Introduction

According to the North American Veterinary Nutraceutical Council, a veterinary nutraceutical is defined as "a substance which is produced in a purified or extracted form and administered orally to patients to provide agents for normal body structure and function and administered with the intent of improving the health and well-being of animals." This definition differs slightly from country to country. It seems that nutraceuticals fall somewhere between food/feed nutrients and drugs. Although the herbal medicines have been used for thousands of years in Ayurvedic, Homeopathic, Siddha, Unani, Chinese, Tibetan, Egyptian, Russian, African, Amazonian, and many other systems, by the turn of the twenty-first century, their use became even more popular throughout the world because of their easy access, affordability, and greater tolerability with a wide margin of safety. Outside the USA and Europe, more than 80% of the population relies upon herbal medicines because they are available over the counter and have fewer side effects. Currently, the nutraceutical industry totals more than $250 billion per year, and the use of nutraceuticals in animal health and diseases is more popular than in humans. Due to overriding factors, such as low cost and safety, today's veterinarians may prefer nutraceuticals over modern medicines.

Unlike synthetic pharmaceuticals, nutraceuticals often consist of many bioactive compounds that hit multi-targets and pathways. As a result, nutraceuticals may exert multiple activities, such as free radical scavenging and antioxidative, anti-inflammatory, immunomodulatory, adaptogenic, sedative, antimicrobial, etc., with diverse pharmacological effects (Gupta 2016; Attiq et al. 2018). By having such biological and pharmacological activities, nutraceuticals appear to have wide applications in many human and animal diseases, such as diabetes, hypertension, periodontitis, cognition dysfunction, arthritis, allergies, gastrointestinal, hepatic, renal, cardiovascular, respiratory, genitourinary, and other body organ/system-related dysfunctions, and cancer. A large number of nutraceuticals in the form of prebiotics, probiotics, and synbiotics are used to promote animals' gut health, but appear to favorably influence the functionality of other vital organs as well. By having multiple bioactive constituents, nutraceuticals often provide synergistic effects and impede drug resistance to antibiotics, which is a global health issue (Lillehoj et al. 2018).

In the present world situation, due to the healthcare crisis and dwindling financial resources, the nutraceutical industry faces many challenges. For a large number of nutraceuticals, no data are available on safety and toxicity due to lack of pharmacokinetics, pharmacodynