each case by introducing synthetic examples along the line segments joining a number (the number depends on the amount of oversampling required) of that case's nearest neighbors. Oversampling is applied to all datasets and concepts separately. After the application of the SMOTE method, the final datasets are produced and eventually the final RFs for the textual and visual features. The final RF predictions are produced by using a late fusion strategy. Specifically from the OOB error estimate (for the entire data set) of each modality's RF, the corresponding OOB accuracy values are computed. Then, these values are normalized and served as weights for the two modalities.

During the testing phase, the RF provides a probability estimate per class for the new unknown case. This is produced by multiplying the probability outputs P_t and P_v of the textual and visual RFs respectively with their corresponding modality weights W_t and W_v and eventually adding them up, as follows

$$P_{fused} = W_t P_t + W_v P_v \,. \qquad (36.10)$$

36.5.2 Quantitative Evaluation of Concept-Based Patent Search

In order to evaluate the aforementioned concept-based techniques and the classifiers proposed, a dataset was created by extracting figures and their captions from 300 patents selected from the A43B and A63C IPC subclasses. The dataset contains parts of footwear and the data extracted were manually annotated. On the basis of advice from professional patent searchers in that domain, the following eight concepts were selected: cleat, ski boot, high heel, lacing closure, heel with spring, tongue, toe caps, and roller skates. The quantitative evaluation is two fold: firstly, for the demonstration of the superiority of the hybrid approach, compared to the unimodal textual or visual case, and secondly, for the comparison between two classification methods; support vector machines (SVM) and random forests (RFs).

Tables 36.3 and 36.4 contain respectively the results of an SVM-based and an RF-based framework used for classifying patent images. The comparison between the two presented frameworks of Figs. 36.6 and 36.8 is done using precision, recall and F-scores, in Tables 36.3 and 36.4, respectively. Although the frameworks use slightly different fusion strategies, there is some indication of the superiority of RF in the patent image classification domain (in comparison to the SVM classification). At this point, we should note that the fusion strategy followed in the case of the SVM classification is a simple early fusion approach where the descriptor employed for hybrid classification was the result of the concatenation of the textual and visual feature vectors.

Regarding the parameters of the methods involved the following setting is applied for the case of RF classification. The number of trees of the RF was defined

Table 36.3 Precision, recall and F-score for the concept detectors, using the SVM classification [36.10]

Concepts	Visual (%)			Textual (%)			Hybrid (%)		
	Precision	Recall	F-score	Precision	Recall	F-score	Precision	Recall	F-score
Cleat	84.38	45.76	59.34	89.13	69.49	78.10	89.58	72.88	80.37

Average	70.4	70.1	69.5	77.1	75.5	75.7	84.5	84.2	84.2

by the OOB error estimate. Thus, after conducting several experiments which involved gradual increase of the number of trees used, it was found that the OOB error estimate was fairly stable after when the number of trees was 1000. Adding more trees did not translate to further improvement of OOB. Hence, the number of trees was set to 1000. Moreover, the number of the subset of variables used to determine the best split during the growing of each tree was set to $\sqrt{k}$, where k is the total number of features of the dataset [36.33]. Regarding the RF outlier detection according to [36.35], a case can be considered an outlier if its outlier measure value is higher than 10. The result of this configuration was that around 2% of the textual modality's cases were detected as outliers and discarded, while for the visual modality no outliers were detected. Finally, the SMOTE oversampling rate for each concept in both modalities datasets was set to 500%, which is equivalent to the generation of 5 new synthetic cases for each real case.

36.5.3 Qualitative Evaluation Through a Patent Search System

One of the first systems that dealt with patent image search was PATSEEK [36.23], while later the PatMedia [36.9] patent image search engine was developed. We illustrate visual results of concept detection through PatMedia in Fig. 36.9. When both features (i. e., visual and textual) are combined, the results are improved as 100% precision is achieved in the top 18 retrieved images. This means that the three erroneous results that appeared in searching only by text or by image, have been assigned a lower score and ranked more than the last retrieved image of the PatMedia interface.

As an illustrative example, the PatMedia [36.9] graphical user interface (GUI) is demonstrated in Fig. 36.10, where searching by concept (Sect. 36.5) or by patent image (Sect. 36.4) are some of the involved functionalities. The quantitative comparison is presented in [36.10], and the PatMedia framework is reviewed in [36.11], while this chapter aims to summarize the overall concept-based patent search, fusing both visual and textual information, supervised machine learning techniques and local binary features.

The user may upload an image to retrieve similar images, in a CBIR scenario, when searching by content. Searching is also available in the case of a textual keyword or in the hybrid scenario. The PatMedia tool integrates all methods that are reviewed in this chapter and serves also as a standalone patent search engine.

Apart from concept extraction techniques in patent images, that are used to retrieve patents through searching by concept, it is also popular to search by pattern and or shape, where effective binary visual descriptors are required. In this regard, we present in detail, in Sect. 36.4, the visual descriptors of Sect. 36.3, known as AHDH, which allow searching by content in an unsupervised manner. The AHDH binary features were introduced in [36.8] as visual descriptors for binary images, and they have been evaluated in the context of patent image retrieval.

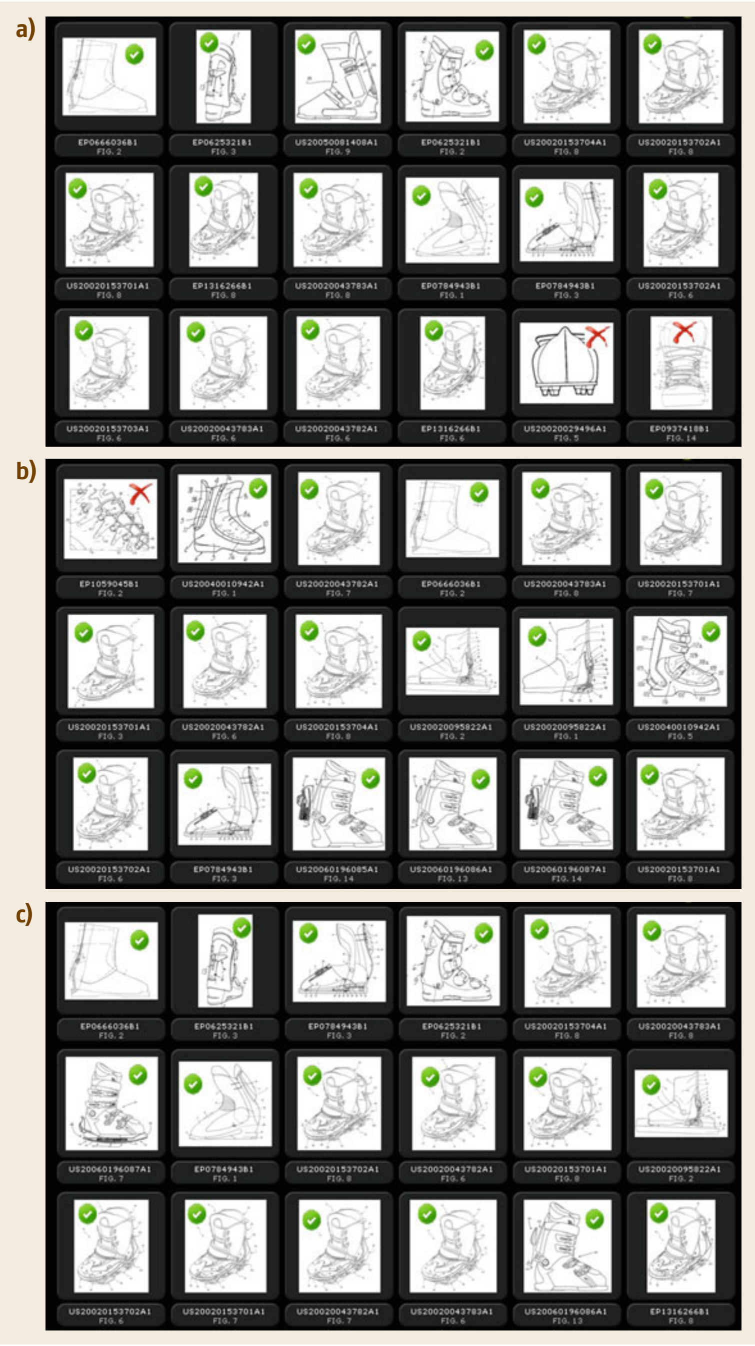

Fig. 36.9a–c PatMedia retrieved results. **(a)** Results for *ski boots* using textual features; **(b)** results for *ski boots* using visual features; **(c)** results for *ski boots* using the hybrid approach. The *green tics* indicate that the results retrieved are correct while the *red X* indicates the wrong results

36.6 Conclusion

The growing number of patent applications submitted worldwide necessitates the development of advanced patent search technologies. Effective and fast patent search relies on content-based and concept-based patent image retrieval while also fusing both textual and visual modalities that appear in each patent. By considering the visual content of patent images, we facilitate and improve the performance of patent search tasks such as patent invalidation and competitive intelligence research. In this chapter, we described state-of-the-art techniques in both directions, as well as their demonstration within user-friendly patent search systems and tools. Both techniques could be incorporated into existing official patent search systems that are mainly text-based and help them in overcoming the limitations imposed by using strictly textual descriptions which may be incomplete or in different languages.

In regard to content-based techniques, an algorithm called AHDH which is oriented towards handling patent images is described. The AHDH algorithm produces a visual feature representation of the patent images which considers their special characteristics and achieves very good performance compared to other similar algorithms. However, the major limitation of the algorithm, which seems to be the main factor restraining its performance, is the absence of inherent geometrical invariance. Therefore, further research on the AHDH algorithm should move in the geometrical invariant direction. Moreover, given that centroid hierarchical partition produces a plethora of shape-based statistical characteristics, such as density histograms, centroid locations, and blank regions, another idea with potentially interesting results would be to combine these vectors through a machine learning algorithm in order to further improve the algorithms performance.

Following the trend of modern image retrieval towards concept-based image search, the AHDH algorithm is used in a concept-based patent search framework. Different machine learning algorithms were evaluated, including SVM and RF and the experiments realized indicated that RF outperform SVM. Although the framework was for a limited set of concepts, the methodology presented using RF is scalable and the application of SMOTE minimizes the need for training data. Moreover, given that we can limit the search within patents of the same IPC class, the framework can target each time only a specific set of concepts relevant to the corresponding IPC class. A drawback of concept extraction techniques is that they require a training set for each new concept introduced, hence there is a need to have manually annotated images by experts.

Finally, from an application point of view both the concept retrieval and the content-based retrieval using query-by-example method modules could be parts of a larger patent retrieval framework. Such frameworks can also include other functionalities including full text and semantic search for the whole patent document. An example of such a framework is the PatMedia search engine.

Ioannis Kompatsiaris is Research Director at CERTH-ITI, the Head of the Multimedia Knowledge and Social Media Analytics Laboratory and Deputy Director of the Institute. His research interests include multimedia, big data and social media analytics, semantics, human computer interfaces (AR and BCI), eHealth, security and culture applications.He is the co-author of 129 papers in refereed journals, 46 book chapters, 8 patents and more than 420 papers in international conferences.

37. Methodological Challenges for Creating Accurate Patent Indicators

Ulrich Schmoch, Mosahid Khan

The chapter deals with new methodological issues of retrieval for patent indicators linked to the change of the patent system in the last 20 years and the new ways to access patent data. In particular, it describes international flows of patent applications between the US, Europe, and Southeast Asia, and illustrates methods for an appropriate cross-country comparison. A central topic of this chapter is the implications of the frequently used Patent Cooperation Treaty (PCT) route of patent applications on the conception of search strategies and the interpretation of search results. Furthermore, the possibilities of search with the new international Cooperative Patent Classification (CPC) are explained. In addition, the patenting activities of very large companies and patent value are discussed.

37.1 New Methodological Issues

It used to be quite difficult and expensive to get access to patent data. In the recent past, various patent databases have been provided by private vendors or public authorities at low cost or that are even free and with comfortable conditions of technical use. Examples are the European Patent Office's (EPO) statistical database PATSTAT and their search platform Espacenet, as well as the patent search tool Patentscope of the World Intellectual Patent Office (WIPO). This situation tempts many researchers to conduct quick and suboptimal patent searches, and they are not aware of the inanity of their results. Many basic aspects of the methodology of patent indicators were already alluded to in the former version of this handbook, in *Hinze* and *Schmoch* [37.1]. Since then, new methodological issues have emerged. Against this background, we will address the most important new stumbling blocks in patent searches and in creating accurate patent indicators. The views expressed in this paper are those of the authors and do not necessarily reflect the views of the Fraunhofer Institute for Systems and Innovation Research or the World Intellectual Property Organization.

37.2 International Patent Flows

As a basic principle, granted patents are territorial rights that only apply to the country for which the patents have been granted. For example, if a patent is granted in China, it will not be enforceable in Japan unless a patent for the same invention is applied for and granted in Japan. The legal system and the economic and geopolitical situation differ substantially by country. For instance, the scope of protection of an application in Japan is smaller than in Germany, implying a much higher number of patent applications

https://doi.org/10.1007/978-3-030-02511-3_37

Table 37.1 Patent applications by residents and industrial R&D expenditures for selected countries, 2013 (after [37.2, 4, 5])

	Patent applications by residents	Industrial R&D (2010 million dollars in constant prices and PPPs)	Ind. R&D/appl.
Germany (DPMA)	50 414	64 259	1.27
US (USPTO)	287 831	305 311	1.06
Japan (JPO)	271 731	117 571	0.43
South Korea (KIPO)	159 978	53 507	0.33
China (SIPO)	704 936	214 324	0.30

per expenditure on research and development in Japan compared to Germany; South Korea has a strong orientation of external patenting towards the United States, whereas European countries have a primary external orientation towards other European countries, etc. In addition, the propensity to patent varies across country, industry, and firm size. Therefore, comparisons of patent application data across offices should be undertaken with care. However, many providers offer easy access to databases with a broad coverage of national patent applications from about 50 patent authorities. The databases are generally derived from the file INPADOC, formerly offered by a private company, at present by the EPO. The most popular version of such an encompassing file is PATSTAT, offered by the EPO at low cost. Therefore, many users consider all available data without paying attention to the differences of countries and industries.

Furthermore, despite harmonization of patent law (e. g., the Trade-Related Aspects of Intellectual Property Rights (TRIPS) agreement), patent law still differs across offices. A search for a specific topic in patent databases without defining basic criteria will lead to an inscrutable mix of applications from different patent systems. In particular, the average economic value of a patent application at different offices can vary considerably. In addition, the value of patents varies within an office. The application behaviors at national offices often differ considerably, even if the formal patent laws seem to be quite similar. Different application fees, different incentives of the government or of the employers, different interpretations of claims, or different patent cultures can be the underlying reasons. The considerable implications for statistics can be seen in a comparison of domestic patent applications at selected offices (Table 37.1).

The technological innovation activity of a country is closely linked to its research and development (R&D) by industry. Therefore, the ratio of industrial R&D to the number of patent applications of residents may be considered as an indicator for the average value of a patent application. The comparison of the US, Germany, Japan, South Korea, and China shows a higher average level for Germany and the US and a lower one for Japan, South Korea, and China. Regarding patent statistics, this implies that counting all patent applications worldwide without any specification generates meaningless data, as domestic systems with quite a high

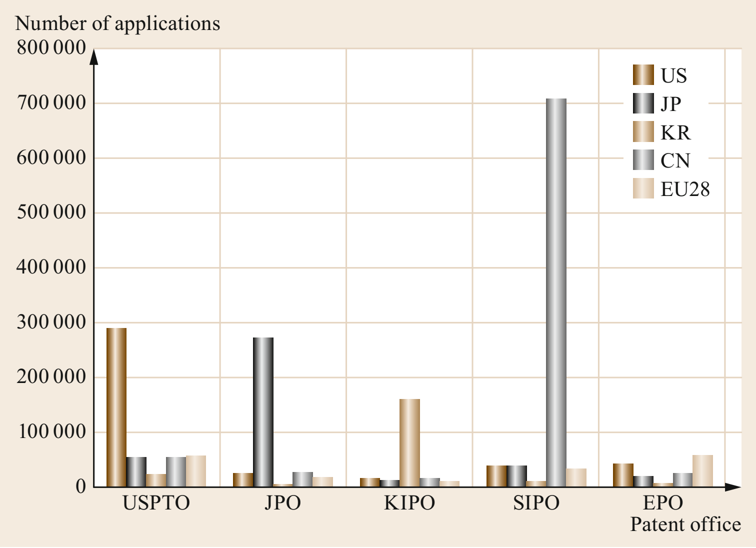

Fig. 37.1 Number of applications at IP5 offices by applicants from IP5 countries, 2013 (after [37.2, 3])

Part E | 37.2

propensity to patent dominate the results without a clear link to economic or technological value.

The consequences of this application behavior may be demonstrated by the number of applications by different countries at the so-called IP5 offices. IP5 is a forum of the five largest intellectual property offices, namely (Fig. 37.1):

1. China (State Intellectual Property Office of the People's Republic of China—SIPO)
2. Japan (Japan Patent Office—JPO)
3. South Korea (Korean Intellectual Property Office—KIPO)
4. The US (United States Patent and Trademark Office—USPTO)
5. The European Patent Office (EPO).

From Fig. 37.1, it is obvious that the domestic countries substantially dominate the application numbers at their domestic office, e. g., US applicants at the USPTO or Chinese applicants at SIPO. From a statistical perspective, this is called domestic advantage. At the EPO, a less important regional advantage of countries in the European Union (EU) becomes visible as well. Furthermore, there exist regional preferences of the countries of origin. For instance, Japanese or Korean applicants file more applications at the USPTO than at the SIPO or the EPO, or EU applicants prefer the SIPO over the KIPO. Thus, without any confinement, the search results will be dominated by domestic filings. For instance, 85% of Chinese applications at the IP5 offices are applied for at the SIPO; in contrast only 70% of the US applications are applied for at the USPTO. In consequence, the distortion between countries illustrated in Table 37.1 is directly visible in patent statistics.

The search for appropriate systems for country comparisons has always been a major concern of patent methodology. Various concepts were presented in *Hinze* and *Schmoch* [37.1]. The most relevant approach in the 1990s and at the beginning of the 2000s was the triad concept focusing on Japan, the US, and Europe [37.1, 6]. However, with the substantial growth in patent filings originating from Southeast Asia, in particular China and South Korea, the results of the triad approach are no longer considered appropriate. This change is directly reflected in the patent flows between the major countries, represented by the so-called IP5 offices.

Examining the present patent flows between IP5 offices, applications to the EPO originating from the US are higher than those from Japan and China and particularly those from South Korea (Fig. 37.2). However, the number of applications from these three Southeast Asian countries combined (CJK) prove to be clearly

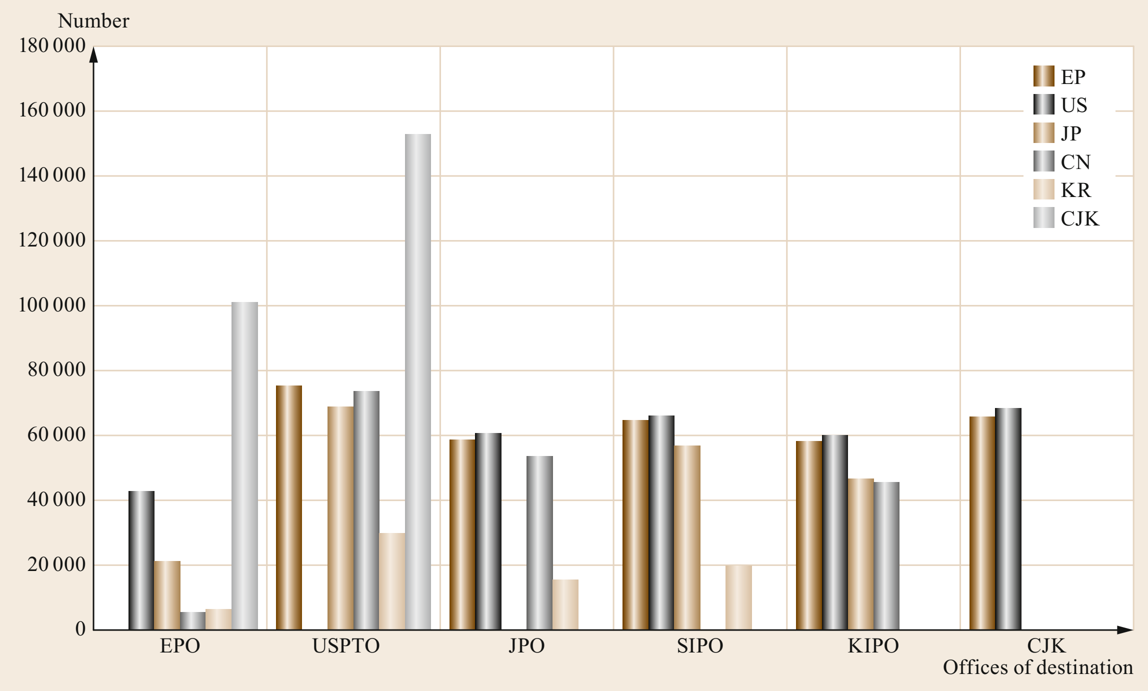

Fig. 37.2 Number of total patent applications from selected countries/regions of origin to selected external patent offices, 2014 (after [37.5])

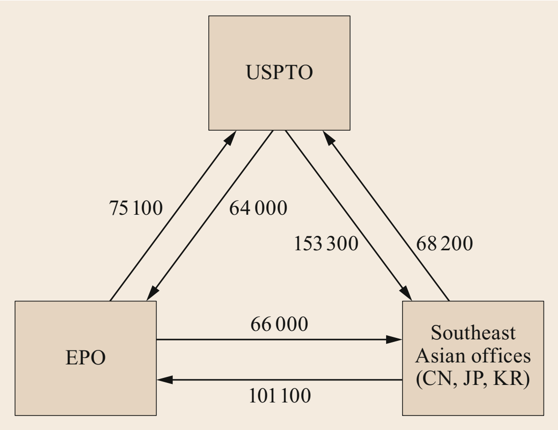

Fig. 37.3 Patent flows between offices of the new triad, 2014 (after [37.5])

higher than those from the US. The Southeast Asian countries exhibit a special interest in the US market. The flows from Europe and the US to the three Southeast Asian offices (CJK) prove to be nearly equivalent. Therefore, the combined flow from Europe (EU countries) or the US to at least one of the three Southeast Asian offices is only slightly higher than the flow to one of the offices.

Against this background, it is easy to conceive a new triad model with the three poles USPTO, EPO and large Southeast Asia Offices (SIPO, JPO, KIPO) combined. The resulting flows are illustrated in Fig. 37.3. In this graph, the substantial flows from Southeast Asia to Europe and particularly to the US become obvious.

Looking at the development over time, Fig. 37.4 documents the enormous increase of the flows from Southeast Asia to Europe and the US between 2000 and 2014, primarily linked to the growth of flows from China and—to a lower extent—from South Korea, and more recently from Japan. The flows from Europe (EP) and the US to Southeast Asia (CJK, JPO, SIPO, and KIPO) have increased as well, but to a lower extent.

This new international structure requires new approaches to achieve appropriate data for country comparisons replacing the outdated old triad concept. The methodological basis of such an approach must be to achieve samples with comparable economic values of the patents compared. For this purpose, it is useful to consider the costs of patent applications in more detail.

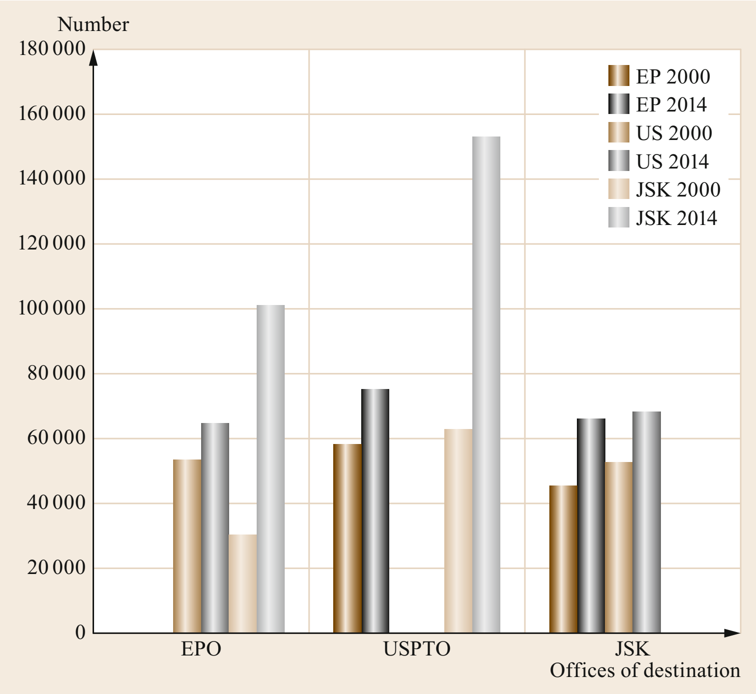

Fig. 37.4 Patent flows between offices of the new triad, 2000 and 2014 (after [37.5])

37.3 Costs of Patent Applications

The costs of patent applications depend on a variety of different factors, and it is important to consider all elements in order to become aware of the relevant ones. Table 37.2 lists the most important costs linked to a patent application.

The official fees in a country comparison were analyzed in detail by *Van Pottelsberghe* and *Danguy* [37.7] and *De Rassenfosse* and *Van Pottelsberghe* [37.8].

To give an impression of the order of the magnitude, the official fees for application, examination, and renewal are shown in Table 37.3 for the IP5 offices.

Table 37.2 Major cost elements of patent applications

Official fees
Application fees
Search fees, examination fees
Grant fees
Annual renewal fees
Foreign application fees
Foreign examination fees
Procedural fees
Patent attorneys' costs
Draft of patent application
Studying the search results and the examiner's reports, answering the examiner's report
Monitoring of the regular payment of renewal fees
Organizing the transfer to national offices in the case of an EU application (identifying correspondence attorneys, translating the applications)
Organizing applications in foreign countries and/or PCT applications at the end of the priority year and translating the original applications
Attending and acting in the examination process of the applications in foreign countries
Studying the relevant documents in case of opposition, answering the examiner's questions

The official fees can be assessed as generally moderate. The search and examination fees at the EPO are distinctly higher than at the USPTO or Deutsches Patent- und Markenamt (DPMA, German Patent and Trademark Office). In all five cases, the maintenance fees increase progressively and achieve high values especially at the USPTO (at the USPTO, the maintenance fees do not have to be paid annually but every 4 years (according to the USPTO, patents are renewed at 3.5, 7.5, 11.5 years, etc.). To make the data comparable with other offices, the average per year was calculated in Table 37.3). Consequently, only very valuable patents will be maintained up to the maximum limit of 20 years [37.9].

The costs of the patent attorney primarily concern the draft of the application and the legal assistance in the search and examination procedure. These costs largely depend on the complexity of the application, ranging from extremely simple to highly complex, e. g., from an electric switch to an MRI (magentic resonance imaging) scanner. Estimates for patent attorneys' costs are given in Table 37.4 (the cost estimates are based on the specifications of the websites of various patent attorneys).

In the total costs of patenting, the shares of the patent attorneys' costs are generally larger than those of the official fees. Due to the plurality of cost items, only rough estimates are possible as to the total costs of a patent application: The costs of an application with a period of validity of 10 years will be in the range of €20 000–30 000 for a national application, a European application with 5 designated countries and a realised transfer to these countries may achieve a level of €70 000–90 000, an international application with transfer to the EPO and 5 designated European countries and transfer to a further 5 non-European countries

Table 37.3 Selected official fees at five selected offices (as of September 2016)

Currency	USPTO $	EPO € ($)[a]	JPO Yen ($)	SIPO Yuan Renminbi (CNY) ($)	KIPO KRW ($)
Application fees (online)	280	120 (133)	14 000 (129)	950 (143)	66 000 (57)
Search fees	600	1300 (1468)	–	–	–
Examination fees	720	1635 (1809)	118 000 (1085)	2500 (376)	p.cl. 143 000 + 44 000 (125 + 38 p.cl.)
Maintenance fees, year 4	450	585 (647)	6400 (59)	1200 (181)	p.cl. 40 000 + 20 000 (34 + 17 p.cl.)
Maintenance fees, year 12	1850	1575 (1742)	55 400 (509)	4000 (602)	p.cl. 240 000 + 55 000 (207 + 47 p.cl.)

Table 37.4 Estimates of patent attorneys' costs for selected items (as of September 2016)

Procedural step	USPTO $	DPMA € ($)	EPO € ($)
Draft of patent application	5000–16 000	2000–5000 (2200–5500)	3000–6000 (3300–6600)
Search and examination procedure	1000–3000	1000–5000 (1100–5500)	1000–5000 (1100–5500)

Source: Websites of various US American and European patent attorneys, selection of most frequently indicated costs

will reach total costs of about €120 000. The relatively high costs of European and international applications compared to national ones are due to the fact that these applications are finally transferred to several national offices.

In conclusion, it is obvious that the costs of achieving and maintaining a patent are considerable and are not spent just for the honour of having a patent. Without the expectation of substantial economic returns, a patent application will not be filed.

37.4 Patent Applications to Foreign Countries

A further important element for understanding the structure of the international patent system is the legal basis and typical paths of applications to foreign countries.

For statistical analyses, the first application—the so-called priority application—is the most important one, as it is the point in time nearest to the time where the invention was generated. In some countries, it is possible to submit modifications of the application, which adds new embodiments of the priority application, e. g., the continuation-in-part applications at the USPTO or the divisional applications at the EPO. Consequently, an application can have two or more priority dates, the original and the subsequent ones. To avoid double counting of the same invention in a statistical analysis, only the first priority date should be counted.

The date of priority is the relevant point in time for defining novelty. An identical or very similar publication of the object of application earlier than the date of priority implies a rejection of the application.

An important action after the filing of the priority application is the application for the same invention in several countries within the so-called priority year. In most cases, the priority application is submitted to the domestic patent office. However, there are some exceptions. For example, in the first instance, Canadian applicants tend to file at the USPTO, while Swiss applicants prefer to file at the EPO. In principle, it is necessary to file a patent application to every country where protection is striven for. However, some exceptions exist, where the multi-country application process is simplified:

- Patent applications filed at the EPO
- The international patent applications filed via the PCT
- Patent applications filed at the OAPI (Organisation Africaine de la Propriété Intellectuelle)
- Patent applications at the ARIPO (African Regional Intellectual Property Organization)
- Patent applications filed at the EAPO (Eurasian Patent Organization)
- Patent applications filed at the GCCPO (Gulf Cooperation Council Patent Office).

To benefit from the priority claim of first application, applicants need to submit applications at foreign jurisdiction within 12 months after the priority date.

For the present context, patent applications filed at the EPO and the international patent applications filed via the PCT treaty are relevant and discussed in more detail.

The EPO is a regional patent office that was established in 1978 under the European Patent Convention (EPC). It is a centralized system for applications and granting of European patents for the EPC member states. Currently, there are 38 members—28 EU members plus 10 others, including Switzerland and Turkey. The EPO is responsible for granting European patents, but patents granted by the EPO must be validated at national patent offices to be enforceable in those jurisdictions. National offices may require translation of European patents into one of its official languages and additional fees for publication. Applicants decide whether to validate EPO patents in all EPC member states or a selection of member states. On average, EPO patents are validated in the three large economies, namely France, Germany, and the UK. To summarize, at the EPO, the application and the examination is centralized, the final protection refers to special selected countries and is national.

The application at the OAPI refers to 16 member countries of the Francophone part of Africa. The office can grant regional patents on behalf of the member states, thus the OAPI is a central application and examination office. The ARIPO represents 19 African countries, most of them anglophone. It is a central authority for receiving applications. The EAPO centrally receives and grants Eurasian patents valid on the territory of the ten member-states of the Eurasian patent convention, all of them former member countries of the Soviet Union. The GCCPO receives and grants patents valid in the GCC (Gulf Cooperation Council) member countries.

The PCT is an international patent law treaty that was concluded in 1970. The PCT system facilitates the filing of patent applications worldwide and makes it possible to seek patent protection for an invention simultaneously in each of a large number of countries by first filing a single international patent application. The granting of patents remains under the control of national or regional patent offices. The application is made at a receiving office (RO) in one language. The next step is a search performed by an International Search Authority (ISA), resulting in a search report with a written opinion regarding the patentability of the invention that is the subject of the application. It is optionally followed by a preliminary examination, performed by an International Preliminary Examining Authority (IPEA). The ROs, ISAs, and IPEAs are selected at existing patent offices, e.g., the USPTO or the EPO, working on behalf of the WIPO. In the final step, the inventor/applicant must decide whether he/she will pursue the application and in which countries he/she will really seek patent protection. A possible option within PCT is also an application at the EPO, the so-called Euro-PCT application. The international application has a variety of advantages. In particular:

- The applicant can submit valid applications designated for foreign countries shortly before the end of the priority year, as a translation into a foreign language, and the nomination of correspondence patent attorneys in the designated states is no longer necessary, while it is required in the standard procedure without PCT.
- The applicant receives additional information on the patentability of the application through the reports of the ISAs and IPEAs before making the decision on cost-intensive applications in foreign countries.
- The international phase ends 30 months from the priority date and, therefore, the applicant has to make the decision concerning applications in foreign countries much later than the end of the priority year. At 2.5 years after the priority application, more information is available on whether the invention will be successful in the market and will justify the costs of patent applications in foreign countries.

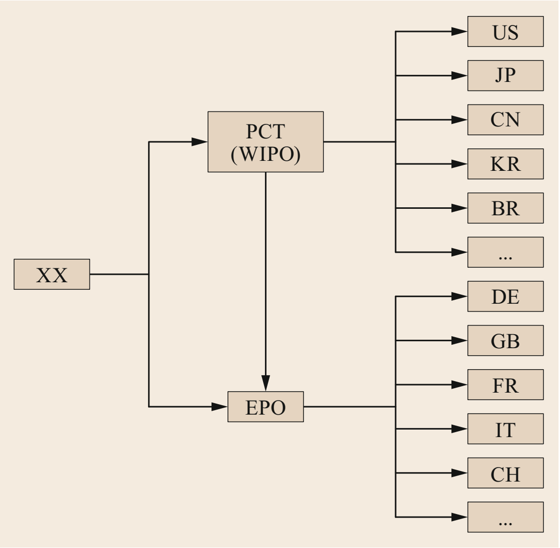

Fig. 37.5 Illustration of procedural paths of international and European patent applications

For example, to seek patent protection in Europe, applicants can submit patent application in each national patent office where he wishes to protect his invention (direct route; this direct route is not illustrated in Fig. 37.5), or he can make a single EPO patent application (EPO route), designating EPC member states, or file a PCT international application (PCT route). Figure 37.5 illustrates the use of the EPO and the PCT systems to seek patent protection in multiple countries.

When counting patent applications for statistical analyses, these structures have to be taken into account. Thus, when counting applications from foreign countries in a specific destination country, all possible ways of applying must be considered:

- Direct applications
- Applications through the EPO
- Applications through the PCT.

All patent applications referring to the same priority application/invention constitute a so-called patent family. Some databases display patent families, so that it is possible to count unique inventions and to assess the international marketing intentions linked to a patent application.

The country codes in Fig. 37.5 follow the alpha-2-code of the ISO 3166-1 standard (https://en.wikipedia.org/wiki/ISO_3166-1) and are also used in patent documents and databases.

37.5 International Country Comparisons

The information on international patent flows, international application paths, and application costs are a necessary basis to conceive appropriate concepts for country comparisons on the basis of patent indicators. At present, three approaches are suggested:

- Patent families with at least two members
- The IP5 approach
- Transnational patents.

A frequently made proposal is to use applications in foreign countries, as these applications imply much higher costs than domestic applications, hence capturing the most valuable inventions. Formally, this means that only patent families (patent families are defined in Sect. 37.4) with at least two members counted, meaning patent families with a domestic application and at least one application in a foreign country. The drawback of this approach is that—due to the specific geopolitical situation—the propensity to patent in foreign countries differs between countries of origin. For instance, the step from the Netherlands to Germany implies a family size of two members, as does the step from China to the US. Counting only families with at least three members improves international comparability and captures only high value patents, but still does not lead to a satisfying outcome. Counting on the basis of family size is often used in official statistics, whereas it is less available in online databases. The family size can be determined via an in-house database such as PATSTAT as well. A disadvantage of family-based searches is, of course, that the sample sizes of analyzed patent applications become much smaller. Thus, for more detailed analyses on the country level without a country comparison, the use of domestic applications is still helpful.

Against the background of the current international structures, the OECD suggested the *IP5* approach where patent applications to the five major patent offices in the world are considered [37.10, p. 20]:

1. The EPO
2. The USPTO
3. The JPO
4. The SIPO
5. The KIPO.

The OECD suggests three possible versions of this approach [37.10, p. 20f]:

1. Families of patent applications with members filed with one or more IP5 offices, including single filings. This implies that applications filed only with one of the IP5 offices, i. e., the EPO, the USPTO, the JPO, KIPO and SIPO, are considered.
2. Families of patent applications with members filed at least with one of the IP5, excluding single filings. This implies that applications filed only with one of the IP5 offices ... are considered only in so far as another family member has been filed with any other office worldwide (anywhere in the world, not necessarily with another IP5 office).
3. The most restrictive definition is that families of patent applications are considered only in so far as family members have been filed with at least two IP5 offices. For instance, patents filed with the USPTO will be considered only if an equivalent filing has been made with at least one of the remaining four IP5 offices. This is irrespective of whether equivalent applications in non-IP5 offices also exist.

The first option leads to considerable distortions between countries due to the dominant weight of domestic offices. According to the OECD, the second option leads to appropriate results, and the outcome of options 2 and 3 are very similar [37.10, p. 22]. The major shortcoming of the second approach for practical uses is that it is quite difficult to compute, but it is feasible.

The third approach is easy to compute. It could, however, be that the threshold for Southeast Asian countries is too low, as, e. g., the step from China to Japan is smaller than that from Europe to the US. Furthermore, the approach will yield appropriate data for current years only if PCT applications aimed at the IP5 offices are included. Due to the substantial delay of the transfer from the international PCT phase to the destination offices, these data appear quite outdated.

An alternative to balanced country comparisons is so-called transnational patents. These are patent applications either at the EPO or PCT applications without double counting [37.11]. In other words, these are patent families with at least an application at the EPO or the WIPO via the PCT route. It may be irritating that EPO and PCT applications are treated as equivalent, but the outcomes lead to useful results, as documented in *Frietsch* and *Schmoch* [37.11]. The major advantages of this approach are the generation of quite large samples, the limited delay of 1.5 years after the priority date, and the easy computing of searches.

Figure 37.6 shows a comparison of the IP5, the family ≥ 2 and the transnational approach, for the field of robotics, defined by B25J/IPC and `robot*` as keyword (with open truncation). The IP5 and transnational trends are similar, but not identical, and the absolute level of the IP5 approach is nearly identical to the transnational one. In the most recent years, the curve of the IP5 approach has been sloping downward, as the PCT applications not yet transferred to one of the IP5 offices were not included. The curve based on families with at least two members (foreign-oriented families) is lower than the two others in absolute terms, but the trend is similar. Yet again, one can observe a downward slope in the most recent years.

The authors of the transnational approach conceived it at a time when the growth of PCT applications was visible but less pronounced than currently. In 2000, 57% of the EPO applications were Euro-PCT applications; in 2012 this share was 72%. It is possible that with an increasing use of Euro-PCT applications and an increasing relevance of Southeast Asia as an economic region, the exclusive analysis of PCT applications may be more appropriate for balanced country comparisons than the transnational approach. The situation must be checked regularly.

To conclude this comparison, the necessity to specify the types of patent applications included is illustrated in Fig. 37.7. Yet again, the relationship between the five major countries is shown for a search without restrictions for the example of robotics according to the approach of transnational patents, the IP5 approach (according to version 3) and the family ≥ 2 approach:

- Without further specification, China seems to dominate the patent applications in robotics by far, a statement which is not realistic at all, according to experts in the field.
- Following the transnational concept, the US is the leading country, and Japan achieves a comparable level.
- In the IP5 approach, Japan is the leading country. In the IP5 approach, the position of Germany appears to be quite far behind, particularly compared to China and South Korea, a result that does not fit with other economic data on robotics. The IP5

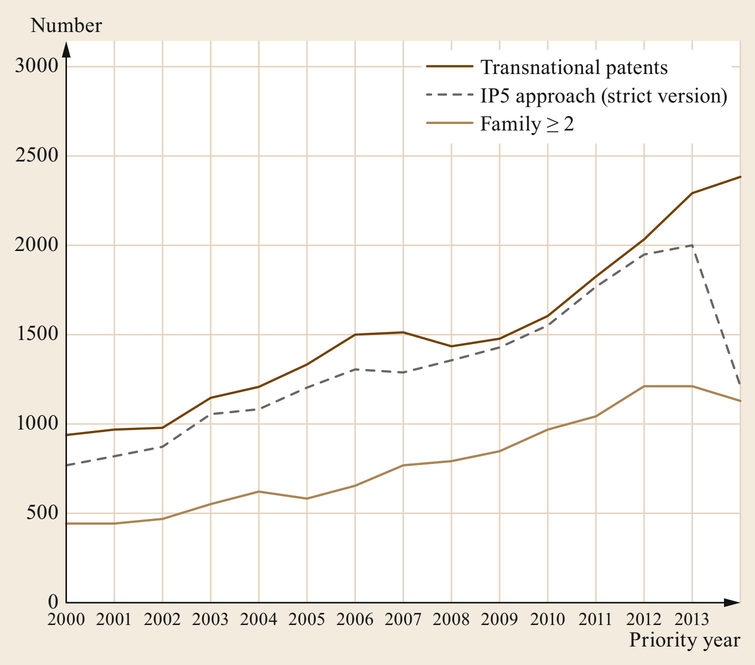

Fig. 37.6 Patent applications in robotics, according to the different approaches (after [37.3, 12])

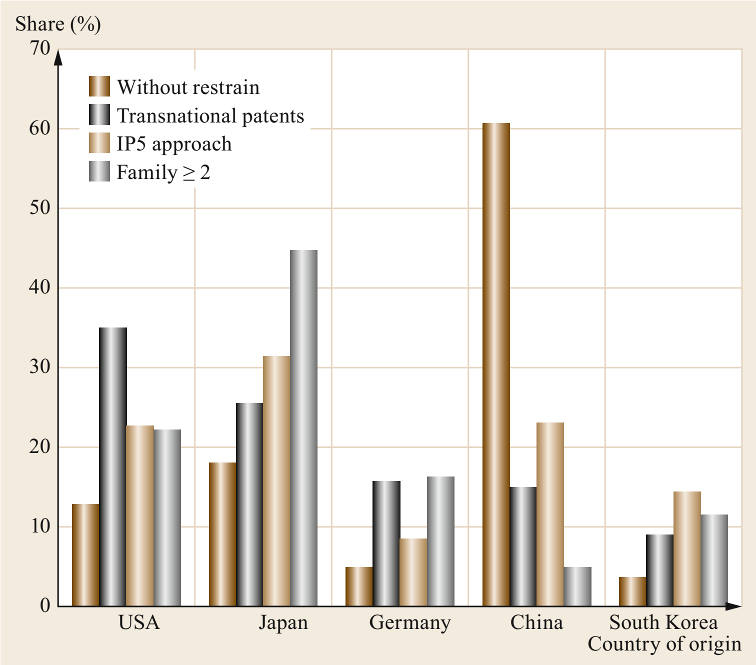

Fig. 37.7 Share of patent applications in robotics for selected countries, according to different counting approaches, 2014 (after [37.3])

approach seems to be better than that, an approach without restraints, but less realistic than the transnational one.

- In the family ≥ 2 approach, Japan earns a higher position than the US, and the position of China is very far behind. Again, the latter approach seems to be less appropriate for country comparisons than the transnational one.

This is only a conclusion for a specific example. A more detailed analysis is necessary. Anyhow, *Frietsch* and *Schmoch* [37.11] were able to show that the relative values between countries in the case of transnational patents highly correlate with input data (R&D shares) and output data on international markets (foreign trade). In any case, a well-considered approach of country comparisons is crucial for appropriate patent statistics.

37.6 Effectiveness of Keyword Searches

A further aspect implying misleading outcomes is the overestimation of the utility of keyword searches. In most cases, the search by codes of the International Patent Classification (IPC) is sufficient, as this scheme encompasses about 70 000 codes. However, in some cases, especially in very new areas, searches by keywords are necessary to complement the IPC searches. Here it is often overlooked that in the European patent systems the legal requirements for patent abstracts are quite low and that in some cases the applicants even try to hide the content of their invention to misinform competitors. The consequences are illustrated by the example of graphene, a new two-dimensional (2-D) material. The example was selected, as in an invention referring to graphene, it seems to be nearly impossible to avoid the keyword `graphene`, thus it is a strong keyword. Looking at the official standard abstracts of applications at the EPO, about 340 applications are found in 2013. For example, in the database PATSTAT, only the official abstracts are documented. The database World Patents Index (WPI) offers enhanced abstracts and titles focused on the technical content of the inventions. With this database, about 700 applications, thus more than double, can be identified (Fig. 37.8). Looking at the full text of the applications, 740 applications are discovered, but it is not clear whether the invention refers to graphene, whether it is compared to graphene, or what other reasons for using `graphene` apply.

In the case of the USPTO, the number of graphene applications identified by standard and enhanced abstracts is equivalent, which documents the high legal requirements for the content of patent abstracts

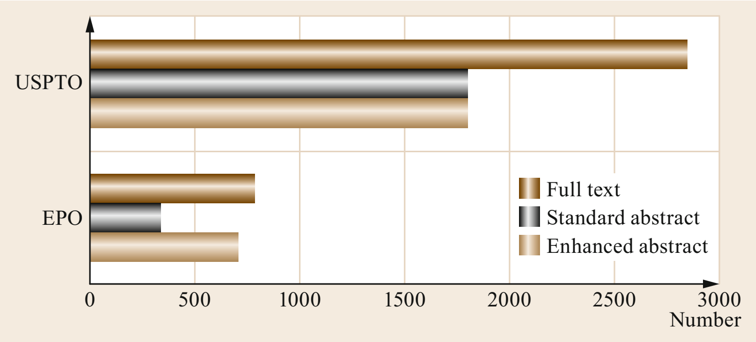

Fig. 37.8 Number of patent applications in graphene at the EPO and the USPTO based on keyword searches, priority year 2013 (after [37.3, 13, 14])

according to the US patent law. Again, the search in the full texts provides more results, but with some uncertainties. The absolute differences between the results for the EPO and the USPTO are primarily due to the fact that the USPTO is a national office and covers many domestic applications, whereas the EPO is a *regional* office aiming at foreign applications.

37.7 Features of the Cooperative Patent Classification

A regular problem of patent searches is the classification of European patents and most other patents worldwide by the IPC and the classification of US patents by the US patent classification (USPC). For many years, the US documents have been also labeled by IPC codes, but the philosophy of the IPC and USPC often differs, and the automatic concordance between IPC and USPC can be misleading. This is not only a problem for scientists, but also for patent examiners in the case of novelty searches. Against this background, the EPO and the USPTO launched the initiative "of developing a transparent and harmonized approach to a global classification system for patent documents" [37.15] in 2010, the Cooperative Patent Classification (CPC). The CPC is already implemented in databases, and the question arises as to whether a search with IPC codes or with CPC codes is more appropriate.

The available experience shows that in most cases the results of IPC and CPC searches are equivalent. Only in new fields, do some differences come up, as illustrated by the example of nanotechnology classified in the IPC as well as the CPC in the class B82. In recent years, the results for the CPC and IPC searches have been almost identical, but between 2000 and 2006 the numbers for the CPC search are substantially higher than for the IPC search (Fig. 37.9). As no systematic reason for this difference can be found, the only solution is to use both classifications in parallel, in particular in the case of new, emergent technologies.

In general, the introduction of the CPC implies considerable advantages for patent searches, so it is explained in more detail.

The CPC was initiated as a partnership between the USPTO and the EPO, where the offices agreed to harmonize their existing classification systems (ECLA and USPC, respectively) and migrate towards a common classification scheme. This was a strategic decision by both offices and is seen as an important step towards advancing harmonization. At the USPTO, the conversion will provide an up-to-date classification system that is internationally compatible (http://www.cooperativepatentclassification.org/about.html).

The migration to CPC was developed based in large part on the existing European classification (ECLA) system modified to ensure compliance with the international patent classification system (IPC) standards administered by the world intellectual property organization (WIPO). The previous European classification system (ECLA) was a more specific and detailed version of the IPC system. The following sections are identical in both the CPC and the IPC:

- A: Human necessities
- B: Performing operations, transporting
- C: Chemistry, metallurgy
- D: Textiles, paper
- E: Fixed constructions
- F: Mechanical engineering, lighting, heating, weapons
- G: Physics
- H: Electricity

In addition, the CPC encompasses:

- Y: Emerging cross-sectional technologies

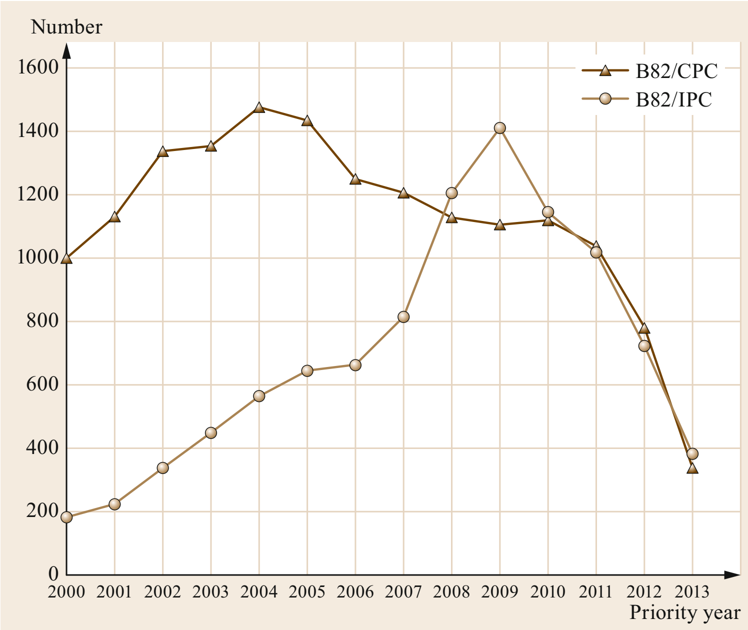

Fig. 37.9 Patent applications at the EPO in nanotechnology (after [37.3])

This new section covers:

- "Technologies or applications for mitigation or adaptation against climate change"
- "Information or communication technologies having an impact on other technology areas"
- "Technical subjects covered by the former USPC".

A detailed list of the presently valid CPC codes is available on a joint website of the USPTO and EPO [37.16, 17].

The CPC will have more subgroups than the IPC (about 70 000) and the ECLA (about 140 000 subgroups) and will achieve a level of about 400 000 subgroups, thus the CPC will provide a very refined classification.

To illustrate the substantial advantages of the CPC, the example of the subgroup B25J 13/086 is shown in Fig. 37.10. Compared to the IPC, nine further subgroups are added specifying the sensing devices (Fig. 37.11). Furthermore, the classification scheme is complemented by a detailed definition of the codes aiming at an internationally harmonized understanding of how technological objects should be classified appropriately. For example, the definition of the main groups and subgroups of the subclass B25J is a document of 143 pages.

In a joint effort, the EPO and USPTO classify all documents with CPC codes from 2013 onwards. According to the CPC annual report of 2015, more than 97% of US documents are classified with CPC codes, as are almost 100% of the documents at the EPO and

WIPO [37.18, p. 7]. For patent statistics, this means that the documents of the large western offices can be searched via CPC with only very few documents missing. In the case of China and South Korea, the coverage is still incomplete, so that the searches should be performed via IPC codes. For documents created before 2013, searches have to be conducted on the basis of IPC or USPC characters. Thus, for longer time series, the old and new systems must be used in parallel. Of course, this is only a problem of the present transition period. In the long run, the CPC will be very advantageous.

In practice, the CPC will be very helpful for using the database PATSTAT, which covers the IPC as well as the CPC, but which is less appropriate for key word searches, as illustrated above. For identifying the appropriate CPC code, it is recommended to start by looking for appropriate IPC codes in standard databases, e. g., in the WIPO file of IPC codes (http://www.wipo.int/classifications/ipc/en/). In the next step, the CPC scheme and definitions can be checked for finer codes of the CPC. Access to the scheme and definitions are provided by the CPC website [37.16]. Figure 37.11 demonstrates the scheme of the subgroup B25J 13/086 for which Fig. 37.12 shows the definition in an illustrative example.

If finer, more specific CPC codes can be identified, they may replace keyword searches and substantially improve the results in databases such as PATSTAT, which exclusively cover the official text elements of patent applications. However, there are still cases where keyword searches cannot be avoided, e. g., in cases of very new emerging fields that are not yet covered by IPC or CPC codes. Furthermore, generic technologies with a broad variety of applications exist in different fields. In these cases, the referring patent applications are generally classified either in the core area of the technology or associated technology areas or areas of application, and there is no common code covering the core technology, associated technologies, and all application areas as a common bracket.

An example for such a situation is robotics. The core technology is classified in the subclass B25J. Associated technologies are measuring, control, or computing. Application areas are machine tools, painting, cleaning, agricultural machines, surgery, etc. For patent searches, this implies that not all patent applications referring to robotics are classified in B25J. For example, a combination of the keyword `robot` with right-hand open truncation and the IPC subclass B25J leads to 2405 transnational patent applications in the priority year 2014, if the keyword search is performed in enhanced abstracts as in the WPI database. In this dataset, only 46% of the documents are identified by the IPC code. This share is even lower, when the search is conductd by CPC codes, if codes of the CPC subclass Y10S (technical subjects covered by former USPC cross-reference art collections (XRACs)) are used in addition to B25J.

Due to the relevance of keywords it is not advisable to perform searches with PATSTAT in these types of cases, as PATSTAT only provides official titles and abstracts, not enhanced abstracts like the WPI. A possible alternative is to identify all publication numbers of patent applications linked to a specific topic, e. g., to robotics, by statistical analysis, to generate a table of publication numbers for robotics in PATSTAT, and to conduct all other analyses such as trend, country, applicant, or subfield analyses in PATSTAT.

A further problem in the context of classifications is the frequent update of classifications. This has been a standard at the USPTO for many years, but until 2005 the IPC was updated every 5 years only. This frequent update means that former patent searches based on IPC codes can become invalid. For instance, in 2016, the WIPO found that a classification of biotechnology of 2005 had to be changed at about 60 positions, where some groups were moved to other subclasses or new codes were introduced. This change in update requires new practices for users of IPC codes. In particular, if searches for some fields are regularly updated, the validity of the IPC definition has to be checked each time.

Patent analyses have found broad propagation in studies for official authorities such as ministries, political commissions, or governmental institutions. This broad acceptance of patent analyses can be seen as a positive trend, however, the expectations of what can be achieved are often too high. A major problem is that politicians are confronted with fuzzy buzzwords and hope that patent analyses can clarify the situation. Typical buzzwords are *internet of things*, *advanced materials*, *advanced computing*, or *photonics*. The problem in these cases is that patent analyses need clear technological definitions. Thus, e. g., the question must be answered as to which types of material may be considered as advanced, polymers, metals, or ceramics with special properties, nanomaterials, special coatings, etc. At the beginning of the analysis, someone must take the decision which materials are advanced ones. A frequent solution is to collect many IPC codes of materials which may be considered as advanced leading to a fuzzy mix of different materials/technologies and thus avoiding a clear decision as to which technologies are relevant. The outcome will be fuzzy as well and is not interpretable in a clear way. Here, we run into typical problems of composite indicators, where the reasons for a positive or negative result cannot be identified [37.19]. Thus, it would be much better to identify ex ante precisely which items are representative for a field.

37.8 Patents of Large Companies

Patent databases represent large, detailed samples of indicators on innovation activity and are a popular source for many types of innovation analysis. The incontestable advantages often seduce scholars into neglecting the shortcomings in patent statistics. As early as 1985, *Pavitt* [37.20] carefully investigated possible problems of patent statistics and enumerated three sources of bias:

1. differences amongst countries . . .
2. differences amongst technologies and sectors . . .
3. differences amongst firms . . . [37.20, p.82].

In the first part of this chapter, we already addressed the typical problem of differences amongst countries. In the case of technologies and sectors, the differences in the propensity to patents are often overlooked. A typical example of different propensities to patents in technologies is the relatively high patent numbers in solar cells versus moderate ones in wind energy. Thus, a direct comparison would lead to higher patent numbers for solar cells, which does not mean that the economic value of solar cells is higher than that of wind mills, but they could be less technology intensive and/or imply more mature technologies, implying less recent patent activity.

In these cases, it is advisable to refer to other sources such as turn-over, R&D, etc., as a reference. As far as firms are concerned, it must be taken into account that the propensity to patent differs even between firms in the same sector or technology. Thus, a higher number of patents is only a strong hint at substantial innovation activities of a firm, not a proof. A systematic bias in patent statistics is the underrepresentation of small and medium-sized enterprises (SMEs). In their perspective, the costs of patent protection in relation to their markets are relatively high and in the case of infringement they have moderate chances to successfully enforce their rights against large firms due to considerable legal costs. Therefore, SMEs often prefer other strategies such as trade secrets or speed to the market [37.21]. Nevertheless, the contribution of SMEs to new technology is considerable, as documented, e. g., in Eurostat 2014. It is necessary to have these limitations in mind, and in some cases, it can be useful to complement patent analysis by surveys to get an impression of the size of the bias.

A further problem of the statistical analysis of enterprises is the appropriate count in applicant lists. In ranking lists of applicants, it is possible that some enterprises appear in different name variants, so that it is necessary to unite these different versions to achieve an appropriate list. To avoid individual manual cleaning, *Magerman* et al. [37.22] developed an automated method of name harmonization with quite advanced methods. However, this approach cannot solve the problem that many large enterprises have affiliations with completely different names, e. g., the affiliation Genentech of Hofmann La Roche would not be identified as part of Hoffmann La Roche by automatic approaches. *Magerman* et al. [37.22, p. 4] correctly state:

> when harmonizing legal entities, every patentee name needs to be checked against historical information on naming practices and ownership to address the following issues:
>
> - Identification of entities (business units, departments, subsidiaries) that may have a different name but belong to the same legal entity
> - Identification of name changes over time
> - Identification of mergers and acquisitions
> - Identification of joint ventures
> - Identification of mother and daughter relationships/subsidiary companies.

Even, if these problems are solved, it is not always possible to add up the patent numbers of different parts of the same entity in applicant lists. In particular in PCT applications, aiming at different countries of protection, it is possible that different subentities of an enterprise appear on the same patent application, for instance, PCT applications exist with two assignees of the same legal entity, e. g., Hoffmann La Roche Inc. (USA) and Hoffmann La Roche & Co AG (Switzerland) or Hoffmann La Roche Inc. and Genentech. Here, the applicants in the final list cannot be added up, but some must be deleted. Thus, also in patent statistics, problems with different name variants similar to bibliometrics exist, but for different reasons.

A relevant recent trend of patent statistics is to analyze enterprises instead of countries with the argument that country boundaries lose relevance due to the high activities of multinational enterprises. However, such enterprise-oriented analyses run into the methodological problems addressed above. The first problem is the appropriate definition of enterprises with all their affiliations and name variants, the second problem the comparison in an international context.

Ranking tables of large international enterprises are provided by the OECD and the WIPO. The OECD invests enormous efforts in the definition of enterprises [37.10, p. 16]. Nevertheless, *Neuhäusler* et al. [37.23] find different results by an automatic approach linked to enterprise databases. Furthermore, it is important to be aware that the company rankings differ depending on the criterion of patent counting. The OECD uses the definitions 2 and 3 of the IP5 approach.

A further provider of company rankings is the WIPO. It rates the patent applications of the companies by the number of families [37.24, p. 11ff]. However, the distribution of the number of family members differs considerably by company, so that a simple ranking is difficult.

To demonstrate the effect of different rating methods of patent applications, we selected 19 large companies that appear in the lists of the OECD and the WIPO. When simply the number of patent families is counted, a list according to Table 37.5 is generated. The analysis is based on simple name searches, so that affiliations with different names are not included. The result is, therefore, not exact. When the same search is based on transnational patents, thus patent families with higher economic value, a quite different list appears (Table 37.6). In Table 37.5, Southeast Asian companies dominate, as also families with one member are included. The effect of the *low average value* of patent applications at Southeast Asian offices as illustrated in Table 37.1 becomes visible. When only patent families with a higher economic value are included, European and US American companies achieve higher positions. To appropriately assess such rankings, it is also necessary to consider the main areas of activity of the companies considered and to standardize the patent numbers with field averages, as the propensity to patent varies by field. To conclude, company rankings based on patents are methodologically challenging and are difficult to interpret.

It may be argued that such lists of very large enterprises do not adequately reflect economic reality. As the economic prosperity of countries depends on the activities of large enterprises as well as SMEs, which

Table 37.5 Ranking of selected companies by the number of patent families, 2014 (after [37.3, 5])

Company	Patent family

contribute to a considerable extent to economic welfare in terms of employment, turnover, etc., or as suppliers or clients of the very large enterprises, it is useful to complement the data for very large enterprises by those of large enterprises and SMEs. For instance, *Frietsch* et al. [37.25] matched the names of applicants from nine different countries with the enterprise names in enterprise reference manuals such as Amadeus. On this basis, it is possible to examine the relevance of large enterprises and SMEs for a country in more detail [37.26]. The possibility of linking such databases to patent data is a considerable advantage of PATSTAT.

37.9 Patent Value

Standard patent statistics assume that patent applications have an equal or at least similar value by counting the number of patent applications. A relevant step towards a more realistic view is the analysis of IP5 applications, the family > 2 or transnational patents, thereby focusing on more valuable patents, i. e., patents targeting foreign market, thus approaching this assumption of similar value. Nevertheless, it is interesting to look at the question of patent value in more detail.

In principle, different types of patent value may be considered: the technological, the economic, the social or the strategic value (a more detailed discussion of the different forms of patent value can be found in *Frietsch* et al. [37.27, p. 10ff]). In the context of this chapter, the focus lies on the economic value.

It is important to be aware that the technological value and the economic one are not identical. For instance, it may be that a measuring device for scientific laboratories is extremely complex and has a high technological value, but the corresponding market is quite small, so that the economic value is moderate. Or vice versa, a technologically simple household appliance may have a broad market and a high economic value.

Several studies were conducted to assess the economic value of patents. A quite revealing one is that of *Gambardella* et al. [37.28] based on a survey of at inventors with referring to about 8200 granted patents at the EPO. Without discussing methodological details, we directly present the main result of this survey, the distribution of values in this large sample. Figure 37.13 shows that the patent value distribution is skewed (see also [37.29]). Since the difference in the logs of the boundaries of the intervals is roughly constant, the distribution in the figure approximates a log-normal. Even the log-normal distribution looks skewed. The estimated mean of the patent value distribution is higher than 3 million Euros and the median is about 400 000 Euro.

This skewed distribution raises the question what an appropriate basis of patent analysis, e. g., for country comparisons, is. For this purpose, we used the data of *Gambardella* et al. [37.28] to estimate the distribution of total values linked to the distribution of Fig. 37.13. We multiplied the mean value of each value class with the number of answers of this class which leads to a distribution of the total values according to Fig. 37.14. Again the distribution of the total values is quite skewed. The highest value class, representing about 1% of all patents, collates about 70% of the total value of all patents in the sample.

As the sample of Gambardella et al. refers to patents granted at the EPO, all these patents are transnational ones, defined as either EPO or PCT applications without double counting. So even in the case of transnational patents a relatively high share of the patents has a moderate value. e. g., about 40% of the patents in Fig. 37.14 have a value below 300 000 Euro.

This analysis raises the question what issue is analyzed by patents. If we use an approach such as IP5, family ≥ 2 or transnational, patents of very low value are excluded. Using the transnational approach, about 40% of the applications of European inventors which are applied exclusively at the domestic office, are excluded. For applications at the EPO, it can be assumed that the applicants expected a potential high value. Patent applications are always risky and only a small share will generate a high economic success. Thus, it is probable that among the 40% of the patents of lower value are many intermediate inventions within a longer technology line, where only the final invention implies considerable economic success. Thus, by the analysis of patents, we observe a broad variety of technological innovation activities including precursors of successful results.

In the case of the right end of the value distribution, most of the applicants will be multinational enterprises (MNEs) which can exploit their inventions in many countries at a world-wide level. As the production of the associated goods will take place in various national affiliations of these MNEs, the inventions will only partly be linked to foreign trade. Of cause, it is possible to analyze such types of inventions by introducing high family sizes of more than 6, but the final question is which type of activities should be examined: activities of MNEs, of SMEs, national comparisons, enterprise comparisons, etc.

Anyhow, *Frietsch* and *Schmoch* [37.11] were able to show that the relative values between countries in the

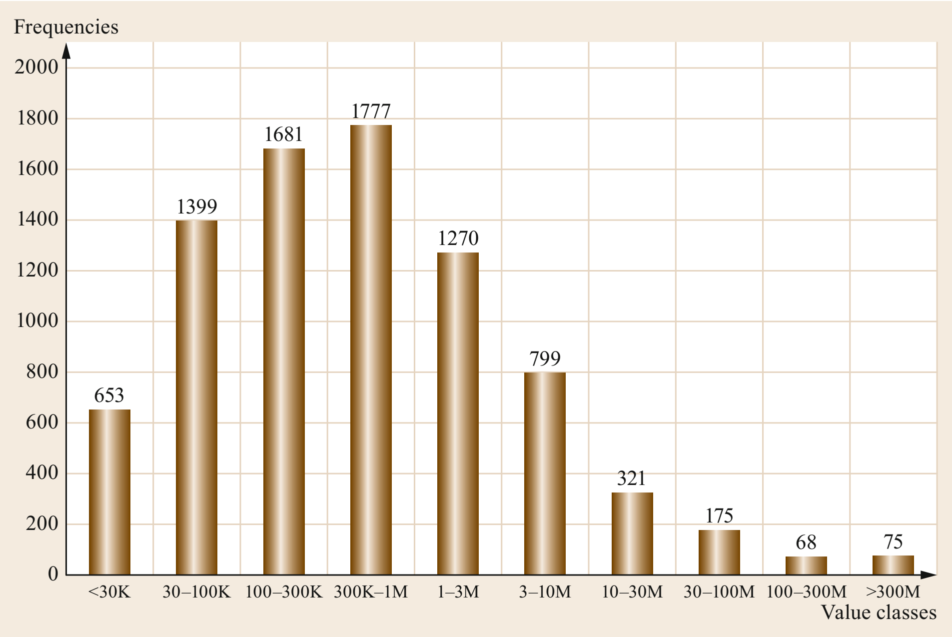

Fig. 37.13 Distribution of patent values (after [37.30], with permission from Wiley)

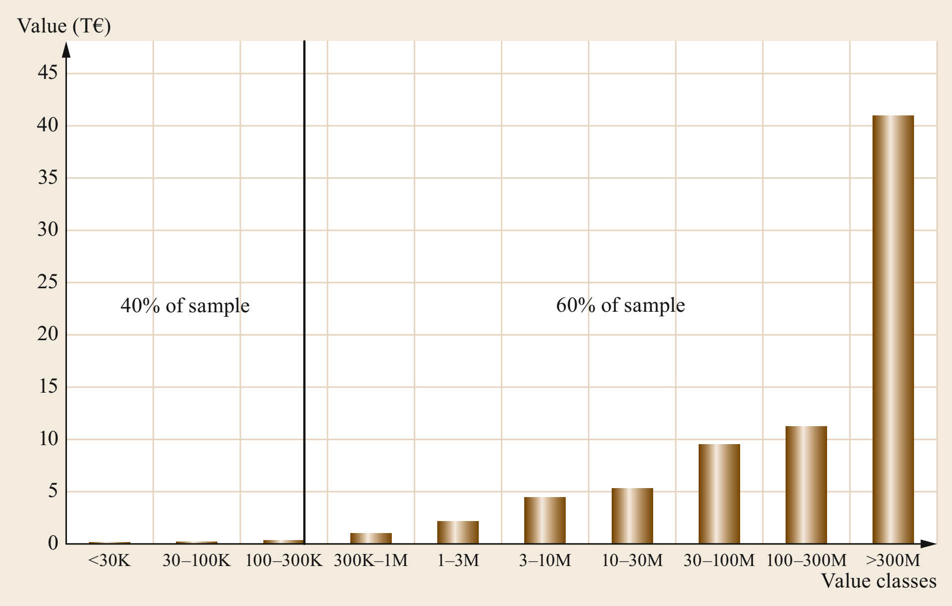

Fig. 37.14 Distribution of total values of patents in the survey of *Gambardella* et al. (after [37.28])

case of transnational patents—thus without focussing on patents with extremely high value—highly correlate with input data (R&D shares) and output data on international markets (foreign trade). *Frietsch* et al. [37.27] tried with a variety of different approaches to improve country comparisons with a more distinct focus on high value patents, but found no convincing solutions. However, in the case of very large enterprises such as shown in Sect. 37.8, it seems to be appropriate to limit the analysis to patents with very high value, e. g., by limiting the analysis to, e. g., more than 6 family members.

Several indicators have been suggested for measuring the economic value of patents.

A primary indicator in this context is forward citations of patents. This indicator was suggested quite early on by *Narin* and *Noma* [37.31] and validated by later studies, particularly by *Harhoff* et al. [37.32]. For this purpose, patent holders were asked to assess the asset value of their patent rights. The survey considered all patent grants with a 1977 German priority date which were renewed to full term, thus a sample of valuable patents. In the latter study, various potential indicators of patent value were compared, and the authors identify forward citations as a strong indicator for patent value. This finding is confirmed by various other studies, e. g., by *Hall* et al. [37.33]. In a later study, *Gambardella* et al. [37.28] confirm that forward citations are the best indicator for patent value, but they find that they explain only a small share of the variation in the patent value.

The major shortcoming of this indicator is the time lag between the submission of an application (priority date) and the possibility of conducting sound assessments. In the case of EPO applications, a time window of at least four years is recommended [37.27]. A fixed citation window is necessary to compare enterprises or countries, as the citation rate increases with a greater time lag. This indicator proves to be useful for individual cases, country comparisons are feasible, but require a complex methodology [37.27, p. 44 ff].

Family size is another indicator of patent value with the advantage that the data are easy to search and are available with the publication of the applications, i. e., 18 months after the priority date. This indicator is useful for comparing the patent value of enterprises within one country. However, the comparison of countries is problematic due to the different geopolitical positions of countries as has already been discussed in paragraph 5. For international comparisons it is recommended to exclusively consider large family sizes of more than 4 family members to compensate the geopolitical bias. In any case, family size appears to be the best criterion to select patent applications with a very high value. A further advantage is the availability at a very early point in time briefly after the priority application.

A further relevant indicator of patent value is opposition. At the EPO, third parties may dispute the validity of a granted patent by filing an opposition 9 months after the publication of the granting decision. As the opposition procedure is time and money consuming, it makes sense to assume that opposition is only raised in cases of valuable patents. The close relation of opposition and value has been shown several times. The disadvantage of this indicator is the considerable time lag between priority date and opposition, the quite small sample sizes—opposition is a rare event—, and the limitation on a simple valuable/less valuable decision; therefore value levels cannot be defined.

In the case of the US law, a post-granting review similar to the EPO opposition is possible under the new patent law of 2012. This relatively new provision has not yet been examined as the link to patent value, but it can be assumed that similar positive validations will be observed.

For litigations, similar considerations as for opposition apply. If litigations occur, a high value of the patent concerned is probable, but the event is quite rare, too. The access to litigation data via databases is difficult, but feasible. There are some studies on this issue, e. g., *Cremers* et al. [37.34] or *Lanjouw* and *Schankerman* [37.35]. Furthermore, many controversial cases are regulated between the interested parties outside of court, as in this area, lawsuits are very expensive.

Another possible indicator of patent value is renewals, assuming that the progressively increasing renewal fees reflect a substantive economic interest in a patent and thus its high value. This indicator is especially interesting regarding the USPTO with its high renewal fees after 10 years. Even if the renewal fees are only a marginal part of the total costs including the other fees and the costs of attorneys, the analyses based on this indicator lead to useful results. The main disadvantages of this indicator are the quite complex analyses which need to be performed and the substantial time lag.

In many studies it has been shown that the size of inventor teams is correlated to patent value. However, the distribution of the sizes is quite uniform, so that it is not useful for distinguishing between specific patents.

The granting of a patent is a value indicator as well. But due to different practices in different patent systems it can only be used within one system. As in the case of opposition, only the distinction between valuable and less valuable is possible. Value levels cannot be defined. Another possible indicator for patent value might be the volume of licensing and portfolio transaction. However, this interesting information is available for spectacular individual cases, but not in a systematic way. Also, the information of some patent offices on licensing is incomplete, as only some applicants use this way of publication to reduce application fees. In most cases, licensing is secret.

All in all, many different indicators for patent values have been suggested. To decide whether a specific patent has a high value, it is recommended to check all these indicators.

Contrary to expectations, the fact that a patent has been granted does not prove to be an appropriate indicator for the economic patent value. Firstly, the examination process is focussed on the technological value and less on the economic one. Secondly, obviously the patent systems are so different that domestic applicants achieve higher granting rates than foreigners. Thirdly, the granting rates differ by field. Fourthly, the time lag between priority and granting date substantially differs by country [37.27, p. 40ff].

According to various surveys of inventors and managers, the distribution of patent values is highly skewed [37.29, 36]. This is not a special characteristic of patents, but can be found in citation distributions in bibliometrics, firm size distributions etc. For patent analyses this means that the measures for country comparisons should be used for cutting off at least the large number of patents with low value. In the remaining samples, a skewed distribution of values cannot be avoided completely. Nevertheless, it is possible to conduct country comparisons without weighting the absolute numbers by citations or other value indicators, as only minor impacts on rankings can be observed [37.27, p. 111]. A strict limitation of the analyses on patents with a very high value would imply that the searches are—de facto—limited to large enterprises and the bias of patent analysis in favour of large enterprises would be amplified.

All in all, a statement of *Gambardella* et al. [37.37] is still valid:

> The 'measure of our ignorance' in this field is still too high. This paper finds that new and better explorations of the determinants of the economic value of patents are an important and largely underdeveloped area for future research.

37.10 The Impact of Legal Changes on Statistics

For practitioners in patent statistics, it is useful to follow the changes in patent law which might influence the statistical outcome. In the case of the US patent law, many reforms were introduced by the America Invents Act (AIA) where the change from the first-to-invent principle to the first-to-file one is the most discussed change (a summary of the AIA is given in [37.38]). However, it can be assumed that the impact on patent statistics is limited. More influential for statistics was the change in 2001 where the possibility of a pre-grant publication was introduced. Since that time, it has been possible to observe new technological developments at the US market at an early stage [37.39].

Patent analyses for European countries are already quite complex, as in addition to applications at the domestic offices, those at the European Patent Office (EPO) and at the world intellectual property organization (WIPO) via the Patent Cooperation Treaty (PCT) must be considered as well. At present a new change is imminent: After many years of negotiations the representatives of the EU member states achieved a breakthrough agreement in 2012: The European Unitary Patent will soon guarantee supranational protection for inventions in 26 countries across Europe. However, only 10 states have ratified the agreement until mid-2016, thus the agreement has not yet achieved legal validity [37.40]. At present, it is difficult to predict to what extent the Unitary Patent will be used instead of the standard EPO patent and what the effects on patent statistics will be. In view of various sceptical voices as to the usefulness of the system [37.41] it seems to be likely that the use will be limited.

37.11 Conclusion

All in all, the technological progress in the provision of patent data offers a variety of new ways of patent analysis. Nevertheless, it is necessary to carefully comply with basic methodological principles to achieve appropriate results. In particular, it is important to focus the analysis on economically important patent applications.

Previously, Mr. Khan has worked as an economist/statistician at the OECD and his research work has been published in peer-reviewed journals.

38. Using Text Mining Algorithms for Patent Documents and Publications

Bart Van Looy, Tom Magerman

In this chapter we present an overview of text mining approaches that can be used to conduct science and technology studies that rely on assessing the (content) similarity between patent documents and/or scientific publications. We highlight the rationale behind vector space models, latent semantic analysis, and probabilistic topic models. In addition, several validation studies pertaining to patent documents and publications are presented. These studies reveal that choices in terms of algorithms, pre-processing, and calculation options have non-trivial consequences in terms of outcomes and their validity. As such, scholars should pay attention to the technicalities implied when engaging in text mining efforts in order for outcomes to become relevant and informative.

38.1 Text Mining and Science and Technology Studies

In this chapter, we discuss the nature and relevance of content analysis for conducting science and technology studies based on text mining algorithms. Text mining is already being used in efforts to delineate specific domains or subfields and/or to identify related developments in different activity realms. In the past, such demarcation relied heavily on existing classification schemes and expert opinions [38.1–8]. Current developments in the domain of text mining offer ample opportunities to improve such efforts by generating, on a large scale, automated results that indicate similarity between documents (e. g., patents, publications) and, hence, enable mapping, categorization, and classification.

Domain studies would not be alone in profiting from algorithms that enable the identification of con-

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_38

tent similarity across documents. Whether and to what extent knowledge spill-overs—between scientific and technological activity realms—are present could benefit from the ability to assess content-relatedness between patents and publications. A similar point can be raised with respect to the diversification strategies of firms. It has been argued that effective diversification benefits from the presence of knowledge spill-overs between existing and new activities. Whether, and under which conditions, this assumption holds, remains a point of scholarly debate, especially when firms are confronted with disruptive innovation. Future research efforts would benefit from being able to assess (dis-)similarities when firms simultaneously exploit existing capabilities and explore novel technological trajectories by analyzing the contents of the patent and publication portfolios of firms.

While the relevance of content analysis by means of text mining to conduct STI (science, technology and innovation) studies is clear, it remains unclear which set of text-mining algorithms will yield relevant (valid) insights when applied to data currently used in studies of science and technology (patent/publication titles and abstracts). In this chapter, we outline the principles and most commonly used algorithms related to text mining and assess their validity when conducting studies in the field of technology and science.

We begin this chapter with a brief outline of the nature of text mining (Sect. 38.1.1) and the origins of quantitative linguistics (Sect. 38.1.2), and follow this by outlining the different ingredients of text mining based on the vector space model (Sect. 38.2). Next, we discuss the rationale behind specific text mining models like latent semantic analysis and probabilistic topic models, and discuss similarity measures (Sect. 38.3). In Sect. 38.4, we present and discuss several validation studies that start from patent documents and publications. These studies reveal that, for science and technology studies, choices in terms of algorithms and calculation methods significantly affect the validity of the results obtained. In order to arrive at a comprehensive overview of relevant observations and insights, this chapter brings together a collection of insights and findings, which—to some extent—have been reported in [38.9–11]. Finally, the section on clustering and topic modeling was developed specifically for this handbook (Sect. 38.5).

38.1.1 Text Mining

Text mining refers to the automated extraction of information from text in order to reveal patterns that are present but not obvious in a document collection. Text mining can imply a broad set of activities, ranging from text categorization, text clustering, information extraction, sentiment analysis, document summarization, named entity recognition, and question answering; it is an interdisciplinary field based on natural language processing, computational linguistics, information retrieval, data mining, machine learning/artificial intelligence (cognitive science), mathematics, and statistics (for more information on the application of text mining and its relation to other fields and techniques, see [38.12–14], for an overview of techniques).

The large-scale availability of computing power has spurred considerable interest in text mining over recent years, together with the observation that the vast majority of (digitally available) information is stored as (unstructured) text.

Notice that text mining techniques go beyond mere information retrieval. Information retrieval helps in finding information based on a user request, and it is obvious that text mining techniques are instrumental in this respect. Indeed, currently information retrieval is probably the biggest application area of text mining techniques. However, information retrieval in itself does not reveal *new* knowledge or insights, it merely surfaces what is already assumed by somebody—the user issuing the search request knows what he/she is looking for (for an elaboration of this issue, see [38.12]). Text mining can go one step further by revealing patterns that were not obvious before. Compelling illustrations have been advanced by *Swanson*, where *unknown* relationships between fish oil and Raynaud's syndrome, migraine and magnesium, and somatomedin C and arginine have been advanced [38.15–17]. The relationship between *migraine* and *spreading depression* on the one hand, and *magnesium* and *preventing depression* on the other, was revealed after a thorough search of the medical literature on migraine, suggesting magnesium deficiency as a factor in migraine. Prior to this remarkable discovery—Swanson is an information scientist, not a physician—there was no indication of this relationship whatsoever; his results triggered additional clinical research, confirming his prognosis [38.18]. These case studies can be regarded as pioneering cases of text mining, providing the foundations for a more formalized study of literature-based discovery based on textual analysis—the so-called Swanson linking [38.19].

38.1.2 History of Quantitative Linguistics and Applications in Science and Technology Studies

The application of text mining techniques in science and technology studies is not new. Quantitative linguistics dates back to at least the middle of the nineteenth century [38.20]. The classical work by *Zipf* [38.21] is considered pioneering in quantitative linguistic (or text) analysis. Since the 1970s, a remarkable increase in activity has been witnessed in this area of information science. As for its application to scientific literature, *Wyllys's* study [38.22] is among the first. Co-word analysis, one of the most frequently used techniques, was founded on the idea that the co-occurrence of words describes the contents of documents and was developed for purposes of evaluating research [38.23]. The extension of co-word analysis to large sets of publications was possible as soon as large textual databases became available in electronic form; also, the increasing availability of computational power facilitated the further development and dissemination of text mining approaches. *Manning* and *Schütze* [38.24] provide a comprehensive introduction to the statistical analysis of natural language, *Berry* [38.25] provides a survey of text mining research, *Leopold* et al. [38.26] gave an overview of data and text mining fundamentals for science and technology research, and *Porter* and *Newman* [38.27] coined the term *tech mining* to refer to text mining collections of patent documents on a specific topic. Other earlier, practical applications in the field of bibliometrics and technometrics were offered by *Courtial* [38.28], *Noyons* et al. [38.5], *Bassecoulard* and *Zitt* [38.29], *Leydesdorff* [38.30], *Glenisson* et al. [38.3], and *Janssens* et al. [38.31].

As mentioned previously, a first and more traditional application of text mining is to be found in the field of information retrieval (conducting patent or publication searches on bibliographic databases). However, text mining offers a much broader range of applications:

- Domain studies: Starting from a set of seed patents or publications that are representative of a technological or scientific domain, concepts and topics can be extracted and used to match concepts and topics from other patents and publications with the purpose of identifying related patents and publications or in order to delineate technological or scientific domains on the basis of a set of patents.
- Trend detection/emerging field detection: Concepts and topics extracted from a set of patents or publications can be identified (first time occurrence) and their evolution over time can be assessed.
- Science-technology spill-overs: Concepts and topics extracted from a set of patent documents can be compared to concepts and topics extracted from a set of scientific publications and vice versa, so that spill-overs between technology and science can be assessed in a fine-grained manner.
- Characterizing the patent and/or publication portfolios of firms, universities, and research institutes in terms of contents and topics.

38.2 Practical Text Mining Procedure

38.2.1 Vector Space Model

Text mining implies a mathematical representation of textual data in such a way that algorithms and data mining techniques can be used. The vector space model (VSM) is a common algebraic representation of text documents. This so-called bag-of-words approach implies that the number of occurrences of each word in a text is counted [38.32–34]. The vector space of a collection of texts is constructed by representing each document as a vector containing the frequencies of the words or terms encountered in that document. Together, these document vectors comprise a term-by-document matrix representing the full text collection. Relatedness of documents can be derived from these vectors, e. g., by calculating the Euclidian distance between two vectors or the angle between document vectors by means of a cosine measure.

38.2.2 Indexing

The encoding of documents into vectors is called indexing. During indexing, a global vocabulary (thesaurus) is built up, assigning a unique identifier to each word encountered in the entire document collection. With this global vocabulary, a vector is constructed for each document comprising as many elements as the total number of unique words in the global vocabulary. For words appearing in the document at hand, the value of the respective elements is equal to the number of occurrences of that word in the document. For words that do not appear in the document, the respective elements are assigned a zero value. Thus, each document is represented by a vector comprising the raw frequencies of occurrences in a (high-dimensional) vector space of terms. As each document uses only a small subset of words to describe its content, the resulting matrix is extremely sparse (typically, more than 99.99% of the vector elements are zero).

38.2.3 Pre-Processing: Feature Selection and Extraction to Deal with Language Issues

Although this numerical representation of the text collection using raw term frequencies within documents enables the application of traditional data mining techniques, such as distance calculation, clustering, and classification (with term vectors as variables and document vectors as observations), results tend to be biased because of typical language issues. First, there are morphological problems, since words can appear in different word forms (e. g., singular versus plural, adjective versus noun versus verb). Second, there is the homonymy, polysemy, and synonymy problem and the hyponymy/hypernymy problem: Words can have different meanings, the same meaning or concept can be expressed by different words, and words can have semantic associations in a hierarchical relation (e. g., animal versus mammal versus cat and dog). Last, not all words are of equal importance in deriving the meaning of phrases, but words with less significance appear with very high-frequency—Zipf's law: The frequency of any word in a text corpus is inversely proportional to its rank in the frequency table [38.21].

As a result, deriving similarity on the original document vectors containing the raw term frequencies of occurring words/terms—and hence, all data mining techniques based on similarity such as clustering and classification—can be biased; two numerically similar document vectors can point to two documents with a completely different meaning because identical words can be used to convey different meanings and because many frequently used words belie the intended meaning. Likewise, two numerically dissimilar document vectors can point to two related documents because meanings and concepts can be expressed through different words, and words can appear in different forms.

To deal with these issues, it may be pertinent not to use the original terms but to engage in prior transformations. Transforming the original data elements into more appropriate features is a common approach in data mining (feature selection and extraction). In practice, for text mining, pre-processing actions such as stemming, stop-word removal, collocations, synonym lists, domain vocabulary, part-of-speech taggers, chi-square tests and information gain, and weighting schemes (e. g., TF-IDF—term-frequency × inverted document frequency—and log-entropy) are commonly used to improve the indexing process and achieve a better grasp of the context of the documents.

Stop-Word Removal and High-Frequency Term Removal

All common words that do not contribute to the distinctive meaning and context of documents might be removed before indexing. Examples include words like and, or, the, a, if, and so forth. Commonly used word lists are available, containing a large set of so-called stop words (e. g., the SMART list of Buckley and Salton, Cornell University). Moreover, as very common words usually convey little information on the meaning of phrases, high-frequency words might be removed as well, by using the distribution as described in Zipf's law.

Stemming and Lemmatization

Instead of indexing words as they appear in the documents, linguistic stems or roots can be used for indexing. The basic idea is to reduce the number of words by introducing a common denominator, called a stem or root, for words that share a common meaning (e. g., am/are/is/be, dog/dogs, or work/workers/working).

The idea behind stemming and lemmatization is to improve the ability to detect similarity regardless of the use of word variants (reduce the number of synonyms, since multiple terms sharing the same stem or root are mapped onto the same concept), but occasionally stemming will create new homonyms due to stemming errors (for a more in-depth analysis of the performance and advantages/disadvantages of stemming, which are language and corpus dependent, we refer to *Lennon* et al. [38.35], *Harman* [38.36], *Krovetz* [38.37], and *Porter* [38.38]).

Lemmatization is done by using a vocabulary or dictionary and applying morphological analysis to match words or terms with the base word or lemma.

Stemming is a more mechanical approach that does not perform a linguistically correct lemmatization but takes a pragmatic/heuristic approach in stripping suffixes from words to combine word variants with shared meanings (e. g., *produc* for product, production, producing). A well-known and commonly used and effective approach is the Porter stemmer [38.39, 40].

Hapax Removal and Low-Frequency Term Removal

Often, a considerable number of words appear only in one document. Such words are called hapaxes and might be removed from the vocabulary because they are of little value in finding communality between documents. Based on that same logic, sometimes words with very low frequencies are removed entirely. Again, Zipf's law can be used to select low-frequency words. Notice that one removes idiosyncratic elements, which might be of special interest as well.

Part-of-Speech Tagging

Instead of selecting or weighting words using frequency counts to reveal relevancy, the part of speech of a word can be used as indicator of relevance. Part-of-speech tagging can be used to classify all words by their part of speech using their context. Next, only nouns or nouns and verbs can be retained as most relevant words. Multiple automated rule-based and stochastic part-of-speech taggers are available (based on probabilistic models, hidden Markov chains, maximum entropy Markov models, perceptrons, support vector machines, ...).

Weighting

Introducing a weighting scheme based on the occurrence and co-occurrence of terms (raw frequencies) might allow us to better distinguish between terms given the specific set of documents under study (e. g., the word *computer* does not reveal the distinctive nature of a certain contribution within a document set covering only papers on computer science). A commonly used weighting scheme is the TF-IDF (term frequency × inverted document frequency) weighting scheme [38.34], in which the raw term frequencies (local weighting) are multiplied by the inverse document frequency (IDF) for that term (global weighting). This results in upgrading the impact of relatively rare terms when calculating distance measures (for a more extensive explanation of local and global weighting, see [38.41])

$$\mathrm{Idf}_i = \log \frac{n}{\sum_{j=1}^{n} \chi(\mathrm{tf}_{ij})}$$
$$\text{with } \chi(t) = \begin{cases} 1 & \text{if tf} > 0, \\ 0 & \text{if tf} = 0 \end{cases} \tag{38.1}$$

and n the number of documents.

Weighting has a similar effect to stop-word removal, since words commonly used across all documents in the document set will be down-weighted compared to medium or even low-frequency words, which carry the most significant distinctive information [38.42]. On the other hand, TF-IDF weighting attributes might introduce extreme weights to words with very low frequencies. Moreover, TF-IDF will not grasp synonyms; hence, weights of commonly used synonyms will be over-rated, as the weights of the individual (synonym) terms will be higher than the weight of the underlying common concept. Despite these shortcomings, TF-IDF weighting is one of the most popular weighting schemes (for alternatives [38.24]).

An alternative weighting schema combining local and global weighting is log-entropy weighting [38.43], where the log of the raw term frequencies plus 1 (to prevent taking the log of 1) (local weighting) are multiplied by the entropy (global weighting)

$$\mathrm{entropy}_i = 1 + \sum_{j=1}^{n} \frac{p_{ij} \log(p_{ij})}{\log(n)}$$
$$\text{with } p_{ij} = \frac{\mathrm{tf}_{ij}}{\mathrm{gf}_i} \tag{38.2}$$

and gf_i the total number of times that term i appears in the entire collection.

Another alternative when the term frequency is not relevant or misleading is binary weighting, where every term frequency greater than 1 is replaced by 1.

Additional Pre-Processing

Additional, more advanced, pre-processing tasks can be performed to further optimize the indexing process. These include proper name recognition and disambiguation, acronym recognition, compound term and collocation detection, feature selection using application-specific domain vocabulary or ontology, and the use of supervised machine learning techniques such as correlation and information gain/entropy (a more detailed description of these topics can be found in [38.44]).

38.3 Specific Text Mining Models

38.3.1 Language Specific Issues and Models

As mentioned previously, natural language text is noisy for a number of reasons, including inconsistencies, typographical errors, author style, and choice of words. It is further complicated by morphological problems and phenomena such as homonymy, polysemy and synonymy, and hyponymy/hypernymy. A numerical representation of text data such as the vector space model does not grasp these particularities.

Furthermore, morphological problems in securing the proper identification of terms, and the fact that not all terms in a text are of equal importance, can be solved by feature selection and extraction techniques as described in the section on pre-processing. On the other hand, there are more fundamental issues with homonymy, polysemy, and synonymy, and hyponymy/hypernyms that are not solved by the preprocessing techniques described. These issues require specific methods to (try to) understand the meaning of words. Examples of such methods are latent semantic analysis, non-negative matrix factorization, formal concept analysis, probabilistic topic models, and Word2vec.

38.3.2 Latent Semantic Analysis (LSA)

Latent semantic analysis (LSA) was developed in the late 1980s at BellCore/Bell Laboratories by *Landauer* and his team in the Cognitive Science Research Department [38.45]:

> Latent semantic analysis (LSA) is a theory and method for extracting and representing the meaning of words. Meaning is estimated using statistical computations applied to a large corpus of text. The corpus embodies a set of mutual constraints that largely determine the semantic similarity of words and sets of words. These constraints can be solved using linear algebra methods, in particular, singular value decomposition.

LSA is a mathematical and statistical approach, claiming that semantic information can be derived from a word-document co-occurrence matrix and that words and documents can be represented as points in a (high-dimensional) Euclidean space.

LSA builds upon semantic similarity and, hence, uses proximity models such as clustering, factor analysis, and multidimensional scaling (see [38.46], for a survey). Discovering latent proximity structure has previously been explored in relation to automatic document indexing and retrieval, using term, and document clustering [38.32, 47, 48] and factor analysis [38.49–51]. LSA builds further on these factor analysis techniques and constructs a concept-by-document matrix using a low-rank approximation of the term-by-document matrix, combining terms into concepts.

LSA rests on the conceptually simple assumption that the representation of any meaningful passage of text must be composed as a function of the representation of the words it contains. Thus, LSA models a passage as a simple linear equation, and a large corpus of text as a large set of simultaneous equations. The solution is in the form of a set of vectors, one for each word and passage, in a semantic space. Dimensionality reduction is an essential part of this derivation.

Optimal dimension reduction is a common workhorse in the analysis of complex problems in many fields of science and engineering. Over 99.99% of cells in the word-by-paragraph or term-by-document matrix representing the documents in the vector space turn out to be empty. This makes the comparison of word or paragraph meanings quite unpredictable. However, after dimension reduction and reconstruction, every cell will be filled with an estimate that yields a similarity between any paragraph and another, and between any word and another. This dimension reduction is crucial and is what accounts for LSA's advantage over most current methods of information retrieval that rely on matching exact words (or terms). It is also what determines its ability to measure the similarity of two essays that might use totally different words.

In practice, LSA is implemented by using singular value decomposition (SVD). A theorem by *Eckart* and *Young* [38.52] states that the rank-k approximation provided by SVD is the closest rank-k approximation

$$\begin{aligned}\|\mathrm{A}-\mathrm{A}_{k(\mathrm{SVD})}\|_2 &= \min_{\mathrm{rank(B)}\le k}\|\mathrm{A}-\mathrm{B}\|_2\\ &= \sqrt{\sigma_{k+1}^2+\cdots+\sigma_n^2}\,. \end{aligned} \tag{38.3}$$

The actual dimensionality reduction is then realized by truncating the SVD decomposition that decomposes the original term-by-document matrix into orthogonal factors representing both terms and documents

$$\mathrm{A}=\mathrm{U}\Sigma\mathrm{V}^{\mathsf{T}}\,, \tag{38.4}$$

with A the original term-by-document matrix, Σ a diagonal matrix with the square roots of singular values of $\mathrm{A}\,\mathrm{A}^{\mathsf{T}}$ and $\mathrm{A}^{\mathsf{T}}\,\mathrm{A}$ ($\sigma_1^2>\sigma_2^2>\ldots>\sigma_n^2$), and U and V containing orthogonal columns of left and right singular vectors, so that only its k largest singular values and corresponding dimensions of U and V are retained

$$\mathrm{A}=\mathrm{A}^{m\times n}\cong\mathrm{A}_k^{m\times n}=\mathrm{U}^{m\times k}\Sigma^{k\times k}\mathrm{V}^{k\times n}\,. \tag{38.5}$$

So, SVD is used to truncate the original vector space model to reveal the underlying or latent semantic structure in the pattern of word usage in order to define documents in a collection. This truncation is considered instrumental to deal with typical language issues such as synonymy, since different words expressing the same idea are supposed to be close to each other in the reduced k-dimensional vector space. Thus, instead of working in the original m-dimensional vector space represented by the original term-by-document matrix $\mathrm{A}^{m\times n}$, it is possible to work with the reduced vector space of lower rank, ignoring all but the first k singular values in Σ and all but the first k columns of U and V. This dimension reduction to k dimensions provided by SVD is the closest rank-k approximation available and might be useful to eliminate *noise* by focusing only on the underlying latent structure.

The k dimensions in the reduced space, or concept space, are now no longer mere words or stems, as in the original vector space, but linear combinations of such linguistic terms or stems. Therefore, the basic unit of analysis has become not just a mere word but a word-and-its-context, a concept (hence, the denomination concept space).

As dimensionality reduction turns the original (extremely) sparse matrix into a smaller full matrix, dimensionality reduction has no positive effect on storage size or calculation time; on the contrary, except for very low values of k, dimensionality reduction will increase the storage size as well as increase the processing time for calculations on the obtained reduced matrix. This makes clear that dimensionality reduction is not about computational simplification but rather a fundamental aspect of the method of dealing with language issues and reducing noise (terms in documents that do not contribute to the meaning of the document or parts of the document). As a consequence, the choice of k is not arbitrary but needs to be chosen carefully to truly represent the underlying latent structure of the data. The choice of the number of concepts to be retained is not straightforward. Current literature recommends 100–300 concepts for large datasets [38.53–55]. For some applications, it may be better to use a subset of the first 100–300 dimensions [38.45]. However, the best choice for k may well be database dependent, as *Berry* and *Browne* [38.56] suggest. We will be revisiting this issue explicitly in this chapter, as several validity exercises will include the assessment of dimensionality reduction (Sect. 38.4). In the context of text indexing, LSA is also referred to as latent semantic indexing (LSI).

38.3.3 Probabilistic Topic Models

Probabilistic topic models such as latent Dirichlet allocation (LDA) [38.57] help to derive the semantic structure from a set of text documents. LDA presumes text documents are derived from a finite set of topics, and that any topic can generate a set of words with a certain probability. So, documents contain multiple topics, and these topics can be represented by multiple words (and any word can be linked to multiple topics with different probabilities). LDA tries to achieve the reverse by deriving the probabilities of every word in the set of text documents being linked to any of the (latent) topics present in the text documents, i. e., the observed distribution of words is used to derive the unobserved distribution of topics. As a result, every word is given a list of probabilities of being linked to any of the topics, and every document is given a list of probabilities of being linked to any of the topics (by combining the probabilities of the words present in the document).

The advantage of this approach is that the individual word is not taken as a feature, but the context of words is taken into account in dealing with synonymy and homonymy/polysemy problems, i. e., the context of words is taken into account to derive the meaning of words. The additional strength of LDA is that words—and, hence, documents—can be linked to multiple topics to effectively deal with homonymy/polysemy issues. Other statistical techniques that try to derive the meaning of words, such as LSA and non-negative matrix factorization, also take the context of words into account but do not address homonymy/polysemy issues. These techniques seek to derive the meaning of words from the context, but they only derive one meaning for any single word. In contrast, the design of LDA is such that multiple meanings can be derived for the same word.

38.3.4 Similarity or Distance Calculation

The similarity measure typically used in information retrieval applications [38.56] is the cosine similarity measure. It is an expression of the angle between vectors, formulated as an inner product of two vectors, divided by the product of their Euclidean norms.

If vectors are normalized beforehand, this formula reverts to the simple inner product. Since, in the original vector space, all vector elements are positive (a word will appear zero times or more in a document), the results are values between 1 (for similar vectors, i. e., pointing in the same direction) and 0 (for entirely unrelated vectors), even after the application of a weighting scheme such as TF-IDF. This yields distances between 0 and 1. However, it no longer holds for vectors in the reduced concept space after SVD (LSA), since vector elements may be negative, which results in a concept-by-document space $V^{k\times n}$ that is no longer positive semi-definite with distances between 0 and (theoretically) 2, although it should be noted that values larger than 1.3 are quite rare in practice. While other similarity measures are possible (e. g., Jaccard, Dice, Euclidean distance—see *Baeza-Yates* and *Ribeiro-Neta* [38.58]), the cosine measure is among the most commonly employed [38.59].

38.4 Document Similarity: Validation Studies

Applying off-the-shelf text mining solutions in science and technology studies is not straightforward. Multiple methods and options are available, but experience with patent and publication data is limited, and more research is needed concerning effectiveness and validity of obtained results. Many options have to be considered during indexing (e. g., stop-word removal, stemming/lemmatization, weighting), modeling and dimensionality reduction (e. g., original document-by-term matrix, LSA, matrix factorization, topic modeling, number of retained concepts/topics), and similarity calculation (e. g., cosine, Jaccard similarity coefficient). Combined, all these options and parameters generate a broad spectrum of possibilities for representing the documents in a vector space and deriving similarity metrics. Although some generally accepted practices exist, there is still a lack of clarity about which options yield better results and under what circumstances.

To obtain further insights into the difference and relevance of options and parameters, we compared the outcome and accuracy of multiple options and parameters in two case studies, a small-scale study on matching patent and publication portfolios of academic inventors and a large-scale study on matching patents and publication for the purpose of identifying patent–publication pairs.

38.4.1 Case Study 1. Comparative Study of Similarity Metrics: Small-Scale Matching of Patents and Publications Within Portfolios of Academic Inventors

In this first case study, we endeavoured to match patent and publications within the portfolios of academic inventors (for a more extensive account, see *Magerman* et al. [38.10]).

For six academic inventors from KU Leuven—four from the Faculty of Medicine and two from the Faculty of Engineering—all WIPO (World Intellectual Property Organization), EPO (European Patent Office), and USPTO (United States Patent and Trademark Office) patents were extracted, where they appeared as inventors. After deduplication of the patent families and removal of patents without abstracts, 30 patents, ranging from 2 to 12 patents per academic inventor, were withheld. Next, we collected all publications of these professors appearing in the Web of Science. This resulted in 437 publications, ranging from 33 to 106 publications per professor (only publications with an abstract were retained). Altogether, the dataset consists of 467 documents.

Similarity Measures

For every patent of a given academic inventor, similarities with all publications of the same inventor are derived based on patent and publication titles and abstracts.

A variety of similarity measures were derived based on following options:

- Stop-word removal: SMART stop-word list plus removal of most frequent words after stemming (*method*, *present*, *result*, *study*, and *type*)
- Stemming/lemmatization: Porter stemmer
- Weighting: No weighting (raw term frequencies) and TF-IDF weighting
- Modeling/dimensionality reduction: No dimensionality reduction (straight cosine on the original document-by-term matrices after weighting) and LSA with $k = 5, 10, 20, 30, 100, 300$ (after weighting)
- Similarity metric: Cosine distance.

Dimensionality reduction is an essential part of the LSA method; it truncates the vector space model to reveal the latent semantic structure in the document collection, mapping terms on latent concepts by combining terms in linear relationships. SVD is applied to obtain a rank-k approximation of the original matrix. Dimensionality reduction is supposed to remove the noise due to polysemy and synonymy present in text documents, but the level of reduction, or the best selection of the rank-k of the truncated document-by-term matrix, remains an open question. Empirical testing suggests that the optimal choice for the number of dimensions ranges between 100 and 300 for large datasets. For small datasets, low values of k (below 10) seem to work equally well [38.3, 60].

In general, a set of documents is indexed and weighted as a whole, and LSA is performed on the index of all documents. We are only interested in relations within the set of patents and publications of the respective academic inventors. As such, there are two options to perform weighting and LSA: perform weighting and LSA on the unified vocabulary of all six academic inventors, or perform weighting and LSA on the case-specific vocabulary of each academic inventor separately. The individual or case-specific approach holds the promise that weighting and LSA are tailored for each professor individually. At the same time, the individual document sets become small; only low k-values can be used for the SVD rank-k approximation.

We include both approaches in our analysis. For the case-specific vocabulary approach, the highest rank-k approximation depends on the size of the smallest document set of all academic inventors, which is 66 (a professor with 2 patents and 33 scientific publications). We opted to include rank-k approximations of 30, 20, 10, and 5 (as previous research on small document sets suggests that even very low values of k might yield relevant results [38.3, 60]). For the global unified vocabulary approach, the highest rank-k approximation possible is 467 (the total number of documents of all academic inventors). We opted to include rank-

k approximations of 300 and 100 and also included 30, 20, 10, and 5 for comparison with the case-specific approach. In the interest of simplicity, we denote the different rank-k approximations by SVD followed by the rank-k approximation (e. g., SVD 30 means we applied LSI using a rank-30 SVD approximation).

Hence, we consider the following options: global unified document indexing (index=U (unified)) and individual case document indexing (index=C (case)); no weighting (weighting=NO) and TF-IDF weighting (weighting=TI); no SVD reduction and reduction to 5, 10, 20, 30, 100, and 300 concepts (the latter two only for the global unified document indexing). Table 38.1 contains an overview of the measures considered.

SVD 0 denotes that no SVD/LSA has been performed, while SVD 30 implies an SVD rank 30 approximation. There are fewer measures pertaining to local case document indexing as it is not feasible to apply higher rank SVD solutions (beyond 300) given the limited size of the datasets implied. It should be noted here that, while Table 38.1 lists 24 combinations, only 23 distinctive measures are implied. When neither weighting nor LSA are applied, global unified document indexing and individual case document indexing yield similar distance measures.

As we are only interested in the relation between patents and publications within the separate document sets of the respective academic inventors, we only calculate the distance between the patents of an academic inventor and all publications of the same academic inventors, and not the distance between patents and publications of different academic inventors. In practice, this means that we have 23 calculations for 2345 different patent–publication pairs.

Table 38.1 Case study 1. Overview of measures

Measure	Index	Weighting	SVD
1	U	NO	0
2	U	NO	5
3	U	NO	10
4	U	NO	20
5	U	NO	30
6	U	NO	100
7	U	NO	300
8	U	TI	0
9	U	TI	5
10	U	TI	10
11	U	TI	20
12	U	TI	30
13	U	TI	100
14	U	TI	300
15	C	NO	0
16	C	NO	5
17	C	NO	10
18	C	NO	20
19	C	NO	30
20	C	TI	0
21	C	TI	5
22	C	TI	10
23	C	TI	20
24	C	TI	30

Comparison of Similarity Values Obtained

For every similarity metric (i. e., for every combination of indexing and similarity calculation options), we compiled descriptive statistics on the distribution of the distance values obtained (distance between every patent and every publication for the six academic inventors—note that this distance becomes zero when two documents are similar, so distance$_{ij}$ is calculated as $1 - \text{cosine}_{ij}$).

Figure 38.1 reveals that one group of measures displays a highly skewed distribution (measures with no or high values of SVD), while other measures are far less skewed (measures with low values of SVD). Figure 38.1 reflects distribution examples for a number of representative measures obtained.

In Fig. 38.1, M1 is the measure with neither weighting nor SVD (LSA), M3 is a measure with no weighting and low SVD (SVD 10) performed on the global document set, M13 is a measure with weighting and medium SVD (SVD 100) performed on the global document set, and M24 is a measure with weighting and medium SVD (SVD 30) performed on the case document set. The lines represent the number of patent–publication and patent–patent pairs with distances within the range indicated on the x-axis (distance buckets of 0.1 expressed as distance—0 is total similarity, 1 is total dissimilarity). The measure with low SVD (M3) is very distinct from the other measures and has a counter-intuitive shape, since one does not expect so many close pairs (more than 1500 pairs have a distance of 0, so are classified as identical). It seems that low SVD maps too many unrelated terms to a small number of con-

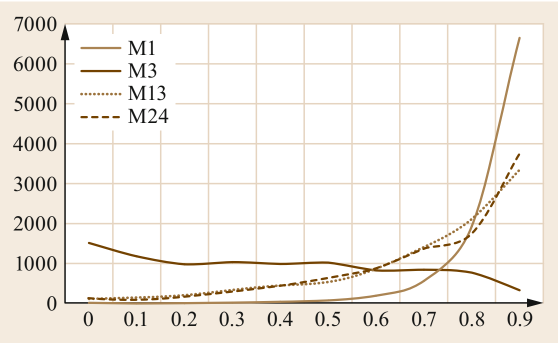

Fig. 38.1 Case study 1. Distribution examples

cepts, artificially creating close pairs. In a following step, we compared the calculated similarity measures with similarity ratings obtained from independent ratings.

Assessment

In order to compare and assess the accuracy of the different measures, all implied patent–paper pairs were rated independently by two researchers. Overall, five researchers—all active and experienced in the field of science and technology studies—were involved in this exercise for all six academic inventors.

Each researcher rated the relatedness between patent documents, on the one hand, and publications, on the other. Three categories were used, ranging from highly related to unrelated, with somewhat related in the middle. In a subsequent step, the scores of each pair were compared, and Kappa scores—indicating between-subject consistency—were calculated. If two assessments differed greatly (highly related versus unrelated), both assessors reviewed and discussed their assessments. After this iteration, Kappa scores were obtained ranging from 0.62 to 0.90, signaling satisfactory and even excellent levels of consistency (the average for the six academic inventors was 0.83).

These assessments figured as the independent variable in an ANOVA (analysis of variance) analysis to assess the relation between the expert assessment, on the one hand, and the relatedness as obtained by the calculated measures, on the other. For the six professors in our study, 16 patents (all patents of four academic inventors and a selection of patents of the remaining two academic inventors—3 out of 9 and 4 out of 12 patents, respectively) were assessed independently in terms of relatedness. Table 38.2 provides an overview of the average R^2 obtained for the measures under study. The higher the observed R^2, the more the similarity measures concur with the independent expert assessments.

Table 38.2 reveals considerable differences between different conditions. If we work with a unified thesaurus, measures that concur most with expert ratings imply the application of TF-IDF weighting with either high SVD values ($n = 300$) or no SVD/LSA at all. Similarly, when opting for a case-based thesaurus, measures that combine weighting, either with no SVD or high levels of SVD ($n = 30$) perform best. Differences with fewer performing combinations are highly significant ($p < 0.0001$). Better performing measures share the characteristic that they are relatively modest in terms of information reduction. Applying no SVD/LSA by definition implies refraining from reducing the initial word space; applying SVD with a relatively large number of dimensions respects the potential richness of the underlying information.

Table 38.2 Case study 1. Accuracy levels obtained for different measures under study

Index	Weighting	SVD	Mean	Std. deviation	N
Case	NO	0	0.401	0.293	16
		5	0.247	0.257	16
		10	0.321	0.254	16
		20	0.362	0.274	16
		30	0.379	0.270	16
	TF-IDF	0	0.459 (3)	0.288	16
		5	0.191	0.203	16
		10	0.356	0.265	16
		20	0.409	0.277	16
		30	0.413 (4)	0.295	16
Unified	NO	0	0.401	0.293	16
		5	0.106	0.135	16
		10	0.195	0.273	16
		20	0.242	0.280	16
		30	0.285	0.324	16
		100	0.341	0.314	16
		300	0.386	0.286	16
	TF-IDF	0	0.489 (1)	0.301	16
		5	0.133	0.185	16
		10	0.202	0.263	16
		20	0.251	0.296	16
		30	0.314	0.335	16
		100	0.340	0.324	16
		300	0.482 (2)	0.285	16

TF-IDF weighing also has a positive impact, albeit smaller than the application of SVD. The positive impact of weighting can be understood as giving emphasis to the distinct elements of documents.

While the observations related to weighting may come as no surprise, the results on SVD are more surprising. As Table 38.2 reveals, SVD performs worst under all circumstances, especially with a limited number of dimensions. The higher the number of dimensions retained, the more the scores approximate the scores with no SVD/LSA applied, but no level of SVD reduction yields higher scores. Given the premises of LSA, we expected better scores for at least some levels of SVD dimensionality reduction. We should bear in mind that the purpose of LSA is to secure better similarities; that means that SVD/LSA is expected to yield better results than a cosine applied to the original document-by-term matrix, at least for a range of k-values.

While the reduction in overall R^2 in Table 38.2 already illustrates how validity fluctuates, scrutinization of specific pairs really reveals the impact of parameter choices. Table 38.3 provides a detailed insight with respect to the distances obtained under different conditions for a patent–paper pair that is highly related and highly unrelated.

Table 38.3 Case study 1. Impact of specific text mining choices on distance measure obtained

Seed patent	Gluten biopolymers
Publication 1 (close to seed patent)	Designing new materials from wheat protein
Publication 2 (far from seed patent)	In-situ polymerization of thermoplastic composites based on cyclic oligomers

Options taken to arrive at similarity measures			**Measures obtained**		**Assessment**
Index	**Weighting**	**SVD**	**PUB 1 (highly related)**	**PUB 2 (unrelated)**	
Unified	NO	5	0.015	0.009	Misleading
Unified	TF-IDF	300	0.102	0.908	Accurate
Case	NO	5	0.051	0.036	Misleading
Case	TF-IDF	30	0.030	0.967	Accurate

It should be noted here that distance is calculated; hence, low values indicate similarity—with a zero value indicating complete similarity; values close to 1 signal no relatedness at all. As Table 38.3 clarifies, applying an SVD solution to a limited number of dimensions ($n = 5$) results in similarity measures that suggest that publication 2 is more related to the patent document than publication 1, whereas, in fact, the opposite holds. This phenomenon manifests itself both when using a unified and a case-based thesaurus. This example illustrates how a strong reduction in underlying information may result in vector spaces that—when used to calculate distances between objects—yield distance measures of a misleading nature. At the same time, the other two examples included in Table 38.3 (unified thesaurus, SVD 300 and case-based thesaurus, SVD 30) strongly demonstrate the feasibility of applying text mining algorithms to detect similarity, even in the case of document sets stemming from different activity realms (patents and publications). Overall, these observations suggest that the choices made, with respect to the set-up of a vector space model and how to proceed when calculating similarity measures, considerably affect the outcomes obtained.

Conclusions

Our findings reveal that different options and methods coincide with considerable differences in terms of accuracy. While several combinations allow us to arrive at practical solutions, certain combinations display low levels of accuracy and even result in misleading similarity measures. For relatively small datasets, options that respect the potential richness of the underlying data yield better results: Either one opts for no SVD or SVD with a relatively high number of dimensions. In addition, weighting has a beneficial impact under these conditions. For a collection of smaller datasets, a global unified indexing and weighting approach does not yield worse results than an individual, case-based indexing and weighting approach. This is an interesting finding because a global unified indexing approach is far easier in practice. LSA seems not to redeem its promise to deal with synonymy and polysemy problems in our setting; all measures involving SVD perform worse than those where SVD is not applied. We suspect this has to do with the low number of documents in the sample, especially given our case-based indexing and SVD approach.

38.4.2 Case Study 2. Comparative Study of Similarity Metrics: Large-Scale Matching of Patent and Publications

In this second case study, we compare more options in a large-scale matching of patents and publications for the purpose of identifying patent–publication pairs—i. e., scientific publications from which the contents (methodology, findings, discovery/invention) are part of a patent publication, in the field of biotechnology—since it is known to be a science-intensive field with substantial science-technology interactions [38.11, 61].

On the patent side, the OECD definition of biotechnology is used to identify biotechnology patents [38.62], defining 30 international patent classification subclasses/groups related to biotechnology. We use PATSTAT (EPO Worldwide Patent Statistical Database) to retrieve all EPO and USPTO granted patents with application and grant year between 1991 and 2008 according to the 30 defined IPC-subclasses/groups (International Patent Classification) related to biotechnology. Since text mining techniques are applied to further identify patent–publication pairs, only patents with titles and a minimum abstract length of 250 characters are withheld, resulting in a final patent data set of 7254 EPO and 80 994 USPTO biotechnology patents; hence, 88 248 patents in total (PATSTAT, edition October 2009).

On the publication side, we select biotechnology publications (articles, letters, notes, reviews) from the Clarivate Analytics (formerly Thomson Reuters ISI) Web of Science database based on the Web of Science subject classification, for the same time period 1991–2008 (volume year). 243 361 publications are extracted from the subject category *biotechnology and applied microbiology*.

To ensure that all potentially related scientific publications are included in the data set, we extend this core publication set with publications from nine related subject categories:

1. *Biochemical research methods*
2. *Biochemistry and molecular biology*
3. *Biophysics*
4. *Plant sciences*
5. *Cell biology*
6. *Developmental biology*
7. *Food sciences and technology*
8. *Genetics and heredity*
9. *Materials for microbiology*.

This results in more than 1.75 million additional publications for the period 1991–2008—a considerable computational challenge for the text mining method to identify patent–publication pairs. In order to lower the number of publications for ease of calculation without losing too many relevant documents, we retain only those publications from this extended set that cite or are cited by at least one publication from our core set, sizing down the additional publication set to 683 674 publications. Finally, we add all multidisciplinary publications from *Nature*, *Science*, and *Proceedings of the National Academy of Sciences of the United States of America*, resulting in 97 970 additional publications. Again, we retain only publication documents with titles and a minimum abstract length of 250 characters, resulting in a final publication set of 948 432 biotechnology-related publications.

Similarity Measures

For biotechnology patents, similarities with all biotechnology publications are derived from patent and publication titles and abstracts.

A variety of similarity measures were derived from the following options:

- Stop-word removal: SMART stop-word list
- Stemming/lemmatization: Porter stemmer
- Weighting: No weighting (raw term frequencies), binary weighting (0 for no occurrence, 1 for one or more occurrences), IDF weighting, and TF-IDF weighting
- Modeling/dimensionality reduction: No dimensionality reduction (straight cosine on the original document-by-term matrices after weighting) and LSA with $k = 5$, 10, 25, 50, 100, 200, 300, 500, 1000 (after weighting)
- Similarity metric: Cosine similarity and three variants of the Jaccard similarity coefficient: the Sørensen–Dice coefficient, the symmetric variant of the Tversky index with $\alpha = 0$ and $\beta = 1$, and the symmetric variant of the Tversky index with $\alpha = 1$ and $\beta = 0$.

To summarize, we compare 40 measures based on LSA by combining 4 levels of term weighting with 9 levels of dimensionality reduction by SVD and no dimensionality reduction at all. For each of these 40 measures, we use the cosine metric to arrive at a similarity value.

We also include three measures based on counting the number of terms that the patent and publication documents have in common. For these measures, we use stop-word removal and stemming, but only take the distinct terms of every document into account (equal to binary weighting for LSA and cosine). To arrive at a metric similarity measure between 0 and 1, three ways of normalization are used:

1. Divide the number of common terms by the minimum of the number of terms of the patent document, on the one hand, and the number of terms of the publication document, on the other (*common terms MIN*).
2. Divide the number of common terms by the maximum of the number of terms of the patent document and the publication document (*common terms MAX*).
3. Divide the number of common terms by the average of the number of terms of both documents (*common terms AVG*).

The second option is more restrictive compared to the first option and only attributes high similarities if both documents are almost identical (intersection of both documents equal to the union of both documents: $A + B \approx A \cap B$). The first option also attributes high similarity if one document is a subset of another document, even if the latter document contains far more information (the intersection of both documents is equal to one of the documents, but the potentially large complement of that one document is neglected: $A + B \neq A \cap B$ but $A \approx A \cap B$). Hence, the first option will yield higher similarity values for the same document combinations than the second option, and the third option will be somewhere in between. Bear in mind that these three metrics are a generalization of the Jaccard similarity coefficient: the symmetric version of the Tversky index with $\alpha = 0$ and $\beta = 1$, and symmetric version of the Tversky index with $\alpha = 1$ and $\beta = 0$, and the Tversky index with $\alpha = 0.5$ and $\beta = 0.5$ (also known as the Sørensen–Dice coefficient). The distances between all seed patents and all target publications are calculated using these different distance-measure variants.

We deliberately decided not to apply more pre-processing tasks, such as compound term and collocation detection, because we wanted to keep the processing simple and automated. These more advanced pre-processing tasks almost always imply greater human involvement and manual attention. In this setting, we wanted to see if a simple automatic approach would work.

Comparison of Similarity Values Obtained: Aggregative Results and Validation with Control Sets

In a first step, we compare the distribution of the similarity values obtained. For each measure, we take the closest publication and the corresponding similarity value for each biotechnology patent; hence, 88 248 similarity values for each measure. Based on these values, we create normalized histograms displaying the proportion of biotechnology patents having a closest biotechnology publication in a given similarity interval (one histogram for every similarity measure).

In order to assess the validity of the measures, we create three control sets for validation containing patents not related to biotechnology:

1. Agriculture
2. Automotive
3. Materials.

For each of these sets, we randomly select 2500 EPO and 7500 USPTO granted patent documents from the same time period based on IPC-codes (respectively IPC class A01 for agriculture, B60 and B62 for automotive, and IPC subclass G01N, G01R, and HO1L for materials). We retain only documents with titles and a minimum abstract length of 250 characters, resulting in a control set of 29 952 patents related to agriculture, automotive, and materials. For these control groups, we again compile normalized histograms displaying the proportion of agriculture, automotive, and material patents having a closest biotechnology publication in a given similarity interval for every similarity measure. Thus, for any given measure, we can combine the histograms of the biotech patents and the patents related to agriculture, automotive, and materials, since we used the relative share of patents that have a closest publication within a given similarity interval and not the absolute number of patents.

Figure 38.2 shows such a combined histogram for the similarity measure using TF-IDF weighting and SVD of rank-300, a commonly used measure. The y-axis contains the proportion of patents that have a closest publication with similarity given by the x-axis (with intervals of 0.05). Five histograms are combined:

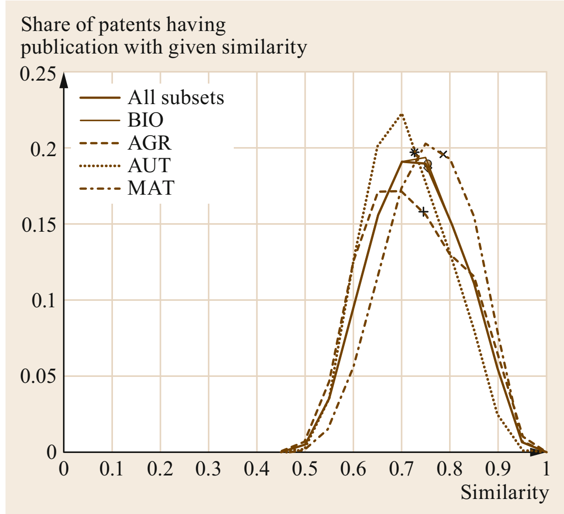

Fig. 38.2 Case study 2. Distribution *patent–closest publication* similarity values according to TF-IDF SVD-300. Frequency count; *markers*=median

one for the biotechnology patents (solid thin line), one for every control group—agriculture (AGR), automotive (AUT), and materials (MAT) (non-solid lines), and one for all patents together—biotechnology patents and all patents from the three control sets (thick solid line).

The distribution of the group of biotechnology patents (solid thin line) falls more or less together with the distribution of all patents (same median value). The relatively high similarity scores are striking. The median similarity for all patents (solid thick line) is 0.76, or 50% of all patents have a scientific publication with similarity above 0.76. These high average similarity values are suspicious, although this could also be considered as a calibration issue. More problematic is the distribution of the similarity measures related to materials patents (dot–dash line). We expect similarity distributions of the sets of control patents to be to the left of the similarity distribution of biotechnology patents. Indeed, those control set patents are, based on the field classification, expected to be less related to biotechnology publications (than biotechnology patents). However, the opposite is suggested in Fig. 38.2. On average, patents belonging to the field of materials are portrayed as more closely related to biotechnology publications than patents belonging to the field of biotechnology. This is very unlikely and suggests that similarity values based on TF-IDF weighting and SVD of rank-300 do not accurately capture the (content) similarity between patent and scientific publication documents.

We observe this phenomenon for all measures based on SVD, and the lower the number of retained dimensions, the worse it becomes (the more distributions shift to the right, the more patents of control groups are more similar to scientific biotechnology publications compared to *biotechnology* patents). Weighting methods have some effect too; distributions based on binary weighting and IDF weighting are shifted more to the left compared to TF-IDF weighting and no weighting at all, regardless of the number of retained dimensions. No weighting at all and binary weighting tend to suffer less from the phenomenon of patents of control groups being more similar to scientific biotechnology publications than biotechnology patents. SVD only seems to yield meaningful similarity values when a high number of dimensions are retained (500 or more) and not in combination with TF-IDF weighting (SVD with 1000 dimensions and TF-IDF weighting still reveals atypical distributions).

Figure 38.3 shows the distribution of the similarity between patents and their closest biotechnology scientific publication according to the similarity measure using TF-IDF weighting without SVD. This distribution makes sense; patents from control groups (agriculture, automotive, materials) are on average less similar to biotechnology patents. Furthermore, there are barely any control set patents that have high similarity with biotechnology patents. The other weighting methods yield similar distributions, although binary and IDF weighting results are slightly more peaked and shifted to the left.

Finally, Fig. 38.4 shows the distribution of the measure based on the number of common terms normalized by the minimum of the term length of both documents (*common terms MIN*). Here, we also observe an expected distribution with control set patents scoring significantly lower similarity values compared to the biotechnology patents. All measures based on the number of common terms yield expected results, although *common terms MIN* yields the highest distinctive power between biotechnology patents and control set patents. Indeed, this measure seems to yield the best distinctive power of all measures under study.

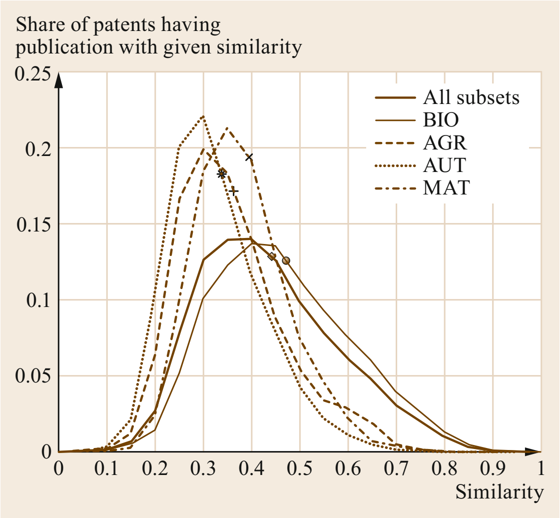

Fig. 38.3 Case study 2. Distribution patent: closest publication similarity values according to TF-IDF without SVD. Frequency count; *markers*=median

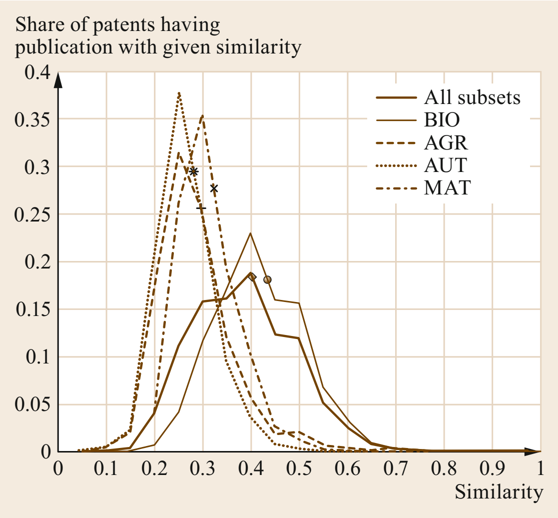

Fig. 38.4 Case study 2. Distribution patent: closest publication similarity values according to number of common terms normalized for minimum term length (common terms MIN). Frequency count; *markers*=median

Preliminary Conclusion

When comparing the distribution of the similarity between patents and their closest scientific biotechnology publication, with the distribution of similarities obtained by comparison with other fields (agriculture, automotive, materials), questions arise regarding the validity of LSA-based measures when matching patent documents and scientific publications. Not only do LSA-based measures yield remarkably high similarities, they also fail to rate non-biotechnology patents as less similar to biotechnology publications than biotechnology patents. This suggests that these measures do not reflect real similarities present in the document collection. The fewer dimensions that are retained, the more the similarity values obtained seem to deviate from the real relations between the documents. This effect is reinforced when using TF-IDF weighting, a commonly used weighting method. Similarity measures based on the cosine metric without dimensionality reduction seem to perform better, in combination with any of the tested weighting schemas, as well as the measures based on counting the common number of terms. The one normalized by the minimum of the term length of both documents (common terms MIN) seems to yield the best results.

These noteworthy results mean that patent–publication combinations yielding high similarity values deserve a closer look. Table 38.4 contains the similarity scores of a patent–publication combination scoring high on TF-IDF in combination with SVD (ranging from 0.928 to 0.995 according to the number of retained dimensions). The title of the patent is:

> Process and rotary milking parlor for the identification of a milking stall and an animal, in particular a cow, in a rotary milking parlor.

The title of the scientific publication is:

> Growth-behavior of lactobacillus-acidophilus and biochemical characteristics and acceptability of acidophilus milk made from camel milk.

The title and abstract of both documents make clear that they are only (very) marginally related; both are about milk, but the patent is about an apparatus for milking, while the publication is concerned with a comparison of cow milk and camel milk with respect to the characteristics of lactobacillus acidophilus fermentation. The similarity scores obtained contain considerable variation among weighting methods and dimension reduction.

Specifically, TF-IDF in combination with SVD yields high scores; other measures yield lower scores, better reflecting the weak relationship between both documents, although all weighting methods yield high values for high levels of dimensionality reduction (low values of k, right-hand side of the table). In general, binary and IDF weighting yield lower scores compared to no weighting or TF-IDF weighting, although there are some exceptions. The measures based on the number of common terms yield low scores (0.10, 0.07, and 0.08 for *common terms MIN*, *common terms MAX*, and *common terms AVG*, respectively), in line with the real similarity between the two documents.

The non-linear relation between similarity scores and dimensionality reduction should be noted; lower numbers of retained dimensions do not necessarily yield the highest similarity scores. For example, the results for raw, i. e., non-weighted, term vectors are interesting; starting from 0.837 for 1000 dimensions, it increases to 0.905 for 300 dimensions, and then decreases to 0.368 for 50 dimensions, to increase again for lower dimensions. This example confirms that the choice of the right level of dimensionality reduction is far from straightforward and that the weighting method has a considerable impact on the results.

Assessment

To assess the validity of LSA-based measures and to obtain greater insight into the contribution of weighting and dimensionality reduction levels on their performance, we set up a validation exercise at the level of individual patent–publication combinations. We selected 250 patent–publication cases with variation in similarity values amongst measure variants. For those 250 cases, we carried out an independent assessment of experts to rate the similarity on a five-level scale, and we checked the consistency between the expert assessment and each of the 43 measures for the 250 selected validation cases. This allowed us to select the best performing measures.

A group of 9 people with experience in the field rated all validation cases (patent–publication combinations) assessing the extent to which the contents of the patent document and the scientific publication cover the same invention/discovery using a five-level scale: not related at all, somewhat related, related, highly related, and identical. The two independent scores were unified by taking the average of the two scores and rounded to arrive again at a five-level score. To deal with potential disagreement amongst raters, two final scores were retained: a conservative one by rounding the average of the scores down to the nearest integer and an optimistic one by rounding the average up to the nearest integer.

Given the expert assessment of the 250 validation cases, an ANOVA-type analysis can be used to check the consistency between the expert scores (conservative and optimistic) and the calculated similarity values. Table 38.5 contains the results of the generalized linear model (GLM) regression based on 250 patent–publication validation cases for the conservative expert score. This table contains the R^2 value of the model

Table 38.4 Similarity scores for patent US7104218 and publication A1994PC04400005 according to various measures

Weighting method	Dimensions retained (SVD)									
	All	1000	500	300	200	100	50	25	10	5
Raw	0.511	0.837	0.873	0.905	0.754	0.391	0.368	0.608	0.691	0.673
Binary	0.083	0.057	0.025	0.023	0.056	0.087	−0.030	0.492	0.763	0.750
IDF	0.095	0.168	0.162	0.260	0.375	0.403	0.504	0.532	0.698	0.738
TFIDF	0.364	0.928	0.973	0.986	0.991	0.991	0.995	0.980	0.959	0.960

Table 38.5 Consistency between (conservative) expert similarity assessment and similarity measures according to measures (R^2 values of GLM regression based on conservative expert score of 250 validation cases)

Measure		R^2	Measure		R^2
Raw	No SVD	*0.61*	Bin	No SVD	*0.77*
	SVD 1000	0.34		SVD 1000	*0.65*
	SVD 500	0.31		SVD 500	*0.63*
	SVD 300	0.30		SVD 300	*0.58*
	SVD 200	0.31		SVD 200	*0.51*
	SVD 100	0.30		SVD 100	0.45
	SVD 25	0.22		SVD 25	0.38
	SVD 5	0.11		SVD 5	0.20
IDF	No SVD	*0.80*	TF-IDF	No SVD	*0.71*
	SVD 1000	*0.63*		SVD 1000	0.45

	SVD 300	*0.54*		SVD 300	0.26
	SVD 200	*0.51*		SVD 200	0.21
	SVD 100	0.49		SVD 100	0.17
	SVD 25	0.46		SVD 25	0.14
	SVD 5	0.21		SVD 5	0.11
Common terms (weighted by min number of terms)					*0.82*
Common terms (weighted by max number of terms)					*0.68*
Common terms (weighted by avg number of terms)					*0.75*

for every measure, with the conservative expert score as a dependent variable and the similarity values of the given measure as an independent variable (values in italics are R^2 values higher than 0.50).

Table 38.5 shows that the application of SVD has a negative impact on the performance of similarity measures. For all weighting methods, dimensionality reduction results in significantly lower R^2 values, i. e., less congruence between the similarity score obtained according to the measure and the similarity score as assessed by the experts; the larger the dimensionality reduction, the lower the R^2 values obtained. This is especially the case when no weighting or TF-IDF weighting is used—this is noteworthy, since the combination of TF-IDF weighting and SVD dimensionality reduction is commonly advanced as relevant for text mining purposes. Binary and IDF-weighting outperforms no weighting and TF-IDF-weighting, whether or not SVD is used. The combination of IDF-weighting without SVD, i. e., a cosine metric based on an IDF-weighted document-by-term matrix, yields the highest R^2 (0.80) of all cosine-based measures. It is also striking that simple metrics based on the number of common terms score very highly, and even more so, the metric based on the number of common terms weighted by the minimum number of terms of both documents (*common terms MIN*) yields the highest R^2 value (0.82).

When the optimistic expert scores are used instead of the conservative ones, results remain the same; despite small changes in R^2 (upward for some measures, downward for others), conclusions about SVD, the weighting method, and the best measures are confirmed.

Similarly, when we convert the five-scale expert scores to two-scale expert scores (identical versus non-identical) to focus on the identification of patent–publication pairs, results remain the same.

Our ANOVA results reveal that the similarity measure, *common terms MIN*, best matches our five-scale expert validation. Of course, it comes as no great surprise that measures based on the number of common terms perform that well; the more terms in common, the more one can expect both documents to be similar. Yet, on the other hand, these simple measures based on the number of common terms can miss relevant matches because they do not deal with language-related issues such as homonymy, polysemy, and synonymy. It is worth noting that, despite this lack of complexity, these measures come closest to the expert assessment of similarity—clearly beating LSA measures that claim to deal with typical language issues. Another noteworthy observation concerns the consistency between *common terms MIN* and the presence or absence of a publication author in the list of patent inventors—a strong indication of whether or not the patent and publication are identical, i. e., share the same contents (methodology, findings, discovery). All patent–publication combinations with a similarity of 0.59 or above, according to this measure, have a publication author listed as patent inventor, and all combinations with a similarity of 0.50 or below do not have a publication author listed as patent inventor (with one exception with a similarity value of 0.16). These observations add to the validity of the results obtained.

Patent–Publication Pair Classification

The objective of this study is not only to identify the best measures, or more specifically the best combination of pre-processing options and distance measures, but also to use those insights to identify patent–publication pairs, i. e., scientific publications from which the contents—methodology, findings, discovery/invention—are closely related to a patent document and vice versa.

The results reported corroborate the use of the measure, *common terms MIN*, to classify patent–publications pairs. However, this measure can be misleading when one document is far shorter than the other document. When almost all terms of the patent abstract are present in the publication abstract, a high similarity is obtained when using the minimum number of terms from both documents as the weighting factor. This approach seems to make sense in general; if the abstract of one document is a subset of the abstract of the other document, they can be regarded as identical. However, when one of the documents is too small, or when the difference in length is too great, using the minimum number of terms as the weighting factor might lead to unreliable results (even for human experts, it remains difficult to assess similarity in these cases). A correction is needed for document combinations with one small and one large document. Instead of adding an absolute criterion based on document size, we examined the impact of an additional relative measure, since we already had one measure available: the measure, *common terms MAX*. So, we combined the primary criterion based on the measure, *common terms MIN*, (e. g., above 0.55) with a secondary criterion based on the measure, *common terms MAX*, to correct for doubt cases. It is clear that setting thresholds on the primary criterion (*common terms MIN*) and the secondary criterion (*common terms MAX*) is a trade-off between false positives and false negatives, or precision and recall. To determine good thresholds for *common terms MAX*, 50 additional cases were validated to cover a broad spectrum of combinations of *common terms MIN* and *common terms MAX*.

Table 38.6 contains precision and recall for different thresholds on the primary and secondary criteria (optimal precision, optimal recall, and balanced precision/recall) based on all 300 cases rated by experts (both for the conservative and the optimistic expert scores). Optimal precision scores can be obtained with a recall of approximately 0.51 (numbers in italics on the optimistic side of the table), optimal recall scores can be obtained with a precision figure of approximately 0.81 (numbers in italics on the conservative side of the table), and balanced precision/recall scores of approximately 0.90 are possible for both precision and recall simultaneously (e. g., *common terms MIN* above 0.55 and *common terms MAX* above 0.30).

However, we have to keep in mind that the precision and recall figures listed in Table 38.6 are not representative for the total population because the similarity values obtained for *common terms MIN* and *common terms MAX* are not equally distributed in the validation sample and the total population (the validation sample includes proportionally more identical document combinations). There are many more patent–publication combinations scoring low on the proposed distance measures in the total population, whereas our initial calculation of precision and recall rates from sample data contained an over-representation of patent–publication combinations scoring high on the respective distance measures. Recall rates in particular suffer from this issue. However, the magnitude of the difference between the precision and recall rates averaged over the validation sample and the real rates based on the distribution in the global population heavily depends on the representativeness of the low-scoring cases in the validation set. More validation cases with lower scores are needed to obtain a more reliable estimate of the real precision and recall.

Table 38.6 Precision and recall for different thresholds on primary criterion and secondary criterion (optimal precision, optimal recall, balanced precision), based on conservative and optimistic expert scores for 300 validated cases

		Conservative		Optimistic	
Primary criterion	Secondary criterion	Precision	Recall	Precision	Recall
0.50	0.10	*0.81*	*0.99*	0.88	0.98
0.50	0.32	0.91	0.92	0.94	0.88
0.50	0.61	0.98	0.55	*1.00*	*0.51*
0.55	0.10	*0.82*	*0.98*	0.88	0.97
0.55	0.30	0.90	0.93	0.93	0.89
0.55	0.61	0.98	0.55	*1.00*	*0.51*
0.60	0.10	0.83	0.95	0.98	0.94
0.60	0.29	0.91	0.92	0.94	0.88
0.60	0.61	0.98	0.55	*1.00*	*0.51*

Conclusions

The most notable finding of this study is the poor performance of SVD-based measures, even when commonly used pre-processing options and levels of dimensionality reduction are deployed (e. g., TF-IDF weighting in combination with SVD with 300–1000 dimensions).

When it comes to the influence of weighting, Table 38.5 shows that weighting methods taking into account term frequencies (no weighting at all and TF-IDF weighting) perform worse compared to weighting methods ignoring term frequencies for all levels of dimensionality reduction. In line with these findings, we also witness better performance for the measures based on the number of common terms, measures that also ignore term frequencies.

Looking at individual cases provides us with a measure of insight into the implications of choosing a particular weighting method. In general, including term frequencies is expected to generate better results, since the number of times a given term appears in one document is an indication of the importance of that term in that particular document. However, for our patent–publication document combinations (mostly of a rather moderate length and with highly technical content), this additional notion of importance derived from term frequencies seems to be of less relevance in assessing the similarity of the documents. Indeed, when looking at multiple document combinations, the human judgment on similarity is far more driven by the kinds of terms in the documents rather than the number of times a particular term appears in a document. This observation explains why weighting methods taking into account term frequencies do not perform better, but it does not explain why they perform so much worse. Again, looking at individual cases reveals some additional insights.

First of all, stemming errors and tokenization and parsing issues sometimes cause artificial inflation of term frequencies, magnifying the impact of the underlying stemming and tokenization errors. An example of a patent–publication combination where the amplification of a stemming error results in misleading similarity values for weighting methods, taking into account term frequency, is a patent document about an incubator with external gas feed and a publication about gibberellin metabolism in suspension-cultured cells of *raphanus-sativus*. Both documents have nothing in common, yet score highly on some measures (and score significantly higher on measures that include term frequencies). Both documents have only two (stemmed) terms in common, *feed* and *ga*. However, the stemmed term *ga* occurs 9 times in the patent document and 29 times in the publication document, resulting in high weights when the term frequency is included. However, the stemmed term *ga* in the patent document is a stemming error derived from *gas*, while the stemmed term *ga* in the publication document is an abbreviation of *gibberellin* and has nothing to do with the stemmed term *ga* in the patent document. For weighting methods not taking term frequency into account, this stemming error counts as just one (albeit wrongly) matching term but, for weighting methods using term frequency, this stemming error is magnified and leads to erroneous results.

Secondly, we observe that words with a particular meaning—and, hence, very relevant in the assessment of similarity—tend to have smaller term frequencies compared to natural language words with a more general meaning. For weighting methods including term frequencies, the weight of these more general natural language words becomes too influential in the derivation of similarity by the cosine metric. Weighting terms by their respective IDF values only partially corrects this problem; TF-IDF performs better than no weighting at all, and IDF performs (slightly) better than binary weighting, but TF-IDF still performs worse compared to binary or IDF weighting.

38.5 Clustering and Topic Modeling Case Studies

Structuring and topic detection of text documents is about finding relevant relationships between documents based on the topics described in the text documents. The standard method for (unsupervised) structuring is clustering. Clustering entails combining documents into sets of related documents based on some underlying similarity criterion. The idea is that documents sharing the same contents or topics will be clustered together, which allows one to discover the topics present in the document collection.

However, clustering text data could well be less effective compared to traditional clustering of numerical data. Vectorizing textual data leads to a high dimensional but extremely sparse data space, making it difficult to differentiate in distances; in a high dimensional but sparse feature space, every pair of elements seems distant. On top of this curse of dimensionality, linguistic issues can also bias distance metrics. As described previously, the linguistic phenomena of synonymy, homonymy/polysemy, and hyponymy/hypernymy result in biased feature/term vectors; partial similarity in feature/term vectors does not necessarily imply partial similarity in the underlying text documents, and different feature/term vectors do not imply differences in content. As a result, distance measures directly derived from a vector space of text documents do not always capture the semantic structure of the underlying text documents; the same idea can be expressed in a variety of words, and identical words can have different meanings.

As cluster techniques rely on some sort of distance metric, it is by no means straightforward for cluster techniques to effectively deal with the semantic issues within text data and produce relevant clusters.

Probabilistic topic models such as LDA help to derive the semantic structure from a set of text documents. By definition, they directly reveal the latent topic structure of a document collection (LDA presumes text documents are derived from a finite set of topics and that any topic generates a set of words with a certain probability, so the result of LDA is a linkage between words and (latent) topics, on the one hand, and documents and (latent) topics, on the other). In this respect, it should be noted that each document can be linked to multiple topics.

We compared both methods in a small case study on structuring a data set that we had used previously (patents from biotechnology, agriculture, automotive, and materials).

38.5.1 Case Study 3. Comparative Study of Topic Detection: Clustering

In this study, we applied clustering on a set of patent documents from four different technological fields:

1. Biotechnology
2. Agriculture
3. Automotive
4. Materials (field selection based on IPC technology classification).

For every field, we randomly selected 10 000 patents (with no overlap, every patent document in the sample is only part of one of four fields).

To validate the stability/generalization of the models, we split the data set into two samples and ran all models twice, once on each half of the dataset. This resulted in two subsamples, each with 20 000 patents, evenly distributed over the four technological fields (5000 biotechnology, 5000 agriculture, 5000 automotive, and 5000 materials). This allowed us to compare results for different data sets.

Again, we began with the titles and abstracts, removed stop words (SMART stop-word list, Salton and Buckley) and applied stemming (Porter stemmer). On this occasion, we compiled a document-by-term matrix in two flavors: one based on the raw term frequencies and one based on TF-IDF weighting.

Figure 38.5 contains the word clouds for each of the four technological fields for the first subsample (after stemming). The words displayed in the word clouds clearly reflect the four technological fields and are quite distinctive in each case. For example, *cell*, *protein*, *sequence*, *peptide*, *DNA*, *acid* for biotechnology; *plant*, *seed*, *flower*, *fish* for agriculture; *vehicle*, *control*, *wheel*, *brake* for automotive; and *layer*, *surface*, *semiconductor*, and *substrat* for materials.

Method

As the method is intended for use on large data sets with millions of patents, we chose k-means as one of the most used non-hierarchical cluster methods. As the Euclidean distance is not appropriate in the case of high-dimensional data, we used spherical k-means clustering. We clustered term vectors derived from patent titles and abstracts and assessed the relevance of the obtained clusters in a quantitative way. As we know, the samples contain patents from four technological fields and we set the number of clusters to four. The genetic algorithm was used for hard clustering, with 50 runs. The clustering was performed twice for each subsample, once for the document-by-term matrix based on TF values (term frequency) and once for the document-by-term matrix based on TF-IDF values.

Validation

The key issue with unsupervised techniques is the validation of the clusters/topics obtained, i. e., whether obtained clusters/topics are relevant. We wish to escape reliance on internal cluster evaluation methods (e. g., homogeneity, silhouette), since they may not be very meaningful in the case of text data (if clustering cannot grasp the semantics of underlying patent data, intrinsic evaluation measures are irrelevant), and since these intrinsic evaluation measures sometimes use the same criteria adopted by the cluster method to allocate objects. Intrinsic cluster evaluation methods can shed light on the density or homogeneity of clusters but not on the relevance of clusters. We anticipate the same problems with internal LDA evaluation methods (log-likelihood, perplexity).

External validation is needed to assess the relevance of the clusters/topics obtained. However, a manual, expert-driven assessment is very time consuming, given the magnitude of the data. Moreover, as multiple

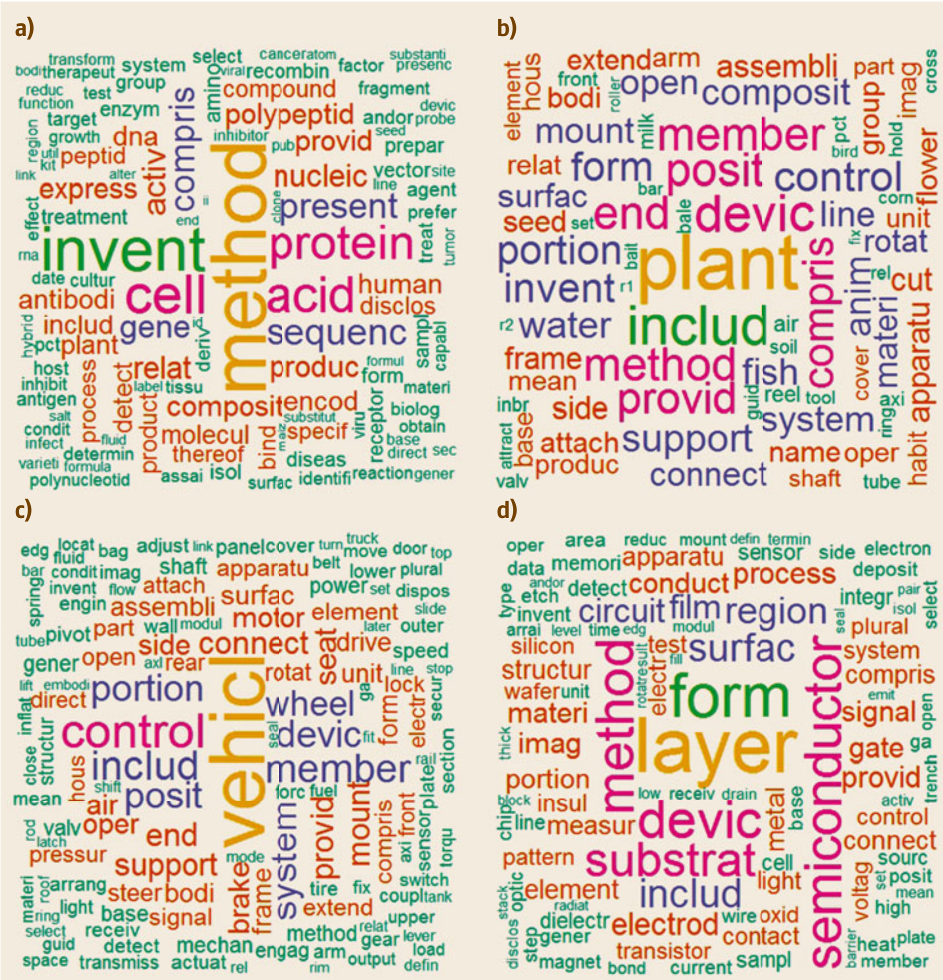

Fig. 38.5a–d Word clouds of the four technological fields for the first subsample: **(a)** biotechnology; **(b)** agriculture; **(c)** automotive; **(d)** materials

parameters/models need to be evaluated, multiple cluster/topic solutions need to be validated. This requires an automated approach in order to quickly asses multiple models.

In our validation setup, we made use of the known (a priori) technology fields of the patents in our data set (biotechnology, agriculture, automotive, and materials). As every patent in our data set is part of one of the four technology fields used to make the patent selection, a cluster solution or topic solution should coincide with the original patent technology classification. By comparing the known patent technology class with the cluster/topic allocation generated, the relevance of the allocations generated can be validated.

Results

Table 38.7 contains the contingency tables for the four cluster solutions. The left-hand side contains the solutions based on TF values, the right-hand side those based on TF-IDF values; the top contains the solutions for the first subsample, the bottom for the second subsample. Each contingency table contains the number of patents per cluster, for each technological field. For example, in the first sample based on TF values, 191 of the 5000 biotechnology patents were classified in cluster 1, 4431 in cluster 2, 28 in cluster 3, and 150 in cluster 4.

The contingency tables show that all four cluster solutions accurately identify biotechnology patents and that, at least, TF-based clustering clearly identifies automotive patents, while agriculture and materials patents are scattered over multiple clusters. However, in a pure unsupervised setup without a priori knowledge of the real patent characteristics, we can only rely on the cluster information. With regard to the technology classification, all cluster solutions reveal rather heterogeneous clusters; for every cluster, patents are scattered all over the technological fields, with the sole exception of materials. Each cluster solution seems capable of generating

a rather homogeneous cluster for materials, i. e., a cluster with high precision (but, yet, low recall).

Differences between clustering based on term vectors with TF values and clustering based on term vectors with TF-IDF values are not pronounced in this respect. TF values yield two clusters that combine biotechnology and agriculture, one materials cluster, and one leftover cluster. TF-IDF values yield only one biotechnology/agriculture cluster and one cluster that combines agriculture and automotive (and, again, one materials cluster and one leftover cluster). It is striking that using TF-IDF values yields more balanced clusters, i. e., the total number of patents per cluster is more evenly distributed.

Results are remarkably consistent over the two subsamples; both subsamples reveal the same pattern (note that it is not the exact cluster label that is relevant but the distribution over the cluster; in the case of the TF-based solution, cluster 1 and cluster 4 contain the same kind of documents in the two subsamples, while clusters 2 and 3 are switched).

In general, the cluster solutions are not in line with the technology classification. That so many documents from different technological fields are clustered together means other relations have been found. The question is whether these relations are relevant, or whether they are artefacts due to linguistic issues. There are clearly interesting indications that clustering can reveal new insights; equally, it would be unwise to ignore those indications that suggest clustering is inappropriate for (patent) text documents.

However, although cluster solutions are not in line with the technology classification at a first glance, cluster results are clearly not random; all cluster solutions produce one cluster where a very heavy emphasis on biotechnology is combined with a heavy emphasis on agriculture, which makes sense, since agriculture and biotechnology do have some relationship, and one cluster with a mixture of agriculture and automotive, which is a less obvious link. Indeed, they all produce one cluster with a sole emphasis on materials, and finally one leftover cluster. However, although these patterns may make sense, it is not possible to derive a relevant interpretation when no a priori knowledge is available. Indeed, without the known technological classification, it would be impossible to establish which cluster is homogeneous, which cluster links two fields, and which cluster contains leftovers to be reclassified.

38.5.2 Case Study 4. Comparative Study of Topic Detection: Probabilistic Topic Modeling

In this study, we applied probabilistic topic modeling on the exact same set of patents documents of the four above-mentioned technological fields (biotechnology, agriculture, automotive, and materials) to assess probabilistic topic model performance by comparing resulting clusters and topics. Data pre-processing was the same, so the exact same document-by-term matrix was used.

Method

LDA was used to derive topics from the two subsamples independently. Again, we set the number of topics to four and used two methods to estimate probabilities: Gibbs sampling [38.63] and variational expectation maximization (VEM) [38.57], each with five runs. For the Gibbs sampling, we took 1000 burn-in iterations and again 1000 iterations. As LDA requires integer counts, we only used the document-by-term matrix with raw term frequencies.

Results

Table 38.8 contains the contingency tables for the four LDA solutions. The left-hand side contains the solutions based on Gibbs sampling, the right-hand side those based on VEM; the top contains the solutions for the first subsample, the bottom for the second subsample. Each contingency table contains the number of patents per topic, for each technological field. To illustrate this, in the first sample based on Gibbs sampling, 61 of the 5000 biotechnology patents were linked to topic 1, 4575 to topic 2, 247 to topic 3, and 117 to topic 4. It should be borne in mind, however, that, with topic models, documents are linked to multiple topics with different degrees of probability. To construct the contingency tables, we retained only the most likely topic for every document (we will return to this later).

As for the cluster solutions, the contingency tables again reveal that all four LDA solutions clearly identify biotechnology patents, while the other technological classes are scattered over multiple topics (except for the VEM solution in subsample 2, where *materials* is clearly identified instead of *biotechnology*). Again, if we rely only on the topic information, the topics revealed are not consistent with the technology fields. However, once again the same patterns evident in the cluster solutions are disclosed: one topic with a combination of biotechnology and agriculture, one topic with a combination of agriculture and automotive, one topic with materials, and one leftover topic (although, again, the VEM solution on subsample 2 is deviant).

Differences between LDA solutions based on Gibbs sampling or on VEM are more pronounced. In the first subsample, the results for the *biotechnology–agriculture* topic and the *agriculture–automotive* cluster are similar, while characteristics of the *materials only* and the *leftover* topic differ. In the second subsample, patterns differ with a less pronounced link between biotechnology and agriculture. Again, we see a remarkable consistency between the two subsamples with the LDA solutions using Gibbs sampling but not with VEM. It seems that the estimation method does matter, and it would appear that Gibbs sampling yields more stable results than VEM (although we would need further sampling to confirm this).

For our practical purposes—unsupervised extraction of topics—LDA does not seem to do a significantly

better job than clustering; in general, patterns revealed by the topic models are in line with the patterns revealed by the cluster solutions. The fact that topic patterns deviate from the technology classification does not mean that results are irrelevant; the topic distribution obtained can make sense, but it is not possible to make a relevant interpretation when no a priori knowledge is available (which topic is homogeneous, which topic links two fields, and which topic contains leftovers to be reclassified). In a normal unsupervised setup, additional analysis of underlying words and documents is needed to assess relevance.

Figure 38.6 contains the top 20 words for each of the 4 topics in the first subsample based on Gibbs sampling (words with the highest probability of being linked to the topic).

Figure 38.6 confirms that almost all words in topic 3 can be linked to materials, words of topic 4 can be linked to automotive and materials, and words in topic 2 can be linked to biotechnology and agriculture. In topic 1, word links are less pronounced. It seems topic 1 combines agriculture and automotive, because those words can appear in both contexts, while topic 2 combines biotechnology and agriculture, because there is some intersection. In the case of topic 4, it is less clear why material patents are included but are not part of cluster 3. This quick analysis seems to suggest that LDA is able to detect relevant links (the interplay between biotechnology and agriculture) but is not always able to disentangle the context of words (the combination of *agriculture* and *automotive* and, to a lesser extent, *materials* and *automotive*). A more detailed

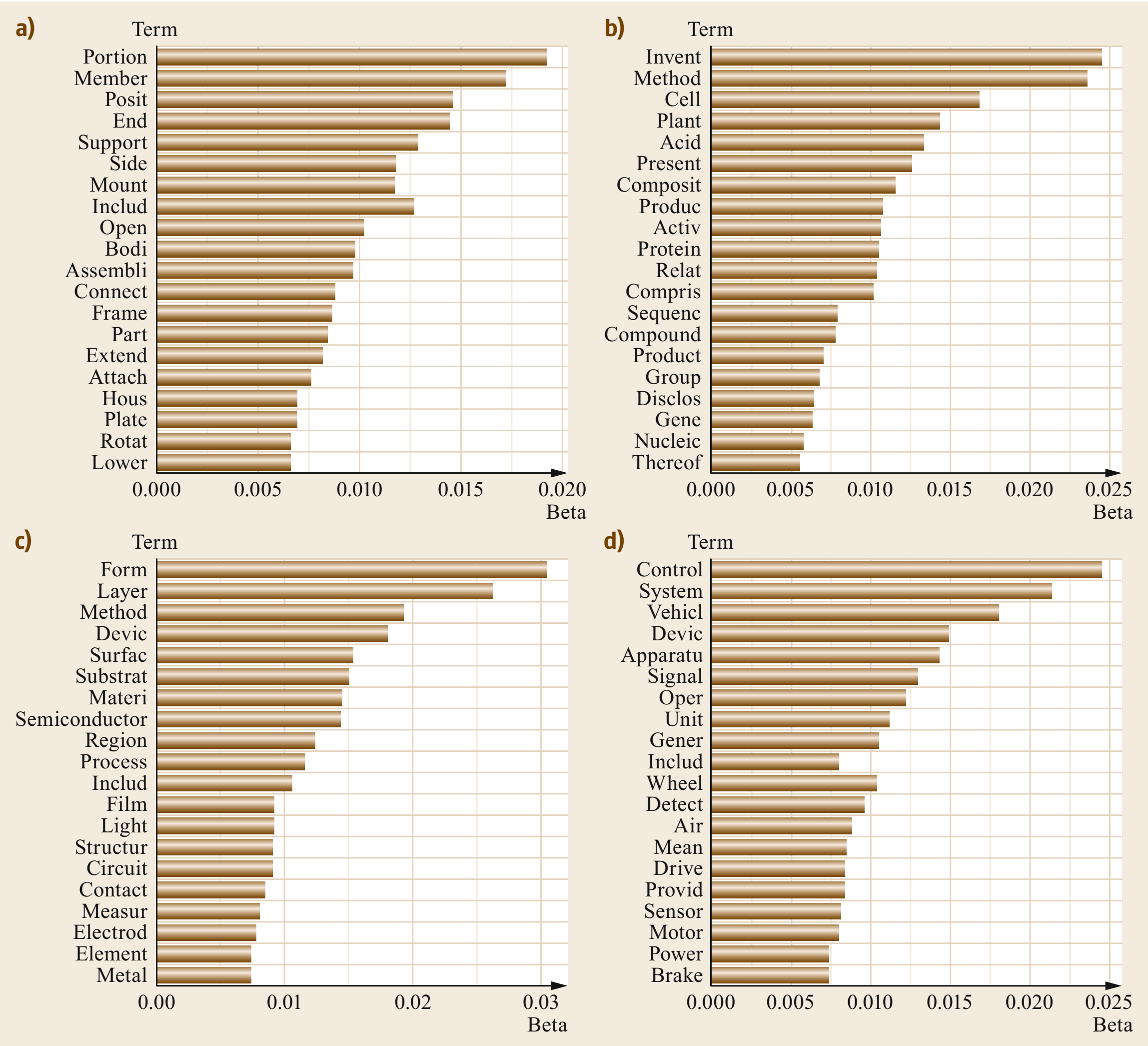

Fig. 38.6a–d Top 20 words for every topic (subsample 1, based on Gibbs sampling). **(a)** Topic 1; **(b)** Topic 2; **(c)** Topic 3; **(d)** Topic 4

analysis of the underlying documents is needed to confirm this.

38.5.3 More Clusters/Topics

More fine-grained clusters/topics might be needed to disentangle technologies; if biotechnology and agriculture are closely related, and agriculture and automotive are somewhat related, a four-topic solution might be inappropriate in revealing our technological patterns. Since more clusters/topics might be needed to reveal subtopics, we designed cluster and topic models with more clusters/topics (e. g., 10, 25). This only partially solved the heterogeneity in found clusters/topics. Some cluster/topics are clearly more homogeneous, but yet a large number of patents are still attributed to heterogeneous clusters/topics.

38.5.4 Retention of Only Single-Topic Documents

Topic models assign all documents to all topics with a given probability. All contingency tables listed previously are based on the primary or main topic of each document, i. e., the topic with the highest probability. The fact that documents are linked to multiple topics can explain the difficulties in finding a good fit between the topic solutions based on the primary topics and the technological classification. To isolate the effect of documents linked to multiple topics, or topics only linked with a very low probability, we analyzed the influence of document selection based on the probability of the topic allocation. We compiled multiple contingency tables where only documents with increasing certainty or reliability of topic allocation are retained, i. e., in compiling the contingency table, we retained only documents with increasing levels of probability of allocation to the topic with the highest probability, combined with increasing levels of the difference in probability between the topic with the highest probability and the next topic. For example, a document with the highest likelihood of being linked to a topic with a probability of 70%, and 8% probability for the second most likely topic, is regarded as a reliable or certain allocation. On the other hand, a document with the highest likelihood of being linked to a topic with a probability of 50%, and then 45% for the second most likely topic, is not regarded as a reliable or certain allocation for that first topic.

Table 38.9 contains an overview of every topic allocation for the first ten documents. Document 1 is an example of a certain or reliable allocation to the primary/main topic: The most likely topic is topic 2 (column T1), with a probability of 0.58 (column P1), while the next likely topic is topic 3 (column T2), with a probability of 0.15 (column P2). Document 3 is an example of an uncertain or unreliable allocation to the primary/main topic: The most likely topic is topic 3, with a probability of 0.33, while the next likely topic is topic 2, with a probability of 0.32. Both topic 2 and topic 3 can, therefore, be regarded as the primary/main topics for this document.

We compiled contingency tables for different degrees of certainty based on the absolute values of the probability of the most likely topic (column P1) and the difference between the probability of the most likely topic and the next likely topic (column D12), but each contingency table resulted in topic allocations that are very close to the one that took all primary topics into account.

38.5.5 Mixed Approach: Cluster Topics

Another approach is to mix both methods. First, derive topics from the documents and then cluster on the retrieved topics instead of the original (weighted) term frequencies. We experimented with a topic model containing 100 topics, followed by clustering with four clusters but, once more, we found results that were remarkably close to the topic model solution incorporating four topics.

Table 38.9 Overview. Every topic allocation for first ten documents

Doc	Topic	Tech	T1	T2	T3	T4	P1	P2	P3	P4	D12	D23

38.5.6 Conclusions on Clustering and Probabilistic Topic Modeling

In this study, we have sought to investigate the potential of two unsupervised techniques—clustering (spherical *k*-means clustering) and probabilistic topic modeling (LDA)—in order to reveal relations in a large patent collection without a priori knowledge. We did so by using a sample compiled of documents from four different technological fields and by conducting a quantitative analysis on the resemblance between the cluster and topic structure, on the one hand, and the technological fields, on the other.

The results obtained are remarkably stable amongst runs, parameters, and subsamples. All models yield the same pattern in both subsamples, except for LDA models based on VEM. Furthermore, the number of topics retained, the number of iterations for the Gibbs sampling, the distribution of term occurrence over the documents (only retaining terms with distinctive power), and the certainty of allocation of a document to a given topic (topic models assign documents to all topics with a given probability) do not seem to influence results (although further sampling is needed to obtain confirmation).

We do not observe a clear difference between cluster solutions and LDA solutions in retrieving homogeneous and relevant clusters/topics; both methods yield remarkably similar patterns. However, none of the methods clearly reveals the technological fields in the data sample, although both methods reveal patterns that are clearly not random.

It is not because the solutions obtained fail to match the technological fields within the data sample that obtained cluster or topic results lack relevance. The fact that all models yield more or less the same pattern might well indicate that relevant relations beyond the predetermined technological fields are revealed, although it is also conceivable that both methods suffer from the same linguistic issues. A more qualitative study of the data is required to further assess the relevance of obtained clusters/results: Are the documents in the homogeneous materials cluster and the homogeneous materials topic the same? Are the documents within the mixed agriculture/biotechnology cluster and the mixed agriculture/automotive topic assigned to the same agriculture and biotechnology subcluster and subtopic? Can we find a link between the agriculture and biotechnology patents combined in the same cluster/topic when we manually inspect those patent documents? And, equally so, for the less obvious link between *agriculture* and *automotive*? A quick analysis based on the top linked words reveals that biotechnology and agriculture patents are combined because there is a degree of overlap between the two fields, while agriculture and automotive are combined because the same words occur in different contexts.

Unless this more qualitative study is conducted, it is not possible to say whether one method is clearly better than the other, and whether deviations from the technological classification are due to unknown but relevant relations or stem from linguistic issues. The quick analysis based on top linked words suggests that both phenomena occur. For one topic, an interplay between biotechnology and agriculture is discovered while, for another topic, the link between agriculture and automotive seems to be an artefact. Hence, LDA would seem incapable of disentangling all word contexts.

The patterns revealed of both techniques are so similar that we are currently inclined to argue that LDA is not superior in dealing with the linguistic issues that might hamper traditional clustering of document term vectors. For very large data collections, clustering might be considered superior to topic modeling because of the higher computational efficiency of clustering versus topic modeling. On the other hand, topic models could still be relevant, because this technique explicitly assigns documents to multiple topics, which has the appearance of a more natural model for a text document collection. Yet, again, spherical *k*-means also permits fuzzy clustering with documents assigned to multiple clusters. In that respect, it is worth investigating whether topic models or fuzzy clustering can be instrumental in deriving more appropriate distance measures (deriving the similarity of documents based on the similarity in (fuzzy) cluster or topic allocation instead of directly based on the document term vectors).

38.6 Conclusions, Discussion, Limitations, and Directions for Further Research

In this chapter, we outlined the building blocks required to engage in text mining in order to assess the similarity of documents and to structure large text document collections: parsing text documents into terms, pre-processing those terms (stop-word removal, stemming/lemmatization, weighting), compiling a document by term matrix, calculating similarities and, finally, structuring documents into clusters or topics.

All these steps involve a number of choices and, hence, yield a multitude of outcomes. When applying text mining techniques to documents typically used in the STI domain (most notably patents and publications), our findings reveal that these choices have non-trivial consequences. The cases discussed reveal a significant impact on the similarities obtained; the same pair of documents can be classified as either related or unrelated depending on the choices made. Even well-established choices (stemming, TF-IDF weighting) do not always result in valid similarity indicators. Similar conclusions relate to SVD-based measures. LSA is one of the methods intended to derive meaning from the context of words, and it is advocated for its ability to yield better similarity metrics. Our validation studies reveal that the dimensionality reduction involved may result in inferior similarity metrics; the fewer dimensions that are retained, the more the similarity values obtained seem to be misleading (by overestimating the underlying similarity). Furthermore, the promise of probabilistic topic models—another method intended to deal with specific language issues—is not upheld by our observations; the patterns observed do not differ significantly from traditional (spherical) cluster approaches.

Combined, our observations strongly suggest that, in order to harvest the potential of text mining in the field of STI studies, we should refrain from merely adopting off-the-shelf text mining solutions. Investing in validation efforts will remain on the agenda for years to come, e. g., comparing viable approaches based on full text documents (patents/publications/company documents pertaining to new product development/innovation strategy, and so on). While this premise clearly implies additional efforts and resources, we remain convinced that such efforts will pay off. Validated approaches will inform us of a multitude of topics and issues in an unprecedented way. We hope that this chapter inspires colleagues to become involved in unlocking the potential of text mining in our field of research.

bart.vanlooy@kuleuven.be

Bart Van Looy is Professor Innovation and Organization at the Department of Managerial Economics, Strategy and Innovation (MSI), Faculty of Economics and Business, KU Leuven. He is co-promotor of ECOOM (responsible for activities pertaining to technometrics/patent analysis) and a member of INCENTiM, a research division of KU Leuven Research and Development. His current research focuses on innovation processes (firm level) and regional innovation systems (entrepreneurial universities and science–technology interactions).

Tom Magerman

Faculty of Economics and Business
KU Leuven
Leuven, Belgium
tom.magerman@kuleuven.be

Tom Magerman is Lecturer at University College Leuven-Limburg (Applied Informatics) and Affiliated Researcher at the Faculty of Economics and Business, KU Leuven. He has a background in informatics and obtained a PhD in Applied Economics; he is active in the application of text and data mining techniques in the field of innovation studies (patents, publications, and science-technology interactions). Current research topics include record linkage, approximate string matching, natural language processing (NLP), and performance tuning for big data applications.

39. Application of Text-Analytics in Quantitative Study of Science and Technology

Samira Ranaei, Arho Suominen, Alan Porter, Tuomo Kässi

The quantitative study of science, technology and innovation (ST&I) has experienced significant growth with advancements in disciplines such as mathematics, computer science and information sciences. From the early studies utilizing the statistics method, graph theory, to citations or co-authorship, the state of the art in quantitative methods leverages natural language processing and machine learning. However, there is no unified methodological approach within the research community or a comprehensive understanding of how to exploit text-mining potentials to address ST&I research objectives. Therefore, this chapter intends to present the state of the art of text mining within the framework of ST&I. The major contribution of the chapter is twofold; first, it provides a review of the literature on how text mining extended the quantitative methods applied in ST&I and highlights major methodological challenges. Second, it discusses two hands-on detailed case studies on how to implement the text analytics routine.

39.1 Background

The quantitative study of science, technology and innovation (ST&I) is an independent subdiscipline of science and technology studies (STS) [39.1], and a research area that has been seen notable growth since the 1980s. This subfield of STS utilizes social science approaches to examine the relationships between ST&I via quantitative methods. Within the context of STS, ST&I refers specifically to the production and utilization of codified technical and scientific knowledge [39.2]. A wide range of qualitative approaches are available for ST&I research, for instance, laboratory ethnography [39.3] which utilizes systematic observation of participants in science and technology settings—in other words, observing or interviewing scientists and engineers. Other qualitative methods use interviews with expert panels, which is the approach found in the Delphi method [39.4]. Although qualitative research results are rich in detail and quite rigorous, they are not scalable. Therefore, if automatic tracing of technological development and innovation activities on a worldwide scale or country/organization level is desired, quantitative methods would be far more useful.

Quantitative ST&I approaches have been established as an independent stream of literature through the introduction of various methods and indicators enabling empirical research using patents, scientific papers [39.5–9] and other quantifiable sources. Analyses of empirical data with quantitative techniques increasingly contribute to ST&I endeavors. Mining research and development (R&D) electronic data sources [39.10–12] can provide firms with technical intelligence capabilities.

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_39

There is a long history of research related to the quantitative analysis of science and technology. The development of approaches for measuring scientific output dates back to as early as 1926, when *Lotka* [39.13] examined the scientific productivity of chemistry and physics researchers. Later, in 1949, Zipf's law, with its insight into word frequency versus rank frequency in natural language, provided a statistical basis for quantitative textual analysis. In 1965, the work of *Derek de Solla Price* [39.5] laid a strong foundation for the quantitative study of science and technology (S&T) using citation patterns. The creation of the Science Citation Index (SCI) by Eugene Garfield in 1965 was a turning point in quantitative STS, and since that time, numerous bibliometric methods have been developed based on statistics related to the production and distribution of documents rather than the textual content of the documents themselves; such methods include, for example, bibliographic coupling [39.14], citation [39.6] and co-citation analyses [39.7]. Later, co-word analysis [39.15] enabled examination of technical phrases extracted from the abstract, title or keywords. More recently, the proliferation of data sources and increasingly complex analysis in S&T management have led to the application of data-mining methodologies to textual data [39.16–22]. The trend in quantitative ST&I research of using increasingly complex methodologies is evidenced by the emergence of concepts such as *tech mining* [39.16], which applies text mining to the natural language of research documents with the aim of extracting valuable intelligence.

Despite the considerable attention given to quantitative methods in ST&I and the clear research advantages brought by text mining, there is thus far no consensus on a particular quantitative method, R&D or innovation indicator within the research community [39.1]. The quantitative study of ST&I has become distanced from the mainstream of qualitative ST&I and has become aggregated with fields like information science (informatics) [39.1]. Yet, there is a lack of comprehensive knowledge on how to fully exploit the potential of text mining to satisfy ST&I research objectives. Therefore, a major goal of this chapter is to present a state-of-the-art text-mining framework for application with ST&I research.

Narrowing our focus to the application of various text-mining techniques to ST&I data sources, the contribution of this chapter will be twofold: First, a systematic literature review covering text analytics techniques utilized in research articles in the ST&I research area is presented. The main objectives are to identify the types of text-mining methods that have been used to address ST&I research questions and to highlight the current challenges from a methodological perspective. Second, two hands-on case studies with detailed descriptions of the methodological process are presented to illustrate:

1. How to apply text mining to enhance a conventional patent search by capturing contextual information rather than using a Boolean search and identifying and discarding irrelevant documents
2. How to cluster scientific publications based on their content similarity and define the underlying topics.

For the purposes of hands-on application, the two case studies are complemented with Python programming codes to enable adoption of the methods by researchers and practitioners.

39.2 Literature Review on the Application of Text Mining

For literature review, the data collection process was started by formulating a search query on the Web of Science (WoS) database based on a list of terms including text mining, text analytics, document clustering or classification, machine learning and tech mining. The keywords were selected by the manual screening of recently published papers in terms of *authors' keywords* and *keyword plus* assigned by WoS. VantagePoint software was used in an iterative process for keyword consolidation. The first result list contained the WoS categories of computer science and linguistics as dominant clusters. Since this paper focuses on the application of text mining in ST&I, the search query was limited to articles classified under the WoS categories that gained the largest citations from ST&I methodological papers. A previously published literature review by *Martin* et al. [39.1] has identified highly cited research fields by papers in the quantitative study of science and technology [39.1, p. 1188]. The WoS categories selected for this study are similar to *Martin* et al. [39.1] as follows: *Business, management, economics, multidisciplinary science, social science interdisciplinary, operation research management science, and information science and library science, computer science multidisciplinary application and planning development*. To ensure the relevancy of the selected WoS category and articles, the analytics option of the WoS database was used to repeatedly screen top journals while selecting and excluding WoS categories. The titles and abstracts of the resulting 590 records were then manually screened to evaluate the relevancy of articles that employed text-mining techniques to address ST&I research questions.

As a result of the screening, a fine-grain sample of 154 papers from 18 journals was selected for the literature review process. The top three journals, namely, *Expert Systems with Applications*, *Technological Forecasting and Social Change* and *Scientometrics*, accounted for more than half of the 154 papers reviewed (Table 39.1). The annual distribution of the selected journal articles (Fig. 39.1) shows a steady growth of papers using text mining-based methods under the ST&I research theme. The year 2006 was selected as a starting point, because the predecessor to this Springer Handbook, titled [39.23]: *Handbook of Quantitative Science and Technology Research: The Use of Publication and Patent Statistics in Studies of S&T Systems* was published in 2005.

To examine field-specific topics, keyword co-occurrences based on Pearson correlation between the author-assigned keywords were analyzed in VantagePoint software. Figure 39.2 shows two distinct clusters. Keywords on the left represent text-mining and machine learning methods and concepts, while the cluster on the right describes ST&I subfields and scientometric tools. The relationship between the clusters shed light on ST&I research areas that take advantage of text-mining techniques. For instance, patent mapping has a strong correlation with the subject-action-object text-based method (Fig. 39.2), which indicates that many authors carried out patent mapping using a text analytics approach. To examine correlations in more detail, the 154 papers were reviewed based on the concepts presented in Fig. 39.3. The papers were examined and annotated in terms of three criteria: their major practical or theoretical contributions to ST&I, the data sources used to support the research objectives, and the principles of the text mining-based methodology utilized:

- *Contribution to ST&I*: This criterion divided the papers in terms of their contribution to consideration of ST&I research objectives or development of research tools in operationalization of the research targets. As can be seen in Fig. 39.3, many research tools have benefited from the application of text-mining methods. The arrow suggests these developed research tools can be used to fulfill research objectives in multiple subfields of ST&I; for instance, patent mapping in operationalization of technology forecasting activities, technology transfer and detection of technological opportunities. Science mapping and quantitative measurement of multidisciplinarity have been utilized in research evaluation projects. The literature-based discovery method and measurement of S&T interaction have been employed in research papers utilizing technological opportunities analysis (TOA).
- *Data sources*: The increasing availability of electronic documents, the enormous amount of information stored in ST&I data sources and rapid growth of social web documents have opened up new oppor-

Table 39.1 Top six journals

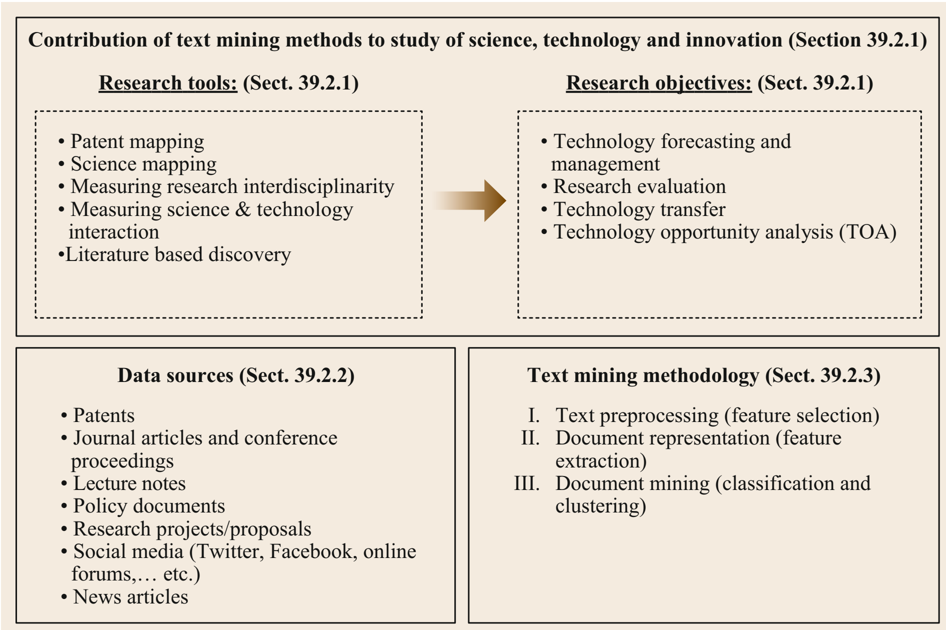

Fig. 39.3 Conceptual components of the literature review

tunities for social scientists to analyze and use these data in their research projects. Sect. 39.2.2 discusses the data sources used by the reviewed papers.

- *Methodological approach*: While the main role of ST&I data sources is data storage and responding to users' search queries, a substantial stream of research is directed largely toward the development of methodologies to extract data, and to process and reveal useful information. Text mining has been applied in ST&I research as a complementary tool to bibliometric approaches. *Leopold* et al. [39.24] presents an overview of text mining and its relation with natural language processing and machine learning, and how the techniques work together to tackle research problems in science and technology studies. As a continuation to [39.24], Sect. 39.2.3 evaluates ST&I papers from the perspective of text-based methodologies employed during the last decade.

39.2.1 Contribution of Text Mining Methods to Study of Science, Technology and Innovation

Research Objectives

The final labeling of 154 papers resulted in 112 documents directly contributing to the enhancement of research tools or fulfilling the ST&I research objectives. The contribution of the remaining 44 records can be summarized as purely methodological; proposing a new text analytics method or the improvement to existing approaches, which is tested on ST&I-related data sources (e. g., news articles, social media, scientific publications).

A number of research subfields were identified in the selected papers. The largest subfield is related to technological forecasting (TF) and management (Fig. 39.3), and approximately one-third of the collected papers examined subjects in this area. In the past, forecasting of technological development relied on qualitative methodologies (e. g., expert opinion and the Delphi method), and text mining-based methods provided data-driven evidence to back up forecasting practices in ST&I. According to *Porter* et al. [39.25], technology forecasting is a broad concept that intersects with several research activities: technology monitoring [39.26], technology assessment [39.27–29], technology road mapping [39.30–33], foresight research [39.34, 35] and impact analysis [39.36].

Technology monitoring refers to the process of identification and evaluation of technological development trends that are critical to a firm's competitive position. Departing from the established citation-based analysis, *Lee* et al. [39.26] built a mathematical framework based on patent keywords that can overcome the limitations of conventional patent citation maps. The major drawback of citation-based methods for most technology forecasting purposes is that only citing-cited patents are considered and it usually takes some time for a patent document to receive a citation so that it would be included in the analysis. Thus, a clear limitation to using patent citation-based methods is that patents without citations are omitted.

In the context of technology assessment, *Britt* et al. [39.28] suggested that the overhead costs associated with technological readiness could be reduced by utilizing text-mining techniques to exploit the technology readiness reports [39.28] and to semantically cluster textual documents. Automatic interpretation of technology readiness documents can allow firms to keep abreast of rapid changes in the market. *Kostoff* et al. [39.27] classified scientific publications based on content similarity as part of a methodology used for country-level technology assessment. Similarly, *Alencar* et al. [39.29] assessed the nanotechnology development efforts of Japan, the USA and Europe based on textual content analysis of patent abstracts.

Technology road mapping (TRM) is a strategic product planning tool first introduced to the academic community in 1987 by the Motorola company [39.37]. The approach links strategic management goals to product development at the firm level. Conventional TRM methods emphasize qualitative and expert knowledge rather than utilizing quantitative information. However, a recent biometrics analysis and review of TRM research shows growing use of quantitative approaches in operationalization of TRM [39.38]. The application of text mining enables the exploitation of a large quantity of important information sources, from product manuals to patent documents, that might otherwise be left untapped [39.31, 33]. The extracted key information consists mainly of the most important keywords that frequently occur in the documents which serve as input for the examination of the relationships among the documents. *Yoon* and *Phaal* [39.32] identified a series of data-mining and text-mining techniques that can be specifically used in TRM to yield important information from raw textual data. *Lee* et al. [39.39] formulated a technology-driven road map by combining text-mining techniques with citation network analysis to extract information from patent data.

Foresight research is another core avenue of research focused on supporting decision-making processes related to ST&I policies and activities at the country level. Foresight is operationalized by mainly qualitative approaches, such as communication and discussion with stakeholders, systematic interviews and expert panels. The combination of conventional foresight research methods with quantitative methods has shown promising research output [39.34]. A case study was carried out by the Center for Management and Strategic Studies (CGEE) in Brazil [39.34] that made use of text-mining techniques in combination with expert opinion to analyze nanotechnology R&D activities. The data-driven output of their foresight practice assisted funding agencies in the decision-making process.

Research evaluation is the process of measuring the impact of academic publications in the scientific community, and research evaluation commonly uses bibliometric approaches. An increasing number of researchers have questioned the validity of raw citation counts as a proxy for research evaluation and journal and author ranking [39.40], which has led to consideration of alternative text-based approaches [39.41–46]. *Liu* et al. [39.41] enhanced the performance of scientific publication ranking by combining full text citation analysis with document content analysis. The analysis of the papers' textual information characterizes the citation relationships between the papers. As a result, the published papers could be ranked based on their scientific contribution to the associated topic, rather than the number of received citations. In comparison with traditional citation-based journal ranking approaches, the new journal ranking system favors new publications with significant contributions to the field from not well-known authors who have not yet received many citations.

The detection of core documents within a particular circle of the scholars is an important topic in research evaluation. The concept of core documents was introduced by *Henry Small* in 1973 using a classical co-citation method [39.7]; later, the detection of core documents was carried out based on bibliographic coupling by Glänzel and Czerwon in 1996. Recently, *Glänzel* and *Thijs* [39.42] extended the notion of core documents by merging bibliographic coupling with a lexicon similarity component. In the case of missing citation links, the new hybrid method [39.42] is able to connect documents with textual similarity and calculate term frequencies to label the citation-based clusters. Investigating research trends, *Sunikka* and *Bragge* [39.43] applied a research profiling approach [39.39] built upon text mining to distinguish two new niche research streams in marketing and management research.

When tracing research trends, the detection of leading scientists' names (eponyms) is as important as identifying their research output. *Cabanac* [39.44] performed a semi-automated text mining of 821 *Scientometrics* papers that led to the unveiling of numerous already known and emerging eponyms. Other work utilizing text mining for research evaluation purposes includes [39.45], where the impact of European Union (EU)-funded research in social sciences and humanities on EU policies was evaluated by analyzing the content of research papers and policy documents, and [39.46], where, based on the assumption that research quality is dependent on the educational system, institutions' research capability was assessed by analyzing the contextual relationship between lecture material and research output.

Technology transfer refers to the dissemination of technologies from the original producers to a group of firms or non-commercial actors (e. g., universities) that are seeking to exploit external knowledge and innovation. The underlying tasks in successful technology transfer include the detection and acquisition of high-value technologies and/or commercialization of a firm's technological output. In [39.47], a text-mining approach based on TRIZ (theory of inventive problem solving) theory that enables the automatic detection of a promising solution from patent texts was employed to address a technological problem related to floating wind turbines. The function-based patent analysis method proposed in [39.48] provided firms with knowledge about the potential applications of a particular technology in different industries. It was argued in [39.48] that there is a lack of consistency between industries in the use of terminology to describe different technologies with similar functionality. First, the terminologies used to express a functionality in patents were extracted. Second, the authors in [39.48] linked these terminologies to similar functions in different industries. This linkage process may lead to the detection of additional applications for a technology. Other work using text analytics to ascertain technological and business opportunities from patent documents include [39.49–52].

Research Tools

A number of scientometrics studies have designed research tools based on text analytics methods that fulfill multiple research objectives in ST&I (Fig. 39.3). As a subfield of TF activity, such tools attempt to detect emerging technologies (ET), make new scientific discoveries or identify hot subjects in social media and news. Classical tools for the detection of ETs are bibliometric analysis and citation-based approaches; this section focuses on methods utilizing text mining or combining text mining with other approaches.

The available established ST&I-related data sources are designed primarily for data storage and information retrieval and not for the purpose of scientometrics research. For instance, major ST&I data sources like patent and publication databases are designed to facilitate data storage and easy information retrieval through a classification systems and to be organized by patent examiners and librarians, respectively. It is thus a challenging task to link database classification schemes to specific products [39.53] or industries [39.54] to retrieve relevant information for the detection of ETs. Extraction of topics from the abundance of user-generated information available in social media or news streams requires advanced text-mining methods to be used. Therefore, numerous studies have explored alternative quantitative methods to circumvent the limitations of traditional approaches for data retrieval from ST&I data sources.

The science, technology and innovation policy (STIP) research group at the Georgia Institute of Technology devised a bibliometrics-based search strategy [39.55] using text-mining software (VantagePoint) to capture the emergence of nanotechnology research output. In addition to the formulation of a search query for the bibliometric analysis of nanotechnology, *Kostoff* et al. [39.56] identified institutions and countries with mutual interest in nanotechnology research by using similar terminologies extracted from the literature as a proxy to map them into the corresponding institution or country. Newly emerging science and technology (NEST) has been studied by a combination of bibliometric analysis and text mining in support of technology management and policy [39.57]. Literature-based discovery (LBD), whose foremost advocate is *Ronald Kostoff*, refers to a particular type of text mining that seeks to identify nontrivial information from a large body of documents, and the approach has been applied to a number of real-world case studies, for example, to discover resolutions for water purification and the treatment of human diseases [39.58–61].

Several studies [39.62, 63] argue that current text-mining methods for the detection of emerging research topics overlook the novelty of subjects by focusing only on frequency measures. *Tu* and *Seng* [39.62] proposed two indices based on publication time, journal volume and subject frequency to capture the novelty of the research topic, and *Tang* et al. [39.63] proposed a blended index by integrating a text similarity measure with word frequency at the sentence level for real-time novelty mining. To uncover latent research topics in the e-commerce field, *Cheng* et al. [39.64] utilized a chance discovery method grounded in artificial intelligence that evaluates data from the perspectives of term frequency and association links. Other work exploring research trends includes research by *Delen* and *Crossland* [39.65], who described a semi-automated text-mining method to detect research trends, and *Yang* et al. [39.66] proposed a link-bridged topic model (LBT) that combines linkage between documents defined by co-citation and a document's textual content.

Patent mapping is a patent analysis tool that has been used for many different purposes in technology management, and various text-mining methods have greatly facilitated its implementation. An extensive procedure for automating the whole patent mapping process by incorporating text-mining techniques for summary extraction, text segmentation, term association, document cluster generation and topic identification is described in [39.67, 68]. The manual implementation of these tasks requires an analyst with knowledge and expertise in the disciplines of information retrieval, natural language processing, technology domain knowledge, and business intelligence. According to [39.67], the creation and maintenance of a patent map on *carbon nanotube* technology from 100 patent documents takes five analysts more than a month. The proposed automated patent mapping tool [39.67] facilitates the detection of previously unknown and useful patterns from large patent text repositories. *Trappey* [39.69] studied patent summary extraction by combining ontology and the concept clustering approach to capture general knowledge and the core meaning of patents in a given domain. Other studies utilizing text-mining methods for the construction of patent maps, for instance *Lee* et al. and *Son* et al. [39.39, 70], have proposed a keyword-based patent map for discovering undeveloped or unexplored technological fields and significant rare keywords [39.71] from patent databases. A text mining-based patent map has been developed to support the merger and acquisition (M&A) decision process by evaluating firms from the technological perspective [39.72]. Keyword-based patent maps show the topology of the target technology, from which researchers can learn about core technological information. In patent maps, the relationship between core technologies within a technology domain is lacking. A recent patent map proposed by *Choi* [39.73] combined a keyword-based patent map with a community network approach that informs researchers about the interaction between essential technology elements, highlighted as important keywords, in corresponding technology fields.

Retrieval of relevant patent documents is an essential step prior to any mapping and patent analysis task. The dominant approach for finding similar patents or retrieving relevant patents for a technology domain is construction of complex search queries based on international patent classification (IPC) classes and/or keywords. However, such patent searches are challenging as regards linking IPC classes to an industry [39.54] or product-level analysis [39.74]. The IPC classification scheme has been designed to ease the process of storing documents by examiners and does not directly facilitate the retrieval process. Furthermore, patent classification schemes are somewhat subjective, as they are based on examiners' judgment [39.75], and IPC classes are often considered too broad or detailed to be applied directly to a specific area of technology or research interest. Recent studies have introduced semantic patent retrieval systems as a complement to keyword-based [39.76] methods or in combination with bibliometric coupling [39.77]. *Venugopalan* and *Rai* [39.78] applied a machine-learning algorithm to classify patents into relevant/irrelevant groups based on extracted linguistics features.

Science mapping represents a family of tools that have been widely applied by the scientometrics community for research evaluation, measuring research interdisciplinarity and visualizing knowledge structure. Several studies have attempted to use text analytics to execute subject-based journal classification schemes [39.79, 80], build keyword-based knowledge maps that illustrate key information from a research proposal repository [39.81], and compensate the absence of semantic linkages in existing word co-occurrence-based knowledge maps [39.82]. Mapping of scientific disciplines facilitates the identification of boundaries and measurement of interdisciplinarity. Interdisciplinary research (IDR) is a mode of research that integrates concepts, theories and techniques from different disciplines [39.83]. IDR has a crucial role in pushing scientific boundaries forward, as it seeks to solve research problems whose solutions lie beyond a single body of knowledge [39.84]. Topic mapping and text analytics of research proposals have provided useful new information about IDR [39.85].

The debate regarding the interaction between science and technology (S&T) has a long history in scientometrics, dating back to 1963, when Toynbee compared S&T to dance partners [39.86]. The S&T relationship dynamic is central to policy-oriented research and innovation studies [39.87]. S&T interaction has also been measured by a set of diverse bibliometric indicators pertaining to scientific and technological advancement (patents and publications) [39.88, 89]. The feasibility of applying text-based semantic analysis to illustrate the topical overlap between patents and publications has recently been examined [39.90]. A study by *Magerman* et al. [39.90] shows that using the latent semantic indexing technique is a valuable approach in detection of content similarity between patent–paper pairs, but may not yield an accurate outcome in small data sets. Another study led by *Magerman* [39.91] incorporates semantic text analysis with patents' forward citations to detect patent–paper pairs in the field of biotechnology. The results showed that scholars who are involved in both scientific publishing and technological patenting have a larger scientific impact than their peers whose activities are restricted to scientific publishing. A Taiwanese research group's exploration of biofuel patent papers using a text-based clustering approach led to the identification of potential scientific and technological applications for micro-algal biofuels [39.92].

39.2.2 Data Type

Over two-thirds of the papers in our sample utilized either patents or scientific publications as major data sources (approximately 107 records). The remaining records exploited other sources of knowledge to provide evidence for ST&I research. For instance, content analysis by the National Science Foundation (NSF) provided new information for measuring interdisciplinarity [39.85], novel technological solutions, and new ideas derived from descriptions of research projects awarded grants from the National Institute of Standards and Technology (NIST) in the United States [39.93] or the Ministry of Defense in Germany [39.36]. For capturing interest in an emerging research topic from outside the academic domain, data sources other than patents and scientific publications have been explored using text analytics.

Text sentiment analysis [39.94], a new frontier in text mining, involves the analysis of social media data. A topic discovery system presented by [39.95] aimed to reveal implicit knowledge present in news streams. *Ma* et al. [39.96] used machine-learning techniques to predict the future popularity of Twitter topics based on keywords with hashtags. *Lu* et al. [39.97] utilized text analytics to detect hot topics in online health communities that might provide knowledge about patients' needs and interests. The exploration of market changes via online news articles by applying text analytics [39.51] enables companies to identify business intelligence factors.

39.2.3 Text-Mining Approaches Used in the Reviewed Literature

The core functionality of the text-mining approach lies in the identification of concept co-occurrence patterns across document collections [39.98]. In practice, text mining utilizes algorithmic approaches to identify distributions, frequency sets and associations of concepts at an inter-document level to illustrate the structure and relationships of the concepts as reflected in the corpus [39.98]. The main goal of text mining is to derive implicit knowledge from textual information by applying an array of methods from statistics, natural language processing and machine learning. Text-mining algorithms require a mathematical representation of text documents; thus, a wide range of text extraction and transformation approaches are available for use. Almost all the reviewed articles followed all or at least part of the three major text preprocessing and modeling phases shown in Fig. 39.4.

Step A

The main objective in the first phase is extraction of valuable informative terms (features) from the text. The reviewed articles [39.42, 50, 62, 67, 99] applied various feature extraction approaches, which can be categorized as morphological analysis, syntactical analysis or semantic analysis. Morphological analysis was utilized as a text preprocessing routine by most of the papers. The first step in the process is tokenization, which reduces sentences to words (tokens) and removes punctuation. Next, stop-words such as `a`, `the` or `and` that carry no semantic meaning are eliminated. This is followed by stemming, a linguistic normalization technique in which a token is reduced to its root (stem) by removal of derivational suffixes. For instance, all variations of the verb `applying`, `applied`, `applies` are transformed to `appl`. In some cases, the final word's appearance might not be recognized by the user or the text analytics algorithm. As a remedy, one or more sophisticated morphological methods known as lemmatization can be used to convert the words of a sentence to their dictionary base.

Continuing with the above example, lemmatization would return `appl` to a common form of `applying`, `applied`, `applies`. N-gram is another common method that allows analysis to be conducted at single word (unigram) or phrase level, i. e., phrases that consists of two or three words (bigram, trigram, etc.). Syntactical analysis provides knowledge of the grammatical structure of the sentences. The meaning of a sentence is easier to interpret once the correct grammatical and semantic information has been defined. For instance, in part-of-speech (POS) tagging, a sentence

Text mining steps

A: Feature extraction	B: Feature selection	C: Document mining
• Morphological analysis • Syntactical analysis • Semantic analysis	• Vector space model (VSM) or Bag of worlds (BOW) • Sequence-based representation • Dimension reduction methods	• Clustering • Classification

Fig. 39.4 Methodological steps in text mining

is often annotated by its noun, verb, adjective, adverb, and so on. POS is used in [39.100] to make sense of a bilingual English-Chinese document collection as part of a proposed business intelligence system.

Semantic analysis incorporates lexicons and dictionaries to categorize words with similar meanings. Semantic lexicons are the backbone of sentiment analysis studies, which attempt to measure the emotion of information posted on social media in news articles [39.101], online forum discussions [39.102], customer reviews, tweets and Facebook statuses or comments [39.103]. *Li* and *Wu* [39.102] integrated text mining with sentiment analysis to evaluate the emotional polarity of an online sport forum using the HowNet (http://www.keenage.com) lexicon. Other studies have applied sentiment analysis to social media to capture information about social aspects of a topic, for example, for research objectives such as competitor analysis within an industry [39.103] and opinion mining [39.104].

Step B

Feature selection is the second phase in text processing, where the documents are represented based on a fixed informative subset of terms by the removal of redundant information. The vector space model (VSM) [39.105], which is grounded on the singular-value decomposition (SVD) method, is a document representation approach found in many of the articles reviewed [39.30, 39, 67, 77, 91, 106, 107]. The VSM represents documents as weighted high-dimensional vectors, where the dimensions pertain to individual features such as words or phrases. When only words are used, the model is called a bag of words (BoW). The weight assigned to vectors is often calculated by standard weighting schemes such as simple term frequency or term frequency inverse document frequency (TF-IDF). TF-IDF measures are widely used to show the high-frequency words across the collection or rare terms. For instance, a study by [39.71] was able to extract particularly rare terms for a patent document retrieval process by combining TF-IDF with a term association metric [39.45, 67–69, 91, 108]. Despite being a common word-ranking system in information retrieval, the TF-IDF function does not consider the length of documents. The text available in social media news, patent abstracts and full-text articles differs in terms of size. To achieve more robust representation, recent studies [39.109, 110] have applied the Best Match 25 (BM25) weighting scheme, which includes a document length normalization component.

The high dimensionality of VSM models poses challenges to examination of the subject of the document. Additionally, many features are weighted as a zero value, which means they do not appear in the term vectors. The existence of many vectors with zero values is known as a sparsity problem. The dominant dimensionality reduction approach is principal component analysis (PCA) (or singular-value decomposition), which transforms high-dimensional data to a low-rank estimation of sparse matrices. PCA captures vectors with larger variances, since the high-variance components contain more information. PCA was applied by *Zhang* et al. [39.99] for ST&I text analysis to consolidate topical content from patent/publication text. Other reviewed papers that have applied PCA either for dimension reduction purposes or for grouping of similar words include [39.39, 57, 68, 90, 97, 111–113].

Another common approach in feature selection is representing documents based on a term's syntactical order. The POS tagging process can be used to produce a sequence-based representation of the documents. Recently, the subject-action-object (SAO) structure, which is composed of subject (noun), action (verb), and object (noun), has attracted research attention [39.47, 48, 114]. The SAO method reflects the key concepts and structural relationships between a sentence's components. Using the SAO approach, valuable findings in patent abstracts could be uncovered by extracting the provided solution to the technological problem [39.47]. For example, *Choi* et al. [39.114] illustrated the relationship between product components, various technologies and their particular functions from patents related to the proton-exchange membrane (PEM) fuel cell. Other scholars have applied SAO to identify the potential applications of a particular technology [39.48].

Step C

In the last step, the text analytics and machine-learning approaches will be employed for semantically organizing documents extracted from ST&I databases. The challenge in data analysis at the document level falls into two main tasks: document classification and clustering. In the machine learning literature, the former task refers to the categorization of documents in a supervised manner based on a set of predefined patterns, which is called the training data set. The latter task is unsupervised classification or clustering of documents on the basis of their similarity without a priori knowledge from training data. Within our 154 sample articles, the proportion of papers that applied clustering algorithms is larger than those employing classification approaches. It may be assumed that clustering is more appealing due to the effort, time and cost associated with training a supervised algorithm.

The different supervised algorithms utilized by the reviewed articles are shown in Fig. 39.5 (for detailed mathematical background on the methods, please refer to [39.24]). Papers that used commercialized software

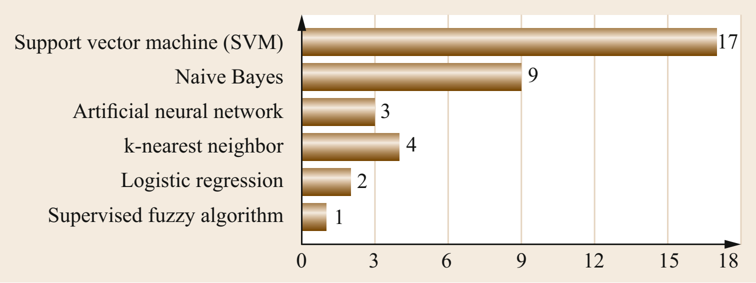

Fig. 39.5 Supervised classification algorithms utilized by reviewed papers

or feature selection methods or did not reveal the algorithm used have been excluded.

As can be seen in Fig. 39.5, the most frequently applied classifier is a relatively new learning approach, the support vector machine (SVM), introduced by Vapnik in 1995 to solve two-class pattern recognition problems. SVM also performs well on high-dimensional data, and has been employed, for instance, to detect patents relevant to solar photovoltaics technology [39.78] and to establish a cross-language patent retrieval system for Japanese-English patents [39.115]. The case study discussed in Sect. 39.3.1 employs the SVM classification algorithm to execute an automatic patent classification task.

The second commonly used method, probabilistic naive Bayes (NB), classifies documents based on an assumption that the terms (document features) are all equally important and are independent of each other. An NB algorithm has been applied to categorize tweets based on their sentiments (positive or negative discussion) [39.116] and for organization of news articles in the Portuguese language [39.35]. A bundle of methods like SVM, NB, *k*-nearest neighborhood (a distance-based algorithm) and logistic regression are applied in [39.96] at different stages of their methodology to predict and classify future popular topics on Twitter, which might be valuable information from marketing and economic perspectives.

The most common document clustering approach (Fig. 39.6) is classic PCA [39.99], which also represents the other reviewed articles that used its substance methods, such as factor analysis [39.56] and multidimensional scaling (MDS) [39.33]. In addition to document clustering, MDS can be used for dimension reduction purposes. However, PCA methods suffer from excessive information loss when pruning the data dimensions; moreover, they cannot account for correlated words within the given lexicon of the corpus. In other words, count-based methods that rely on merely the co-occurrence of words are not very accurate in document clustering tasks due to not being able to account for polysemy (words with multiple meaning) and synonymy (multiple words with similar meaning). As a possible remedy, latent semantic indexing (LSI) [39.79, 117], which includes the context (document) of the words, has been proposed. For instance, the two keywords `cell` and `electrode` are related to each other as a part of fuel cell technology, but may not co-occur many times. LSI as a context-based clustering method matches documents with context similarity, based on the probability of neighboring words in a particular document, rather than matching the keywords. The disadvantage of the LSI function is the absence of a solid probabilistic foundation.

The probabilistic latent semantic indexing (PLSI) method proposed by *Hofmann* [39.118] was a significant step forward in document clustering methods, as it provided a probabilistic structure at the word level as an alternative to LSI [39.66]. The PLSI model draws each word of a document from a mixture model

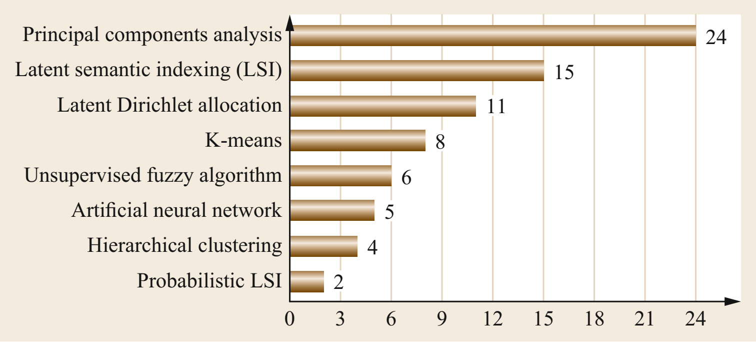

Fig. 39.6 Unsupervised clustering algorithms utilized by reviewed papers

specified via a multidimensional random variable. The mixture model represents the *topic*. Therefore, each word originates from a single topic, and different words of one document can be drawn from various topics. Even though PLSI is a valuable contribution to the text clustering field, it lacks a probabilistic model at the document level, because documents in PLSI are represented as a list of numbers, with no generative probabilistic model for the numbers. The limitations of PLSI at the document level cause problems such as over-fitting, as the number of parameters grows linearly with the size of the corpus.

The latent Dirichlet allocation (LDA) method [39.119] overcomes the limitations of PLSI and provides probabilistic models for both documents and words [39.85, 120]. LDA is a predictive model that draws latent topics from textual data. In LDA, documents are represented as a random mixture of latent topics and each topic is based on the distribution of the words. Another family of predictive models is the artificial neural network [39.121]. The remaining papers used the following clustering methods: *k*-means from partitioning methods [39.32], hierarchal clustering [39.81] and unsupervised fuzzy algorithms [39.27].

In general, all the above text mining-based techniques for document representation, clustering and classification are dependent in some way or another on distributional semantic models (DSMs). The term DSM dates back to the 1991 study by *Miller* and *Charles* [39.122], in which semantically similar words are placed near each other since they tend to have a similar contextual distribution. For example, vector space models (VSM) are count-based models [39.123] where semantically similar terms are embedded in a close neighbor in a vector.

Count-based methods compute the statistics of how often a word co-occurs with its neighbor words in a large text corpus, and then map these count-statistics down to a small, dense vector for each word. Recent studies [39.124, 125] show that predictive models can outperform count-based models in the natural language processing context, as they directly predict a word from its neighbor terms. Despite the shift toward predictive models, very few studies have applied them in the ST&I field to solve problems with science mapping [39.126] or clustering patent documents [39.78]. Motivated by this gap, the case study in Sect. 39.3.2 below considers the science mapping task using a predictive LDA model.

39.3 Case Studies

This section offers step-by-step guidance to utilizing text mining and machine learning, using Python packages, for automatic patent classification and clustering of scientific publications based on their content. The automatic patent classification example refers to a situation where a set of patent documents is available, for example, patents related to fuel cell electric vehicles (FCEV), and researchers wish to collect similar patents. The clustering of scientific publications example illustrates how research themes can be derived from a set of scientific publications on a broad subject. In this case, too, fuel cell technology, which is a multipurpose technology, is used as an example.

39.3.1 Case Study 1: Automatic Patent Document Classification

Using IPC codes to retrieve relevant patent documents has been shown to have limited value when studying electric vehicle (EV) technology [39.74]. *Pilkington* et al. [39.74] investigated the technological development of EVs using the patent class *B60L11*, which returned a significant number of irrelevant patents not necessarily related to electric automobiles. *Pilkington* [39.74] emphasizes that a clear boundary is required between generic patents related to electric device technologies and automotive-oriented patents. This may be achieved by using an archive of reliable keywords [39.127, 128]. However, a keyword-based Boolean search carries the risk of missing documents that lack the listed keywords. Another challenge is inconsistency among the terminologies used by patent applicants, inventors, researchers and attorneys. Phrases and terms become outdated at some point as new concepts, innovative materials and processes emerge. In addition, such database searches are based on the match of exact wording, which is merely a means of finding phrases without contextual meaning. Additionally, a lack of familiarity with the area of technology for which the patent data are being gathered can complicate construction of an exhaustive keyword list. For instance, a patent search query using `electric` and `vehicle` in an attempt to search for `electric vehicle`-related patented technology would produce patents related to any type of vehicle that uses an electric current [39.129]. The high number of irrelevant patents reduces the reliability of the search outcome.

For the purpose of this experiment, this case study was designed with the aim of using text mining to recognize patents relevant to the vehicle industry by capturing contextual information within the documents. The goal was to differentiate patents related to automotive engineering with a specific focus on fuel cell electric vehicles (FCEV) from irrelevant documents within a complex data set. The test set of 218 744 patent documents was gathered from the PATSTAT (EPO Worldwide Patent Statistical Database) database using the search terms `car`, `vehicle` and `automobile` for US-granted patent abstracts between the years 2005 and 2014. The patent search created a heterogeneous test set of technologies from automotive to medical applications.

The case study used the support vector machine (SVM) learning model to distinguish FCEV patents from non-FCEV patents. SVM is a powerful two-class pattern recognition classifier; in other words, it is able to answer yes or no questions, which makes it a suitable method for categorizing patents as relevant or irrelevant. Prior to the classification task, the SVM needs to be trained by a predefined labeled data set, called a training set. The training set formed in this study included 1374 records split into relevant (positive) and irrelevant (negative) groups. The positive group was collected based on a random selection of 700 patents related to fuel cell electric vehicles (FCEV) gathered using a cooperative patent classification (CPC) class (Y02T90/34). The CPC classification scheme is an extended version of IPC jointly developed by the European Patent Office (EPO) and the United States Patent and Trademark Office (USPTO). The main objective of CPC is to provide a harmonized classification system and improve patent searches through the provision of more detailed technology classes. It should be noted that at the time of this research, the Y02T class related to *Climate Change Mitigation Technologies* related to *Transportation* was not complete, which means that not all relevant FCEV patents could be retrieved relying merely on the CPC code. The FCEV patent abstract descriptions included information related to the electric motor, internal combustion engine (ICE), hybrid, plug-in and battery electric vehicle technologies. The negative group in the training set included inventions irrelevant to the vehicle industry, for example, patents in the areas of textiles, musical instruments and speech recognition.

Text Preprocessing

The abstract section of the training and test sets needs to be preprocessed before executing the SVM classification task. The Python code uses Pandas packages to import the patent abstract stored in a comma-separated values (CSV) file (Fig. 39.7). The built-in text processing uses functions from Scikit-learn (an open-source Python library that implements a range of machine learning, text processing and visualization tasks) and the Natural Language Toolkit (NLTK), which is the leading Python platform for human language analytics. Python libraries were used as the main platforms to conduct the text-mining steps. The full implementation of preprocessing and SVM classification was done in iPython. For the purpose of demonstration, the following snapshots illustrate the steps in detail. The first step is importing all required Python packages and the patent abstracts (Fig. 39.7).

The vector space model (VSM) was adopted for document representation using the feature extraction function from the Scikit-learn package (Fig. 39.8). The sentences from the document's abstract were transformed to lowercase and broken down into words. The reduction of sentences to keywords or phrases is called tokenization and is operationalized by the NLTK Python package. Phrases with combinations of two or three words (bigrams or trigrams) with the minimum frequency of *one* are included in the analysis.

The next preprocessing step is pruning words with very high values. Words that occur in more than half of the data collection have limited differentiating value in classification tasks. The cutoff value for removal of words was set as words occurring in more than 50% of the documents. Once the documents have been transformed into a compact representation of term vectors, the terms need to be weighted across the document collection to indicate their importance. The TFidfVectorizer Python function was used to assign weights to the term vectors.

```
#import csv, NLTK and scikit-learn packages
import sklearn, nltk
import as pandas as pd

#import patent abstracts from csv file using pandas package
train_data = pd.read_csv ("filename.csv")
train_labels= pd.read_csv ("filename.csv")
```

Fig. 39.7 Setting up the required Python packages and importing patent abstracts

```
#formulate the tokenization function and store tokens as a list
def tokenize(text):
tokens = nltk.word_tokenize(text)

#import TFidfVectorizer from scikitit-learn package
from sklearn.feature_extraction.text import TfidfVectorizer
#operationalise the vector space model and text-preprocessing
vectorizer = TfidfVectorizer(lowercase = True,
analyzer = 'word', preprocessor = None, tokenizer = tokenize,
ngram_range = (1, 2),  #consider bigrams and trigrams
min_df = 1,          #pruning word frequency threshold
max_df = 0.5,
stop_words = 'english', #enforce English stopword
use_idf = True)

#apply the VSM model to train-set and test-set
train_vectors = vectorizer.fit_transform(train_data)
test_vectors = vectorizer.transform(test_data)
```

Fig. 39.8 Implementation of SVM classification using the Scikit-learn Python program

SVM Implementation

Implementation of SVM classification comprises two steps (Fig. 39.9); the SVM classifier first needs to be trained based on the labels *relevant* and *irrelevant*, and then the trained algorithm is applied to predict relevant and irrelevant documents in the test set.

Results Evaluation

The classification task aimed to assign patent documents in the test set to the FCEV-relevant category. To evaluate the SVM performance, the test set was labeled based on the relevancy of the associated IPC code to FCEV technologies. The utilized IPC codes were retrieved based on the three major technology components of FCEV: *fuel cell technology* (H01M486, H01M496, H01M824, H01M1208), *brush-less* or *electric motor* (H02K19, H02K49) and *electric/battery-supplied vehicle* (B60L710, B60L722, B60L8, B60L9, H02J7). The labeling process of the test set resulted in 3447 documents out of 218 077 related to FCEV technology, and the remaining documents were annotated as other. This means that by using the list of relevant IPCs, only 3447 patents from the initial collection were recognized as patents relevant to FCEV.

Taking IPC classes as a baseline, true positive (TP) and true negative (TN) are relevant documents that the SVM predicted correctly and falsely, respectively. False positive (FP) and false negative (FN) are those patents defined by IPC as irrelevant to FCEV technology, where the latter is predicted to be relevant to FCEV technology. The SVM classification performed poorly (about 33%) calculated by the evaluation measures of precision (TP/TP + FP), recall (TP/TP + FN) and *F*-score (2TP/2TP + FP + FN) (Table 39.2).

The FN category comprises those patents that the SVM classifier predicted as being relevant to FCEV technology, but they were labeled as *other*. Qualitative screening of the FN category (4970 patent document titles and abstracts) indicated that about 3231 documents were relevant to FCEV technology components. During the qualitative screening, the labels of 3231 records in the FN category were updated and categorized under the *relevant* class.

The second round of evaluations is based on new FN values, and results are presented in Table 39.3. The implication is that IPC was not an ideal baseline for assessment of the SVM performance. The qualitative review of the documents showed that the SVM is

Table 39.2 SVM classification performance considering IPC as a baseline

Evaluation	Precision	Recall	*F*-score
Evaluation based on IPC as a baseline	0.483	0.251	0.33

```
#train SVM classifier with the vectorized train-set data
classifier_rbf = svm.SVC()
classifier_rbf.fit(train_vectors, train_labels)

#apply the trained SVM on the test-set collection to predit
prediction_rbf = classifier_rbf.predict(test_vectors)
print(classification_report(test_labels, prediction_rbf))
```

Fig. 39.9 Implementation of SVM classification algorithm

Table 39.3 SVM classification performance against qualitative labeling of the test set

Evaluation	Precision	Recall	F-score
Evaluation based on qualitative screening	0.733	0.737	0.735

capable of correctly predicting the right class for a substantial portion of the documents, with an F-measure of 0.735. It can be argued that the algorithm performance has been improved using qualitative labeling of the test set, while it still shows about 27% error.

This case study provided an automatic approach for a patent retrieval process. Utilization of the machine learning classifier can be considered as a complementary technique for a patent search task. The classifier can be useful for situations where researchers possess a set of patents and need to collect more patent documents with similar topics. It should be also noted that the precision of algorithm classification performance highly depends on the quality of the training set.

39.3.2 Case Study 2: Science Mapping

In the second case study, fuel cell publications are examined and research themes are identified using an unsupervised classifier. Fuel cells are seen as having great potential for use in non-combustion engine vehicles. Fuel cells were invented in 1838 [39.130], and a number of trials to develop a device for practical applications have been carried out. Expensive materials and the low conversion efficiency have discouraged the development of fuel cell technology and, for decades, fuel cells remained an uninteresting technological option. Only in the past 25 years have fuel cells taken leaps forward in maturity. The family of fuel cells offers a variety of solutions, ranging from large stationary applications to small milliwatt systems [39.131]. The most significant expectations had been expressed for portable, stationary and transportation solutions.

For this case study, data were downloaded from published English journals and conference articles from the ISI Web of Science using a search query for `fuel cell` or `fuel cells` in the title, abstract, descriptors or identifiers of a publication. The search query is not limited to any time window. This search resulted in a data set of 75 479 articles, from which the bibliographical data were downloaded. Figure 39.10 gives the count of publications from 1996 until 2016 and shows the growth of the publications has been significant. A clear increase in publications is apparent from the late 1990s. The data were searched in mid-2016; thus, data for 2016 are incomplete and cannot be used as a yearly total value.

This case study uses an LDA algorithm to cluster the publications. LDA, unlike supervised or reinforced models, creates an outcome relying solely on its for-

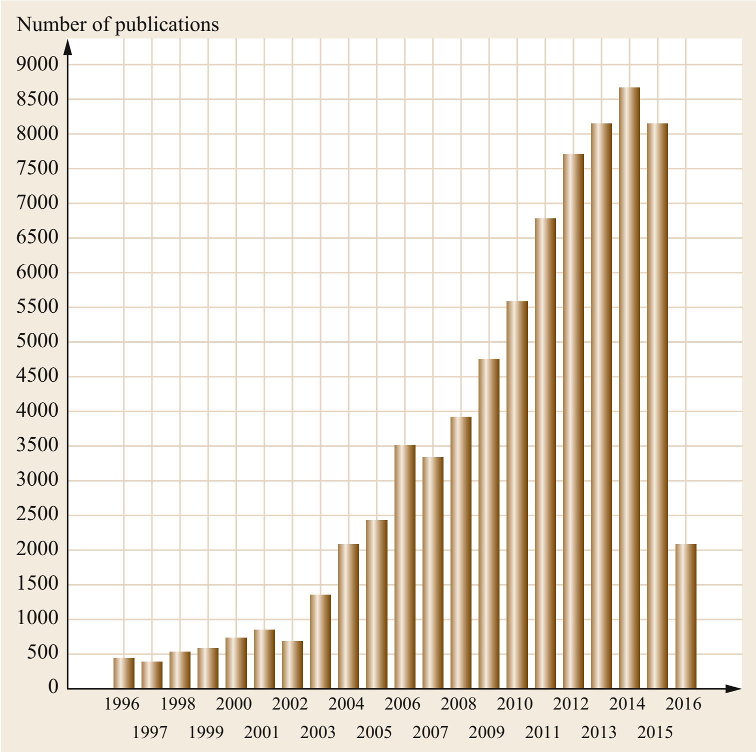

Fig. 39.10 Number of scientific publications related to fuel cell technology

mal framework. Several studies have investigated the applicability of LDA to uncover patterns from text collections drawn from different sources, for example, scientific publications [39.126, 132] and patents [39.111, 133, 134]. LDA is a soft classification algorithm, which means that the algorithm classifies inputs by giving a probability of the item belonging to each cluster. As researchers often strive for hard classifications, there is a need to reduce the dimensionality of the LDA results to one class. Approaches for this task can be simple, such as using the most probable class as the class an item is assigned to, or more elaborate, for example, dimension reduction using a modularity algorithm [39.135] or PCA. Simple hard classification selection of the most probable topic loses a significant portion of the LDA results, whereas the other approaches integrate the soft classification as a part of their results.

Analyzing scientometrics data with topic models, specifically LDA, has attracted significant research interest in recent years. *Yau* et al. [39.132] analyzed the effectiveness of different approaches for topic modeling, including LDA, and considered specifically the algorithms' precision and recall on a human-labeled document set. *Suominen* and *Toivanen* [39.126] used LDA as a method to create a science map. In the patent domain, *Venugopalan* and *Rai* [39.78] applied topic modeling to patent data looking at knowledge spillovers. In the photovoltaic context, the authors were able to reduce the dimensionality of the input data, highlighting an aggregation of the patents' knowledge content. *Lee* et al. [39.134] analyzed technological convergence using LDA to identify keywords from the document corpus. *Suominen* et al. [39.133] used patent data to structure the knowledge portfolio of telecommunication companies. Using full-text patent data, the study structured the technological portfolios of the selected companies and created a forecast of the technology pathways of the sample companies.

Text Preprocessing

In the preprocessing phase (Fig. 39.11), the Python package Pandas was used to import the flat file and to identify whether fields had varying data types.

```
#Import, read data and create variables
import pandas as pd
from nltk.stem import WordNetLemmatizer
wnl = WordNetLemmatizer()
df=pd.read_csv(filename, sep="\t", header=0, encoding="latin-1")

#Creating a list of abstracts, identifiers and publication years
abList = df['AB'].tolist(), utList = df['UT'].tolist()
pyList = df['PY'].tolist()
#Pre-processing-Creating a list to store pre-processed abstracts
abPrecessed=[] , idProcessed =[]
counter=0

#For loop to pre-process abstracts
for line in abList:
        #Here we exclude absracts shorter than 100 characters
        #Remove item from utList and pyList if abstract removed
        if len(line)<100:
                continue
        else:
                #Removing stopwords given in a user created
                data= ' '.join([word for word in line.split()
                        if word not in stopwords])
                #terms containing a number removed
                data = ' '.join(s for s in data.split()
                        if not any(c.isdigit() for c in s))
                #lemmatization
                data = " ".join([wnl.lemmatize(i)
                        for i in data.split(" ")])

                abProcessed.append(data)
                idProcessed.append(utList[counter])
                pyProcessed.append(pyList[counter])
        counter += 1
```

Fig. 39.11 Preprocessing for LDA analysis

The WordNet lemmatizer was imported from the NLTK package for word consolidation. For stop-words, the code relies on a user-provided list. Although a stop-word implementation could be provided through NLTK, there is some case specificity regarding what should be removed from the input data. In addition, as the objective is to use the LDA with science abstracts, research has shown that excessive word removal prior to analysis can diminish the quality of the results [39.132].

As the source data is abstract, aggressive preprocessing can in practice yield extremely short input per document (e. g., a 100-word abstract with excessive preprocessing can be cut to one with little or nothing to analyze). To avoid including abstracts with little or no content, the code includes an `if` statement excluding abstracts smaller than 100 characters. This limit is arbitrary and can be changed dependent on the input used. The main goal here is to exclude documents with no or extremely short abstracts.

After preprocessing, the Gensim package was utilized to run the LDA algorithm (Fig. 39.12). First, the code imports the required packages; thereafter, the code uses the list created in the preprocessing stage to create a corpus tokenized for analysis. At this stage, Gensim offers an option to implement stop-word removal, but as this was implemented at the beginning of the analysis, it was not done here. Gensim also includes an option to remove words with either high or low occurrence rates in the corpus. In the code, the `limitBelow` variable removes the words that appear fewer than `limitBelow` times. The variable `limitExtremes` keeps only the first `limitExtremes` most frequent words. The `limitAbove` variable is a fractional filter to keep words which are contained in no more than `limitAbove` documents. These variables are given as parameters to `filter_extremes`.

After creating the corpus and before running the analysis, the LDA requires several further inputs in addition to the data for the model. One of the most significant inputs is selection of the number of topics created by the model. There is currently no consensus on the most practical method for assigning the number of topics. Some researchers have claimed that a trial-and-error method of testing a different number of topics

```
from gensim import corpora, models, similarities, matutils
from gensim.models import ldamodel
from itertools import izip as zip
import numpy as np
import scipy.stats as stats
#Variables
limitBelow = 20, limitAbove = 0.9, limitExtremes = 50000,
valueMin =1,valueMax =100, valueStep =1

#create a dictionary
dictionary = corpora.Dictionary(line.lower().split()
                    for line in abProcessed)
# remove stop words and words that appear only once
once_ids = [tokenid for tokenid, docfreq in
                        dictionary.dfs.items() if docfreq <= 1]
dictionary.filter_tokens(once_ids)
# remove gaps in id sequence after words that were removed
dictionary.compactify()
#Filter extremes
dictionary.filter_extremes(no_below=limitBelow, keep_n = limitExtremes)

class MyCorpus(object):
def __iter__(self):
 for line in abProcessed:
  yield dictionary.doc2bow(line.lower().split())
FCcorpus = MyCorpus()
# Parameters are the corpus and dictionary for the data,
# lower and upper bound of the topic evaluation and
# max and step between topics to be evaluated
lVector = np.array([sum(cnt for _, cnt in doc)
                        for doc in FCcorpus])
kl = klDivergence(FCcorpus,dictionary, lVector, valueMin,
                        valueMax, valueStep)
```

with given input data will produce results that are most convenient for human interpretation [39.136]. However, a number of other mathematical approaches have also been proposed, such as using Kullback–Leibler (KL) divergence to estimate the input [39.137]. In this study, the Python code proposed by [39.137] was used. KL divergence was implemented to estimate the number of topics in the constructed fuel cell corpus.

Figure 39.13 shows the plot of values returned by the function KL divergence. As seen in Fig. 39.13, estimation of the number of topics requires human intervention and simply taking the smallest value of the series is not sufficient. Even if the researcher has a relatively narrow window of expected topics, automating evaluation of a KL divergence plot can be challenging. In the case at hand, the number of topics selected for the analysis was 24 topics. This selection was based on the sharp decrease and value of the KL divergence at 24 topics.

Topic Modeling Results with the LDA Algorithm

Based on the assessment of the number of topics, the final model was created using the LDA model (Fig. 39.14). Gensim offers a convenient means of running a model with three parameters: a corpus, a dictionary and the number of topics. The model can be saved for later use, for example, to infer new documents against the same model.

The model completes with a two-result data set: the probability distribution of documents being classified to a topic and the probability distribution of words being associated with a topic. At this point, the researcher has several avenues through which to approach the results. The documents-topic probabilities can be further used to compare the proportion of topics or study the linkages between topics. The word-topic probabilities can be used as a source for an auto-labeling algorithm or plotting a word-cloud enabling qualitative interpretation of topic content.

To describe the topics, word clouds were implemented using the R word-clouds package, which enables visualization of the topics in a format convenient for human interpretation. Figure 39.15 shows two examples of word clouds from the 22 topics created. The word clouds show the thematic differences in the topics created. For example, Fig. 39.15a describes a vehicle-

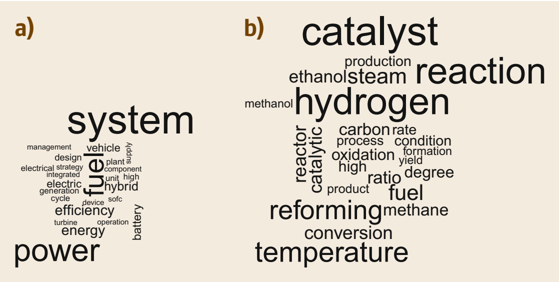

Fig. 39.15a,b Selected topics from the 24 LDA topics: **(a)** topic 1, **(b)** topic 7

related thematic topic; it is also focused on hydrogen as a fuel, storing fuel in a vehicle and the efficiency of the vehicle system.

The document topic probabilities were retrieved using the call `lda[doc]` (Fig. 39.16). This call retrieves top topic probabilities, omitting extremely small probabilities. In practice, this creates a directed vertex from a document to a topic that has a weight that is the probability of a document belonging to a topic. For example, the code in Fig. 39.16 shows the probability distribution of first document in the corpus related to four major topics (topic numbers 7, 10, 12 and 16).

All probabilities creating a bipartite network where nodes are topics and documents and edges are links between documents and topics were extracted, which allowed reduction of the dimensionality of the data in two ways. First, the data were reduced such that the documents were hard-classified to only one class using the modularity algorithm [39.135]. This creates new classes, called communities, that contain both topics and documents. Second, the dimensionality of the data was reduced by transforming the bipartite graph to a one-mode projection, allowing the links between topics to be understood. This transformation can be done for the bipartite graph of topics and for the communities' documents. If done with the latter, it should be noted that a community can include multiple topics.

The bipartite network created from the data consisted of 69 942 nodes and 342 029 edges (Fig. 39.17). Of the nodes, 24 were topics and the rest were documents that remained in the analysis after preprocessing had removed the short documents. Running the modularity algorithm at a resolution of 1.0 produced a hard classification with nine communities. Table 39.4 shows the percentage distribution of nodes to each community, as well as the topics that were hard-classified to a specific community. The average community size is 11.11% ($s = 3.12\%$, $N = 9$), which suggests a relatively equal distribution of nodes in each community. A qualitative assessment of the linked topics, based on the word-clouds, resulted in the labeling given in Table 39.4. Although subjective, the labels give an indication of the content in each community and enable further discovery of the topic content.

The dimensionality of the bipartite network can be reduced to show interactions between the topics. This requires transformation of the bipartite network to a one-mode representation that shows the topic nodes and calculates their interaction based on the shared probabilities between the topics. A bipartite network illustrates the LDA model as a topic-to-topic representation. Figure 39.17 shows the interactions between the topic nodes and reduces the complexity of fuel cell technology development to a few clusters, namely temperature issues in orange, PEM fuel cells in lilac, nanostructures and materials in blue, and hydrogen fuel systems in green.

39.4 Discussion and Conclusion

The major contribution of this chapter is twofold: First, it has provided a summary of how text mining extends the range of quantitative methods applicable to ST&I and highlighted major methodological challenges. A set of 154 articles was examined based on their major theoretical or practical contribution to ST&I, data source utilized, and text-mining technique applied. Second, it has illustrated hands-on detailed case studies showing how a text analytics routine can be implemented.

The literature review shows that considerable progress has been made in terms of incorporating text analytics methods in the development of scientometrics tools to address ST&I research objectives. Scientometrics research tools using citation-based methods that have been partially coupled with or fully developed based on text analytics include science mapping, patent mapping, interdisciplinary research indicators, measurement of S&T interaction and literature-based discovery. Among the ST&I research subfields, the operationalization of technology forecasting and management, research evaluation, technology transfer and detection of technological opportunities has benefited widely from the utilization of text mining. In addition to patents and scientific papers, which are known to be major sources of codified technological and scientific knowledge, other novel data sources (e. g., social media, news streams, policy documents, research proposals) have been exploited over the last decade.

The literature review summarized the text-mining routines practiced by scholars, starting from alternative techniques of text extraction and preprocessing to document modeling. Implementation of the first two text-mining steps described as feature extraction and feature selection (Fig. 39.4) are necessary to process and present the text in a mathematical format suitable for machine-learning algorithms. In general, all document modeling problems can be classified as either supervised document classification or unsupervised document clustering. The first case study presented in this chapter illustrated a document classification challenge where similar patent documents must be collected and classified to a particular known sample of patents, in this particular case related to FCEV technology. The second case addressed the document clustering issue, that is, identifying the underlying topics of an unknown document set. Science mapping is an example of document clustering, as it involves the grouping of scientific publications with similar research themes. Open-source Python libraries were used to implement the case studies, and detailed guidance of their use is provided.

Broadly speaking, analysis of high-dimensional natural language is a complex task due to three prominent challenges: text ambiguity, redundancy and the absence of semantic relationships between words or documents. Ambiguity appears when multiple words have similar meaning (polysemy), redundancy refers to situations where several words share similar meaning (synonymy), and the lack of semantic links occurs when the context of the extracted words is neglected. Dominant text analytics methods such as vector space models (VSM) or principal component analysis (PCA) (i. e., count-based methods) may not be able to overcome all three challenges for document modeling tasks. However, PCA and VSM perform well for word-level analysis whose aim is to extract important keywords in the corpus. The advancement of count-based approaches toward the family of methods with superior performance known as context-based predictive methods [39.123] is well reflected in the literature. While count-based models remain the dominant approach, an increasing number of papers in recent years have applied predictive models to execute science mapping, technology forecasting activities and research evaluation. Acknowledging the advantages of predictive models would affect how future studies in ST&I can shape their research design.

Overall, the analysis supports the contention of an evolution of quantitative ST&I analysis methods from elementary count-based methods and linkage metrics to complex natural language analysis [39.138]. Current natural language analysis studies have laid a firm foundation for future work, and the studies enable a robust understanding of methodological options and limitations when analyzing complex science and technology data. The two presented case studies illustrate that researchers already have a fairly robust armamentarium of natural language and machine-learning-based analysis methods to answer complex ST&I-related research questions.

Samira Ranaei
School of Engineering Science, Industrial Engineering and Management
Lappeenranta University of Technology (LUT)
Lappeenranta, Finland
samiratzn@gmail.com

Samira Ranaei is a Doctoral student at the School of Engineering Science at Lappeenranta University of Technology (LUT) in Finland. She has an Industrial Engineering Bachelor degree and received her Master's in Innovation Management from LUT in 2013. Her research interests are Innovation and Technology Management, Technological Forecasting, and Patent Analysis techniques.

Arho Suominen
VTT Technical Research Centre of Finland
Espoo, Finland
arho.suominen@vtt.fi

Arho Suominen is a Senior Scientist at the Innovations, Economy, and Policy Unit of the VTT Technical Research Center of Finland, while also lecturing at the Department of Information Technology at the University of Turku. His research focuses on qualitative and quantitative assessment of innovations systems with a special focus on data mining methods. He has a Doctor of Science (Tech.) degree from the University of Turku.

Alan Porter

Search Technology, Inc.
Norcross, GA, USA
aporter@searchtech.com

Alan Porter is Director of R&D for Search Technology, Inc., Norcross, GA, USA. He is also Professor Emeritus of Industrial & Systems Engineering, and of Public Policy, at Georgia Tech, where he remains Co-director of the Technology Policy and Assessment Center. He received a PhD in Psychology from UCLA in 1972. He is the author of some 240 articles and books. Current research emphasizes measuring, mapping, and forecasting emerging technologies.

Tuomo Kässi

School of Engineering Science, Industrial Engineering and Management
Lappeenranta University of Technology (LUT)
Lappeenranta, Finland
tuomo.kassi@lut.fi

Tuomo Kässi is Professor Emeritus of Industrial Engineering and Management at Lappeenranta University of Technology, Finland. His educational background is in Technical Physics and Economics. He has worked as an engineer and manager in industry. His teaching and research interests are industrial transformation, management of technology, product platforms, and recently IPR issues and patents. Kässi has been a responsible director in many research projects financed by public or public-private partnerships.

40. Functional Patent Classification

Andrea Bonaccorsi, Gualtiero Fantoni, Riccardo Apreda, Donata Gabelloni

Patent classifications are systematically used in patent analysis for a number of purposes. Existing classifications not only shape the administrative activities of recording and reporting and the search for prior art, but also create the backbone of the construction of science and technology indicators used in economic analysis, policy making, and business and competitive intelligence.

Yet the current classification system of patents, despite significant and continuous efforts to update, suffers from a number of limitations. In particular, it fails to capture the full potential of inventions to cut across industrial boundaries, does not allow fine-grained technology intelligence, and misses almost entirely the opportunities for lateral vision.

We suggest integrating existing schemes with a full scale functional classification, i. e., based on the main functions performed by a technology, rather than on the inventive solutions or their potential applications. The functional approach allows us to overcome most of the limits of traditional classification, due to the generality and abstraction of the representation of functions. In this chapter, we will first review the conceptual background of the functional approach in epistemology and analytical philosophy and illustrate its recent developments in engineering design, design theory, artificial intelligence, computational linguistics, and data mining. We then discuss three short case studies of the application of the methodology for the definition of patent sets (in particular within a technology foresight exercise), prior art analysis, and technology crossover identification and mapping.

40.1 Patent Classifications

Patents are routinely classified into classes by patent offices. The classification process follows international standards, which were established back in history and are regularly updated in order to follow the technological evolution. Classifications are, then, routinely adopted for a large variety of practical and analytical purposes, ranging from prior art search to econometric modeling.

Patent classifications follow a mix of functional and industrial criteria. By *functional* we mean a classification that is based on the engineering principles underlying the technical invention.

In the engineering literature, a function is defined as follows [40.1, p. 72]:

> The function is a property of the technical system, and describes its ability to fulfill a purpose, namely to convert an input measure into a required output under precisely given condition.

A function is a transformation that takes place in the physical space. From a representational point of view, it can be described by a verbal expression (functional verb), usually associated to an object and a modal expression.

This notion is, needless to say, crucial for the working of the entire building of the patent system. Functional descriptions deal with the *novelty* and *utility* requisites of patents. The notion of utility requires that the invention deliver something of value for a user, at least potentially. For the utility to be delivered, what is needed is precisely that a function (perhaps a complex one) is implemented. The notion of novelty requires that this function has never been implemented the way it is implemented in the patent application. More rarely, the function itself is an invention, in the sense that it was not conceptualized before the invention. Industrial criteria, on the contrary, refer to potential users of inventions. They deal mainly with the *industrial* requisite of patents.

The functional language is crucial in the definition of invention, as well as in the doctrine of functional equivalence, stating that solutions that realize the same function should be considered protected by the same patent. Furthermore, it can be shown that some of the most relevant changes in legislation and practice in the last decades, namely the patentability of software and of biotechnological inventions, have been promulgated on the basis of scientific theories about the alleged functional impact of patentability [40.2].

Notwithstanding the foundational role of the concept, legal and economic doctrines and practices rely on a relatively informal definition of functions. The International Patent Classification (IPC) and the Cooperative Patent Classification (CPC), for example, use a relatively loose definition of functions, and use it in a non-systematic and complete way. Furthermore, there has not been any systematic connection with the disciplines in which a great deal of work has been done to define and formalize functions, such as theories of engineering design, theories of systematic invention, or functional analysis.

In this chapter, we argue that the current classification system of patents, despite a significant effort to update, is not able to follow the acceleration of technological developments. New pervasive and transversal technologies, broadly defined as digital technologies, have almost destroyed industrial boundaries and opened new forms of lateral and transversal competition. New products and services are developed by combining existing technologies in novel ways. Very often inventions that were initially conceived for an industry find applications in entirely new domains. To mention just a couple of examples, blockchain solutions, which were initially conceived for the financial industry, now find applications in agriculture, in order to certify the space and time of an inspection of a protected label. Or Second Life, which was intended as an entertainment software platform, is currently largely used as a therapeutic tool.

Under this kind of technological dynamics, existing classifications are almost inevitably in delay. In particular, mixed functional-industrial classifications fail to capture the full potential of inventions to cut across industrial boundaries. Consequently, using existing patent classes does not allow a fine-grained technology intelligence and misses almost entirely the opportunities for lateral vision.

We suggest integrating the existing classifications with a full scale functional classification, based on functional hierarchies and supported for specific tasks by the construction of a large functional dictionary.

The chapter is structured as follows. First, we offer a short overview of the notion of function in a variety of disciplines and comment on recent advancements in computational linguistics that have made it possible to develop large scale dictionaries and classifications. In Sect. 40.3, we discuss in detail the limitations of existing patent classifications. In Sect. 40.4, we offer three short case studies of the application of the methodology. The final section concludes this chapter.

40.2 A Brief History of Functional Analysis

The main elements that characterize functions are as follows:

1. Functions are *abstract* representations–they must be independent on specific technical solutions. This is called solution neutrality.
2. Functions are *normative*–they describe a purpose, or a goal, or a raison d'être of an object, and in this way they describe the conditions under which the object may come into existence, and, correspondingly, the conditions under which the object may not work properly, or its dysfunction.
3. Functions are *hierarchical*–they can be decomposed in an iterative way, moving up to functions of higher abstraction or down to functions of lower abstraction, or higher instantiation. However, there might be multiple hierarchies or different ways to decompose a higher level function.
4. Functions involve a *transformation in the physical space*–they can then be made consistent with physical descriptions.

Due to the novelty of the methodology, it is useful to review briefly the origins of the main concepts and definitions. The notion of function is an established one in engineering and architecture disciplines and has attracted the attention of philosophers, but it has not yet gained universal recognition due to a number of theoretical and practical issues, which we must illustrate in detail.

In the following, we call the attention of the community working on Science and Technology (S&T) indicators to the deeper intellectual roots of some of the concepts that we utilize.

40.2.1 Philosophical Foundations of Functional Thinking

According to Aristotle, the general notion of cause, as conceptualized for physical entities, was not sufficient to explain the relation between some forms of action and the world. In his *Physics*, Aristotle introduced the notion of *telos*, or goal, as the basis for a separate form of explanation, called teleological explanation [40.3, p. 8]:

> Teleological explanation in Aristotle pertains broadly to goal-directed actions or behavior. Aristotle invokes teleology when an event or action pertains to goals: 'that for the sake of which'.

The explanation was found by positing a separate notion of cause, called *final cause*. Final causality worked backward: the existence of a final goal required by necessity the working of individual elements in such a way that their coordination could ensure the working of the whole organism. Interestingly, Aristotle used the notion of *telos* to cover two distinct kinds of final teleology: agency-centered teleology (involving behavior and artifacts, or technology) and teleology pertaining to natural organisms [40.3]. While the distinction between the two classes is one of consciousness (agents are aware of the goal of their behavior, natural organisms are not), the notion of functions can be applied to both fields. According to Aristotle, consequently, the actions aimed at constructing artifacts have value only as manifestations of human goals, that is, they have no internal necessity [40.4].

This notion was rejected after the modern Scientific Revolution. Galileo already asked to reason only in terms of physical causes, leaving the overall *why* to things outside the scientific domain. Notably Darwin, in his rejection of Lamarck's explanation of the adaptation of life, called for a scientific reasoning that moved only from causes to effects and never backward [40.5, 6]. Adaptation comes from random variations that are selected only by virtue of their fitness to the environment and not by virtue of some finalization to superior forms. Variation is random, selection is blind. This is *function without purpose* [40.7, 8].

These arguments were formalized in the twentieth century in two separate traditions. On the one hand, the neo-Darwinian synthesis, introduced by authors such as S. Wright, R.A. Fisher, and J. Maynard Smith, provided the mathematical framework to examine the way in which random genotypic variations could generate new forms or new phenotypes [40.6, 9–11]. On the other hand, the neopositivist philosophy of science rejected the teleological arguments, proposing that arguments outside the physical causality notion, introducing teleology, should not be considered valid [40.12, 13].

Overall, there was a general consensus until the end of the twentieth century on the idea that the notion of function, having inevitably a normative content, should not be admitted in scientific reasoning at all.

This agreement encountered some trouble at the end of the twentieth century, although the streams of thinkers that have criticized the dominant view are still somewhat peripheral. In Kuhnian terms, they point to anomalies in the dominant view, but they still have not gained central ground. Nevertheless, the convergence of critical arguments from a variety of theoretical starting points is an indication of deeper problems.

First, within the philosophy of biology, the notion of pure randomness of variations has been criticized. Starting from the famous metaphor of the spandrels of San Marco in Venice [40.14], *Gould* argued vigorously that variation is not random, but has an internal structure, most likely hierarchical, that makes the probabilities to change in different directions in the space of genetic possibilities highly constrained [40.15–17]. This argument, initially minoritary in evolutionary biology, found support in the recent advancements of epigenetics and systems biology.

Second, the notion of organism has gained prominence in a recent revival of the philosophy of Hegel. The German philosopher tried to conceptualize the existence of complex living entities by positing a new type of causality, called dialectics, as a mutual determination of constraints at different hierarchical levels of reality. Here, the main question is not whether causality can work backward in time (as in teleology) but can work downward, or from a higher-level structure or organism, down to more elementary units. The extent to which dialectics could be used in the philosophy of science is open to debate, but it is clearly on the table. It seems to be a way to give autonomous philosophical foundations to the notion of organization, which is also central in the analysis of complex systems.

Finally, in the last two decades, a number of contributions in analytical philosophy have reintroduced and rejuvenated the notion of function, in a way fully compatible with the procedures of scientific reasoning. In this tradition, starting from the earlier studies of *Wright* [40.18] and *Cummins* [40.19], biological and technological systems are considered an instantiation of a more general class of entities in which the internal working satisfies some general conditions, drawn from the scientific knowledge of the world, for survival or self-reproduction [40.20–24]. Functions may be described in causal terms, according to this analytic tradition, although with some qualifications [40.25, 26].

Summing up, and to make a long story short (for a longer story see [40.27]), we now witness an intellectual landscape in foundational disciplines that is favourable to the development of a general framework, which gives prominence to the notion of functions. This intellectual climate fits nicely with recent developments in the applied disciplines, such as engineering or design, to which we now turn.

The following is not a complete review of existing approaches to functional analysis, which would require a long exposition. There are several traditions, mainly developed in USA, Germany, Russia, and Japan, with a large number of contributions. Rather, we try to identify those contributions that are more relevant for our issue: how to use functional analysis in the field of patent classification and patent search.

40.2.2 The German School of Systematic Engineering Design

While the notion of function is intuitive, the challenge is how to represent it in such a way to be able to manipulate and use the concept in practical terms. This is the object of functional analysis, a stream of scholarship in engineering design whose goal is to develop theoretical frameworks and tools to represent technical problems in an abstract way.

This challenge was taken up systematically by a number of authors, mainly in mechanical engineering, who wrote in German and were active in German-speaking countries. Their books have subsequently been translated into English. Examples of this approach are *Hubka* and *Eder*'s *Theory of Technical Systems* [40.1] and *Pahl* and *Beitz*'s *Engineering Design. A Systematic Approach* [40.28, first edition 1977].

These fundamental books should be interpreted in the light of the professional tradition of German engineers and of their academic training (for a reconstruction of this tradition see [40.29]). German engineers are trained to design new technical solutions by moving from first principles in a highly structured way. The specific rules of reasoning are written down in a formal way and generate lists of suggestions. In some sense, the discipline is one of the systematic examination of many solutions, following a formal list of methods to guide the reasoning process (see also [40.30]).

It is within this tradition that one should understand functional analysis, as a systematic effort to describe and standardize the abstract requirements of design tasks. A development that took place independently but with a similar abstraction goal (and a rather similar time trajectory), should also be mentioned here, i. e., the theory of inventive principles, or TRIZ (the Russian acronym for the *theory of inventive problem solving* [40.31]). While this is not the object of this chapter, the TRIZ literature pushed forward the notion that there is a compact collection of general inventive principles to be applied to engineering problems, whose functional meaning can be made explicit. Indeed, even if treated from a different point of view, functional thinking has a significant role in TRIZ theory.

40.2.3 Artificial Intelligence and Design: From Herbert Simon to the Carnegie Mellon Project

From an entirely different intellectual tradition, a number of scholars of artificial intelligence started to ask whether the design task could be formalized and automatized. This was in clear continuity of the ambitious tradition of cognitive science that started from the automation of well-structured problems, such as chess playing, and moved to ill-structured problems, such as scientific discovery or design [40.32–35]. At Carnegie Mellon, this project was pursued systematically for many years [40.36–40].

The emphasis here was more on the cognitive procedures utilized to move in the design space, called heuristics, than on the initial requirements of design tasks. Nevertheless, the formal definition of requirements in terms of functions was a necessary element of the description of the problem [40.41]. A remarkable example of this tradition is *Tong* and *Sriram*'s *Artificial Intelligence in Engineering Design* [40.42] and *Sriram*'s *Intelligent Systems for Engineering* [40.43].

Interestingly, these efforts did not produce compelling results. The most relevant applications were found in the field of the design of electric and electronic circuits. Applications in the field of architectural design were also explored, but with limited success.

One might argue that the focus on the cognitive procedures missed a point, that is, the language with which people transform the abstract requirement (the *why* of the artifact) into broad ideas, then more precise concepts, down to detailed specifications and design. In other words, there must be an interaction between cognitive processes of the general type [40.44, 45] and the specific representational language in each of the design domains. Such interaction was almost entirely missed in earlier efforts to automatize design, due to the emphasis on discovering and modeling general mechanisms of intelligent behavior [40.35].

40.2.4 Functional Bases

These limitations led to a different strategy, i. e., focusing more on the language than on the cognitive operations in the design space. The task was to develop a language that might be used to write functional expressions that were consistent with grammar and semantic rules.

Interestingly, this intuition was forwarded in the direction of the development of functional languages based on the manipulation of a very *small* set of functional verbs. This strategy followed some sort of Occam's razor argument: the goal was to describe functionally an artifact using the smallest possible number of different functional verbs. The main research goal was parsimony and elegance, rather than coverage and usability in every context. This approach, labeled *functional basis*, was developed mainly in the USA, starting with the pioneering works of *Little* et al. [40.46] and *Stone* and *Wood* [40.47]. A more systematic version was elaborated shortly after by *Hirtz* et al. [40.48] and further expanded by many authors [40.49–51]. The functional basis paradigm created a systematic linkage with earlier traditions of engineering analysis, such as value analysis. Several US research teams created a stream of research that transformed functional analysis into a usable tool.

Over time, however, this approach showed some limitations; in real world applications, it was practically impossible to use functional bases without the help of experts in specific engineering domains. In order to capture the functions of artifacts it was necessary to add several qualifications to verbs that were too broad or general. These limitations were evident when the trend towards automatic text processing became dominant. Functional bases were mainly intended for manual use. They were not suited for the treatment of large collections of texts.

40.2.5 Introducing Behavior in the Functional Representation: The Function–Behavior–Structure (FBS) Model

The limits of functional bases were clearly anticipated in a stream of literature that introduced a new layer of description.

In functional analysis, a distinction is made between the structure of the artifact (i. e., its geometry and material composition) and the function, or the abstract description of its purpose. The function is, however, implemented by the structure of the artifact in a dynamic way, that is, by producing a behavior. This behavior is consistent with the structure and is aimed at delivering the function. In functional analysis, the description of the behavior is absorbed in the functional description, by working with varying degrees of granularity in the hierarchy of functions.

Various authors [40.52, 53] suggested enriching the framework by developing a separate layer, called behavior, within a unitary framework called *function–behavior–structure* (FBS). In this way, functional descriptions can be left more general, and the implementation of functions can be described more carefully in dynamic terms, by following the behavior of artifacts in their context [40.53–56]. This approach is much more flexible and articulated, as it permits the representation of functions in dynamic terms, as well as a more explicit link between the functions and the expected behavior or user expectation [40.57–60]. In other words, in linking structure and function through the notion of behavior, this approach allows us to examine expected behavior by users as an indication of needs. It has received large acclaim in the literature [40.61, 62].

Other authors have also articulated functional analysis in order to accommodate a separate behavior layer [40.52, 63].

40.2.6 The Ontology Revolution and the Role of Computational Linguistics

The developments discussed above (Pahl and Beitz's systematic design, functional bases, and the FBS framework) were developed within the engineering design literature. This literature is produced by a relatively small community, whose main interests are in the construction of formal systems for representing technological problems moving from a deep knowledge of engineering disciplines [40.64]. In other words, this is a minority of scholars in engineering who, in addition to, sometimes (more rarely) in substitution for, deep studies in specialized engineering disciplines, have a propensity for theoretical generalization and formalization.

Parallel to these developments, and initially with no overlappings, the last two decades have witnessed impressive advancements in computational linguistics, and the ability of artificial systems to process large collections of texts has increased enormously. These developments are based on the construction of formal ontologies or abstract representations of entities and their relations. In parallel, powerful statistical methods for the extraction of meaningful information have been developed in the fields of information retrieval and data mining.

After several pioneering contributions, a full-scale effort to develop a functional ontology was promoted by *Kitamura* and co-authors [40.65–68]. The construction of an ontology requires the formal modeling, using knowledge representation concepts and theorems, of the substantive relations among entities [40.69]. This is usually done in interaction between domain knowledge experts (in this case, engineers and designers) and computer science experts.

After the initial effort, the literature on functional ontologies witnessed large adoption [40.70]. Yet, other authors followed a different path: they built functional representations by massively processing technical texts (in particular, patents) in order to automatically extract functional information. This was done without a pre-existing functional ontology, but only on linguistic bases. In particular, *Montecchi* and *Russo* started to apply to the newly created patent classification (CPC) linguistic queries based on the FBS framework and its variants [40.71–73].

Other authors did not capitalize on existing engineering functional frameworks but reconstructed the notion of function on the basis of purely linguistic structures, e.g., actions. This approach is called SAO. The acronym SAO means subject-action-object structures: every verbal construct in which there is a subject doing an action that involves an object. *Yoon* and *Kim* [40.74] developed a patent analysis strategy based on the concepts of natural language processing. Taking advantage of parsing tools like the Stanford Parser or Knowledgist, patents claims are analyzed to reach a level where each of them is representable by a set of SAO structures. This permits a rapid identification of what the components in a new product are, and what their function is. The extracted structures are compared using a similarity measure that is purely linguistic, i.e., does not implement an underlying ontology. A similar approach is found in *Choi* et al. [40.75], while *Park* et al. [40.76] combine the SAO structure with TRIZ inventive principles. These contributions realize the goal of offering a rich language for functional descriptions. They might be labeled *text mining without ontologies*. The underlying engineering, and ultimately physical, constitution is not made manifest.

40.2.7 Functional Dictionaries

Finally, an alternative path was followed at the intersection between engineering design and machine learning, i.e., the development of large *functional dictionaries*. This path followed the notion that cognitive operations in design depend on the representation of the design task in specific, contextual, and semantically rich environments, in which the interplay between function and structure could be produced. This idea was also at the origin of the Functional Basis movement of Hirtz, Stone, Wood, and co-authors. These authors, however, pursued a goal of parsimony.

The functional dictionary approach goes in the opposite direction, developing the *largest* possible dictionary. It also goes in a different direction to the ontology movement of Kitamura and co-authors, in the sense that there is no need to develop a full scale ontology. What is needed is a procedure to generate the largest possible collection of functional lemmas and to demonstrate that the semantic space of design is *saturated*, or there are not any important undescribed elements left. By saturation, we mean a methodology, borrowed from social sciences, in which there is systematic interaction between observed data and modeling until the model includes all elements that are needed to explain the data. In the context of engineering design, this means completeness at two levels: the level of the *categories* of elements needed to describe an artifact and the level of all the various possible *technical implementations* existing in each category. A related crucial factor, to be dealt with properly for the methodology to work, is the domain dependency of many types of technical concepts: saturation in one domain does not guarantee the same in another, and completeness must be achieved at a third level too, that of all sectors of interest. In our case, we tested the dictionary in a dozen applications in highly disparate industries, up to the point where the entries were fully adequate to describe the problem at hand. The construction of large repositories of technical terminology has been investigated by various research groups, especially within the TRIZ community. As an example, the commercial software Goldfire Innovator (http://inventionmachine.com) includes a large database of functions and physical effects; furthermore, the extraction of functional information from patents was pioneered by *Cascini* and co-authors [40.77–79]. Dictionaries for specific sectors have been built by a number of authors (see, for example, [40.80, 81]).

This direction was taken over a decade ago also by the authors of this chapter [40.27, 82–86]. To reach the optimal result, we combined different techniques, ranging from advanced text mining, use of knowledge patterns and structures, and human factor analysis, all revised by experts in the technological sectors examined.

The most important achievement of this research effort was the construction of a functional dictionary containing more than 100 000 lemmas, of which there are approximately 12 000 functional verbs. This dictionary contains functions, behaviors, and structures, defined as atoms of the artifact, in terms of process, action, or task that the artifact system is able to perform. All entries are related to semantically related entries, such as synonyms, antonyms, and hyperonyms.

This approach has opened the way to an automatic procedure to extract functional information from patents [40.87], while keeping full control of the underlying physical description of functions. This dictionary has been repeatedly used in tasks of patent search, patent classification, topics modeling, technology foresight, and design crossover, in the last few years.

More recently, the same dictionary approach was followed in an effort to build up other technical dictionaries referring to advantages/disadvantages of artifacts and to users or stakeholders of artifacts. The idea is to increase the coverage of all the directions in the design space, thus expanding the possible applications. Overall, the following dictionaries have been developed:

- Stakeholders: persons who have relations with a product or service. It has been built by merging multiple lists (e. g., users, workers, patients). Its size is about 77 000 entries [40.88].
- Advantages and disadvantages: positive and negative effects of products/services. These classes could be also defined as benefits and failures. They consist of more than 20 000 entries.
- Components: list of systems and sub-systems contained in products.
- Physical quantities and units of measurement: physical properties of a phenomenon that can be quantified by numbers and units of measurement.

More recently, a *vertical* dictionary has been built, called Technimeter® 4.0 [40.89]. It is a list of technologies and techniques related to Industry 4.0. The dictionary and taxonomy behind the Technimeter are designed to map documents of the new industrial revolution. It has the form of a fully linked graph and consists of about 2000 technologies and 200 000 links. It is in three languages (automatically expandable) and could be easily extended to fields like precision agriculture, the Internet of Things (IoT), smart cities, smart energy, and E-health.

A sample of entries from these dictionaries is given in Table 40.1.

The approach, which is based on large, non-ontological dictionaries is not suited for all type of analyses, at least in its current state of development. When the analysis requires a high level of abstraction with respect to the specific artifact descriptions, such as in the construction of functional diagrams or other functional modeling-related tasks, and in general for every study performed by a human expert, the variety and the details embedded in the database just add unneeded complexity. In such cases, more prescriptive and concise methods, such as those built on functional bases, usually deliver faster results.

On the other hand, in all cases in which the investigation needs to deal with the complexity and fuzziness of natural language, a complete functional dictionary provides, almost by design, an efficient and reliable instrument. This is the case of all forms of software-based, automated analyses of texts, which in turn are the only possible way of tackling large amounts of technical documents in tasks as diverse as information retrieval, knowledge extraction, or document categorization and labeling.

One of the most promising areas of application of the functional dictionary is, indeed, patent classification. We suggest that a full scale functional dictionary allows a fine-grained representation (i. e., retrieval, mapping, clustering, and profiling) of patent information, opening the way to a variety of powerful applications. As a future development, integrating a full dictionary with computational linguistic algorithms may even allow tasks such as constructing functional diagrams in an automated way and comparing them.

In the next chapters, alongside the general discussion about functional classification of patents, we will also provide some examples of use, among others, of the dictionary approach.

Table 40.1 Sample of entries from the functional dictionary, the stakeholder or user dictionary, the advantage/disadvantage dictionary and the Technimeter 4.0 (in alphabetical order)

Functional behavior structure			Stakeholders, pains and gains			Technological aspects	
Functional verbs	Behaviors	Structures/ components	Users	Advantages	Dis-advantages	Units of measurement	Technimeter® 4.0
Abrade	Abraham–Lorentz (force)	Annular, annulus	Academician	Ability	Abandon	ag	Actroid
Absorb	Absorption	Axial, axis	Accordionist	Accessible	Absent	aHz	ADA (programming language)
Abut	Acoustic (shock, wave, ...)	Arc, arched, arcuate	Acoustician	Accommodate	Abuse	aJ	AM (additive manufacturing)
Accelerate	Activation (energy, coefficient)	Ampoule	Acrobat	Accurate	Accident	am/s^2	Advanced audio distribution profile
Access	Adhesion, adhesive	Aperture	Actor	Accurateness	Accidental	aN	Advanced mobile phone system
Acidify	Adiabatic (transformation)	Arm	Acupuncturist	Adaptable	Aggravated	A	AGV (automated guided vehicle)
Acierate	Archimedes (principle)	Axle	Adult	Adequate	Aggravation	Ampere	Aibo (artificial intelligence robot)
Adapt	Auger (effect)	Anode	Aesthetician	Adjustability	Alterations	atto-	AIML (artificial intelligence makeup language)
Add	Austenitization	Antenna	Alpinist	Adjustable	Anxiety	aW	Air cobot
...	...	...	...	...	...	...	...

40.3 Patent Search and the Limitations of Existing Patent Classifications

Patent classification is a necessary part of any patent system, for legal, administrative, and practical purposes. One of the main areas of utilization of patent classification is patent search, which has two main applications: ex ante patent search or the search of prior art done by inventors, assignees, attorneys, and patent officers before and during patent application, and ex post patent search, or the search in databases carried out after the publication of patents.

Patent search can be based on several alternative strategies of query. Some queries are exclusively based on existing patent classifications (IPC or CPC) or industrial classifications, others use other metadata that are included in patent documents. Summing up a patent search is usually done in one or more of the following ways:

1. IPC or CPC classifications
2. The codes of NACE-CLIO, that is, the European Industry Classification (The acronym stands for Nomenclature générale des Activités économiques dans les Communautés Européennes–Classification Input–Output or equivalent national correspondents, such as the Italian ATECO (ATtività ECOnomiche), to identify the name of companies of the field of interest
3. Keywords associated with technologies of interest
4. Full names of companies and/or research centers that develop technologies in the field of interest
5. Full names of inventors.

Interestingly, each of these search strategies suffers from a number of severe limitations. We review them in order.

40.3.1 IPC or CPC Classes

The official patent classifications are the most largely used in patent analysis, both in professional practice and in academic research. In the latter domain, patent classifications are routinely used in the economics of innovation and strategic management literature, in order to address issues such as diversification of companies, related variety, innovation search, or novelty. Yet these classifications suffer from limitations that are not always clearly recognized.

To start with, the large number of IPC codes (more than 70 000 IPC codes among classes, subclasses, groups, and subgroups [40.90] and of CPC entries (more than 200 000) [40.91], while an indication of the effort of IPR authorities to follow the evolution of technology, generates a cumbersome task. Patent officers and analysts are faced with a severe trade-off: using fine-grained classification requires a large specialized knowledge, while using higher-level codes would bring in the patent set lot of noise from distant and unrelated documents. As a matter of fact, the reading of the definitions of patent classes does not solve at all uncertainties in classification and also in information retrieval.

Second, the IPC/CPC classification has its own ambiguities of attribution. Compare, for example, the subgroup *A61B 5/00–Measuring for Diagnostic Purposes* with the class *G01 Measuring*, or the subclass *F16F–Springs; Shock Absorbers* with the equally valid subclass *B60G–Vehicle Suspensions*. It is clear that a patent of interest can be legitimately listed under one or the other code. This means that an incomplete IPC-based query (in particular, a query that fails to recognize these kinds of ambiguities) will miss important information.

Third, there are errors of classification. In some cases, the technology covered by the patent has nothing to do with the patent class, due to mistakes or misprints. However, the most intriguing (and disturbing) classification error is intentional. Applicants submit patent applications that intentionally include misleading information, that lead patent analysts at patent office into misclassification. In other words, companies try to hide the true content of their patents from competitors, for defensive purposes or for creating hidden threats. It is not uncommon, for example, to see inventions for power windows in the automotive sector classified as blinds for use in houses or solutions for gas turbines classified as solutions for standard combustion engines, and vice versa.

Fourth, the speed at which new patent classifications are introduced does not match the speed of technological evolution. Despite significant efforts, official classifications are several steps behind the technological state of the art. In particular, patent classifications are under pressure in following inventions that are transversal in nature. In general, patents with broad cross-field and cross-industry application are classified in several sectors of the IPC classification. On the other hand, CPC has tried to address the issue by introducing the Y class, but for the time being the coverage is far from complete. As a clear example, it has been shown [40.92] that only a tiny fraction (5%) of the relevant patents in the field of bioinformatics is listed under the corresponding IPC code G06F19/10, while all the others are scattered among over 30 codes. A similar problem refers to the case of transversal or interdisciplinary technologies, which adopt several technical solutions and span several applications, and, therefore, can be pertinent to many classes. Consider for example patents for robotics, or IoT. More generally, even standard technologies may have multiple IPC/CPC attributions. A classic case is control software, which can be classified either under pure software classes or under classes related to the specific industrial sector of application.

Finally, the IPC/CPC classification has not yet been adopted in all National Patent Offices.

Summing up, the use of IPC or CPC classification schemes is justified as a first approximation, while it suffers from severe limitations if the goal is to identify emerging technologies and technological trends, as well as to build up strategic technology intelligence tools that allow for lateral innovation, boundary-crossing technologies, and strategic hiding behavior by competitors.

40.3.2 Industry Codes

A suitable alternative to the construction of lists of companies is to rely on industry codes. At the European level, they follow the NACE-CLIO nomenclature.

This approach, too, has various limitations. First, using industry classification creates the same problem of classification errors found for patent classes; sometimes companies are listed in classes that have nothing to do with the reality of their production, due to misclassification.

Secondly, large enterprises and holdings generally operate in more than one industrial sector; thus the reference is to multiple NACE codes, so that a clear association of enterprises to NACE is difficult. Furthermore, in the case of groups or holdings, quite often the parent company is classified under services, although the associated or subsidiary companies are manufacturing enterprises.

Finally, research centers are not classified by industry codes.

40.3.3 Keywords

Keywords are another largely used technique in patent search. After patent classes, keywords are probably the most important search tool. Keywords must be built up after an expert judgment. More recently, the elicitation of keywords by experts in the subject domain is integrated with formal computer language methodologies (ontologies).

In practice, however, it is difficult to characterize completely and precisely a technology using only a limited number of keywords. The larger and more inclusive is the choice of keywords, for example, including all synonyms of a given term, the greater the risk of finding unrelated patents due to polysemy or usage of the word in several other industries. Moreover, assignees may use (inadvertently or intentionally) different terminology to label the same technical concept. The list of variants is not known a priori.

Often inventions are described in ways that defy the precise qualification by means of keywords. Or the same functions are described differently, so leading to the publication of different keywords.

Finally, the labeling with keywords may miss important information. As a matter of fact, even the most obvious keywords may not be present in patent documents. For example, the CPC subgroup F04D 19/042 is about turbomolecular vacuum pumps, and yet there are 52 documents classified in F04D 19/042 that do not contain the term turbomolecular pump or any other variation of such an expression (source: http://www.wipo.int/meetings/en/details.jsp?meeting_id=39303).

40.3.4 Full Name of Assignees (Companies or Research Centers)

It is usually quite difficult to start with a complete list of companies and/or research centers that may be designated as assignees of patents. This is even more so in rapidly growing sectors, due to the massive entry of newcomers, as well as frequent mergers and acquisitions (M&A). A list of the full names of companies can be found in some industrial sectors in sources like industrial repositories, catalogues, trade associations, and associated websites. Complementary sources are the commercial database services.

However, even if a complete list were available, there are several limitations, some of which are similar to those commonly found in bibliometrics and scientometrics.

The well-known problem of harmonization of company names is pervasive: there are countless variations of company names to be found in patents. Harmonization efforts come into play, but they are still incomplete. In addition, companies try to hide their identity by assigning patents to subsidiaries whose corporate links are difficult to reconstruct, or even to their long term suppliers. In many cases, the assignees are inventors themselves, so the name of the company is not visible in the patent data. However, the inventors are employees or collaborators of a company. This information is not available in patent documents, so it must be inferred from other sources. As a matter of fact, the information may be difficult or impossible to reconstruct.

Finally, lists of companies are typically based on criteria for inclusion that refer mainly to the final products, i. e., are based on industry-sector criteria. This corresponds to the traditional notion that members of an industry are only those companies that actively compete in the product markets, or, more formally, those for which the cross-elasticity of product demand is non-zero. This notion was entirely appropriate in an innovation landscape in which there was a strong coherence between the technology owned or controlled by a company and its product portfolio. However, in a landscape of pervasive digital technologies and disruptive business models, this strict correspondence is not warranted. As an example, in emerging technologies, one often finds among assignees names of companies, usually large ones, coming from completely unrelated fields. This means that they are studying the technology. The extent to which they will develop products based on these patents, becoming new entrants and newcomer competitors, is not obvious at all.

40.3.5 Full Names of Inventors

The inventor record in the patent text is a source of crucial information. Many studies have been carried out by using lists of inventors, as well as their affiliation, country of origin, nationality, extracted from given sets of patents. An interesting example is the classification of inventors by country based on automatic tools of disambiguation, which assign a country or region with a certain probability given the frequency distribution of names and surnames.

Inventors are, however, physical persons. Contrary to names of companies and research centers, which create a universe in the order of magnitude of dozens of thousands, names of physical persons are in the order of millions. In addition, for companies there is an incentive to select corporate or brand names that are clearly distinguishable from competitors. This does not happen for physical persons. This means that issues of homonymy are cumbersome and may create lot of noise in data.

In addition, there is no validated list of inventors, for the time being.

For the convenience of the reader, the main limitations of existing patent search criteria and approaches are summarized in Table 40.2.

Table 40.2 Summary of the limitations of existing patent classifications

Search criteria	Limitations
IPC or CPC classes	• Large number of IPC codes and CPC entries generates cumbersome task of classification and information retrieval • Ambiguities of attribution • Classification errors • Strategic information hiding • Mismatch between speed of updating of classification and speed of emergence of new technologies • Cross-field technologies
Industry codes	• Classification errors • Research centers are not categorized by industry codes
Keywords	• Incomplete profiling of technologies using keywords • Polysemy • Ambiguity in the description of technologies by companies • Missing keywords
Full name of assignees (Name of companies or research centers)	• Cost of compiling lists of companies • Completeness of list of companies (new entry, M&A) • Name harmonization • Allocation of patents to subsidiaries with opaque corporate links and/or loyal and strategic suppliers in order to hide patent activity • Allocation of patents to individual inventors who are employees/collaborators in order to hide patent activity • Entry from unrelated industries
Full name of inventors	• Lack of completeness of inventor list • Homonymy

40.4 Functional Patent Classification: Three Case Studies

As mentioned in the previous chapters a functional patent classification (FPC) is based on the main functions performed by the technology, rather than on the inventive solutions or their potential applications. The functional approach allows overcoming most of the above-mentioned limits. One aspect that makes functions such a powerful tool is their generality and abstraction. Representing logical, physical, or teleological concepts, functions are neither domain specific nor domain dependent. As an example, separation, movement, and control are present in every technical domain, what changes is only the structure that realizes these general goals or effects. Therefore, functions can help the identification of connections or even the creation of bridges between distant technologies or industrial areas.

The connection may be found in the two time directions. Looking retrospectively, it is possible to start from a given present-day solution and explore inventions of the past belonging to different sectors, either to make more complete the positioning of a technology and the understanding of its evolution trajectory, or to widen the scope of infringement, opposition, or freedom to operate analyses.

Looking forward, on the contrary, the existing patent corpus can be used to provide inspiration for the inventions of the future, tackling a creative process called *crossover*, i. e., the adaptation of technical solutions from one field to another. The same approach can help in anticipating the evolution of transversal technologies.

Furthermore, the search of prior-art is very important in the every day practice of engineers, designers and IP professionals; however, the projection towards the future provided by crossover is probably even more important, since it leads to new technologies and businesses, and can provide valuable support to the strategic planning of companies and policy makers.

In the following sections, we will review some of the advantages of using FPC in a variety of directions. These include:

- Patent search
- Technology foresight
- Prior art
- Crossover analysis

In the first two case studies, we will show how adopting a functional reasoning and FPC allows a better retrieval of the patents:

- Related to a technological cluster, e. g., during a foresight activity.
- Related to a specific product that a company plan to patent and commercialize without infringing one or more existing IP (in the case of patent search and prior art analysis).

In the third case study, we will discuss how performing a patent search based on functional criteria permits us to identify different technologies that satisfy the same need and apply that to crossover activities, in order to support creative tasks in the conceptual design phase.

These applications are of interest for patent offices, patent attorneys, and patent analysts, as well as for entrepreneurs and venture capitalists, or researchers and analysts interested in technology and competitive intelligence.

40.4.1 Case Study No. 1: Patent Search

There are two main advantages of adopting a functional point of view when performing a patent search. The first is higher recall (in information retrieval; the term *recall* indicates a percentage parameter representing the completeness of a given target document set; in the present case, it gives the fraction of relevant patents that have been actually retrieved over the total amount of existing relevant inventions). Quite often, relevant patents are filed under IPC/CPC classes different from that of the starting patent application, and traditional queries are usually not able to retrieve them, either because they rely too much on the IPC/CPC patent classification, or because the keywords used are too domain dependent. Even similarity search, based on semantic technologies, usually fails in this task, since it still bases its internal representation on the specific terminology of the initial example.

The second advantage is that finding solutions coming from different fields is often unexpected and, therefore, offers additional weapons in the IP dialectics (for example, in patent litigation or opposition), similar to the possibility of utilizing non-patent literature. Moreover, the reverse is also true, that is, using the functional approach it is possible to detect patents that have been hidden in classes that are far away from the obvious one, either for defensive or offensive purposes.

In the foresight activity of the biomedical industry commissioned in 2017 by Toscana Life Science, a non-profit organization in the support of biomedical research and acceleration of startup companies, the starting point was the creation of the set of relevant patents.

The biomedical field has been clustered in 12 areas, defined at high level by using functional verbs that identify the main action performed by the technologies belonging to each area. For example, in the field of surgery, instead of listing individual technologies such as scalpel or cutting laser, we defined the cluster in terms of the main function, i. e., to separate/cut the tissues of a patient. Table 40.3 shows the main functions identified in the exercise. This segmentation is not intended to be exhaustive; it addresses the main ares of interest of the client. It gives a hint to the search strategy that the functional classification suggests.

Let us consider the cluster of technologies which function is to support the motor functions (listed as number 5 in Table 40.3). It contains the products and devices used for the rehabilitation and the aid of the mobility of a patient, such as crutches, wheelchairs, or training equipment.

Taking advantage of the functional dictionary to support the *functionalization* of the search, i. e., considering all possible variants of the functional concepts to be retrieved, we identified in this functional class a global patent set of 133 197 documents, belonging to 45 976 patent families, filed worldwide from 1900 to 2015.

Only a tiny fraction of these patents were filed in the region supporting the study (Tuscany). From the above set, in fact, 267 individual patents filed by assignees localized in the region have been found. They belong to 42 patent families, and their filing date is after 1985. Focusing on this small sample, it appears that some of the patents identified would not have been found, had we used the search criteria listed above.

For example, the application US2006113846_A1 (*Mechanism of motor reduction with variable rigidity*

Table 40.3 Classification of patents for medical devices adopting the similarity of functions performed as criterion for clustering

Segmentation of the technologies according to performed function	
1.	Technologies to remove/separate material
2.	Technologies to provide stimulus to the body
3.	Technologies to measure physiological parameters
4.	Technologies to detect images
5.	Technologies to support the motor functions
6.	Technologies to reach a specific part of the body
7.	Technologies to collect samples
8.	Technologies to pre-process samples
9.	Technologies to increase sample quantity
10.	Technologies to allow interaction of samples and reagents
11.	Technologies to detect signals from body fluid and tissue
12.	Technologies to sterilize the devices

and rapidly controllable) is classified under the IPC groups B25J9/02, F16H19/06 and H02N3/00. These groups are labeled, respectively, *Manipulators positioned in space by hand*, *Gearings comprising essentially only toothed gears or friction members and not capable of conveying indefinitely-continuing rotary motion* and *Generators in which thermal or kinetic energy is converted into electrical energy by ionisation of a fluid and removal of the charge therefrom*. If we had conducted the search using just those IPC classes for which the definition matches the concept of rehabilitation devices or mobility aids (that is, A61F,- *Medical or veterinary science; Hygiene; filters implantable into blood vessels; prostheses; devices providing patency to, or preventing collapsing of, tubular structures of the body; orthopaedic, nursing or contraceptive devices* or A61G,- *Medical or veterinary science; Hygiene; Transport, personal conveyances, or accommodation specially adapted for patients or disabled persons*), we would have not identified the above relevant US application, since it is classified under classes apparently unrelated to the biomedical field.

Rather often, the assignees and the inventor of a patent overlap. This is generally true for US applications, since in that jurisdiction there is the presumption that the inventor is the initial owner of a patent or patent application. Sometimes the inventor is, indeed, a single professional working on his/her own. More frequently, however, particularly in some industries, the inventor is an employee in the R&D department of a company and, by contract, the owner of the intellectual property is the company, not the inventor. In certain cases, the re-assignment to the legal entity from the physical person (inventor) to the company may still be in progress. In other cases, however, companies intentionally leave individual inventors as assignees, in order to hide the invention from competitors. Therefore, if these patents were searched using the names of the companies active in the industry, they would not be retrieved. For example, in the patent IT1252816_B (*Reinforced cotyle for hip joint prosthesis*) Mr. Massimo Giontella is both the assignee and the inventor. We started a search on other documents and discovered that this inventor works for a company (MP srl), and that this company owns several patents that refer to devices for the support of the motor functions. Had we searched for the standard criteria listed above, we would not have been able to reconstruct this hidden connection.

Another interesting remark about the above-mentioned company, MP srl, is that it performs mechanical manufacturing. Indeed, from its website it is not possible to infer that it produces biomedical equipment. For this reason, it would be difficult to retrieve its patents relying on the assignee information only, since it is not listed in any company list in the biomedical industry.

Similarly, we identified an assignee whose industrial classification was *Integrated engineering design services* (Ateco code 71.12.2 in the Italian industry classification). This industrial classification is too generic to infer any relatedness to the medical device industry. Yet it is the classification used for Prensilia, a university spinoff company, whose patent EP2653137_A1 (*Self-contained multifunctional hand prosthesis*) is clearly relevant to the biomedical industry. The patents of Prensilia would have been missed if the query had been based on industry classification only.

Finally, industrial classifications do not cover universities and research institutes and centers. In our case, as many as 34 patents related to the motor functions are assigned to Scuola Superiore Sant'Anna, a university institution. Thanks to the functional approach, it is, therefore, possible to find documents that do not have explicit reference to known assignees. In addition, it is also possible to elaborate on the relations between the technologies of interest and the strategic orientation of companies that do not appear in the core of the industry, and, therefore, are not under the regular scrutiny of competitors.

To sum up, in using the Functional Dictionary illustrated above, the levels of recall and precision were extremely high, by the standards adopted in the computational linguistics community (in information retrieval, the term *precision* indicates the fraction of relevant documents contained in the retrieved set; in the present case, such percentage parameter estimates how many of the patents in a given target patent-set do pertain to the technical area of interest). Functional thinking in general allows finding results that would have been missed otherwise, both by traditional patent search methods and by relying on pre-existing knowledge.

A final comment about the application of functional classification to the field of technology foresight is in order. Here, the functional approach is extended along the *time* dimension. The functional representation of technologies supports the identification of technical trends that project into the future the evolution of solutions, beyond the existing ones. This is a powerful counterbalance to the tendency of experts to reason of future technologies in terms of extensions of already existing solutions. Following the functional approach, the technology foresight may lead to the prediction of forthcoming solutions that fulfill the needs and goals emerging from the analysis, or, stated more formally, the functions of interest [40.93]. In other words, by investigating functions not properly addressed by existing solutions, as well as by extrapolating trends well known from the theory of functional analysis, it is possible to identify the directions along which the next innovative steps will take place. In addition, the functional approach allows the early identification of the potential failures of inventions. Failures can, in fact, be conceptualized as *negative* functions. A functional representation allows early detection of the areas in which the promised deliveries of benefits are likely to be frustrated [40.94].

40.4.2 Case Study No. 2: Prior Art and Out-of-Field Citations

The advantages of retrieving solutions coming from different fields were already pointed out in the previous section. There, the discussion was on search in general, but the same is true for the specific case of prior art search.

However, for anteriority search an objection can arise. How far apart (from the technical point of view) can two inventions be, so that one can still be considered a legitimate prior art of the other? Indeed, one may object that, in principle, there might be a threshold over which two solutions are so different that they can hardly be considered by a person skilled in the art to share a similar inventive step, even if they perform a similar function. However, there is no common agreed upon definition of an objective or measurable *distance* between artifacts that would allow setting such a threshold in a clear way. The judgement about the degree of similarity is usually left to the sensibility and experience of the IP professional. In addition, as a matter of fact, out-of-field citations are, indeed, used by patent examiners, patent attorneys, and companies' IP professionals.

To investigate the degree of usage/retrieval in prior art searches of solutions coming from external sectors, we used a set of over 200 000 patent applications, belonging to the biomedical sector and coming from several jurisdictions, which we had carefully selected for a previous study, and looked at the backward citations. For all data on citations and on search reports, we refer to the European Patent Office's PATSTAT service [40.95].

We assumed a very simple metric to compare any given application with its citations: two documents are considered pertaining to different sectors only if they have a different IPC/CPC class, i. e., if the first three characters of their IPC/CPC code are different. Any difference in the subsequent characters has no relevance for the present purposes. Such a metric, relying on the IPC classification tree, the criticalities of which we have already highlighted, is probably not the most accurate for an in-depth one-to-one comparison but can be easily automated to process large amount of documents, and the results are reliable on a statistical basis.

The study of the above-mentioned patent set led to some interesting results.

First, out-of-field citation is quite common; in almost one out of two patent applications (46%), the examiner cited in his/her search report at least one document belonging to a different sector. (Note that we restricted our analysis to citations made by patent office examiners and third parties only, neglecting the citations made by the applicant themselves. Please also note that the above percentage can be slightly overestimated because some documents have multiple IPC attributions, which may be both in-field and out-of-field.)

Out of almost 4 million backward citations from examiners for the whole set, 32% have a different IPC class with respect to the starting application (again, the exact percentage may be a bit lower when taking into account multiple attributions).

Second, even given the above, examiners very rarely rely on out-of-field citations only. In the various search reports of patent office examiners, around 10 000 applications were found to present prior art that would compromise the validity of one or more claims (X or Y categories of citation according to European Patent Office's convention: category X is applicable where a document is such that when taken alone, a claimed invention cannot be considered novel or cannot be considered to involve an inventive step; category Y is applicable where a document is such that a claimed invention cannot be considered to involve an inventive step when the document is combined with one or more other such documents, such combination being obvious to a person skilled in the art). Of those, about half still presented at least one out-of-field citation, but only 0.3% (29 out of 10621) had *only* out-of-field citations. Even if we included non-invalidating citations (A category and similar), we reach only 0.9% of applications with out-of-field citations only.

Third, out-of-field citations are relatively more important in patent opposition (an opposition occurs when a third party challenges the validity of a patent; data for oppositions can also be found using the PATSTAT service). We found only 153 patent applications within the set that received an opposition. However, the percentage of documents opposed using out-of-field citations only now rises to 4.6% (7 out of 153), i. e., more than ten times the examiner's case.

We now turn to specific examples. Consider, for example, patent application EP1943975 (A1), about an *Holder for storage of surgical or medical equipment with filling template* and assigned to IPC subclass A61B (diagnosis, surgery, identification; a drawing of the invention can be seen in Fig. 40.1a). The only critical prior art (it received the X category) cited by the examiner during his/her search is US5379887 (A), about a *Method and apparatus for managing sewing machine spare parts* and assigned to subclasses B25H (workshop equipment) and D05B (sewing) (Fig. 40.1b). Although the application sectors are very different, the two documents obviously share the same main function, i. e., storage of objects. Reading the patents it is clear that they also share the additional function of displaying the correct position of objects within the box to the user. Similar functions often imply similar solutions, and indeed, as pointed out by the examiner, both patents recur for the display function to a template fixed to the lid.

As for EP 1479353 (A1) instead, a *Control panel* for electro-surgery devices, also filed under subclass A61B, the examiner has found only in-field prior art, such as for example patent DE3923024 (A1) about an *Electrosurgical apparatus with operating, display and safety device*. On the contrary, the patent application received an opposition citing the following three documents:

- DE10022588 (A1) an Electronic device under H04M (telephonic communication)
- de19951100 (A1) an Operating element, filed under H01H (electric switches) and with a clear automotive application
- WO0073867 (A1), an Indicator for a robotic machine, filed under various classes including A47L (domestic washing or cleaning) and concerning a robotic vacuum cleaner.

The documents belong to different sectors, yet they all perform the control and display functions in a similar way.

As a further example consider finally EP1670371 (A1), a *Transport device for sterile media* in A61B; the examiner cited, for example, the *Fluid jet blood sampling device and methods* of US 20020045912, still in A61B, but a competitor filed an opposition citing instead the *Flow control system for liquid chromatographs* of US4137011 (A) under, among others, F04B (positive-displacement machines for liquids; pumps).

Identifying out-of-field citations may be crucial for supporting patent litigation or for defending the competitive position against competitors. A strategy often adopted by attorneys that oppose a patent is to invoke the so called *general common knowledge*: if a solution is adopted in other industries, one should infer that it is largely known. It is, therefore, of crucial importance to carry out an extensive out-of-field search in order to anticipate potential arguments for opposition. Indeed, in a case we studied, there were similar solutions in at least seven (sic) different industries.

40.4.3 Case Study No. 3: Functional Crossover in Food Container Sterilization

As much as functions highlight connections between existing solutions in different sectors, they can be used to create a bridge to reach the inventions yet to be invented, thus fostering the innovation process. Patents can be a very interesting source of ideas to support

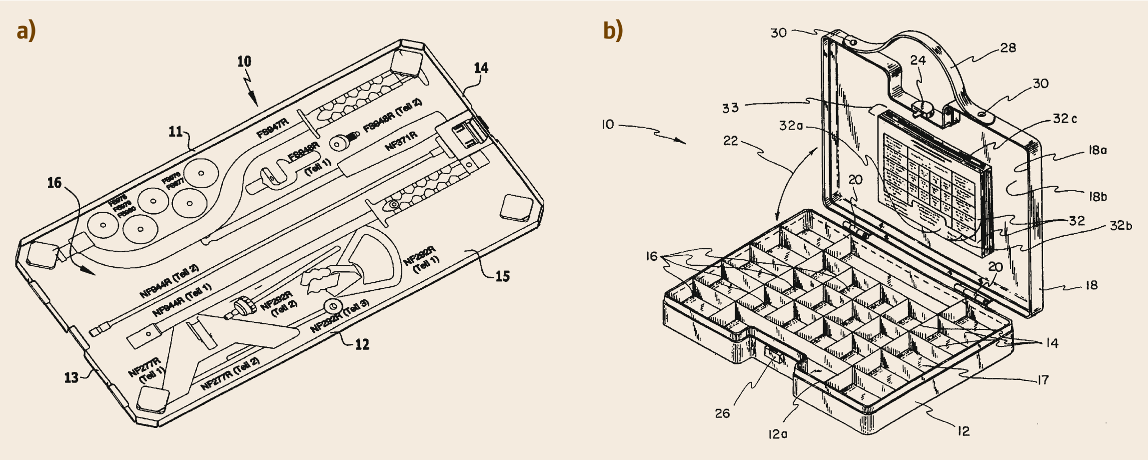

Fig. 40.1a,b Example of similarity of functions in patents from distant IPC classes: **(a)** comes from patent EP1943975 and represents a holder for surgical instruments (after [40.96]), **(b)** from patent US5379887, refers to an holder for sewing machine parts (after [40.97]). The two inventions belong to different industrial areas yet they perform the same function and indeed share also many features and part of the inventive step, as detailed in the text

the activities of inventors and designers in the concept design stage of the new product development (NPD) process. Indeed, understanding what has been created by others can spark creative solutions, in the form of variants or new combinations.

Going further, it is possible to use a technology traditionally developed in one industry to satisfy the needs of users in totally different fields of applications. This goes under the name of *crossover*, and it is a well-known way in which inventions are generated, consciously or not. For example, biomimetic is just a type of crossover, and while it is now a design discipline on its own, humans have always taken inspiration from nature for new inventions.

Crossover requires analogical reasoning, that is, the ability to identify the similarity between the deep structure of problems, beneath the surface of differences [40.98–100]. People capable of analogical reasoning discover similarity where ordinary people see only semantically irreducible problems.

Functional analysis offers a systematic approach to identify similarity across distant industries and products. It builds up abstract representations of the goals of products and technologies, that cut across existing solutions described in structural terms. In fact, the same functions may be found in completely different industries. Harnessing the functional approach coupled with a proper mining of the patent corpus is the most effective way to generate crossovers [40.85, 101, 102]. Several heuristics can be used for this purpose, such as the search for variants, the use of the same physical principles for different functions, the systematic search for synonyms and antonyms, and the like.

We applied functional analysis to the field of food container sterilization. The goal was to identify novel technologies, outside the focal industry. This challenge could not be addressed by relying on any of the search criteria discussed above; no patent classification, no list of companies or inventors, no industry classification, and no keywords were available, and if they had been available, they would not have allowed the discovery of the same result.

The preliminary stage was the formal definition of the main functions of a food container sterilizer (i. e., the destruction or removal of bacteria and other organisms harmful to humans). It is crucial that the functions come to be described in a clear and formal way. This requires a good understanding of the functional paradigm and can benefit from the use of a complete functional dictionary.

The full scale functional representation was then projected on the patent corpus in order to find those technologies that perform the functions, without imposing any restriction on the industrial sector. Following this approach, we identified as many as 50 patents about systems to sterilize materials and surfaces, outside the focal patent classes and industry classifications. In turn, these documents have been classified according to the physical effect underlying the patented technology, such as for example x-rays, gamma rays, plasma, ultrasounds, chemical agents, and so on (the latter classification can be performed in an automated way if a database of physical effects is available).

Table 40.4 shows a sample of results from this analysis.

Table 40.4 Sample of patents identified with an FPC in the field of food container sterilization

Cluster	UID	Title	Filing date	Assignee	Technical sectors
Magnetic field	US4524079_A	Deactivation of microorganisms by an oscillating magnetic field	1983	Maxwell Laboratories	Instruments/medical technology Chemistry/food chemistry Chemistry/biotechnology Chemistry/environmental technology
Micro waves + steam	WO9729016_A1	A method and an apparatus for surface sterilizing items and a system suitable for sterilizing bottles	1997	Clean-Pack Group	Mechanical engineering/handling
Alternate pressure	US6966345_B2	Method for durability treatment of a pumpable material as well as a device therefor	2003	Flow Holdings Sagl	Instruments/medical technology Mechanical engineering/handling Chemistry/food chemistry
Gamma rays	WO0043049_A1	Gamma-irradiation sterilized polyethylene packaging	1999	Pharmacia & Upjohn Company	Instruments/medical technology Mechanical engineering/handling
Ultrasounds	EP2550867_A1	Method for and device for control of microbes in food materials by means of vacuum and resonant ultrasound treatment	2011	University Of Miyazaki/Kaijo Corporation	Chemistry/food chemistry

In Table 40.4 we list a few patents that were identified through the functional approach. They are also classified according to the correspondence between IPC classes and technical sectors developed by *Schmoch* and co-authors [40.103, 104]. It is clear from the table that highly relevant patents are found in industries and technical sectors that have no proximity to the food or packaging industries, such as, for example, medical technology.

After the identification of these patents, it was possible to set up brainstorming sessions aimed at exploring the underlying inventive principles and their relevance for the sterilization of food containers. This activity led to the validation of a large number of product concepts: as many as 55. These concepts were then subject to a process of screening and refining, until a small number was selected for implementation.

40.5 Conclusions and Future Research

The notion of function is at the core of the patent system. However, the legal and economic doctrine of patents, as well as professional practice, have largely ignored the theoretical and empirical developments of this notion in fields such as engineering design and design theory.

It is time to make an effort to put this notion at the core of analysis and practice. We have shown that the theoretical treatment of the notion is now mature, from a philosophical and epistemological point of view, as well as in engineering disciplines. These conceptual developments offer a robust background for a systematic analysis of the notion of functions in the legal and economic doctrine of intellectual property. In turn, this might offer ground for more systematic and formal procedures of patent search carried out at patent offices.

We have also shown that the recent and impressive developments in computational linguistics and the automatic treatment of texts open the way for new applications.

In this chapter, we have suggested the integration between current approaches to patent classification and the functional classification approach. It is clear that a full scale, *pure* functional classification of all existing patents is a long term goal, requiring further research over many years. However, a promising intermediate step might be to compare existing classifications with functional classification in limited, controllable, new areas of technology that require dedicated efforts of updating. Are the current approaches to classify patents, say, in the field of Industry 4.0, appropriate? Or in the field of FinTech? It would be useful to develop a formal framework for the comparison of alternative approaches, based on well-defined metrics drawn from computational linguistics and from graph theory (e. g., precision, recall, predictive power, number, and share of relevant out-of-the field citations identified, and measures of distance in the classification graph).

Another long term goal, which is, however, made realistic by the current developments in computational linguistics, is the definition of formal measures of technological distance and its semi-automatic computation.

Keeping the full scale functional classification as a long term goal, other short term applications are already very promising. In the field of patent search and patent analysis, the functional approach allows us to overcome the limitations of existing classifications, by identifying several relevant inventions that would remain hidden otherwise. Applications to patent search will prove valuable in prior art analysis, freedom to operate, and litigation. Patent offices might find it useful to incorporate it in their routine procedures.

The functional approach offers new perspectives in fields of analysis that use patent datasets for a variety of purposes. It is a powerful tool for the profiling of emerging technologies, beyond existing technology or industry boundaries. It allows the identification of lateral opportunities, analogical solutions, and crossover applications in innovation management. It supports a systematic projection of technologies in the future, in studies of technology foresight, mitigating the cognitive and motivational biases of experts.

A promising direction is the use of large scale functional dictionaries, based on deep engineering domain knowledge, coupled with powerful linguistic tools. Given the success in developing large scale dictionaries based on functions, the same approach should be followed in the effort to reach saturation in dictionaries that deal with stakeholders/users, advantages and disadvantages, and physical descriptions of structures and behaviors.

A large research agenda is therefore open.

Acknowledgments. The authors would like to thank Dario Brugnoli, Giovanni De Santis, Tommaso Pavanello, and Corrado Taviani for support in the development of the case studies.

Andrea Bonaccorsi

DESTEC
University of Pisa
Pisa, Italy
andrea.bonaccorsi@unipi.it

Andrea Bonaccorsi is Full Professor of Economics and Management at the School of Engineering of the University of Pisa. He has authored more than 60 articles in the most important journals in economics of science, technology and innovation. His main research interests are: economics of science (analysis of higher education institutions based on microdata, dynamics of science, research evaluation), and economics of technology (functional analysis, technology foresight, patent analysis).

Gualtiero Fantoni

Department of Civil and Industrial Engineering
University of Pisa
Pisa, Italy
g.fantoni@ing.unipi.it

Gualtiero Fantoni is Associate Professor of Advanced Manufacturing Systems and New Product Development at the Engineering Faculty of the University of Pisa. He received a PhD in Automation, Robotic and Bioengineering from the University of Pisa (2005). His research includes smart grippers in the field of robotics applied to manufacturing and assembly, technical text analysis, and smart programming tools for optimizing production and predictive maintenance.

Riccardo Apreda

Erre Quadro s.r.l.
Pisa, Italy
apreda.riccardo@gmail.com

Riccardo Apreda is Co-founder, former MD and currently Head of R&D of Erre Quadro Srl, a company specialized in software and services for IP valorisation. He received a PhD in Physics from the University of Pisa (2003). His research focuses on development of algorithms for analysis of technical texts; he is also interested in the theory of Engineering Design, in technology foresight and in methodologies to support the innovation process.

Donata Gabelloni

Erre Quadro s.r.l.
Pisa, Italy
d.gabelloni@gmail.com

Donata Gabelloni works at Erre Quadro Srl, Pisa, Italy, where she manages R&D projects on semi-automatic tools for patent analysis and on how to use data extracted from patents to map technologies and trends. She holds a PhD in Management Engineering from the University of Roma Tor Vergata. Her research interests are methodologies for new product development, functional analysis and semi-automatic analysis of technical documents, such as patents.

Part F Patent System, Patents and Economics

41. Computer-Implemented Inventions in Europe

Peter Neuhäusler, Rainer Frietsch

The dispute between proponents and opponents of the patent system has been especially visible with regard to the patenting of computer programs. Different developments have resulted in the fact that there are large differences in the patent practices between the European Patent Office (EPO) and the U.S. Patent and Trademark Office (USPTO). While software *as such* is patentable at the USPTO, the EPO prohibits patenting of pure computer programs and only allows patenting of computer implemented inventions (CII).

In this chapter, we investigate the differences between the European and American patent systems with regard to patenting computer programs by also addressing the historical developments that have resulted in the national differences. Based on these considerations, a definition of CII is derived, which enables us to carry out empirical analyses.

By applying a conservative estimate, our results show that the share of CII filings at the EPO lies at around 25% at present, while at the USPTO a current margin of approximately 33% is reached. Thus, at least every fourth patent at the EPO and every third patent at the USPTO is a CII filing. In order to take account of the factual (technological and economical) relevance of computer-implemented inventions, we argue for clear rules with regard to patenting CII, as they are essential to reduce uncertainties and provide the relevant incentives for innovation.

41.1 Starting Points

Patents and other intellectual property rights are the pillars of every innovation system and provide substantial support for technology development and economic growth of national economies [41.1]. When issuing a patent, the state grants the patent holder a temporary monopoly—usually up to 20 years—on the rights to utilize and commercialize a technological solution. In return, the patent applicant needs to publish all the information about the underlying invention [41.2–5]. This is intended to support investments in new technologies and innovations on the one hand, and increase planning security for companies and research organizations on the other. The disclosure obligation hereby ensures that the knowledge generated in the innovation process is made available to the public in order to spur technological spill-over effects. The basic intention of the patent

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_41

system is thus to promote inventions and innovations within a national economy and to contribute to developing international competitiveness.

Proponents of the patent system emphasize its planning security, the clarity of rules, and the resulting incentives for innovation. Opponents of the system (or parts of it), on the other hand, state that the creation of temporary monopolies slows down innovative activities and prevents competition of the best technological solutions. It is argued that innovation capacities could be enhanced by repealing patents or at least changing parts of the system [41.6–11].

This dispute between advocates and critics of the patent system has been especially visible with regard to patents for computer programs (for a more detailed discussion on software patents see *Blind* et al. [41.12–14]). Similar disputes, albeit with slightly different arguments, can only be found in the field of genetic engineering. Some critics suggest that software inventions are not inventions in the basic sense but rather discoveries that are fundamentally excluded from patenting. Others argue that computer programs do not have a technological content (or a technological orientation) and thus want to exclude software from patenting. This has led to the fact that the patenting practices for computer programs differ across patent offices worldwide. At the USPTO, for example, software *as such* is patentable, while at the EPO, only *CII* can be patented, i. e., computer programs need to have a *technical nature* or generate a *technical effect* in order to be patentable. Consequently, at the dimension of technological content a gray zone between technology and software emerges, which is further enhanced by differing rules at different patent offices for defining software patents or CII and dealing with their patentability. This has become particularly apparent between European and American patent laws.

The objective of this chapter is to first of all to describe the pros and cons of patent systems from an economic perspective and discuss the differences between the European and American systems with regard to patenting software and CII. We will focus on patenting CII and software by also addressing the historical developments that have resulted in the national differences with regard to patentability. In a second step, we will provide a definition of CII and describe its operationalization for use in patent statistics. Finally, empirical trends in CII patenting are presented, and we will demonstrate the differences in the patenting practice for CII at the EPO and the USPTO. In sum, we try to obtain an overview of the current facts and backgrounds with regard to CII patenting to be able to understand their economic implications.

41.2 A Brief Introduction to the Economics of Intellectual Property Rights

One of the oldest questions of public innovation and technology policy is how to protect the results of innovation against uncontrolled use by third parties [41.15]. This is justified by the fact that innovation can be regarded as one of the key factors for economic growth on a micro as well as on a macro level [41.16–20]. The successful completion of an innovation process, however, is not a sufficient condition for attaining the expected benefits of innovation. Companies must also be able to appropriate their innovative results, i. e., they need to prevent competitors from imitating [41.21].

The reason for this lies in the nature of innovations or (technological) knowledge in general. Unlike traditionally produced and traded goods, (technological) knowledge represents public goods, i. e., it is non-rivaling and non-exclusive [41.5, 22]. The aspect of non-rivalry implies that increasing the number of users of technical knowledge does not limit its value, since anyone with the specific knowledge has the potential to achieve the same performance. The aspect of non-exclusiveness implies that third parties cannot (easily) be excluded from using certain goods. Therefore, third parties can reproduce knowledge without further marginal costs, which results in a suboptimal supply of (technological) knowledge, as the original expenditure for research and development (R&D) cannot be recouped [41.23].

Consequently, the production of knowledge and its commodification into an innovation suffers from market failure [41.24]. In the context of economic rationality, companies lack the incentives to invest in R&D. Thus, state intervention and the creation of suitable institutional framework conditions are necessary to enable the generation of private innovation rents and provide incentives for future (private) innovative efforts. The most important institutional structure to prevent this market failure and support the public goods of knowledge generation is the intellectual property rights (IPR) system. It guarantees the IP holder exclusive rights on the generated knowledge and a mechanism to pursue violations of their intellectual property, at least for a certain amount of time [41.15]). This can be understood as an incentive for innovators to develop new knowledge and new technologies. In exchange for this legal security, intellectual property rights are coupled with a disclosure obligation. All the information protected by a property right must be made publicly available after a certain time period (usually 18 months), allowing the diffusion of knowledge and potentially generating spill-over effects. Intellectual property rights are, thus, a state-guaranteed instrument that grants the innovator a monopoly for a specific time period in exchange for making the knowledge available to the general public [41.25].

41.2.1 Patent Law and Supranational Patent Systems

Basic patent law was already being applied in the eighteenth century in many countries and still counts as one of the major prerequisites for private sector innovativeness [41.15]. The protection of a patent is always limited to a national territory. If a company registers a patent in Germany, for example, the underlying invention is only protected in Germany. To obtain the same protection in the USA, a second patent with the same content has to be registered at the USPTO [41.5].

As the European market converged, however, a European patent procedure was introduced in 1978. Since then, it has been possible to apply for a patent at the EPO and designate countries for the patent to be forwarded after is has been granted. If the patent is granted, the patent protection is subsequently converted into national patents [41.5]. The European patent system can, thus, be regarded as a *system of systems* [41.26]. Besides patent law at the European level, however, each state that signed the European Patent Convention (EPC) still has its own national case law with regard to patents [41.26].

In addition to the EPO, there is the *Patent Cooperation Treaty* (PCT), which enables applicants to register their patents in a standardized procedure in all the countries that signed the PCT. The responsible authority is the World Intellectual Property Organization (WIPO) in Geneva. Unlike the EPO and other patent offices, the PCT procedure is only a filing procedure. After being filed at WIPO, patents are forwarded to national or supranational offices to be examined and (potentially) granted.

Patents are still mainly used as protection against imitation and for market security. However, the patent system's existence leads to possibilities to use patent protection for other—strategically motivated—purposes [41.27]. These strategic motives have been gaining importance since the beginning of the 1990s [41.28–31]. Following *Arundel* and *Patel* [41.32], all motives that go beyond protecting one's invention in order to appropriate the benefits based on this invention can be defined as strategic. The most frequent strategic motivation is blocking competitors by attempting to prevent other market players from using technical inventions in the same or neighboring fields of application. This is achieved, for example, by constructing what has become known as patent thickets. The consequence of strategic patenting is that the decision to patent has at least partially been decoupled from the technological necessities of protecting one's own invention against imitation by other players in the market.

41.2.2 Pros and Cons of the Patent System from an Economic Perspective

As mentioned in Sect. 41.2, intellectual property rights are an incentive mechanism of the state to promote the generation and diffusion of knowledge. However, so far, it has not been possible to empirically establish a clear causal link between stronger IPR and a growth of innovation [41.9]. Consequently, intellectual property rights have always been reviewed critically. The key question here is: Do intellectual property rights promote or obstruct innovation? Criticism is frequently formulated in the form of exceptions to the rule, i. e., limited to a type of innovation in specific technologies or based on the differences between small and large enterprises [41.9]. However, some of the critical considerations cannot simply be disregarded. The following section briefly outlines the positive and negative views on IPR and the economic arguments put forward by *Hahn* [41.9], *Guellec* [41.33], and *Mersch* [41.34], before we address the specific conditions for computer-implemented inventions in more detail.

The positive viewpoint usually starts with the already mentioned market failure when knowledge is being generated. There is no incentive for innovators to invest in knowledge production due to the non-excludability of the generated knowledge. This incentive has to be set in order to counteract insufficient investment in innovation in an economy [41.24]. It is further suggested that IPR (especially patents) also support the commercialization of inventions [41.35], by a) preventing imitation and acting as a signal to keep potential rivals out of the patent holder's own research fields or b) enable research to be conducted together with rivals (contractual agreements, licensing, etc.) [41.36].

Finally, due to the disclosure obligation, the generated knowledge is published relatively early after an invention has been made, which fosters sequential innovations and may lead to spill-over effects [41.37–41]. Furthermore, an invention is freely available to everyone after its right to protection has expired. In summary, it can be stated that intellectual property rights support knowledge generation, its commercialization, and its diffusion.

Critics of the patent system, on the other hand, usually present three partially interdependent arguments to demonstrate that intellectual property rights can also be obstructive to innovation. The first argument is aimed at the monopoly status of an IPR holder. The guaranteed monopoly—which is generally understood as an incentive to innovate—leads to an innovative output that is below a (socially) optimal level, since the monopoly holder has the possibility to set a price for an invention that lies (far) above its (estimated) costs. In this case, IPR would limit the diffusion of technologies and, therefore, also the diffusion of the generated knowledge ([41.9], based on [41.24]). A second line of argumentation that was decisively influenced by *Bessen* and *Meurer* for the US patent system [41.6–8] is that the costs of the patent system exceed its benefits. Costs mainly arise due to the legal costs of patent disputes that are caused, among other things, by patent thickets, i. e., unclear patent boundaries, which lead to the occurrence of overlapping patent rights. This argument is particularly valid when the behavior of private actors leads to significant social (legal) costs that have to be borne by the general public. The third argument concerns the already mentioned patent thickets and is of particular interest for new technologies, especially if these are complex ones that rely heavily on earlier technological developments, such as is the case, for example, in the field of software or biotechnology [41.9, 42]. Because this argument is frequently made in connection with computer-implemented inventions, the next chapter addresses this criticism in more detail.

41.2.3 Patent Thickets and the Tragedy of the Anti-Commons

Especially in high technology industries such as communications, computers, semiconductors, or biotechnology, where products are frequently protected by a large number of patents, and the innovation process is strongly sequential and cumulative, patents can lead to coordination problems that can result in significant costs [41.11]. A coordination problem occurs, for example, if a very broad *pioneer patent* is granted in an early phase of technology development. Although coordinated sequential research can still be carried out [41.35], this kind of patent can also represent a barrier to further innovation [41.9], since, at the very least, expenses for coordination and information exchange have to be carried. Although these costs can partly be minimized by early settlements, contracts, and license agreements, a pioneer patent can also have the effect that subsequent research results violate this patent, which, again, can potentially result in expensive patent litigation.

The lack of coordination can also lead to research results being generated multiple times. *Shapiro* continues this train of thought and talks about patent thickets defined as "[. . .] a dense web of overlapping intellectual property rights that a company must hack its way through in order to actually commercialize new technology" [41.11]. Many overlapping IPRs might hinder or even prevent new market participants from accessing certain markets, or lead to the fact that companies have to license a large number of property rights from a wide variety of different sources to commercialize their inventions, which may be a very time-consuming and costly undertaking [41.11].

Patent thickets may be formed unintentionally, but are often encouraged by companies acting deliberately. As already mentioned above, because patents can also be used strategically, companies frequently construct patent thickets around their own core inventions in order to preserve their own technological leeway and protect themselves against rivals who *design around* their core patents [41.27, 43]. This problem has been described more generally by *Michael Heller* [41.10, 44] as the *tragedy of the anti-commons*. It can be understood as a dilemma where many rights holders prevent an (optimal) socially desirable outcome [41.10]. Large patent thickets may lead to a product that cannot be produced, since many individually patented components held by different parties increase transaction costs and costs for the necessary licenses [41.10].

An additional problem in the context of patent thickets is the *hold-up problem*, which has also been addressed by *Shapiro* [41.11]. This addresses the issue that new products may violate an existing patent inadvertently, i. e., without knowledge about an existing patent, which may subsequently lead to unanticipated license costs or patent disputes.

As a solution to these problems, *Shapiro* [41.11] suggests cross-licensing, i. e., an exchange of property rights, and patent pools that issue license packages of one or several companies. This does not fully solve the problem, yet would lead to significantly reduced transaction costs [41.9].

41.3 Patentability of Computer Programs—Historical Developments and the Status Quo

Now that we have discussed the pros and cons of patent systems in general, we can turn to the more special discussion in the case of computer-implemented inventions. National patent systems differ strongly with regard to the patentability of software or computer-implemented inventions. This applies, in particular, to the USPTO and the EPO, as well as further national European patent offices.

41.3.1 The United States Patent and Trademark Office

Nowadays, software or more precisely *software-related inventions* are patentable at the USPTO. The patentability of software at the USPTO, however, has a long history, which will be summarized based on the work of *Evans* and *Layne-Farrar* [41.45] and *Cohen* and *Lemley* [41.46].

In the 1970s, software in the USA was viewed as being equivalent to mathematical algorithms or natural laws and was, therefore, not patentable. This changed, however, in 1981 with the United States Supreme Court case *Diamond versus Diehr* [41.47], which can be regarded as setting the precedent for today's software patenting practice in the US. Specifically, this case concerned a molding process for synthetic rubber, where software was used to control and monitor the respective process. The patent was granted based on the argument that a valid patent claim cannot be made invalid by the fact that a computer is involved. This ruling stipulated that the algorithm contained in the software is not protected as an abstract idea in isolation, but exclusively in its application (in this case, the molding of synthetic rubber). Software *as such*, however, was still excluded from patent protection.

This rule remained until a further precedence case occurred in 1994, namely *In re Alappat* [41.48], before the Court of Appeals for the Federal Circuit (CAFC). This case concerned a patent on an invention to display a wave form on a digital oscilloscope. The USPTO had previously declared this patent invalid, because it was not a *special purpose application*, and the same method would also be applicable on a general purpose computer. CAFC, however, regarded the patent as valid, as a general purpose computer would become a special purpose computer if it were programmed to perform specialized functions based on software instructions. Under this ruling, the claims of a patent only had to be designed in a way that a computer program is implemented on any given machine in order to be considered valid.

The remaining obstacle of "being implementable on a machine" was removed in 1995 (*In re Beauregard*, [41.49]), when a patent claim was approved (or was not refused) which protected the computer programs stored on a tangible medium. This meant that in principle software was patentable *as such* at the USPTO. In 1998, the ruling was further softened by the declaration of the invalidity of the *business method exception* in the *State Street versus Signature Financial* case [41.50], in which a *physical structure* was declared not to be necessary if a process or an idea provided a "useful, concrete and tangible result." Thus, and this is the case today, computer programs, software *as such*, and *(internet) business methods* are patentable at the USPTO even without a concrete physical application.

41.3.2 The European Patent Office

EPO was established through the EPC that was signed in Munich in 1973. The EPC came into force in 1977 and the EPO opened its doors in 1978. Since it opened, the EPO has become one of the most important and influential patent offices in the world. As was already stated in Sect. 41.2.1, the European patent system can be regarded as a *system of systems* [41.26]. Alongside European patent law, there are national patent offices that have their own patent law. However, because the national patent systems in Europe are very similar with regard to patenting computer-implemented inventions, the European patent system is described here as representative of the national economies in Europe.

In contrast to the USA, "programs for computers" as well as "plans, rules, and methods [...] for business activities", meaning what has become known as *business methods*, are excluded from patent protection at the EPO (Article 52(2) of the EPC). Yet, this only concerns software as such, which is regulated in Article 52(3) of the EPC. A product or process of a technical nature may be patentable even if the claimed subject matter defines or involves a procedure for a business activity or a computer program [41.51]. The distinguishing feature here is clearly the *technical nature* of an invention. If computer programs perform functions using technical apparatus, are based on technical considerations, have a technical effect, or influence the physical property of an apparatus [41.12] to the extent that a technical nature is given, such an invention is regarded as a computer-implemented invention by the EPO and is, thus, patentable. The exact definition of a computer-implemented invention by the EPO is [41.51]:

> An invention whose implementation involves the use of a computer, computer network, or other programmable apparatus, the invention having one or more features that are realized wholly or partly by means of a computer program is termed a computer-implemented invention.

This is founded on two decisions of the Technical Board of Appeals in 1998 (T935/97 and T1173/97, also known as *computer program product/IBM*) with regard to two patent applications by IBM, which can be regarded as landmark decisions for interpreting Article 52(2) and (3) of the EPC regarding computer programs [41.52]. Here, it was stated that a computer program cannot be excluded from patentability (T 1173/97)

> [...], if it produces a further technical effect which goes beyond the *normal* physical interactions between the program (software) and the computer (hardware)

This implies that software *as such* is still excluded from patentability at the EPO. Yet, there are difficulties with defining the *technical character* or the *technical effect* for patent examiners.

For this reason, in 2002, the European Commission put forward a *Proposal for a Directive of the European Parliament and of the Council on the patentability of computer-implemented* inventions [41.53]. The core of this proposed directive was to make the patenting conditions for computer-implemented inventions more transparent and more specific, but without granting special rights for CII. Instead, the "general patenting conditions should be defined for the specialized requirements of this field of application" [41.54]. Software *as such* and pure business methods should remain excluded from patent protection [41.55]. After several changes in September 2003, however, this proposal was rejected by the European Parliament in July 2005, which is why the decision of the Technical Board of Appeal is still valid at the EPO. This means that computer-implemented inventions can be patented, but only if they have a *technical character* [41.26].

41.4 Definition and Operationalization of Computer-Implemented Inventions

Now that we have a better overview of the recent legal situation with regard to patenting CII, some empirical analyses will provide further information to dig deeper into the economic implications of CII patenting. To this end, however, a technical demarcation of CII for the use within a patent database is necessary. This technical demarcation can be achieved in different ways, for instance, by using technology classifications (e. g., the International Patent Classification (IPC)) or text searches within patent documents.

However, a technical demarcation first of all requires a definition of computer-implemented inventions that can be operationalized. The definition used here is based on the works of *Allison* and *Lemley* [41.56], *Bergstra* and *Klint* [41.57], *Bessen* and *Hunt* [41.58], *Josefsson* [41.59], *Rentocchini* [41.60] and *Xie* and *Miyazaki* [41.61], as well as the definitions used at the *European Patent Office* [41.51] and the *European Commission* [41.53]:

> A computer-implemented invention covers every invention for which a computer, computer network, or other programmable apparatus is used and which has at least one novel characteristic that is realized wholly or partly by means of one or several computer programs. The invention can cover topics related directly to ICT (Information and Communications Technology), e. g., compiling back-ups, data compression, or it can be indirectly related to ICT and only used to control other appliances or devices. Although programs for computers are as such explicitly excluded from patentability (at least at the EPO), a product or a method that is of a technical character, i. e., produces a further (technical) effect beyond the normal functional interaction of program and computer, may be patentable, even if the claimed subject matter defines or at least involves a computer program.

41.4.1 Overview of Already Existing Operationalizations

Economists have already addressed the issue of a technical definition and demarcation of computer-implemented inventions in earlier works. These approaches, however, vary greatly across the respective studies. On the one hand, this is because it is difficult to classify computer-implemented inventions, which is even aggravated by the very technical descriptions of the inventions in patent documents. On the other hand, the objective pursued by the respective authors often differs, which is partly due to the different constraints with regard to patentability at different patent offices, as described above. Economists from the US, for example, often strive to cover the entire software field because software *as such* is patentable at the USPTO. Since this is not the case at the EPO, different definitions apply here.

Graham and *Mowery* [41.62, 63], for example, applied a definition of *software-related inventions* based on technology field classifications for their analyses at the USPTO. In total, 11 IPC-classes (IPC classes G06F 3/*, 5/*, 7/*, 9/*, 11/*, 12/*, 13/*, 15/*; G06K 9/*, 15/*, and H04L 9/*) [41.62] or 12 classes of the U.S. patent classification (USPC) (USPC classes 345, 358, 382, 704, 707, 709–711, 713–715, 717) [41.63], respectively, were applied for their definition. Their assumption was that the entire universe of software patents cannot be mapped exactly over time, but that the IPC or USPC classes used "provide longitudinal coverage of a particularly dynamic and important segment of the overall software industry." To increase the accuracy of their hits, Graham and Mowery additionally limited their analyses to patents of the 100 largest software companies in the USA.

Bessen and *Hunt* [41.58], however, argue in their analysis of software patents at the USPTO, that patent classifications are insufficient to identify software-related inventions, because it is not clearly visible from a patent classification whether the technology is actually a software-related invention. The authors of the study, therefore, use a broad keyword search in the patent specification and description, in which the words *software* or *computer* and *program* must appear.

A combination of several approaches, i. e., a limitation to certain patent classes and keywords appearing in the patent documents is also possible. This was applied by *Allison* and *Tiller* [41.64] in their USPTO study of software patents linked with internet technologies. Similarly, *Schmoch* [41.65] used several procedures—i. e., keywords, a fine-grained IPC class definition, a broader IPC definition, and the keyword *method*—and combined these procedures to identify software patents. He found that especially the keyword *method* led to an increase in the number of software patents. Another possible strategy to identify the relevant patents is to combine search terms with a limitation to companies producing software, as was carried out by *Chabchoub* and *Niosi* [41.66] in a study for American and Canadian companies.

A comparison of these demarcations by *Layne-Farrar* [41.67] (with the exception of *Chabchoub* and *Niosi* [41.66]) shows that *Bessen* and *Hunt* [41.68] identify by far the largest number of patents as *software patents*; the keyword approach, therefore, provides a very broad basis of results. However, *Layne-Farrar* [41.67] was also able to show that the search used by *Graham* and *Mowery* leads to misclassifications of software patents in about 10% of cases, where pure hardware was flagged.

Similarly to *Bessen* and *Hunt* [41.58], *Xie* and *Miyazaki* [41.61] use a keyword search to demarcate the relevant patents at the USPTO in a study of software-related patents in the automobile industry. In contrast to *Bessen* and *Hunt* [41.58], a larger number of keywords is used for the search within titles, abstracts, and patent claims. In addition, for each of the keywords used, *Xie* and *Miyazaki* [41.61] calculated the quality criteria of recall and precision to assess the accuracy of each individual keyword.

41.4.2 The Demarcation of CII

As a basis for the operationalization of CII in this paper, we draw on the work of *Xie* and *Miyazaki* [41.61], who evaluated the effectiveness of keyword search strategies for the identification of CII patents, employing a sample of embedded software-related patents in the domain of automobiles.

As a first step, we selected all the keywords with a precision value above 90% from the keyword list provided by *Xie* and *Miyazaki* [41.61] (Table 41.1). The precision measures the share of correctly identified elements in all identified elements, whereas the recall measures the share of all correctly identified elements in the total number of relevant elements. Precision, thus, indicates the accuracy of a method, while recall indicates its yield. Generally, an increase in precision implies a lower number of errors but also leads to lower recall rates and vice versa. This high-precision approach of *Xie* and *Miyazaki* [41.61] reduces the overall number of hits, but also means that there is a higher probability of only capturing patents that actually protect computer-implemented inventions. We searched for these keywords in the titles, abstracts, and claims patents of all patent filings at the EPO. Unfortunately, we did not have access to the patent claim data at the USPTO, which is why we could only search titles and abstracts here.

In a second step, the patent applications identified via the keyword search were crossed with the WIPO list of 35 technology fields [41.69]), in order to be able to calculate the shares of identified patents in total patent applications of the respective technology field. In computer technology and data processing, 74% of all filings were identified with our keyword search. This makes it clear that, as already indicated by *Layne-*

Table 41.1 List of keywords

Keyword	Recall	Precision
[Micro]processor	18.6	100
Chip	0.7	100
Comput% program	8.8	100
Controller	26.0	100
Data	31.9	100

Monitoring	10.3	93.3
Imaging	2.9	92.3

Source: Own presentation based on *Xie* and *Miyazaki* [41.61]. Note: Recall and precision are illustrated here when using the keywords in titles, abstracts, and patent claims following *Xie* and *Miyazaki* [41.61]. For the analyses here, only keywords with more than 90% precision were used. In addition, the keyword *information* was excluded from the demarcation because of too many Type II errors

Farrar [41.67], patents filed in the field of computer technology and data processing can partly be classified as pure hardware. Across all the other technology fields, the share of patents identified using keywords is much smaller. However, it is apparent that computer-implemented inventions can be found across the entire range of technology fields. Besides the fields related to electrical engineering, where the shares of CII patents are mostly above the 50% mark, there are comparatively high shares in medical technology (24%) and in mechanical engineering and automobile manufacturing (between 10 and 18%). Even in fields related to chemistry, shares of 4 to 6% were found. The scattering of patents across all fields indicates that any limitation to specific technology fields would result in a large number of CII patents being unidentified. Yet, a demarcation based purely on IPC classes would probably produce a large number of irrelevant hits, as discussed by *Layne-Farrar* [41.67].

In the third step, the full texts of ten patents per technology field tagged as CII by our keyword search were examined manually by experts in the field. It was found that none of the patents identified in the field *pharmaceutical products* were actually intended to protect a computer-implemented invention. To eliminate this erroneous classification, all the patents that belong exclusively to this technology field were excluded from the analysis, i. e., they were tagged as *pure hardware*.

In a final step, the distribution of the identified CII patents was calculated according to the classes of the IPC at the four-digit level. To a large extent, the results mirror the picture resulting from the analysis of the technology fields, i. e., we find a large spread of CII patents across technologies. During the manual identification, however, several filings that were suspected of protecting software *as such* (these were not necessarily granted) were found. In order to rule out that patents for software *as such* appear in our analysis, we excluded the patent classes H04L 29/06, G06F 11/30, G06F 17/24, G06F 17/30, G06Q 10, G06F 9/00, G06F 9/06, G06F 9/2, G06 9/3, G06F 9/4, and G06F 9/5 (including existing sub-classes) in case these were the only classes stated on a given patent filing. This does not imply that all these patents actually concern software *as such*, but only that including them would generate a larger fuzziness of hits. To this extent, our demarcation represents a conservative estimate, and its results in terms of numbers should be positioned at the lower end of the *real* distribution.

However, even with this stepwise procedure, we cannot rule out that our classification is incorrect for a certain share of patents, although the conservative approach should ensure that software *as such* is excluded to the greatest extent possible. As already argued by *Graham* and *Mowery* [41.62], the entire universe of patents for CII cannot be exactly identified, even though we have tried to eliminate potential sources of errors as far as possible.

41.4.3 The Database

The patent data for were extracted from the *EPO Worldwide Patent Statistical Database* (PATSTAT), which provides information about published patents from more than 80 patent authorities worldwide. We restricted our analyses to filings at the EPO and the USPTO. All the filings were counted using the year of the worldwide first filing, i. e., the priority year. This is the earliest registered date in the patent process and is, therefore, closest to the date of invention. For further analyses, we also introduced a distinction by the type of patent applicant, i. e., whether it is a large or small or medium sized enterprise (SME). In order to identify SMEs within the database, we matched PATSTAT with *Bureau van Dijk's* global company database *ORBIS*, where information on the number of employees is available. The matching routine is based on a probability matching (Levenshtein distance) of the name of the patent applicant in PATSTAT and the company name in ORBIS. For the identification of companies, we first of all excluded single inventors by comparing the names of the inventor with the name of the patent applicant. Subsequently, universities and other research organizations were manually coded, which resulted in a dataset featuring companies only. All companies with less than 500 employees were then classified as SMEs, and all others were tagged as large firms. Companies with no available employee information (or the ones that could not be identified during matching to ORBIS) were classified using their patent numbers, i. e., all the companies with less than 10 filing applications in the period 2000–2011 were coded as SMEs. In a final step, the lists of SMEs and large enterprises were manually checked and corrected. Besides the information on employees, the ORBIS database allows us to find out the sector classification (NACE codes—Nomenclature Statistique des Activités Énomiques dans la Communauté Européenne/Statistical Classification of Economic Activities in the European Community) of the respective companies. This enables us to analyze and calculate the spread of CII filings across economic sectors.

41.5 Empirical Trends in CII Filings

In this section, we will provide some empirical trends in CII patenting. This is first of all on the level and amount of CII patents to provide some evidence on the magnitude of CII in the U.S. and Europe. Apart from that, we will provide some further rather basic empirical facts about the enrollment of SMEs within the field and the spread of the technology across economic sectors.

The absolute numbers of CII filings at the USPTO and the EPO are depicted in Fig. 41.1. In 2012, about 120 000 CII patents were filed at the USPTO. There was an obvious growth in CII filings between 2001 and 2005, before the figures started to decline during the economic crisis of 2008 and 2009, which, however, is a trend that is obvious across all technology fields. In 2010, the figures started to climb again to reach their peak in 2012.

Similar trends are visible at the EPO, albeit at a lower level overall. It is interesting to note that although the trends are similar in relative terms, the search of keywords in patent claims leads to a much

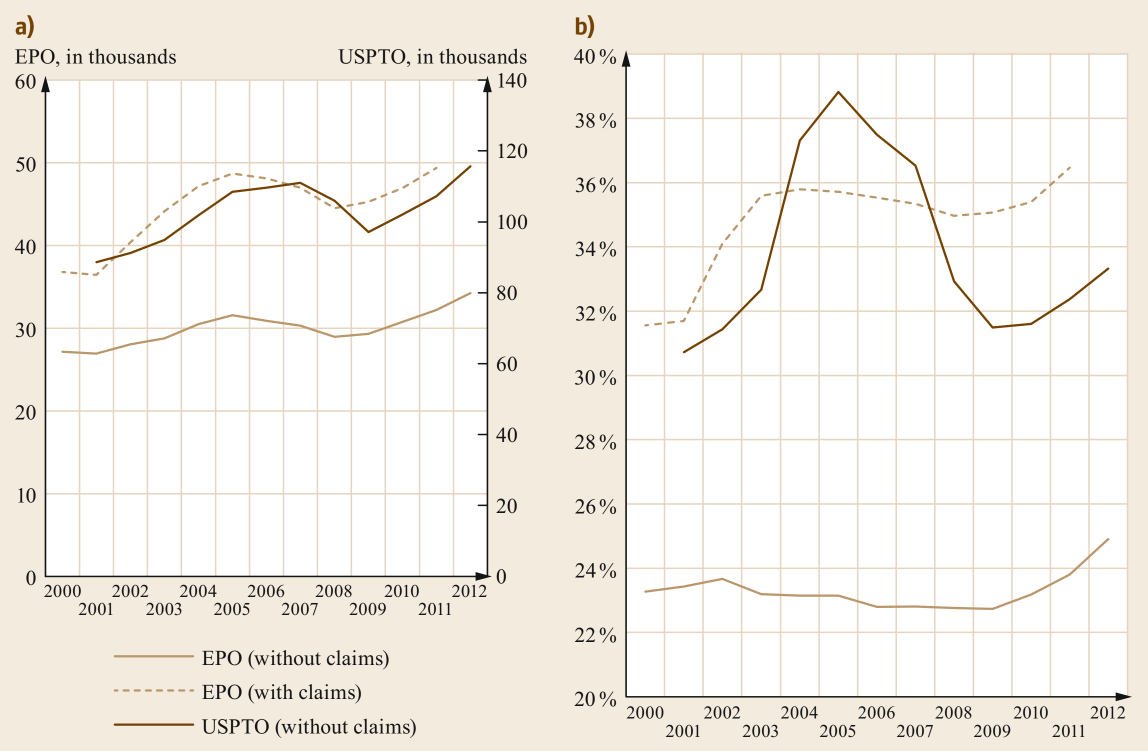

Fig. 41.1 **(a)** Absolute number and **(b)** shares of CII applications at the EPO and the USPTO. Source: EPO-PATSTAT, own calculations

larger absolute number of identified CII filings, implying that a) neglecting patent claims in keyword searches, especially in CII, delivers quite conservative, lower-bound estimates for the true amount of filings, and b) the *real* USPTO figures probably are larger than the ones identified in our search. If the search is limited to the titles and abstracts of the patent filings, the number of CII filings at the EPO amounts to a current margin of approx 34 000. If patent claims are included in the search, this figure increases to about 50 000 (in 2011).

When looking at the shares of CII filings in all filings (at the respective patent office), it can be found that about 32 to 39% of all applications at the USPTO can be classified as CII patents. Yet, the development is quite dynamic. While the shares increased steeply between 2001 and 2005, it declined almost as quickly again afterwards. After the economic crisis in 2009, however, we once again observe a rise in CII filings. The situation at the EPO, however, varies depending on the definition used. If patent claims are included in the search, a rising trend emerges that is similar to that in the US at the beginning of the millennium. However, the decline at the EPO is much less dramatic. If the search is restricted to titles and abstracts, it becomes apparent that the share of CII filings remains more or less constant over time at around 23% of all EPO filings until 2009, where an increase in filings can be observed. This indicates two things. The first one is that especially at the beginning of the 2000s, fewer IT-relevant keywords in the titles and abstracts of patents were used, and the claims delivered more detailed descriptions. The second one is that the rise in the shares of CII filings occurred after the crisis of the *new economy* and at the same time as the above mentioned European Commission's *Proposal for a Directive of the European Parliament and of the Council for the patentability of computer-implemented inventions*. Unfortunately, we do not have the data to control whether there are causal relationships between these events and the rise in CII shares.

Overall, however, it can be concluded that almost one-third (or more conservatively, i. e., without including claims, approximately one-quarter) of all patent filings at the EPO and at the USPTO are CII applications. We, therefore, do not target a marginal phenomenon but discuss a major share of patent filings at the respective offices. These figures on their own are evidence that clarification is needed with regard to the definition and demarcation of the *technical character* or *technical effect* of an invention at the EPO in order to take account of the factual relevance of such inventions. The patent system should provide clear rules for applicants (and potential applicants to decrease uncertainty and related costs).

This issue is especially relevant for SMEs. From Fig. 41.2, it becomes apparent that SMEs are underrepresented in the field of CII at the EPO and the USPTO. In other words, the share of SME filings on average is larger in total patent filings than it is in the field of CII. While the total share of SME filings at the USPTO was about 25% in 2012, SME shares in CII only reached 21%. For the EPO, the effect is even more strongly pronounced. Here, the average share of SME filings reached 29% in 2012, while the share of SME filings in CII was 23% (or 22% in the case when patent claims are used in the search).

Besides the dimension of size, the sectoral distribution (NACE Rev. 2, 2-digit) of CII patent filings offers interesting insights (Fig. 41.3). It can be found that CII patents are spread widely across economic sectors. Not only firms from the electrical industry, i. e., *computer, electronic, and optical products* and *electrical equipment* file CII patents. In fact, approximately 41% of all CII applications within manufacturing at the EPO orig-

inate from other industries (Fig. 41.3a). This further depends on the search strategy and the patent office under analysis. With claims in the search included, this share even rises to nearly 60%. At the USPTO (Fig. 41.3b), the share is somewhat smaller, with 33%. It can, thus, be seen as a cross-cutting or *general purpose* technology, where technology is not only used but also developed in other sectors. This is further backed by the Herfindahl–Hirschman index (HHI) calculations provided in the lower panel of the Fig. 41.3c. The HHI is a concentration measure ranging from 0 (equal distribution) to 1 (full concentration). Here, relatively small concentration values can be observed. The main non-electronics related sector where CII filings are produced is *machinery and equipment* which, with 17%, has a high proportion of CII patents. Nearly every fifth CII patent within manufacturing is thus filed by a company from the machinery sector. This share even becomes larger when taking into account the full-text of patents in the keyword search. Consequently, we can talk about a computerization of mechanical engineering, which is often summarized under the catchphrase *digitalization* or *Industry 4.0*. Computer technologies are not just applied here but also contribute to technological advance. Relevant shares of CII patents, however, are also found in the chemical industry (chemicals and pharmaceuticals), especially at the EPO. CII patents are, therefore, also filed by companies in economic sectors that, at least at first sight, have nothing to do with computer technology.

Finally, it is interesting to take a closer look at the legal status of CII filings (Fig. 41.4), especially against the background that software as such is not patentable at the EPO (this analysis could only be performed for the EPO, as the USPTO data was not available). First of all, it was found that CII patents are withdrawn more frequently than the average patent, although also the average withdrawal rate has increased since 2005. This might have two reasons. First, computers and related technologies mature rather quickly as technological progress in the field has been quite fast paced, especially in the past 20 years. It is, thus, a reasonable strategy for patent applicants to withdraw their filings before grant in case there are new technological developments to avoid further procedural costs at the patent office.

A second reason could be that signals from the patent office, i. e., preliminary search reports, communications, etc., which provide the applicant with the information that his or her patent only has a low chance of being granted (anticipated refusal), might lead to an early withdrawal. This is also reflected in the lower grant rate of CII filings, which, however, converged to a certain extent with the average grant rate in 2009/2010. With the data at hand, we are not able to test whether this has to do with a certain share of software *as such* that is filed at the EPO. Yet, the higher withdrawal and smaller grant rate at least point in this direction.

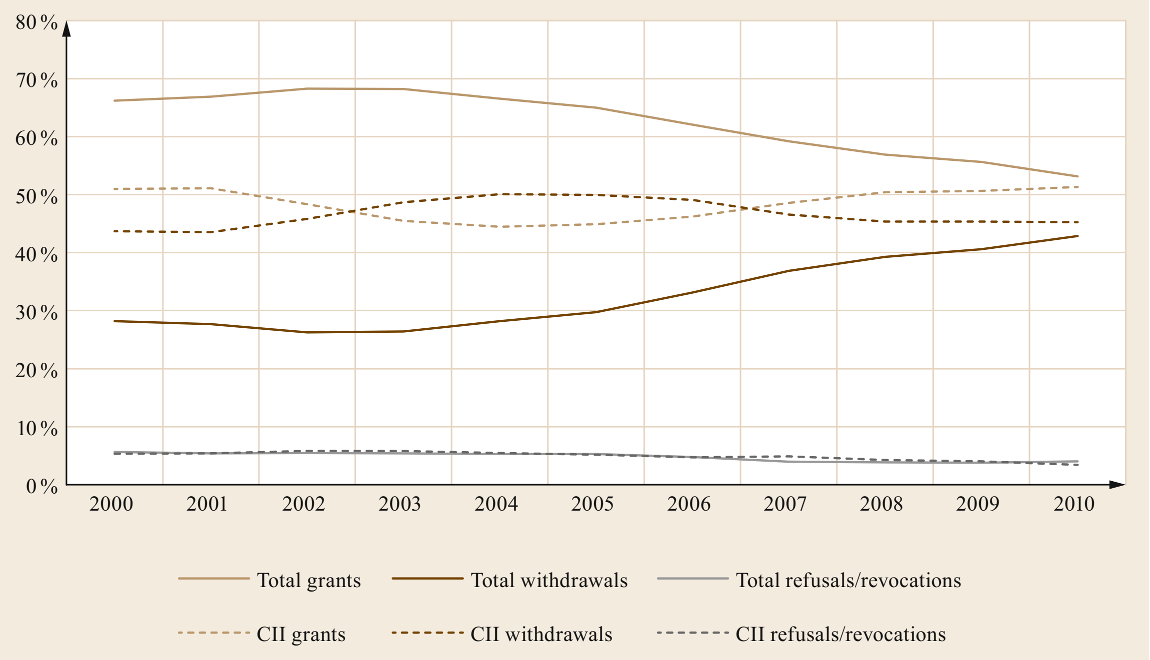

Fig. 41.4 Legal status of CII filings at the EPO. Source: EPO-PATSTAT, own calculations

41.6 Summary and Implications

With regard to patenting computer programs there are still large differences in the European and the U.S. patent system. While software *as such* can be patented at the USPTO, the EPO prohibits patenting pure computer programs. The distinguishing feature for the EPO is the *technical character* of an invention. A computer program is only patentable if it is of *technical nature* or has a *technical effect* that goes beyond the *normal* physical interactions between a program (software) and a computer (hardware). A product or process of a technical nature may, thus, be patentable even if a computer program is included.

These differences are, of course, reflected in the numbers of CII patents being filed. We applied a conservative estimate, which places the share of CII filings at the EPO at around 25% at present, while at the USPTO a current margin of approximately 33% can be reached. Unfortunately, data availability limits this analysis to the EPO. However, using the EPO figures as a benchmark, we would expect even higher shares for the USPTO when including the patent claims in the search. It can, therefore, be concluded that at least every fourth patent at the EPO and every third patent at the USPTO is, in fact, a CII filing, i. e., we are indeed talking about a major share of filings at the respective offices.

In addition, we found that CII patents are filed more often by large enterprises than by SMEs. In comparison to the total patents, CII shares are over-represented in the portfolios of large firms. CII patents are also widely spread across economic sectors. Not only firms from the electrical industry file CII patents. Computer technologies are to a large extent not only used, but also produced by firms from other sectors, mostly within the machinery industry. However, we should not focus solely on the *computerization* or *digitalization* of machinery. Patents for computer technology can, to a greater or lesser extent, be found in almost every industry of the manufacturing sector, among them also the chemical and pharmaceutical industry.

These trends provide evidence that clarification is needed with regard to the definition and demarcation of the *technical character* or *technical effect* of an invention at the EPO, in order to take account of the factual relevance of such inventions. Clear rules are essential to reduce uncertainties and provide the relevant incentives for innovation. With regard to patenting computer programs, these seem to be at least partly lacking at the moment. This weakens the patent system, which is designed as an incentive mechanism to generate and diffuse knowledge and increase innovative capacity. Yet, the benefits of the system need to exceed its costs. Increased uncertainty, however, is a cost factor for patenting firms, i. e., for information search, etc., which might lead to *social* costs through the emergence of patent thickets that can lead to an increase in costly patent disputes. Overlapping patent rights can also block (further) technological developments, especially for new and complex technologies, which manifests itself, for example, in high market entry barriers for innovative companies. For products that consist of many single components, overlapping patent rights also raise transaction costs, e. g., due to high licensing costs or the (too) high risk of a patent lawsuit. This may also be a reason why especially small companies, which tend to lack the relevant resources, file relatively fewer patents for CII.

Overall, and especially given the backdrop of lower patent shares of SME—it must be ensured that planning security in the patent system is guaranteed by clear and transparent rules. This starts by defining the *technical character* of an invention at the EPO. Taking this argument a step further, it would be desirable to have uniform rules for CII patenting worldwide to reduce transaction costs and ensure an innovation fostering patent system.

rainer.frietsch@isi.fraunhofer.de

Rainer Frietsch is Deputy Head of the Competence Center Policy – Industry – Innovation and Coordinator of the Business Unit Innovation Indicators at the Fraunhofer Institute for Systems and Innovation Research ISI. Rainer completed business training in wholesale and import/export trade. After that he studied Social Science at the University of Mannheim. He holds a PhD in Economics from the Karlsruhe Institute of Technology (KIT).

42. Interplay of Patents and Trademarks as Tools in Economic Competition

Sandro Mendonça, Ulrich Schmoch, Peter Neuhäusler

Integrated manufacturing-service systems have been receiving attention recently. The phenomenon of services-to-artifacts companies, namely those specializing in intermediate goods and complex equipment, is increasingly instrumental for long-run competitiveness in fast-changing, high-quality global markets. The debate has so far has remained largely qualitative, and the effective role and relevance of services is rather fuzzy. Against this background, this chapter brings in empirical evidence concerning the evolving business models of a variety of leading innovative manufacturing companies. For this purpose, over 50 manufacturing companies listed in the European Union (EU) research & development (R&D) investment scoreboard are analyzed in terms of patents and trademarks. In particular, trademark strategies are studied in greater depth, and they are sub-divided into *goods* and *services* marks and into *high* and *low* sophistication. Service marks are used as a supplement to patents, as the service component of industrial offerings is not covered by classic indicators of technical change. The economic data from the EU (EU Scoreboard R&D, sales, growth, employees, profits, or investment) are linked to the patent and trademark data in order to see which balance of goods and service capabilities leads to favorable economic results.

42.1 Pattern of R&D-Intensive Enterprises

A core topic of economic discourse is the identification and promotion of robust strategies for industrial success. In the field of innovation studies, and at least since *Schumpeter*, private industry is largely perceived to be at the forefront of the process of technical change and that substantial resources are at stake when pushing forward the innovation frontier. This process is known to be complex, that is, characterized by strong non-linearities [42.1] and feedback between heterogeneous players [42.2]. Competitiveness is, thus, defined as a pattern of economic achievement having its roots in the micro-level decision-making of innovative firms in tradable sectors.

Different approaches are followed to understand, measure, and provide forward-looking strategic guidelines on the phenomenon of sustained industrial innovation. In the economics of technical change, much work deals with the impact of the level of R&D on economic performance (see, e. g., the contribution by [42.3]). In innovation studies, more broadly defined, it has been known for some years that large global innovative industrial corporations nurture portfolios of productive knowledge, which are weaved into ever more sophisticated products [42.4]. More recent discussions deal with the integration of services in manufacturing firm offerings, and new evidence points to increasingly complex business models that deliberately make services part of manufacturing activities [42.5–7]. A further line of enquiry is related to the pivotal role of softer dimensions of corporate positioning, namely marketing creativity, delivery characteristics, and design innovation that support and promote harder, functional, and technological propositions [42.8, 9].

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_42

All these unfolding combinations of elements certainly contribute to the economic advance of manufacturing enterprises, but it has been difficult to assess their specific relevance as effects are often described primarily qualitatively. Against this background, we take large sophisticated firms as bundles of capabilities [42.10, 11] and try to quantitatively capture some of these features with innovation indicators [42.12, 13]. We try to derive stylized facts for a few leading industrial/service firms advancing global offerings based on engineering excellence but also branding capabilities.

In Sect. 42.2, we present our basket of indicators to map and measure industrial profiles and trends. In Sect. 42.3, we present the data, the sample, and sources. In Sect. 42.4, the commonalities and particular trajectories characterizing the sample are identified. Finally, in Sect. 42.5, we conclude by arguing how our approach and findings matter to what is a topical and increasingly policy-relevant contemporary agenda.

42.2 The Approach to Studying the Interplay of Patents and Trademarks

In order to quantitatively assess the elements behind industrial success we collected a variety of data for a sample of European manufacturing firms. In our case, these are engaged in intermediate goods and capital equipment. The empirical material includes economic data on sales, profits, and R&D investment on the one hand, and the *output* innovation indicators on the other:

- Patent applications
- Trademark applications.

In our study, patent applications are taken to represent purposeful knowledge activities conducted with a view to launching new or improved technological-based artifacts. We are aware that in many cases, innovative activities are based on R&D, but also other origins of innovation are possible, e. g., the expertise of workers or ideas of clients. It is also clear that the proof of the ultimate value of patents is contingent on market outcomes and can hardly be inferred from the technologies' characteristics [42.14]. The pioneering work of *Grilliches* [42.15] and *Patel* and *Pavitt* [42.16] have made these and other advantages and limitations well known. The new developments of globalization and informatization undoubtedly cause stress in terms of analysis, but the indicator can be used with workable adjustments so as to yield useful and important insights [42.17–19].

Trademarks stand for customer-relevant symbols and corporate signs that make the offerings of a firm distinct, traceable, and accountable in the marketplace. These intangible assets emerge from deliberate efforts to build visibility, differentiation, and reputation. An advantage of this type of data is that it can reveal to what extent and in which directions services are being developed as part of the overall business model of a firm. From the early work by *Schmoch* [42.20] and *Mendonça* et al. [42.21] to the recent reviews by *Graham* et al. [42.22] and by *Schautschick* and *Greenhalgh* [42.23], we have learned that trademark data yield relevant information regarding innovation and differentiation.

As trademarks refer to symbols or signs and not technology, they are not submitted to an examination process. It can be assumed that a new mark is created in the context of a new product, and indeed it can be shown that trademarks are closely linked to innovation [42.20, 21]. On the one hand, compared to that of patents, the classification of trademarks is much less detailed, so that for technology-oriented analyses patents continue to be the better option. Trademarks, on the other hand, reflect the orientation on active marketing and new product prospection. A specific advantage of trademarks is that they cover not only tangible products, but also intangible ones. Innovative initiatives by knowledge-intensive services industries seem, indeed, well covered by trademark evidence [42.24, 25]. By the same token, in principle, the service-orientation in manufacturing could also be picked up. Unlike patents, it has been observed that trademarks have a comparative advantage in smaller firms and start ups [42.26, 27]. However, trademarks can track big corporations as well. Hence, this exercise attempts to provide an illustration of how the service activities of larger manufacturing R&D performers can be analyzed quantitatively through trademarks.

42.3 Empirical Basis of the Analysis

We collected economic data on sales, profits, and R&D for a sample of manufacturing enterprises from the *EU Industrial R&D Investment Scoreboard* of the top 1000 EU enterprises [42.28]. In this database, the key economic data for top R&D investors are compiled according to their absolute performance in R&D spending. Thus, by definition, all enterprises in our sample are R&D intensive. As the criterion is the absolute investment in R&D, the implication is also that the focus is on larger enterprises.

We collected data for the 10-year period 2005–2014 for four specific *medium-high-tech* sectors:

- *Automobiles and parts* (20 companies)
- *Health care equipment* (12)
- *Electronic equipment* (9)
- *Industrial engineering* (21).

During the collection, it proved to be decisive to identify enterprises that are included in the dataset for the complete 10-year period. That is to say, data for many enterprises are not available for all the years. In particular, and for reasons not documented in the source, in the health care equipment sector most enterprises appear only for a few years. Thus, in the end, the dataset was somewhat small but sufficient for rough statistical assessments. In the spirit of the Scoreboard source, one advantage of such a limited dataset is that it was possible to collect patent and trademark data for consolidated groups, i. e., in addition to the core enterprises, their affiliates, identified through their websites, were included. Another advantage of a managing a small sample was developing an awareness of the variety of individual strategies, which generally disappear in very large samples.

For these 62 enterprises, we collected the patent applications for the observation period. We analyzed patent applications and not granted patents, as the grants for the last years of our period are not yet available. Furthermore, grants do not necessarily represent higher values, as other elements are relevant for grants [42.14]. The analysis of applications proves to be more appropriate for reflecting innovation activities. In order to make the patent applications of enterprises from different nationalities comparable, transnational patent applications were analyzed that represented a sample of patent applications with higher economic value [42.29]. For the search, the database World Patents Index (WPI) in the version of the host STN (Science Technology Network) International was used, as it is based on patent families facilitating the search for transnational patents. For transnational patent applications, applications at the European Patent Office (EPO) or international applications at the World Intellectual Patent Organization (WIPO) are analyzed without double counting. Both types of applications are available in WPI (for more details, see the Chap. 37 in this Handbook).

For our sample, we also collected trademark applications. Trademark applications for the following national territories were compiled, ensuring that key continents were covered, in particular, North America (Canada, the United States), Latin America (Brazil, Mexico), Asia (China, Japan, Malaysia, South Korea), Europe (including Switzerland and Turkey). Since these kinds of industrial companies are export-oriented, cross-country trademarking information was compiled used community marks (for the 28 member states) and international patents (the variable number of countries being designated through the Madrid system, an official procedure for applying and managing registration worldwide). For the Nice class breakdown, we divided the period into two 5-year periods and isolated only a few types of marks (US, EU, and worldwide) in the sample of firms.

42.4 Assessment of Indicators

In this chapter, some key patterns of patents and trademarks in the sample analyzed are described to aid the understanding of the basic structures of the sample and to illustrate the long-term trends of the use of patents and trademarks.

42.4.1 Some Key Patterns of Patents in the Sample Analyzed

There are 88 020 patent applications overall in our database for the period 2004–2015. The aggregate of companies applied for a total of 7604 in the year 2004 and 9324 in 2015, an overall increase of 22.6% in this 10-year period. However, as depicted in Fig. 42.1, development over time was not smooth. There were years of vibrant dynamism in the beginning of the observation period and years of lethargic performance at the end, as well as moments of negative growth.

We can just note that the evolution of the technological achievement of the firms is connected to broader economic factors and external conditions. The short-term perturbation between 2007 and 2011 may be

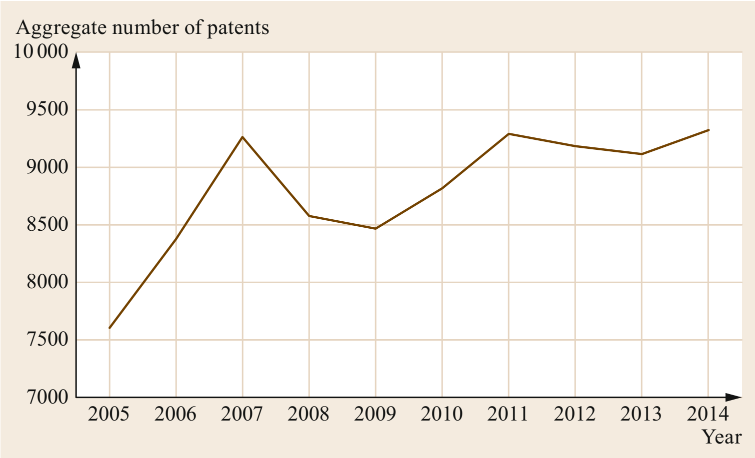

Fig. 42.1 Aggregate patent applications by the 62 firms in the sample. Source: WPI (STN), own computations

attributed to the global financial crises. From the patterns that emerge it is also possible to see that the slop of trend seems flatter after that, which hints at something of a long-term technological effect coming out of the economic crises. Only by 2014 did aggregate applications just surpass those of the peak year 2007. The ratio of patents to sales (m€) dropped from 22.6 in 2005–2009 to 19.5 in 2010–2014. It is as if economic austerity translated into technological austerity. This smaller emphasis on science and technology by companies weakened by adverse times may, of course, have rebound costs in terms of diminished future economic potential.

There is substantial variety in terms of industrial behavior (Fig. 42.2). For instance, the automobile and parts sector appears almost stagnant, whereas electronics is the most volatile. Moreover, health care equipment shows the most vibrant performance and, curiously, industrial engineering's strong growth was broken when the acute phase of the crisis was subsiding.

42.4.2 Some Key Patterns of Trademarks in the Sample Analyzed

There is a total stock of 12539 trademark applications in our dataset. This is much less than the number of patents, which shows that intermediate-input industries *do* trademark [42.20] but in much lesser volume compared with their patenting performance and compared with final consumer product industries [42.21]. There are, however, some interesting inter-industry variations (Table 42.1). For instance, the automobile sector appears to be quite patent *and* trademark driven, whereas electronics firms appear to emphasize both types of intellectual property rights less.

The evolution of trademark fillings was wobbly. As Fig. 42.3 shows, applications trended downwards in spite of a burst during 2011 and 2012. This burst was as large, but deflated rapidly. As Fig. 42.4 confirms, the trademark pattern contrasts with that of patents; patenting had a negative fluctuation from 2007 to 2011 but

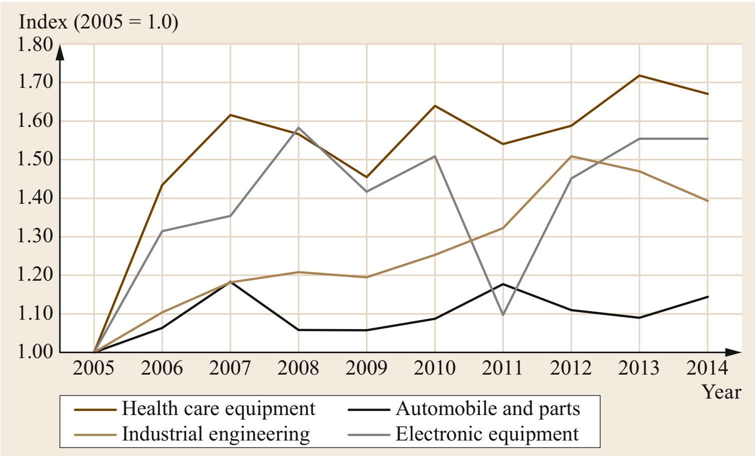

Fig. 42.2 Patenting per industry, index numbers (index base 2005)

Table 42.1 Distribution of total patents and trademarks by industry 2005–2014

	Patents (%)	Trademarks (%)
Automobile and parts	73	40
Health care equipment	9	29
Electronic equipment	3	8
Industrial engineering	15	23
	100	100

Table 42.2 Trademark applications and Nice class fillings by industry, percent change considering 2005–2009 and 2010–2014

	Applications (%)	Classes (%)
Automobile and parts	11.1	29.0
Health care equipment	−1.2	−34.1
Electronic equipment	0.4	−17.5
Industrial engineering	3.3	15.0

soon recovered, while trademarking jumped for a couple of years only to keep on sliding down, further distancing itself from the patenting trend. This observation is of interest, since research into the impact of the latest economic crisis is still unfolding [42.30, 31].

Certainly, these are aggregate figures; therefore insights are to be gained by breaking down per industry and type of trademark information. Some industries stagnated in terms of trademark applications, or even receded; only the auto sector pushed markedly up, 11.1% from 2005–2009 to 2010–2014 (Table 42.2).

In as far as trademarks are concerned, it is also revealing to consider class findings. In an analogue way to patents, the findings for trademarks are assorted into classes (the international Nice classification system) and typically to more than one class. These are selected by the applicants and carry a cost, which means this information is quantitatively and qualitatively rich. Table 42.2 shows that class requests tend to follow the signal of changes of trademark fillings (generally speaking, not always). For instance, the auto sector expanded applications but expanded the number of classes per trademarks even more, while the health technol-

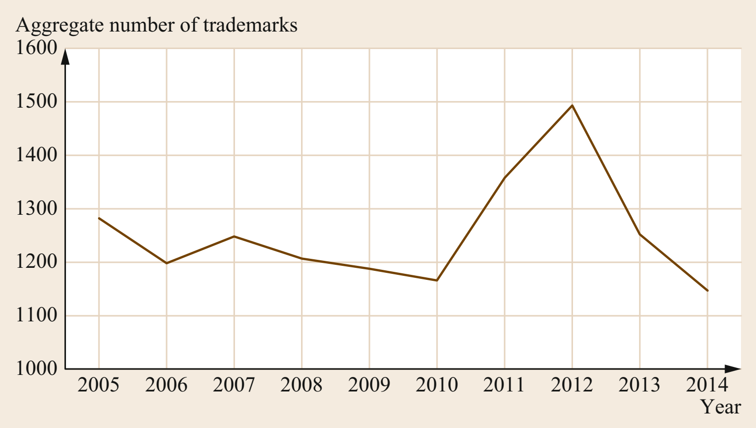

Fig. 42.3 Aggregate trademark applications by the 62 firms in the sample

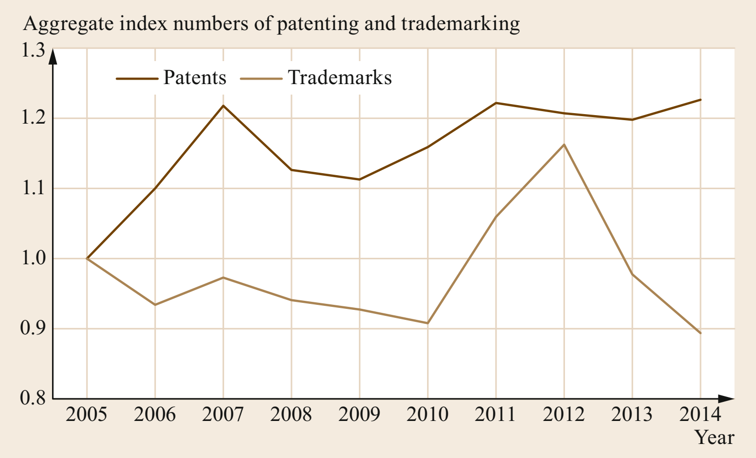

Fig. 42.4 Aggregate patenting and trademarking, index numbers

ogy sector diminished applications but even more so the number of classes per trademark.

Classes indeed yield another, finer level of analysis. It is possible to analyze, for instance, the dynamics of goods (classes 1–34) and services (classes 35–45). Pooling all the firms for all the years we find that 28.7% of all filled classes are service classes. As Table 42.3 shows, and as expected, there are different industry profiles and time dynamics. The health technology sector becomes the most service oriented, while the electronics business loses that status.

Next, we can re-classify class fillings according to their "sophistication" [42.32], especially to access if and to which extent manufacturing firms are active knowledge-based services [42.24]. In a way akin to the OECD (Organisation for Economic Co-operation and Development) typology, it is possible to re-organize Nice classes according their *technology* (in the case of goods) and *information* (in the case of services) *intensiveness*. This is done in Table 42.4.

From Table 42.4, it is clear that in our the sample, the firms' capabilities are mostly located in Nice classes that correspond to medium-high-technology (MHT) capabilities: 6214 trademark classes fillings of all the firms throughout the entire period. However, it should be borne in mind that these compose less than one-third of all the classes. This key stylized fact is important and is yet another instance underlining that *diversity* matters. It also reinforces previous observations that used patent as data and thus serve to portray these firms as *multi-knowledge corporations* (see [42.10, 11, 18, 33], which consider this a major advance of innovation studies in the last 20 years).

Table 42.3 Proportion (in percentages) of service trademarks in the overall portfolio of firms, by industry

	2005–2009	2010–2014
Automobile and parts	20.6	25.5
Health care equipment	35.6	36.2
Electronic equipment	43	36
Industrial engineering	28.0	27.9

It is notable that the second group of salient trademark classes are grouped into the *H-I* category. In fact, the single most trademarked individual class is Nice class 42 which refers to:

> Scientific and technological services and research and design relating thereto; industrial analysis and research services; design and development of computer hardware and software.

The other important services classes are classes 35 (business services) and 41 (education and recreation services). The nature of the complementarity between these types of service marketing resources with manufacturing capabilities is something worthy of further scrutiny (for a recent appraisal of the challenges of productive knowledge diversification, see [42.34]). This stylized fact suggests that the *profile* of knowledge configurations matter.

Finally, Table 42.4 also displays the dynamics of diversification as measured by corporate marketing resources. It suffices to note that the most sophisticated type of services are either the *most invested* into (the automobile sector, the engineering sector) or the least divested (the health care sector, the electronics sector). This trend is an important indication of the *direction* of diversification.

42.4.3 Patents, Marks, and Profitability

In this section, we will look at the link of patents and marks to profitability in order to understand which elements or combination of elements have an impact on profit. For this purpose, it is necessary to look at the specific characteristics of the dataset and run various analyses.

Key Techno-Economic Characteristics of the Sectors

The enterprises under analysis are part of four sectors characterized by high fluctuation and high competition. In the database of the EU scoreboard, the number of

Table 42.4 Scope of *sophistication* among the 62 firms, structure, and changes

	Pooled industry (absolute number)	Automobile and parts (change) (%)	Health care equipment (change) (%)	Electronic equipment (change) (%)	Industrial engineering (change) (%)
HT	5843	*28*	*−27*	*−8*	*17*
MHT	6214	*10*	*−23*	*−9*	*2*
MLT	1256	*48*	*−7*	*−38*	*35*
LT	1419	*47*	*−46*	*9*	*59*
H-I	3653	*75*	*−27*	*−26*	*45*
L-I	1850	*40*	*−56*	*−46*	*−13*

The *pooled industry* column displays all the data for all the companies for the period 2005–2014; percentages in *italics* are variations rates of class fillings between 2005–2009 and 2010–2014. *HT* high-tech, *MHT* medium-high-tech, *MLT* medium-low-tech, *LT* low-tech, *H-I* high-information-intensive, *L-I* low-information-intensive.

entries and exits within the four selected sectors is quite high. The variety within our dataset is still considerable, as the list of average, minimum, and maximum values for the different enterprise features clearly depicts (Table 42.5).

There are remarkable differences between the sectors along economic lines: The average profit rate (profits over sales) in health care is 13.0, in industrial engineering it is 7.8, or the average R&D rate is 8.2 in electronic equipment and 4.5 in industrial engineering, the average volume of sales in this period is 49.9 billion Euro in the automobile and parts sector, and 18.3 in electronic equipment. This variety shows that the conditions in the different sectors are quite specific, so that the values of the optimal economic performance for the different parameters may differ by sector.

Table 42.5 Features of the enterprise sample by sectors, 2005–2014

	Average	Min.	Max.
Total sample			
Sales	49.9	1.6	537.5
Profit rates	8.8	−31.8	27.3
R&D rate	5.4	1.1	14.9
Patents/sales	19.7	0.1	69.0
Product marks/sales	7.8	0.5	25.4
Service marks/sales	3.1	0.0	23.6
Automobile and parts			
Sales	117.4	4.7	537.5
Profit rates	5.8	−0.4	21.1
R&D rate	5.0	1.3	9.8
Patents/sales	17.1	0.3	42.0
Product marks/sales	5.0	0.5	23.7
Service marks/sales	1.5	0.1	5.1
Health care equipment			
Sales	31.1	2.5	143.0
Profit rates	13.0	2.4	20.9
R&D rate	6.2	1.8	11.4
Patents/sales	21.0	1.8	69.0
Product marks/sales	9.3	1.1	23.8
Service marks/sales	2.5	0.6	6.7
Electronic equipment			
Sales	18.3	3.2	65.7
Profit rates	8.3	2.0	20.4
R&D rate	8.2	1.1	14.9
Patents/sales	21.7	0.1	63.7
Product marks/sales	11.0	1.3	49.4
Service marks/sales	7.0	0.3	23.6
Industrial engineering			
Sales	35.6	1.6	89.9
Profit rates	7.8	−24.4	19.2
R&D rate	4.5	1.5	11.7
Patents/sales	20.6	4.7	60.6
Product marks/sales	8.2	0.8	25.4
Service marks/sales	3.2	0.5	18.3

Even within a sector, the parameters vary considerably, even for enterprises with similar products. A good example is that of producers of tyres, which are part of the automotive and parts sector. Tyre companies figure among the most vibrant and the most troubled of the automobile sector: Continental's sales grew by 136% between 2004–2009 and 2010–2014, while Pirelli practically stagnated at a rhythm of 4%.

Analysis of the Link of Profitability to Patents and Marks

For the analysis of the link of profitability—as a performance indicator—to patents and marks, the numbers of patents, product marks, and service marks were standardized by sales in order to compensate the different enterprise sizes. The computations were made for the 62 enterprises for the periods 2005–2009, 2010–2014, and the whole period 2005–2014. First we calculate specialization, e. g.,

$$\text{profit rate index} = \frac{\text{company profit rate}}{\text{average profit rate of the respective sector}}$$

to see whether the profit rate is above or below average. In order to eliminate the specific conditions in the four sectors, all data were normalized by the sector averages of the different parameters in the respective observation periods leading to a range of values between 0 and infinity, with 1 as a neutral value, i. e., values equivalent to the averages. As for this indicator, the values in the range of 0–1 are very concentrated; they were transformed to a symmetric scale, where the range is between −100 and +100 and the neutral value is 0.

$$\text{Trans profit rate index} = 100 * \text{tanhyp}(\ln(\text{profit rate index}))\,.$$

This procedure is equivalent to that used for specialization indices, see, e. g., [42.35, p. 7].

The following analyses were conducted:

1. Linear regressions between profit rates and patents/sales, product marks per sales, service marks per sales, total marks/sales, and share of service marks within total marks.
2. Lagged correlations between the parameters of 2005–2009 as to the profit rates of 2010–2014.
3. Limitation of the analyses on enterprises with profits above average in order to see whether these enterprises have specific features.
4. Analyses without outliers, i. e., without the upper and lower 5% of the cases, in order to check the robustness of the regression analyses.

As for linear regressions, the values were generally positive for 2005–2009, but on a very low level, and negative for 2010–2014. The lagged correlations did not lead to better results. The most positive regression results were achieved for enterprises with profits above average for the link between profit rates and product marks/sales and total marks/sales for the period 2005–2009 ($R^2 = 0.428$ and $R^2 = 0.423$, both with a significance level at 5%). This suggests that enterprises with high profit rates distinguish themselves from other enterprises by an explicit use of marks.

These analyses invite critical appraisal. The results may be explained by a few major reasons. First, it is reassuring that the correlation between R&D rate and patents/sales is positive with a coefficient of 0.5. Thus, there is a positive link, but other elements such as inventions based on sources other than R&D or different propensities of enterprises to patent play a role as well.

Second, the correlation between the variables and the profit rates are generally not linear, but rather quadratic. When doing the computations for the sample without outliers, the quadratic correlation for patents/sales exhibits an increase until the average level of 1 and a decrease for values above 1 (Fig. 42.5). This pattern tells a story of companies struggling if they have too few patents (perhaps not signaling that they are technological players) or too many (perhaps employing too many resources in strategic patenting, a behavior that could eventually be costly in terms of reputation). The implication is that there would be an optimal value for patents/sales. The relation seems to be the opposite for service marks over sales, meaning that some manufacturing companies can fare very well with a small number of very powerful service brands (say, ElringKlinger) or with a massive array of service brands (say, Nokian Tyres). The same outcome is found for the analysis with the non-parametric Lowess estimator, which approximates the sample locally. The LOWESS (locally weighted scatterplot smooting) estimator shows a roughly similar structure for product marks/sales, service marks/sales, and total marks/sales.

These correlations appear to be quite weak. This may be a consequence of the small sample of enterprises. With a larger sample, stronger correlations would probably have been found. Nevertheless, the small sample brings out the considerable variety in the behavior of firms, which would have been overlooked in a larger sample.

Finally, methodological caveats have to be taken into account. All enterprises of our sample may be considered as competitive, as they have survived for a longer period in competitive markets. Therefore, parameters other than profit rates may be more appropriate to reflect economic success, especially when there is evidence of curvilinear relationships [42.36].

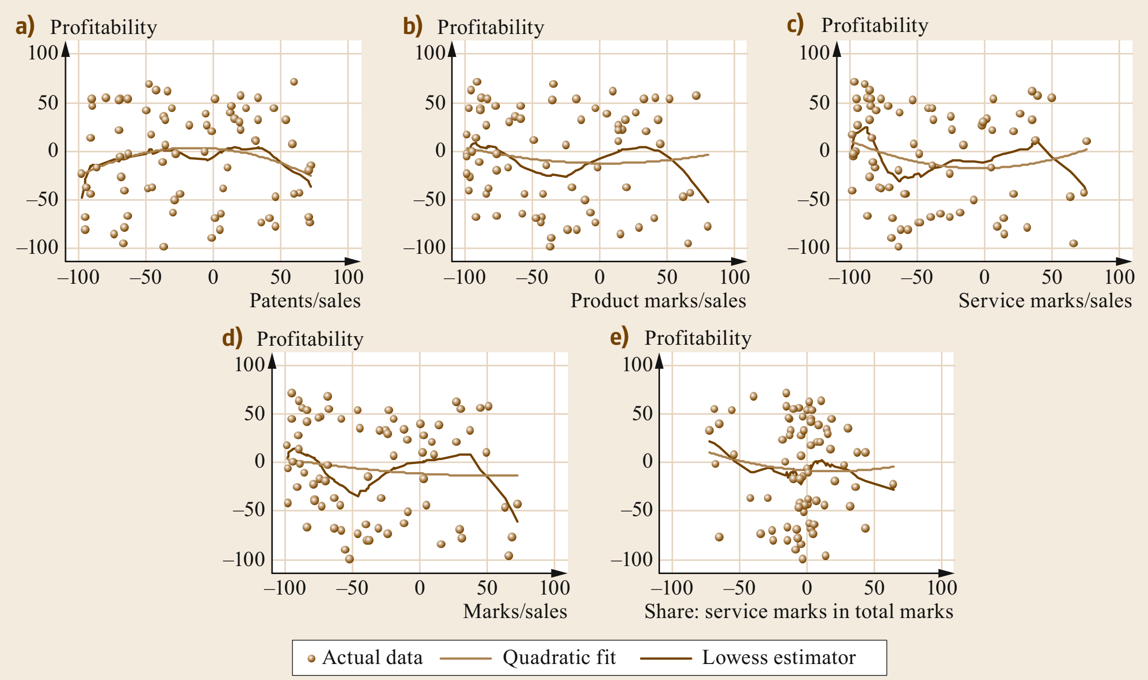

Fig. 42.5a–e Graphical representation of the relationship between profitability and various variables (outliers excluded). **(a)** Patents/sales; **(b)** product marks/sales; **(c)** service marks/sales; **(d)** marks/sales; **(e)** service marks in total marks

High absolute profits despite moderate profit rates due to a high level of sales can be an economic target as well. Another potential parameter can be the low variance of profit rates linked to profit rates above average. A further potential parameter may be a kind of *sharp ratio* or *reward-to-variability-ratio*, similar to this index in financial markets, which incorporates the profit rate in a certain period of time standardized by the absolute level of sales and the volatility.

Some Illustrative Examples

To illustrate the the connection between profit rates and the pattern of the explanatory features, some illustrative cases are presented. A striking observation for all parameters is that enterprises with the same values for, e. g., product marks achieve completely different profit rates. In detail, obviously, other strategic elements decide on the economic success. An interesting example is the producers of tyres whereof four are in the sector *automobiles and parts* (Table 42.6).

In this case, there are considerable differences in the R&D intensity, and these appear linked to that in patents/sales. For Continental, this can be explained by a broad product range, which encompasses tyres, automated driving, power trains, safety, etc. Michelin has a product range of automotive accessories, but the highest profit rate is achieved by Nokian Tyres with a low number of patents and a low R&D rate. The number of marks is higher than those of Michelin and Continental, but lower than that of Pirelli. The enterprise is specialized on winter tyres with high performance features. Compare the annual report 2016 of Nokian Tyres [42.37], where the orientation to tyres for extreme conditions is exposed as key strategy of the company. Thus, it aims at small, specialized niches with considerable success.

Another example comes from ElringKlinger, the features of which are shown in Table 42.7. ElringKlinger is a supplier of automotive parts in the area of motors and in-cabin elements. The profit rate is largely above average (in Table 42.7, the transferred indices in the range of −100 to +100 are used), but dropped a little bit between 2005–2009 and 2010–2014. The economic success is linked to a high R&D intensity and a high number of patents. The competitive strategy aims at high quality and innovation speed compared to competitors in Mexico, Hungary, or China, e. g., by developing tools for lightweight components (see the annual report of 2016 [42.38]). In 2005–2009, the level of product marks was above average and in 2010–2014, the level of service marks rose as well. Thus, in this specific case, the link of profitability to patents, product marks, and service marks is shown.

The enterprise Essilor is leading in the area ophthalmic optics and visual health; in addition to standard lenses, the company offers anti-fog, anti-reflective, polarized, or photochromic lenses (according to the annual report [42.39]). Again, the profit rates are largely above average. In this case, the activities in product and service marks have always been high (Table 42.8).

Table 42.6 Characteristic parameters for producers of tyres, 2005–2014

	Patents/sales	Product marks/sales	Service marks/sales	R&D intensity	Profitability	Sales
Nokian Tyres	0.3	6.8	5.1	1.3	21.1	11.5
Michelin	11.6	3.4	1.4	3.7	8.3	179.9
Pirelli	8.6	13.2	3.2	3.3	3.9	56.1
Continental	23.7	4.6	1.3	6.0	7.0	246.8

However, high profits are not always linked to high patent or R&D activities, trademarks may make the difference. The company Kone, specialist in elevators, has a profile as shown in Table 42.9. The profit rate is very high, but in 2005–2009 all parameters were below average. The R&D and patent levels remained moderate in 2010–2014, however, the activities in marks rose remarkably. The strategy aims the orientation at the needs of the customers, which is also linked to new technologies, but at a moderate level (see the annual review of 2016 [42.40]).

In the case of the enterprise TomTom, specialized in navigation systems, the profit rate was moderate in 2005–2009 and even became negative in 2010–2014 (Table 42.10). Especially since 2012, it has raised its R&D intensity substantially, obviously to cope with the requirements in a very competitive market. However, it may be that the high investment in R&D is the reason for the actual losses, notwithstanding being a major asset for the next years. Thus, the company is performing R&D in the context of autonomous driving, a key area of the next years (see the annual report of 2016 [42.41]). In any case, the number of patents and service marks increased in parallel to the up-take of R&D.

The different examples show that the link of profits to patent, trademark, or R&D activities is not so simple and has to be embedded into the context of specific markets and enterprise histories [42.42]. Overall, the different parameters depend on corporate and industrial trajectories, but the analysis reveals that this industry is indeed exhibiting a [42.43, p. 270]:

> changing mix of innovation from traditional *hard* science-based research toward a greater emphasis on *softer* competencies in design and trademarks.

42.5 Conclusions

Contemporary companies from intermediate manufacturing industries nurture diversified knowledge portfolios and are increasingly offering integrated *product-service* solutions. Capturing these trends and understanding the patterns calls for a new wave of innovation studies and techno-metric work that combines the indicators patents and trademarks, while distinguishing between goods and service marks, as well as gradations of sophistication within mark categories [42.44, 45].

The optimal configurations of capabilities that are relevant for the economic success of manufacturing enterprises are not straightforward, as they are contingent of the market context and individual strategies. Patents have a positive impact on profits until a certain maximum level, which depends on the specific situation in the respective sector. In any case, a minimum level of patents is necessary to achieve economic success.

Trademarks also emerge as relevant for the economic success of upstream industries, and the relevance of these assets increased between the two observation periods 2005–2009 and 2010–2014. The most crucial point is that our findings point to the fact that the use of service marks augmented considerably and, in particular, especially those in knowledge-base classes. The knowledge base of large and export-oriented manufacturing firms is distributed along technological resources but also covers particular marketing capabilities.

The core thesis of this chapter, that this, the emphasis that a growing service orientation of manufacturing firms matters for performance, must be further tested and buttressed. More work can and should be invested in linking service sophistication to particular industrial profiles. One promising methodological step could be the building of composite empirical constructs, combining degrees of tangibility and sophistication. Marks and softer kinds of innovation are increasingly important, and further work should be channeled to this area, especially to consider more downstream sectors as well [42.45–47].

With respect to strategy, bundling and unbundling technological and marketing resources is likely to remain challenging. The definition of economic success by profit rates has obvious shortcomings and further research is necessary to achieve satisfying concepts. Plus, the conditions of learning resilience that enable companies to withstand economic crises certainly deserve further study. Finally, this multifaceted agenda may be of benefit to policy-makers, as modern productive organizations are evolving combinations of resources, which are unlikely to respond linearly to linear or unidimensional strands of policy.

Peter Neuhäusler is a Project Manager at the Competence Center Policy - Industry - Innovation at the Fraunhofer Institute for Systems and Innovation Research (Karlsruhe). He studied Social Sciences, majoring in Micro- and Macro-Sociology, Applied Social Research, and Quantitative Methodology at the University of Mannheim and graduated with a diploma in 2008. Peter Neuhäusler was awarded his Doctoral degree in Innovation Economics at the Technical University of Berlin in 2012.

43. Post Catch-up Trajectories: Publishing and Patenting Activities of China and Korea

Chan-Yuan Wong, Hon-Ngen Fung

This chapter seeks to explore the sequential cyclical growth of science, technology, and science-based technology for two economies—China and South Korea—in the course of transitioning to the postcatching-up phase. Both China and South Korea intend to capitalize on scientific and technological knowledge in order to transition to the postcatching-up phase of development. This chapter highlights the production trajectories of science and technology towards the postcatching-up phase in terms of:

1. Scientific publications
2. Granted patents
3. Copatenting pattern
4. Forward citations
5. Science-based patents.

China and South Korea have been active in terms of scientific publication and patenting activities. In regard to patenting, both economies have shown the capability to produce patents and are able to converge the growth of patents with that of publications. This chapter highlights a generic cyclical growth path for science, technology, and science-based technology in the course of transitioning to an advanced knowledge-based economy. It is nonetheless important to explore if there are different paths pursued by other emerging economies.

43.1 Background

The *BRICS* countries along with the *next 11* economies are recognized as nations with promising outlooks for investment and economic growth. These emerging economies are acknowledged to be both dynamic and quickly catching up with the industrialized economies with South Korea and China, in particular, close to achieving advanced industrialization. The scientific and technological catching-up process of these two economies has been a subject of great interest to many development economists and innovation scholars [43.1–3].

South Korea stands out as one of the most successful economies, especially in terms of scientific and technological capability. It achieved this through capitalizing on its resources to support conglomerate firms, which invested in and expanded productive industries during the early catching-up phase. Upgrading and exporting are the essential activities that South Korean firms must carry out in order to receive support from the state. The expansion of many South Korean conglomerates led to massive employment, human resource and skill development, income distribution, and—as a result—socioeconomic development [43.4]. There are many studies explicating how firms from different industries evolved and what catch-up strategies were adopted—first to learn process capabilities, and then to develop sophisticated technologies via highly organized R&D and brand development [43.5–9]. The size of the firms and collective upgrading efforts (well-coordinated activities organized by the state) allowed South Korean firms to be able to compete with other advanced economies in certain capital-intensive industries such as automotive, telecommunications, iron and steel, and construction.

South Korea acquired productive routines for manufacturing industries and benefited from the export mar-

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_43

ket. Many South Korean firms leveraged these gains and utilized the growing local technological market as a test bed to explore niches [43.10, 11]. South Korea saw concerted efforts to develop their scientific and technological knowledge stock for advanced science-based industrial development [43.8]. It is reported that there is high participation of productive firms in academically oriented activities. South Korea has witnessed growth of a dynamic and extensive network in its innovation system which would prove instrumental for knowledge-based industrial development [43.12, 13].

Conversely, China has experienced significant industrial development since the economic reforms in 1978 [43.14], with particularly noticeable development in the coastal regions. The industrial policy of China was instrumental during the early catching-up phase, attracting foreign direct investment (FDI) from multinational corporations that capitalized on labor-intensive manufacturing industries. China then pursued systematic reforms in its production and institutional structures in order to develop indigenous technologies. It instituted a policy experimentation routine to execute different approaches to economic and industrial catching-up strategies. The routine seeks to manage complex challenges in appropriating lessons from the successes of one sector or region for application in others [43.15–17]. There was a wide range of support from the state to create an institutional routine for R&D and to build linkages between productive firms, public research institutions (PRIs), and universities. Indeed, China has witnessed tremendous state-targeted R&D programs in recent years [43.3] to acquire an institutional *path-creating* routine, a routine of adopting emerging technologies for industrial upgrading [43.18], which allows for the emergence of niches. China has also witnessed significant growth in scientific publications and technological patenting since the early 2000s and mid-2000s, respectively [43.8, 19], with a significant percentage of R&D investment over GDP. While South Korea manifested relatively advanced innovation systems that were instrumental for knowledge-based industrial development, it is expected that China will rely on the momentum from growing knowledge-based industries, as its commitment to science and technology is quite evident.

Both South Korea and China intend to capitalize on scientific and technological knowledge to transition to the postcatching-up phase of development. Many studies highlighted their attempts to mobilize resources and create intellectual capital for advanced technology development [43.9, 19–23].

In the case of South Korea, there has been consistent support from the government to advance scientific and technological capability. Commitment to building research infrastructure started early (since the 1970s), and favors scientists and engineers from universities and research institutes who publish their findings or patent their inventions. It is noted that joint research activities between industrial engineers and academics are not uncommon in South Korea and such activities have been mandated by government-sponsored research programs since the 1980s [43.21, pp. 642–643]. The programs target research areas which would empower industrial technologies, and have indeed supported several leading firms in the development of frontier technological products. This in turn stimulated more joint research activities in the postcatching-up period (since 2000) and the demand for basic research to develop science-based technologies in universities and public research institutions [43.22].

In addition, there has been commitment from the state to empower small- and medium-sized enterprises (SMEs) with scientific and technological knowledge. There are incentives and support for SMEs to participate in joint activities with research and development (R&D) consortiums. In addition, the state established a public procurement system for emerging technologies developed by SMEs or start-ups. Through patenting analysis, *Doh* and *Kim* [43.1] found that the supports for SMEs established by the government are effective in building strong research relationships in Korea's networked economy.

In the case of China, it is noted that funding for R&D has been growing since 1997 and it is expected that this commitment to R&D will allow China to match the European Commission target of 3% of GDP expenditure in R&D. The increase in funding is seen as a factor that will *push* the increase in publications. China established a reward system under the long-term plan for the Development of Science and Technology [43.24] to incentivize scientists and academics who can perform academic publishing and patenting activities. In addition, *Zhou* and *Leydesdorff* [43.25] noted that there has been an increase in Chinese returnees who studied abroad, contributing to the stock of scientific knowledge (publications). They also observed that China has been playing an important role in publishing in nanorelated sciences, and this can be seen as a building block for nanotechnology development. It is also noted that policies shifted dramatically since 2003 (particularly in technology)—from horizontal to direct government interventions—in order to achieve the desired industrial structure. Since 2006, many megaprojects targeting emerging industries such as biotechnology and new materials were launched, and massive government stimuli were disbursed in 2009 to ensure such projects were implemented even during the global financial crisis. The projects indeed shaped scientific and technological activities via a policy process developed in a systemic manner that connected the vision of national leaders with stakeholders such as local governments, firms, and interest groups [43.3].

It is noted that both economies witnessed a substantial rise in scientific publications and patenting activities. This chapter highlights the production trajectories of science and technology towards the postcatching-up phase in terms of:

1. Scientific publications
2. Granted patents
3. Copatenting patterns
4. Forward citations
5. Science-based patents.

We wish to explore if there is a growth pattern for science, technology, and science-based technology in the course of a transition towards the postcatching-up phase. Thus, the perspective of convergence between scientific and technological activities to achieve science-based technology development is taken into consideration in the analysis. The development will be assessed from aspects of both quantity and quality (impact in terms of citations) of publishing and patenting trends.

Our systematic review of science, technology, and science-based technology production in South Korea and China will provide insights and a possible understanding of cyclical development in the transition towards the postcatching-up phase. The term *cycle* denotes an illustrative period stretching from the entry to the decline of a particular production [43.18, 26]. In what follows, a cycle refers to a specific production (science or technology) that would cover project entry, take-off, maturity, and ultimately the achievement of carrying capacity. The production of Japanese scientific papers illustrated in Fig. 43.1 can be seen as a typical example of a science production cycle for an economy. Japan witnessed publication entry in the early 1990s and take-off in 1998, ultimately producing at its carrying capacity since the early 2000s.

Meyer [43.27] and *Wong* and *Goh* [43.28] maintained further that a process of systemic change in a science (or technology) production may occur where a new institutional setting outgrows, replaces, or coevolves with the old one. A new cycle may emerge if the *push*-oriented production process (producing science for specific applications or industrial technology, ultimately witnessing dual flow in advancing science and technology) is linked to production that is experiencing *pull* by market demand forces [43.28]. The concomitance between science and technology is projected in *Bernadas* and *Albuquerque* [43.29].

We seek to provide a model in the broad sense, as a stylized framework of science and technology development processes emphasizing an approach to advanced development. Our assessment of publishing and patenting activities in the economies of China and South Korea will provide a useful guide for policymakers in other emerging economies who aspire to creating similar trajectories for their own advanced phase of development.

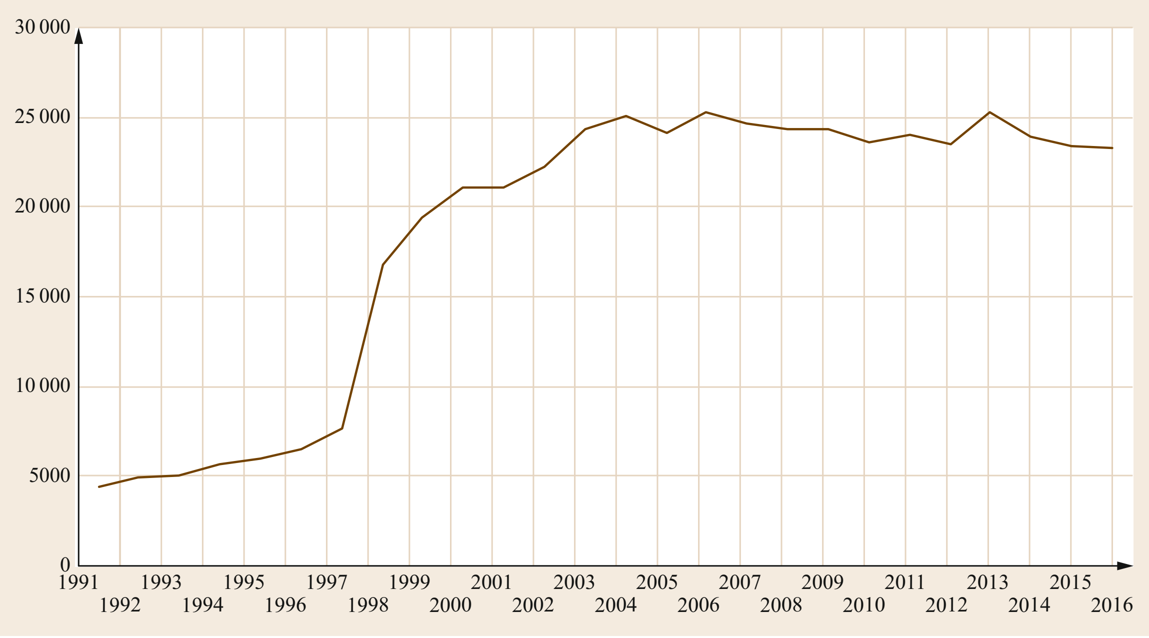

Fig. 43.1 Scientific publications of Japan. Data is extracted from the Web of Science (WoS; SCIE and SSCI) accessed on 23 July, 2017

43.2 Conceptual Framework and Data

43.2.1 Narrative Framework

Science-push and *market-pull* has been a subject of discussion among innovation scholars and it is useful as a narrative model in many policy and management frameworks. The implications of *science-push* with sequential *pull* informs policy-makers about how to mobilize resources for science (scientific knowledge) in an economy. The commitment would in turn create a spillover effect in the economy. The model provides the aspiration that the resultant scientific knowledge would be translated into technological knowledge (by the agents of change in the innovation system). The translation process would lead to the emergence of new industries and niches [43.28, 30].

The translation process is explained in the literature as a necessary link in any commitment to bridge scientific knowledge with technological knowledge. Many economies established intermediaries [43.31, 32] to ensure that the knowledge generated from universities and public research institutions is codified and applicable—that is, capable of diffusing services and has market demand [43.33, 34]. Areas of modern technology—such as biotechnology and nanotechnology—in large part emerged from the collective efforts to link scientific knowledge with industrial applications. The implication of *market-pull* basically informs policy-makers about the importance of research consortium networks in an economy that supports/allows capable entrepreneurs to translate scientific knowledge into useful applications—as they search for and define niches and create (socio-)economic value [43.32]. The ultimately increasing returns would fuel the interaction between science, technology, and economic growth. *Bernadas* and *Albuquerque* [43.29] suggested a comprehensive model that postulates the stages of development of science, technology, and economic growth (Fig. 43.2). Such a virtuous cycle of development is evident in many advanced economies. In addition, there are many emerging economies that show signs of attaining a highly functional structure that would fuel science, technology, and growth.

Schmoch [43.30] depicts the typical order of development for science-based technologies. He observed that there are basically two cycles of development before the emergence of market demand (the third cycle) and realization (diffusion) of a particular technology (product). While the two preceding cycles are projected via publishing and patenting trends, the third cycle is projected via the sales trend of the particular technology. It can be argued that the positive interaction between science and technology is triggered after a breakthrough in output of scientific articles [43.28]. *Javenpaa* et al. [43.35] extended the study of *Schmoch* [43.30] in illustrating cycle sequences for different technologies. There are technologies developed via a sequence of concomitant cycles as observed by *Schmoch* [43.30], and there are other technologies that diverge from the

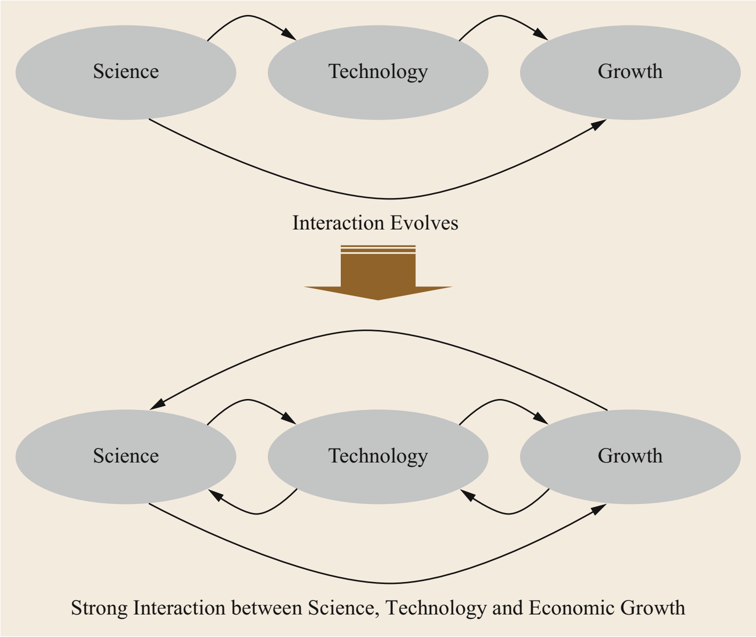

Fig. 43.2 The evolution of interaction between science, technology, and growth. Adapted from [43.29] with permission from Elsevier

typical sequence. This is particularly evident when technologies are explored via a nonscience route (e. g., tinkering).

43.2.2 Data

This chapter seeks to explore the typical type of scientific and technological development attained by emerging economies. The publishing and patenting performance of China and South Korea are used as indicators to reveal the science and technology trajectories acquired by economies that are in transition towards the postcatching-up phase. We are interested in highlighting whether the selected economies attained a concomitant cycle that would fuel science and technology activities for knowledge-economic development.

The process of scientific exploration and technology development has been relied upon as a means to unearth new discoveries and potential solutions to industrial and social issues. This study derives its content from scientific articles (publications) and patents. Scientific publications indicate the production of credible scientific knowledge and includes articles, reviews, and conference papers. The rigorous peer-review process which accompanies each scientific publication would also indicate credibility and transparency on the part of the knowledge producer. Some studies used scientific publications as an indicator to reflect the size and quality of the university education system. It enables one to connect the production of scientific publications with the provision of highly skilled graduates. Conversely, the production of patents indicates the accumulation of novel, inventive applications for industry; this sheds light on the innovative capacity of the subject. A subset of patents covered in this chapter is characterized by their citation to publications (as other references), which indicates the scientific base that exists at the foundation of the patent. We conjecture that there will be an increase in science-based patents for both economies.

The historical series of publications listed in Scopus and utility patents granted by the US Patent and Trademark Office (USPTO) have been extracted for this study. This chapter utilized Scival as a means to extract data from Scopus regarding China and South Korea. Scival is a part of the Elsevier research management suite and acts as an analytics platform for Scopus data after 1996, used in this context to capture the number of publications and forward citations of articles emerging from South Korea and China between 1996 and 2015 [43.36]. While we find the Scopus database instrumental for us to assess the historical series of publications, it is noted that the citation rates of the selected economies are in contrast to that of Clarivate Analytics' Web of Science, which may be due to the contrasting data structures during the early building-up stage. The chapter also categorized the data set based on subject areas and subcategories as defined by the Scopus Classification which covers 27 major subject areas and 313 subcategories. The CWTS (Center for Science and Technology Studies) Classification of individual journals is also utilized to identify the orientation and target audience of the various journals that authors from South Korea and China most commonly publish in [43.37].

The patent data is derived from the USPTO through Patsnap, a patent search engine that covers various patent offices worldwide. For the purposes of this chapter, patents were extracted for assignees originating from South Korea or China between the years 1996 and 2015. In this case, the assignees were classified based on keywords in their assignee name to determine whether they are categorized as university or industry. While we managed to extract valuable data to develop our analysis, we observed a general decline phenomenon for patent citations of many economies since the early 2000s. This may be attributable to the high workload of the USPTO's search engine and thus it is unable to provide us with accurate citation reports.

This chapter also sought to classify the patents extracted in order to assess the level of research and development intensity (RDI). The first step of this process is the concordance of the patent subclasses based on the concordance for IPC8 to NACE Rev. 2 [43.38]. This is followed by a series of steps to translate the patent subclasses to ISIC Rev 3.1 [43.39]. This process allows for the patents to be classified based on the classification released by OECD (Organization for Economic Co-operation and Development), which groups different product classes based on R&D expenditure divided by value added, over R&D expenditure divided by production [43.40]. This process is an extension of prior attempts to develop a coarse concordance between patent classes and product classes [43.41, 42].

The evolution of networks established for joint patenting activities are studied in detail. We review the literature on how the selected economies match their scientific resources with technological activities, and assess the effectiveness of their matching efforts by projecting the convergence process between scientific publications and patenting activities. The chapter utilized VantagePoint—a text mining software developed by Search Technology Inc.—to conduct the joint patenting mapping exercise with the focus on the top 30 patent assignees. The mapping is done by measuring the similarity index between patent records by assignees (node) in the various fields, which determines the thickness of the lines (edges) between the nodes.

43.3 Findings and Discussion

43.3.1 Science

Figure 43.3 shows the scientific publication performance of the two economies. China—a large emerging economy with rich resource endowment for science—is performing on a much larger scale in scientific publication. China witnessed its take-off point in 2003, growing from 24.6 papers per million population in 1996, to 125.7 in 2006, and achieving 269.6 in 2015. It is believed that there was a general push for science—as in many emerging countries—and the production has grown exponentially since.

Although the growth of China eclipsed that of the other relatively advanced economy, South Korea, the latter's production of scientific publications is nonetheless noteworthy for this study, as its take-off point appears to be similar to that of China. South Korea—a highly capable economy in performing high tech innovation since the 1980s (when many South Korean business conglomerates believed that the semiconductor industry was the basis of every other industry and stepped up their investment to upgrade capabilities for semiconductor technological innovations [43.43])—attained a much steeper growth curve before its take-off point as compared to China. The production of scientific publications by South Korea grew at a much quicker rate after the take-off point, from 192.4 papers per million population in 1996, to 580.2 in 2006, and reaching 1253.9 in 2015. The momentous growth in publications of the two economies may be due to the arrival of the respective take-off phase in their publishing cycles. This may be attributable to the commitment of the economies to incentivize scientists and researchers from universities to publish their research findings. Conversely, the universities are keen to recruit productive scientists to produce scientific papers. They also enforced the *publish or perish* performance criteria to evaluate the performance of faculty. This led to a significant increase in scientific publications from the emerging countries such as China and South Korea. Many publishing houses for scientific results have since then expanded their production to accommodate the demand.

In addition, the funding for academic research activities has been favorable and substantial particularly for those who are involved in the targeted fields [43.3, 20]. It seems that their resources (both in terms of hu-

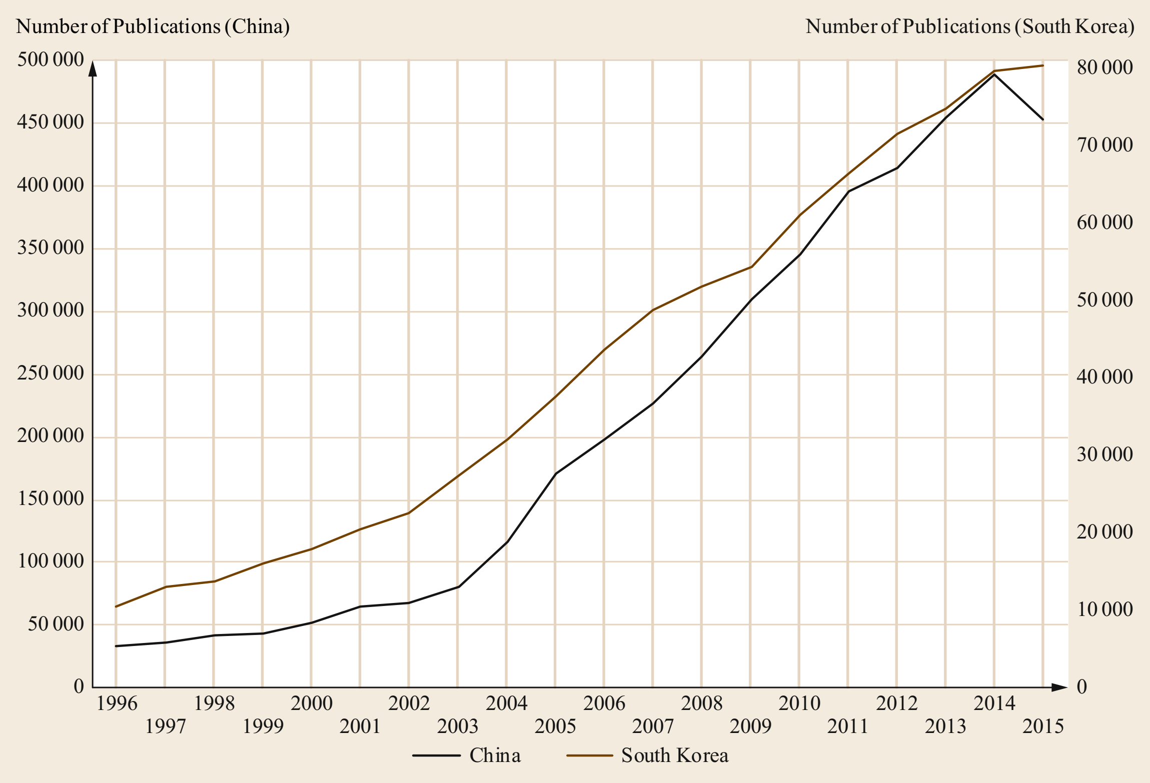

Fig. 43.3 Scientific publications of China and South Korea

man capital and finance) for science are far from being exhausted, and thus, it is unlikely the economies will achieve their carrying capacity soon.

The publications of the two economies prior to the take-off year saw a tremendous impact as measured by citations per article (Fig. 43.4). For the case of South

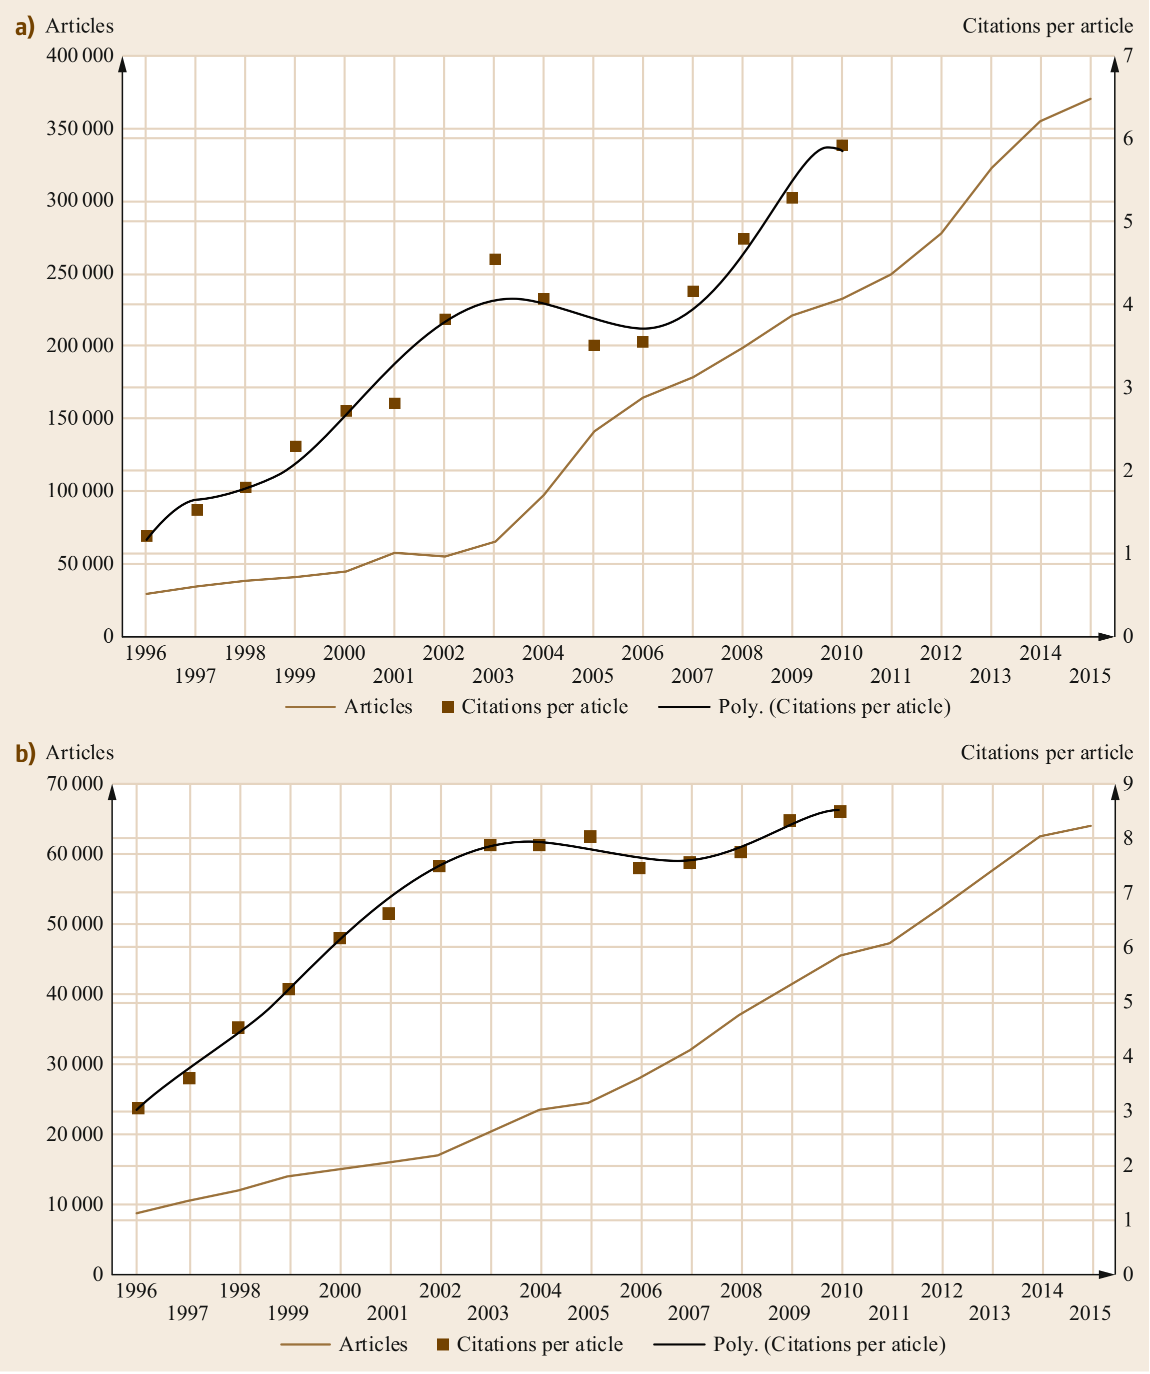

Fig. 43.4a,b Publications (in terms of articles in journals) and citations per article of China **(a)** and South Korea **(b)**. Yearly citation counts are adjusted to a 5 year citation window. This is due to the assumption that a citation cycle of a publication would end by the close of a 5 year period. *Bornmann* and *Leydesdorff* [43.44] used citation counts of 3–5 years to study the research landscape. The citations per article trend is plotted from 1996–2010

Korea, citations since then reached their first cyclical peak in 2003–2005. The cycle of high-impact scientific articles witnessed a saturation point and received relatively lower citations per article in the following years. The significant citations count by the early 2000s can be attributed to the *push* factor for scientific publications. Many articles published during the take-off year would tend to cite articles published in the previous five years, hence the citations trend is a normal phenomenon as it reflects the systematic conduct of the research process. The *quantifiable* aspect of impact for each article has seen a recovery since 2008 and this may due to the transition towards the *pull* phenomenon, which implies the significant application of science. For the case of China, its citations per article trendline showed a noticeable hump-shaped curve. Again, this reflects a cycle of citations in its publication trend. The upward citations rate started to resume after the take-off point for publications that emerged in 2003. It is noted that the trends for citations that are based on Web of Science data are noticeably different from those of this study. We conjecture that the contrasting trends can be attributed to the contrasting data structures of the two databases.

In terms of subject areas, chemical engineering- or chemical science-related areas tend to dominate the landscape of top publications of the two economies (Table 43.1). Chemical engineering with subcategories of *Colloid and Surface* and *Chemistry Catalysis* emerged as the top areas in terms of citations per publication. China seems to also have given research priority to other scientific fields such as pharmaceutical-related, material-related, and energy- and environment-related areas. In addition, China is also productive in *archaeology*, a subarea of *arts and humanities*. While South Korea also performed in energy- and environment-related and material-related areas, it also targeted multidisciplinary-related (which saw tremendous growth and a high number of authors involved), medicine (clinical genetics in particular), and nursing as top research priorities.

Figure 43.5 provides an overview of the share of joint publications between universities and industries for science. This reflects the joint commitment of two different entities in the innovation system to produce science for potential applications. Conversely, China witnessed an increase in its share of joint publications (all types), from less than 1% in 2003 (the take-off period) to about 1.3–1.6% afterwards. This shows a commitment to bridging science and industrial applications. Conversely, South Korea performed at a relatively higher level of joint publications within

the 3–6% range—for comparison, in 2015 Germany attained a share of 3.5%, France 3.2%, Denmark 5.8%, and Italy 1.9%. South Korea's commitment to joint research activities began early (in the 1980s), attaining a highly functional innovation system by 1996 when its share of joint publications was higher than that of China. It is noted that collaboration between scientists from universities and public research institutes and industrial engineers is not uncommon in the context of South Korea. It is also noteworthy that South Korea's share has been declining since 2007. *Kwon* et al. [43.45] maintained that the cross-authorship within entities in Korea has been steadily eroding as universities and industries seek to internationalize their collaboration structures. We on the other hand, conjecture that this phenomenon can be attributed to recent efforts of many universities in advanced economies to venture into emerging science and technology. The knowledge may be too niche for industrial players to identify its immediate applications, hence many universities are commercializing it via university start-up mechanisms.

Table 43.2 shows the top journals by publication counts for the two economies. The journal titles are listed in the Scopus database, and many of the titles are also listed in the WoS. We sought to match the WoS's journal titles with Leiden University's CWTS field orientations of different journals to identity the targeted readership of the journals [43.37]. There are journals oriented towards advancing scientific knowledge among the peers of a particular field, and there are journals established to inform medical or industrial practitioners about the potential applications of new sciences. Table 43.2 lists the orientation of journal titles that are listed in the WoS.

China produced 225 965 publications in the top 20 journals of China. We observed that 69% of the publications are also listed in the WoS. Many of these publications are intended for both internal circulation (within scientific communities of China) and dissemination abroad. There is a substantial number of publications that are meant for circulation among peers in a particular field. China produced 85 720 publications that are meant for university-oriented science. Publications for application-oriented science account to about 45% of the total WoS-listed publications in top journals of China. The science *push* commitment of China seems to have an impact on university-oriented science publications. As China continues to bridge science for new applications, it is expected that the orientation will shift towards application-oriented science in the near future.

Conversely, South Korea's publications manifested a slightly different development pattern. It produced 68 267 publications in its top 20 journals, of which 91% are listed in the WoS. From the total WoS listed publications, 89% are oriented towards medical or industrial applications. This implies that South Korea has achieved a concomitant stage that empowers a virtuous cycle of science and technology development. Most of the scientific publications that South Korea produces have industrial applications, while it still seeks to retain some commitment to advancing basic science (university-oriented). This can be attributed to the early commitment of the South Korean government in bridging science (produced by the academics) and technology for industry. The effort to advance application-oriented science would ultimately advance science-based technologies of South Korea.

43.3.2 Technology

Many studies have reported on the significant efforts made by China and South Korea in terms of indigenous building technology [43.4, 6, 15, 16], advancing capabilities for high-tech industries, securing IP protections for their inventions, and branding their innovations for markets abroad [43.9, 19]. They have both been active in patenting, with their patenting trend showing significant growth in the past few years. China witnessed its take-off point for patenting in 2009, about 6 years after its take-off point for publishing activities—going from just 0.02 patents per million population in 1996, to 0.3 in 2006, and reaching 5.3 in 2015. Conversely, South Korea witnessed its take-off point for patenting in 2005 and achieved growth comparable to that of its publications before convergence in 2014 (Fig. 43.6). It witnessed a capacity of 31.1 patents per million population in 1996, expanded to 119.3 in 2006, and reached 360.5 in 2015. The phenomenal growth of patenting in the two economies appears to echo that of publications. It is noted that the two economies are keen to routinize patenting activities to develop identified technologies that would spawn niches in the global production value chain.

Both economies—but China in particular—achieved significant reductions in the gap between publications and patents. The ratio between publications and patents for China in 1996 was 1385 : 1, reduced to 744 : 1 in 2000, further reduced to 168 : 1 in 2010, and reaching 62 : 1 in 2015. This reflects the national commitment toward correlating development of science with technology, which is particularly crucial for the catching-up economies. The importance is in order for catching-up economies to be able to translate scientific results into technology that empowers socioeconomic activities [43.29]. In this respect, South Korea achieved a low gap in the 1990s, attaining a ratio of 7 : 1 in 1996 and ultimately reducing it further to just 4 : 1 in 2015.

For patenting impact, South Korea seems to have witnessed a (full) cycle of patent citations—from a rapid increase of citation counts in the 1990s, to plateauing in the early 2000s, and subsequently declining since then (Fig. 43.7). For the patent citations, we utilize 5 year patent citation windows. While the decline of citations may imply a waning of the patenting impact of Korea, it may also be attributable to the high workload of USPTO's search engine making it thus unable to provide accurate citation figures for the examination report.

Nonetheless, we also note the decline in citations per patent over time, which we conjecture is due to ventures into long-cycle types of emerging technologies (e. g., science-based technologies such as medicine) [43.46, pp. 45–69] and [43.47, p. 51]. The ventures have yet to achieve significant impacts (in terms of citations) for these economies. We also ob-

served a significant increase of other references (i. e., not patents) backward citations per patent since the take-off points of the respective economies. Other references backward citations reflect possible input of scientific knowledge in crafting an invention. The patenting performance of South Korea seems to have caused a *pull* for scientific knowledge for new inventions or creation of new applications or niches. Conversely, China witnessed a consistent increase in patenting impact.

Table 43.3 shows the translation results of concordance between patent classifications and the level of technology. We observe that the selected economies have been keen to patent their inventions that are categorized as high tech and medium high tech. The share of patents in the two levels of technology has increased, while the share of low tech has fallen. This is evident particularly for the case of China. The *pull* for scientific knowledge in these two economies can be attributed to the pursuit of high tech patenting. The *pull* factor and significant efforts of these economies to bridge science and technology have indeed led to the increase of co-owned patenting between those from the universities and those from industry. Table 43.4 shows a significant increase in terms of co-owned counts over the decades in the selected economies. China's copatenting counts increased from virtually none in 1996, to 277 in 2015. Meanwhile, South Korea witnessed an increase from 1 to 335 in the same period of time.

Figure 43.8 shows the copatenting networks of China and Korea, which are mapped based on data of the top 30 assignees of each economy, extracted from

Table 43.4 Co-owned patenting between university and industry of China and South Korea

	China		South Korea	
	U	U-I	U	U-I
1996	4	0	1	1
2005	23	13	35	17
2015	644	277	659	335

the respective patent documents. We observed that there are different entities featured in the network. China's patenting landscape is dominated by many private firms and there are a number of network links for copatenting activities. Public research institutions such as the Chinese Academy of Sciences and China Academy of Telecommunications Technology are featured in the landscape. Universities such as Peking University and Tsinghua University are also featured in the landscape and their patents are coventured with those from the industries.

By contrast, South Korea manifested a much wider network for copatenting activities and the landscape is dominated by private firms, with Samsung Electronics emerging as the key player in the map. Many universities and PRIs are visibly featured and their influences in technology are evident. Korea Advanced Institute for Science and Technology (KAIST) emerged as one of the prominent influential players in the patenting landscape. It has links connecting private firms and PRIs for copatenting activities. This echoes our earlier observation on the concomitant stage for science and technology attained by South Korea for knowledge-based economic development.

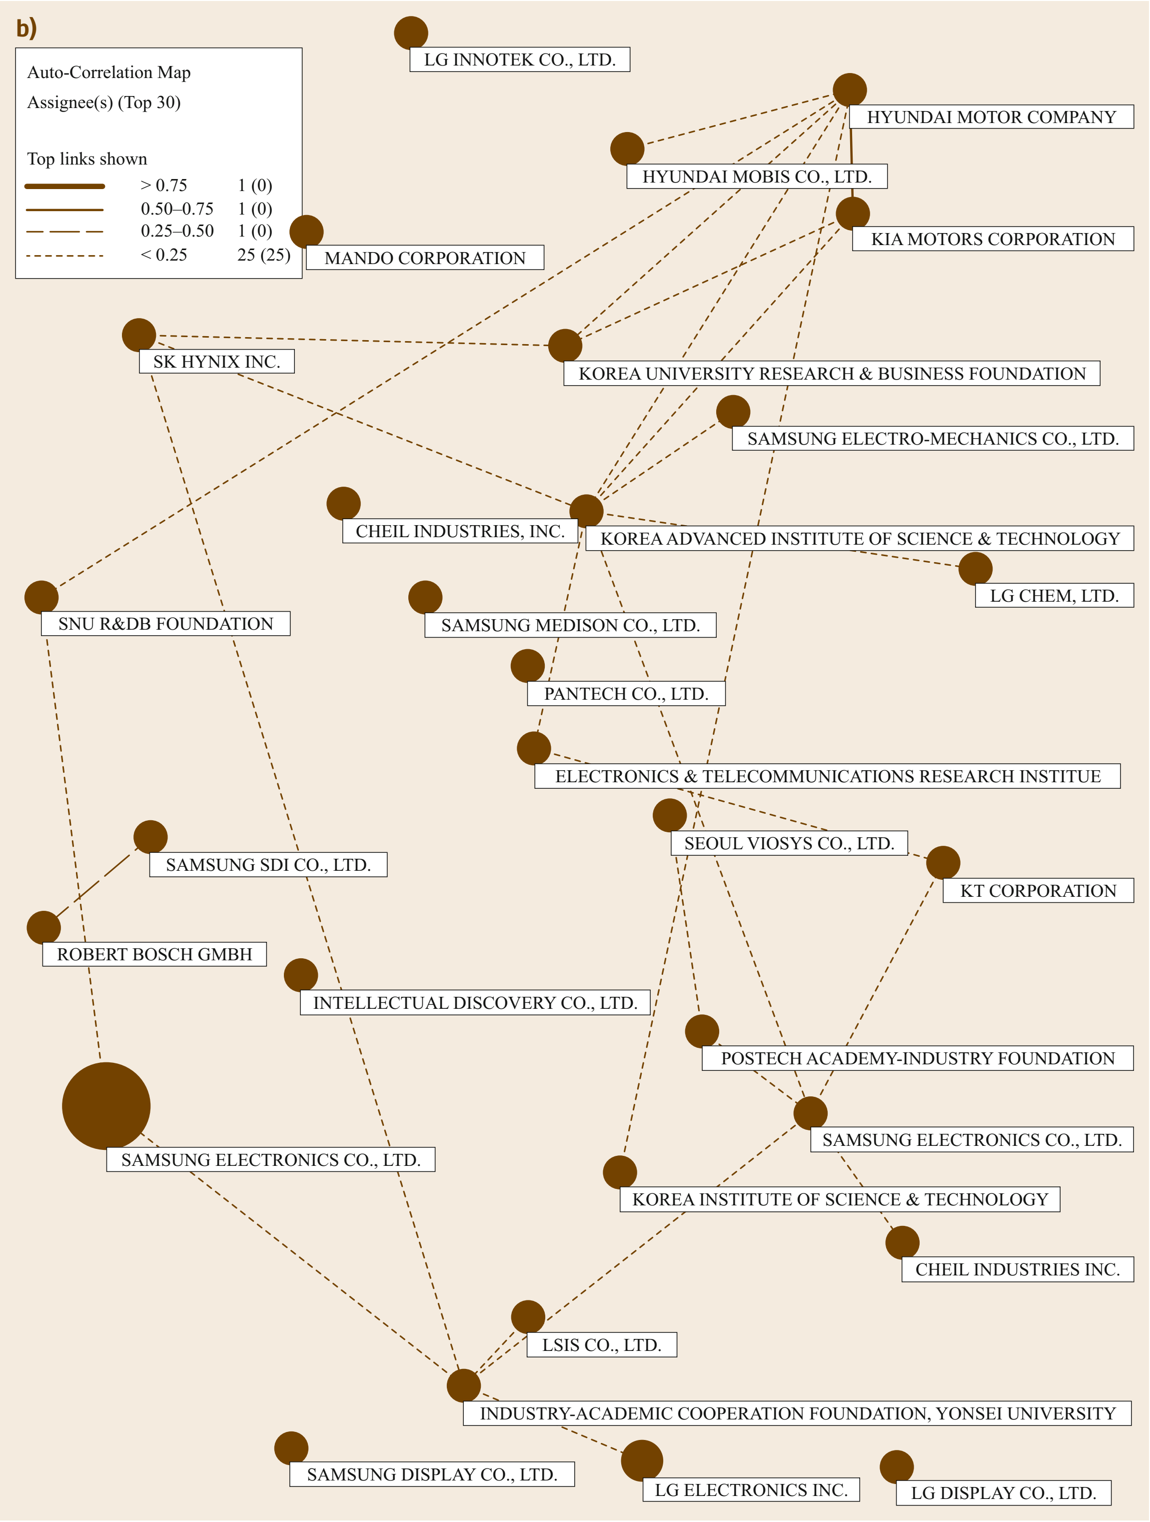

Fig. 43.8a,b (continued)

43.4 Conclusion

This chapter sought to explore the growth patterns for science, technology, and science-based technology of two economies in the course of a transition towards the postcatching-up phase. Publications and patenting data are instrumental in exploring this growth, as well as measuring elements of academic–corporate linkages that stimulate interactive learning. China and South Korea have been active in performing scientific publication and patenting activities. They witnessed tremendous impacts in terms of citations per article and a cycle of citation counts—showing both a rise and a decline. Both economies achieved a significant share of joint publications between universities and industry. South Korea in particular was able to produce a high share of application-oriented publications. The early efforts of linking science to industrial technology emerged to bear results. The links and the resultant application-oriented publications are important—particularly in the postcatching-up phase of development—as the economy sought to appropriate science-based technologies for growth.

In terms of patenting, both economies have shown the capability to produce patents and are able to converge the growth of patents with that of publications. The ratio between publications and patents for the two economies has been reduced, and our observations imply a high correlation between scientific production and technology. University–industry links for copatenting are evident and South Korea in particular had manifested a network that enables high-tech production. Technical universities such as KAIST, PRIs, and private firms featured visibly in the university–industry patenting network. This implies strong interaction between academics, researchers, and industrial engineers in terms of research activities in the context of South Korea. The network can be acknowledged as conducive for production of science-based technologies, as strong interaction between stakeholders is seen as the key factor in achieving a functional innovation system in an economy. By comparison, the patenting activities of China manifested fewer links, however, the pursuit for science-based technologies is markedly determined. Many indicators imply strong efforts towards achieving a functional innovation system.

On the basis of the cases of China and South Korea, this chapter highlighted a generic growth path for science, technology, and science-based technology in the course of a transition towards an advanced, knowledge-based economy. It is nonetheless important to explore if there are different paths pursued by other emerging economies. Therefore, a more comprehensive understanding of cyclical growth of science and technology should be sought.

Hon-Ngen Fung is a Lecturer at the KDU University College. His research interests focus on scientometrics, innovation systems, and science and technology policy. He has published in several international journals including *Scientometrics*, *TechnologicalForecasting and Social Change*, and*Social Science Information*.

44. Standardization and Standards as Science and Innovation Indicators

Knut Blind

The focus of innovation policies has shifted from knowledge creation and protection (e. g., by patents) to knowledge diffusion (e. g., via open access) in order to promote their implementation. This has led to an increasing need for innovation indicators that reflect the implementation of knowledge within innovative products and services. Standardization as a kind of open innovation process, and standards as its output, represents a new type of innovation indicator. In this chapter, we begin with a discussion of existing opportunities for using standards and standardization as innovation indicators, including three specific examples of input, throughput, and output indicators. Next we identify challenges that must be addressed to close the data gaps—which are still very significant when compared with patent data. In addition, the broader concept of quality infrastructure is introduced in order to point out the complexity of standards implementation, and its close link to innovation as well. The chapter concludes with examples of how decision makers in industry and policy could make use of a comprehensive database of standardization and standards to evaluate innovation policy initiatives.

44.1 Background

In the 1990s, the increasing relevance of intellectual property rights (IPR), particularly with regard to patents and the accessibility of patent data via resources such as PATSTAT (Worldwide Patent Statistical Database), provided by the European Patent Office and the OECD (Organisation for Economic Co-operation and Development), led to a virtuous cycle accompanied by the broadening of areas of investigation and improved data quality. However, despite the increasing relevance of IPR, the number of patent applications, especially in Western countries, has been stagnating or even decreasing [44.1]. In parallel, the increasing opportunities and demands for measuring the scientific productivity of countries, research institutes, and even individual researchers has led to the development of bibliometrics as a new discipline based on scientific publications and related information (see other contributions in the handbook). Recently, however, the importance of accessing, disseminating, and implementing knowledge—in contrast to knowledge creation and protection—has been receiving greater attention from policymakers. One example is the shift in focus of the current European Framework Programme Horizon 2020 from research to innovation, and fostering open access to scientific data and open innovation [44.2, 3].

Methods for measuring the implementation of innovative ideas have been addressed by researchers focusing on patents, but the question of whether patents are actually used can only be answered by inventor surveys, such as those recently reported by *Torrisi* et al. [44.4] and *Ploschka* [44.5], or by specific case studies, for example, focusing on complex products such as laptops [44.6]. Certainly, analyzing innovative ideas that have actually been implemented in new products is the more accurate, but much more cumbersome approach. An alternative and complementary approach is the analysis of the development and implementation of standards, as the additional effort to develop common standards is a strong indication that the innovative ideas are eventually implemented in products and processes, and are not used only for strategic purposes, such as the use of patents to block competitors or

W. Glänzel et al. (Eds.), *Springer Handbook of Science and Technology Indicators*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-02511-3_44

in negotiations [44.4, 7]. Examples of the most recent standardization activities include topics such as cybersecurity, blockchain, fifth-generation wireless systems (5G), the Internet of Things (IoT), cloud and big data, additive manufacturing, artificial intelligence, robotics, and augmented/virtual reality. Furthermore, standards also include product and process characteristics (e. g., *Lorenz* et al. [44.8] in the case of biotechnology), which is less the case for patents [44.9]. Finally, standards not only address innovative technological aspects, but increasingly encompass services [44.10, 11]. These include online gaming and management systems [44.12], focusing particularly on quality management [44.13], and recently extending to issues such as environmental management [44.14] and corporate social responsibility [44.15]. In contrast to patenting, which takes place within closed inventor teams, and in addition to open-source activities focused specifically on software [44.16], standardization in publicly accredited national, European, or international bodies and informal consortia, particularly those active in information and communication technology (ICT) [44.17] and increasingly in multimodal form [44.18], is serving to generate common knowledge, which is especially interesting for the knowledge sourcing of small and medium-sized enterprises [44.19]. In summary, standards and standardization provide opportunities to generate innovation indicators that not only cover a much broader spectrum of innovation, but also reflect dynamic and open innovation processes via the development of common standards, their revision, and eventual replacement by the next generation of standards [44.20].

44.2 Definitions and Processes

The regulatory framework generally comprises regulations released and enforced by governmental institutions. Industry and other affected stakeholders may complement these governmental regulations by self-regulatory coordination [44.21]. Their efforts can result in voluntary commitments and standards released by publicly accredited or even administrative standardization bodies.

Standardization is defined according to European standard EN 45020:2006 as the

> activity of establishing, with regard to actual or potential problems, provision for common and repeated use, aimed at the achievement of the optimum degree of order in a given context. [44.22]

The benefits of standards are generally differentiated as follows: securing interoperability, especially in network industries; assuring quality, health, and safety; and the generic functions of both reducing variety and enabling the exploitation of economies of scale and information sources such as scientific publications and patents [44.23, 24]. Given its tried-and-true processes, standardization enjoys a high degree of legitimacy and is uncontested in terms of antitrust legislation.

The result of a standardization process is a standard, defined according to EN 45020:2006 as

> a document established by consensus and approved by a recognized body, that provides, for common and repeated use, rules, guidelines or characteristics for activities or their results, aimed at the achievement of the optimum degree of order in a given context.

recently confirmed by OECD/Eurostat [44.25].

Standards are the result of standardization work at the national, regional (European), and international levels. Anyone can submit a proposal for a new standard. Standards are drafted by committees set up by national standardization bodies, the European Committee for Standardization (CEN) and the European Committee for Electrotechnical Standardization (CENELEC), or, on the international level, the International Organization for Standardization (ISO) and the International Electrotechnical Commission (IEC), working in agreement with defined principles and rules of procedure and design. Any party interested in the drafting of standards is able to participate in the work of standardization bodies. The term *interested party* refers to such groups as manufacturers, consumers, retail businesses, science or research institutes, insurance companies, governmental authorities, or testing institutes dispatching experts to the working body or one of its specialist areas. National interests are represented in CEN/CENELEC and ISO/IEC by experts and delegations from the national standardization bodies. Their staff takes care of coordinating standardization work at the national, European, and international levels. Standards are reviewed for relevance at least once every five years. If a standard is shown to fall short of the state of the art, its content will be revised or the standard will be withdrawn altogether.

There are various ways for experts from businesses and organizations to become involved in standardization work (Fig. 44.1). The type of involvement and the amount of effort required depend on the interests and available resources that stakeholders may have.

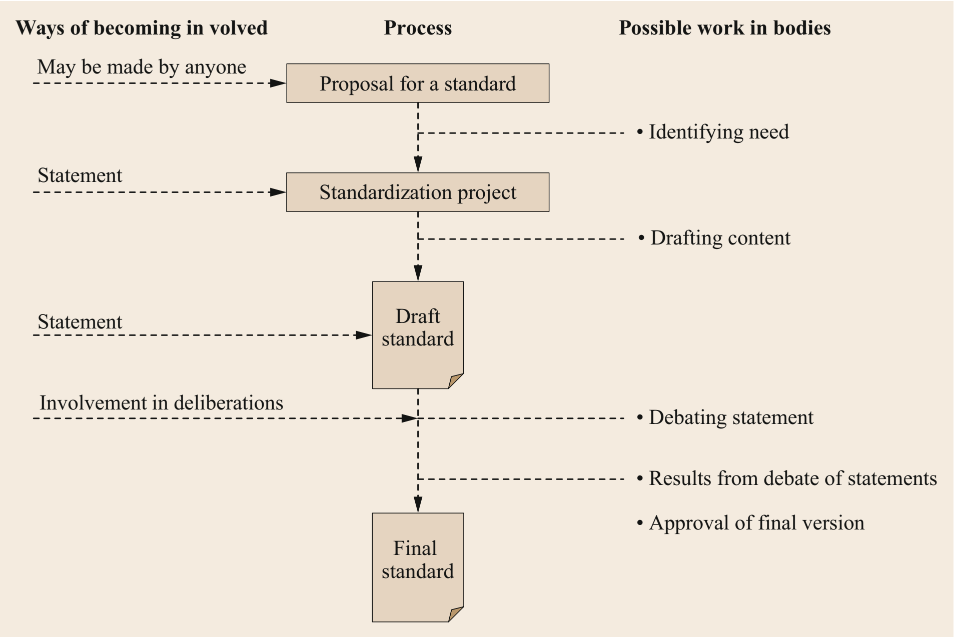

Fig. 44.1 The standardization process based on [44.26]

44.3 Current Opportunities

Standards contain knowledge that is relevant not only for the production of products and services, but also for all interested stakeholders active in the research [44.27, 28] and development [44.8, 29] process. Examples include both the terminology and the measurement and testing standards facilitating communication within research and development, and also health, environmental quality, and safety standards necessary to create trust among early adopters of innovative new products and services, in addition to compatibility standards as the basis for generating positive network externalities [44.30].

Standardization can also be linked to both scientific publications [44.31, 32] and patenting. Thus far, only standard-essential patents with higher value as measured by forward citations have been the subject of intensive empirical investigations, starting with the seminal contribution of *Rysman* and *Simcoe* [44.33] based on linking patent databases with information provided by the standards development organizations (see the most recent review by *Pohlmann* and *Blind* [44.34]). The work in this field has been further extended to the analysis of motivations and strategies for including patents in standards [44.35–38] and their impact on innovation [44.20] or company performance [44.39, 40].

In parallel, company participation in standardization bodies [44.11, 41, 42] and consortia [44.43] has been studied extensively based on either surveys or membership information [44.44], and confirms the generally positive relationship between innovation activities and success on the one hand, and standardization on the other. However, in contrast to the large body of literature on individual inventors, individual researchers' involvement in standardization is a rather unexplored topic, as the information is largely confidential and can only be accessed via internal databases [44.31] or surveys [44.5, 45]. Here, the relationship to researcher performance measured by scientific publications or patent applications yields ambivalent results [44.31], whereas the inclusion of publications in standards—as in the case for standard-essential patents—generates both more and longer-lasting citations (e. g., for biotechnology *Raven* and *Blind* [44.32]).

In addition to standards published by standardization bodies or consortia, numerous company standards are developed, particularly by large companies, both for internal use and for coordinating their supply chains [44.46], which according to *De Vries* [44.47] might even outweigh the number of applied formal standards. However, these documents are either confidential, such as trade secrets, or available only to suppliers. Therefore, they are not suitable as a basis for constructing representative and valid indicators, although they do codify internal company knowledge, processes, and preferences that may complement inventions, patents, or even trade secrets.

On a macroeconomic level, similar to the case with patents, a generally positive association has been found for the impact of standards as indicators of countries' or industries' innovativeness, measured as stocks of standards provided by a commercial database operated by standards development organizations, on economic growth [44.48], trade [44.49], and global value chains [44.50]. While the number of existing standards [44.51] is a rather imprecise measure, the International Organization for Standardization (ISO) provides data about the implementation of the most important management standards, such as the more than one million certifications for the ISO 9001 quality management system [44.52] and the ISO 14001 environmental management system. However, whereas the relationship between the ISO 9001 certification and innovation is uncertain on the company level [44.53], the link between ISO 14001 and innovation is positive, at least at the country level [44.54]. In contrast to the dominance of Western countries in providing input into standardization processes, data regarding the implementation of these management standards is available for all of the more than 150 member countries of ISO, allowing for global analyses. Recently, *Ehrich* and *Mangelsdorf* [44.55] analyzed the impact of certifications related to private standards on trade flows in the food sectors, again with a focus on developing countries.

Unfortunately, systematic data regarding the implementation of other standards is not available. A first study focused on the number of standards implemented, for example, in the production of a laptop [44.6]. In a recent work, *Ploschka* [44.56] identified the implementation of standards within the whole product portfolio of a company manufacturing hydraulic products. Although this approach requires significant effort, this study confirms at least the feasibility of such an approach.

Nevertheless, the options for data collection have since been expanded within country-wide company surveys. For example, previous British editions of the Community Innovation Survey included questions about the role of standards as innovation sources and barriers [44.57, 58], and German editions of the community innovation survey have explicitly distinguished between standards and regulations as barriers to innovation on an ongoing basis, thus enabling longitudinal analyses [44.59]. A recent survey of the active involvement of German companies in standardization [44.60] revealed that 10% are actively involved—a share similar to that for patenting. In fact, the majority of companies are following both strategies. In addition, data provided by national standardization offices are matched to the community innovation survey, for example, in the Netherlands [44.11] and Germany [44.61]. Together, these studies show positive correlations between innovation activities and success on the one hand, and the role of standards as information sources or participation in standardization on the other.

In 2012, the German Standardization Panel was launched with a pilot survey addressing the 10 000 companies active in the national standardization body DIN e.V. Since then, seven annual panel surveys have been conducted and have included more than 1000 companies constituting over 10% of the universe of standardizing companies. Efforts are currently under way to involve the more than 100 000 German companies purchasing standards, assuming that they implement standards without being actively involved in standardization [44.62]. With the fifth wave of the panel starting in October 2016, the German Ministry of Economic Affairs and Energy (BMWi) has taken over patronage for the envisaged long-term initiative. Research and other institutions such as test laboratories are an additional group targeted for surveys, in order to complement the business perspective (see *Blind* et al. [44.50] for a pilot study focusing on a research institute).

Examples

To illustrate the actual opportunities for using standards as innovation indicators, we present three examples, representing input, throughput, and output indicators.

According to the Commission of Experts for Research and Innovation (EFI) [44.63], standardization is an important factor in the commercialization of innovative technologies. Since we have no internationally comparable information about efforts invested in standardization, we must rely on data provided by the International Organization for Standardization (ISO). By participating in the committees at ISO, a country can make a significant impact on global technical infrastructures. German companies are more frequently involved in the work of the ISO than companies of any other country, as measured by the number of German secretariats (Fig. 44.2).

The more than 3500 committees at ISO have formulated and published over 20 000 international standards and standards-type documents, totaling almost one million pages. The largest share of documents, at 27.3%, covers engineering technologies, while 21.8% relate to material technologies (Tab. 44.1). The other half of the ISO standards include electronics and information technology and telecommunications, at 17.7%, and another 10.7% involve the transportation of goods. A cross-sectional category including generalities, infrastructures, sciences, and services is responsible for 9.3%. Agriculture and food technologies constitute

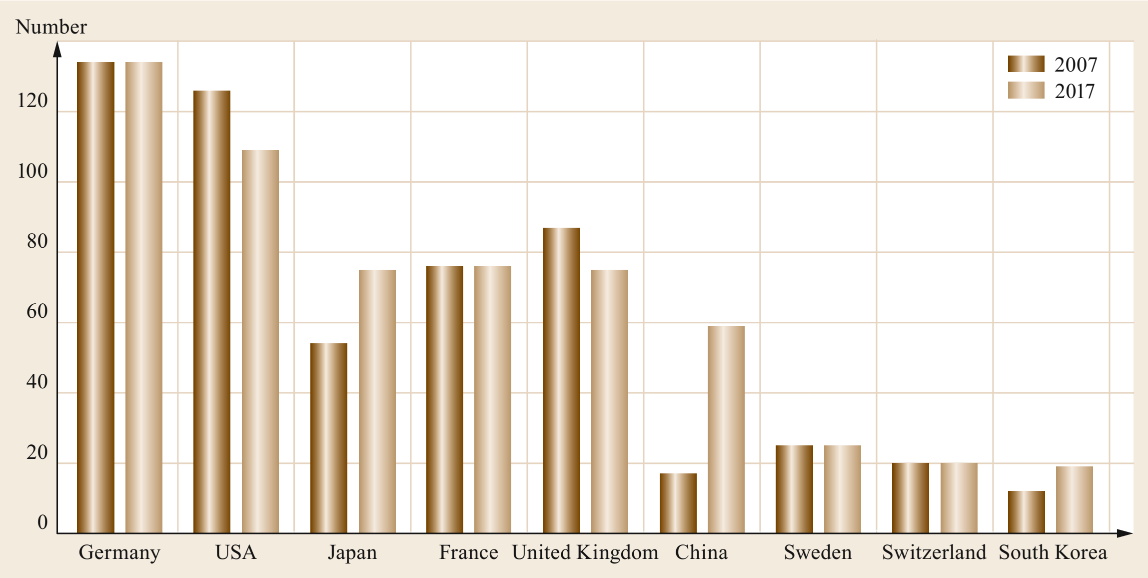

Fig. 44.2 Number of secretariats listed by the technical committees and subcommittees of the International Organization for Standardization (ISO). Source: Own diagram based on ISO (2007:15) and [44.64]. ©EFI-Commission of Experts for Research and Innovation 2017

5.6% of ISO standards, and 2.5% focus on construction. Another important set of standards, focused mainly on health, safety, and environmental protection, represents 4.1%. Finally, 1% of the ISO standards deal with special technologies, including new areas. Information regarding the ISO standards can be accessed through the ISO homepage. Professional database providers, including national standardization bodies, offer bibliographic data regarding standards released by the majority of ISO members, primarily as a resource to support industry with their standards and technical regulation inquiries; these are only partially useful for scientific purposes such as the construction of innovation indicators.

Most of the 166 national members of ISO include the stock of ISO standards in their national stock of standards, especially since few members still produce a significant number of national standards. However, the integration of ISO standards reflects the economic capacity, and thus the capacity for innovation, of the various countries, as national industries are not interested in international standards related to technologies in which they are not active. Finally, like patents, the stocks of standards can be considered throughput indicators, because the publication of standards does not guarantee their implementation. However, the standardization process—in contrast to patenting—requires the exchange and even the common production of knowledge between the participants, generating an economic impact even before implementation.

Table 44.1 Shares of ISO standards by technical sector as of the end of 2016 [44.65]

Technical sector	Shares (%)
Engineering technologies	27.3
Material technologies	21.8
Electronics, information technology and telecommunications	17.7
Transport and distribution of goods	10.7
Generalities, infrastructures, sciences, and services	9.3
Agriculture and food technology	5.6
Health, safety, and the environment	4.1
Construction	2.5
Special technologies	1

In addition to the more than 20 000 ISO standards, the International Electrotechnical Commission (IEC) provides nearly 10 000 international standards focusing on electrotechnology, and the International Telecommunication Union (ITU) maintains a portfolio of around 5000 standards. In Europe, the three standardization organizations—the European Committee for Standardization (CEN), the European Committee for Electrotechnical Standardization (CENELEC), and the European Telecommunications Standards Institute (ETSI)—are responsible for almost 30 000 standards, which include the majority of ISO standards.

Table 44.2 shows the stock of national standards including international and—for the European countries—European standards for a selected sample of

Table 44.2 New standards, withdrawn standards, and total stock of standards in selected countries at the end of 2017 (Source: Based on [44.66])

Country	New documents per month	Present stock	Withdrawn documents with substitution per month	Withdrawn documents without substitution per month
Germany	380	39 575	367	20
United Kingdom	573	41 452	177	379
Russia	495	33 310	11	12
Austria	319	32 564	199	11
China	301	34 482	89	0
South Korea	296	20 250	232	9
France	235	38 903	88	171
Spain	151	31 643	110	13
United States (ANSI)	136	11 155	92	14
Poland	118	29 584	59	19
Sweden	107	24 047	98	20
South Africa	64	7556	15	18
Brazil	56	8744	35	11

countries. We see that most European countries provide European and international standards, and only large countries, namely Germany, the United Kingdom, and France, still maintain a significant number of national standards. In the United States, there are several sector-specific standardization organizations that provide additional standards. Therefore, the total number of standards is much higher than those administered by the American National Standards Institute (ANSI). Emerging countries have a significantly lower, but growing, number of standards. There is also a significant dynamic in the stock of standards: 10% are newly published each year, and almost the same share are withdrawn. Thus, over a period of 10 years, there is a complete turnover in the stock of standards.

Finally, the implementation of standards can be considered an output indicator. However, as with patent implementation, the challenge lies in the lack of a database. The only internationally comparable database regarding the implementation of standards is the ISO survey of management system standard certifications [44.67]. The *ISO Survey* is an annual survey of the number of valid certifications of ISO management standards worldwide (Tab. 44.3). To compile this information, accredited (i. e., independently evaluated) certification bodies are asked each year to provide information about the number of valid certificates that they have issued (ISO itself does not perform certification and therefore does not issue certificates). This results in the most comprehensive overview of certifications to these standards currently available, notwithstanding the fluctuations in the number of certificates from year to year due to differences in the number of participating certification bodies and the number of certificates they report. In particular, the more than one million certifications of ISO 9001 quality management standards and the over 300 000 environmental management standards certifications enable the construction of indicators by country, which over time reflect the diffusion of management innovations.

44.4 Future Challenges

In our critical evaluation of existing opportunities for using standardization activities and published standards as research and innovation indicators, we observe significant fragmentation in various dimensions. Consequently, a comprehensive approach is needed.

In contrast to the basic Community Innovation Survey that is mandatory for all Member States of the European Union, standardization has been included in the national editions only in the United Kingdom and Germany. In addition, the questionnaire versions are not even aligned between these two countries, and consistency over time, i. e., between different waves, has not been achieved within the British survey. Specific efforts in setting up panels wholly dedicated to standardization have been implemented only in Germany so far. No attempts have yet been made to expand this nationally focused initiative to other countries or to the European or even international level.

Table 44.3 Number of certificates issued related to the most important ISO standards [44.67]

Standard	Number of certificates in 2015
ISO 9001 (Quality management system (QMS))	1 033 936
ISO 14001 (Environmental management)	319 324
ISO 50001 (Energy management)	11 985
ISO 27001 (Information security management)	27 536
ISO 22000 (Food safety management)	32 061
ISO/TS 16949 (Quality management system for the automotive industry)	62 944
ISO 13485 (Medical device QMS)	26 255
ISO 22301 (Business continuity management)	3133
ISO 20000-1 (IT service management systems)	2778
Total	1 519 952

In addition, whereas PATSTAT provides patent data in a standardized format for all major patent offices, a similar database is not available for standards. High-quality data, while available for a few European countries, does not exist for the majority of European countries or the OECD member states. Furthermore, the rather decentralized standardization system in the United States, with several hundred standardization bodies, represents a fragmented landscape itself, which poses a challenge for country-specific approaches in Europe. A review by *Zoo* et al. [44.68] revealed that quantitative studies on standards in emerging economies are rare, and those that do exist focus primarily on China.

To effectively address these two dimensions of fragmentation, both aspects must be considered. On the one hand, the topic of standardization would need to be included in the basic Community Innovation Survey module required for all member states, on a regular cycle of every 4 or even 2 years. Alternatively, an international standardization survey could be established, as we observe a shift in standardization activities not only from the national to the European level, but to the international level as well, driven by the numerous standardization consortia active at the international level. On the other hand, the fragmentation and heterogeneity in quality related to standards databases would require a joint international initiative similar to those achieved by PATSTAT.

In addition, two further challenges that have not yet been successfully tackled by the Community Innovation Survey or existing patent databases should be noted. As we know from the vast amount of previous research, close interaction between the various stakeholders and institutions is needed to realize a well-functioning innovation system [44.69]. However, the community innovation survey is focused on businesses and their perspectives. This narrow focus must be widened to include both research institutes and other institutions on the one hand, and consumers on the other. Such an expansion would also be beneficial for standardization surveys, given the potentially important contributions of research institutes to the development of standards already validated by research on standard-essential patents and publications, and the high relevance of users for their implementation. However, public sector stakeholders must be integrated as well, as they contribute to standardization, for example, in aligning standards with the regulatory framework, and they must rely on standards, as in the case of public procurement [44.27].

As already mentioned, existing patent databases provide information only on the application details and current legal status of a patent, and not its actual implementation in products and services. Although we can assume that stakeholders would not invest resources in a standardization process unless they were interested in implementing the standard, as there would be little strategic motivation (e. g., blocking competitors via standards) [44.19], we face a similar measurement challenge related to standards. Standards databases generally do not provide information on their implementation, and the exception of the *ISO survey* [44.67] focuses on the few very visible management standards relying on certification data. However, this type of information would provide valuable insight into the dissemination of standards. This becomes even more relevant by considering that developing countries benefit mainly from implementing and not from developing standards, as was recently argued and confirmed by *Zoo* et al. [44.68].

As discussed in an earlier work by *Blind* [44.70], the focus on standardization and standards as innovation activity and results must be widened to encompass the whole quality system, a term first mentioned by *Guasch* et al. [44.71], or the whole quality infrastructure, a term introduced by *Sanetra* and *Marbán* [44.72]. A quality infrastructure is a system of institutions that jointly ensure that products, processes, and services meet certain predefined specifications. Most notably, it enables companies to improve both their production processes and their products, facilitating compliance with regulations or international requirements, especially international standards. The elements of quality infrastructure, in addition to standardization and the standards created, include conformity assessment (i. e., certification), accreditation and market surveillance, as well as metrology. These components are highly complementary to standards, as well as to technical regulations recently introduced by the OECD, in partnership with other organizations [44.73], for countries' analysis of policies targeting small and medium-sized companies. As an example, it is not possible to formulate a standard regarding the properties of a product unless the respective measurement units are defined, and adequately calibrated measurement instruments exist. The standard is effective only if producers comply with it, which is more likely if there are incentives to do so—for instance, if compliance could be signaled to potential consumers through a certification scheme. The impacts of certification increase in significance in proportion to the trust that customers have in the certification institute, which is higher if an accreditation body has evaluated the competence of the certifier (e. g., *Blind* et al. [44.74]). The high interdependence between the various elements of the quality infrastructure requires a comprehensive or holistic approach in which these elements and their activities are perceived as integral parts of a complex system (for a first economic framework see [44.58]). They cannot be tackled as independent activities isolated from the functioning of the whole. This is an important consideration when setting up a new quality infrastructure or improving an existing one. It requires an understanding of how the components support each other, the embedding of each element within the whole system, and the framing of this infrastructure as a pillar of the national economy or innovation system [44.75].

The overall availability of data regarding standardization activities or standards (see *Blind* [44.76, 77] for surveys) and their impact on—or more appropriately, their interrelation with—innovation [44.78] and companies' commercial success must now catch up to the already available data on research and innovation activities on the one hand, and their successes and impacts on the other. In addition, going one step further requires including other innovation system actors in such survey approaches, as well as addressing the implementation of standards within the national quality infrastructure to better capture their effective dissemination over time, countries, and industries.

44.5 Relevance for Decision Makers in Industry and Policy

These new opportunities to collect data regarding standards and their implementation could be used by decision makers in both industry and policy.

Recent studies (e. g., *Großmann* et al. [44.29]) reveal that, despite the relevance of patents and standards for new product development, they have not yet been integrated into strategic (technology) management. Screening of the existing standardization landscape and stocks of standards, however, might inform companies' decision makers of opportunities to set their own standards, as well as the need to implement existing standards. Recent reviews of both traditional technology transfer channels [44.79] and open innovation [44.80, 81] do not include the option of standardization, even though knowledge sourcing in standardization processes is particularly relevant for small companies [44.19]. Clearly, opportunities for standardization are far from being effectively exploited by industry.

From a policymaker perspective, available indicators related to both standardization and standards can be used to evaluate existing research and innovation programs and to design new programs, as well as to assess a country's innovation policy and system in general. One example is the Lead Market Initiative (LMI) established by the European Commission [44.82], which focused primarily on the three instruments of public procurement, legislation, and standardization [44.83]. The final evaluation of the LMI [44.84] could have been based on rigorous quantitative analyses using time-series data, even allowing the application of a difference-in-differences approach. The European research and innovation program Horizon 2020 that has been ongoing since 2014 also includes standardization processes and standards, in addition to scientific publications and patents, as success indicators for innovation [44.85–87]. Here again, control groups of companies not being promoted by the program and previously not involved in standardization could be generated based on the Community Innovation Survey, including sections on companies' involvement in standardization and implementation of standards.

As discussed in the section on examples, the Commission of Experts for Research and Innovation (EFI), which advises the German federal government, has included the number of secretaries within ISO by country as a performance indicator, in addition to scientific publications and patents, in their annual report on research, innovation, and technological performance in Germany [44.63]. Since the dominant position of both Germany and the United States is challenged by the expanding international standardization activities of China and Brazil as emerging countries, future innovation policy initiatives might consider subsidizing companies' participation in international standardization committees to represent national interests, both in a commercial sense and in ethics debates related to genetically modified organisms or privacy issues such as data protection in the cloud [44.88].

Furthermore, standards are an element of the national regulatory framework [44.3], and constitute a technical barrier to trade (TBT) at the international level when standards differ between countries. This was a critical issue, for example, during the now abandoned negotiations on the Transatlantic Trade and Investment Partnership (TTIP) [44.89, 90]. Since institutions are important elements of national innovation systems, institutional changes have implications for the level and direction of innovation. Consequently, historical data regarding the impact of standards on innovation could provide a sound database for an ex ante assessment of the effects of institutional changes as a result of standardization systems in the European Union and its Member States on future innovations (see *Blind* [44.76, 77] for current insight into the impact of standardization and standards on innovation). In this context, it should be mentioned that standardization bodies are increasingly performing foresight analysis in order to anticipate future challenges, enabling a proactive rather than reactive approach [44.91].

In summary, the policy relevance of standardization in relation to innovation is evolving and progressing from the OECD members to the global level, especially in the large and fast-growing emerging countries. Yet, despite the launch of the LMI by the European Commission 10 years ago [44.82] and the recent incorporation of benchmarking measures focusing on small and medium-sized companies into OECD policy [44.73], the potential for standardization as an effective and efficient instrument for promoting innovation is still not fully exploited by policymakers. For example, in the European Commission's new publication [44.3] on open innovation, open science, and openness to the world, in addition to the value of international collaboration in science and research as a means of fostering open innovation to improve scientific quality and research results, the importance of global standard-setting is discussed as a way to more effectively tackle global challenges, facilitating participation in global value chains and new and emerging markets. However, standards are not explicitly considered in regulatory reform measures, for example, in the implementation of strategies to promote open innovation. Similarly, in efforts to promote open science, standards are not accepted as another output of research and innovation activities in addition to publications and patents, although this was addressed in Horizon 2020 [44.87]. Because the potential for standardization as a strategic management and policy instrument has not been effectively exploited, the related use of standardization and standards as science and technology indicators is still limited. However, the opportunities described may serve to drive the integration of standards into the portfolio of existing and well-established science and technology indicators.

Acknowledgments. A previous shorter version of this paper was presented at the OECD Blue Sky Forum on Science and Innovation Indicators in Ghent in September 2016. The author thanks two anonymous reviewers for their comments, which helped me to improve the chapter significantly. Funding has been received from the European Union's Horizon 2020 research and innovation programme under Grant Agreement No. 778420—EURITO.

Knut Blind

Institute of Technology and Management
Technische Universität Berlin
Berlin, Germany
knut.blind@tu-berlin.de

Knut Blind is Professor of Innovation Economics at the Technische Universität Berlin. He studied Economics, Political Science and Psychology at Freiburg University. He was awarded a BA at Brock University (Canada). He received his Diploma in Economics and his Doctoral degree from Freiburg University. In April 2006, Knut Blind was appointed Professor of Innovation Economics at the Technische Universität Berlin. He also held an Endowed Chair on Standardisation at Rotterdam School of Management between 2008 and 2016.
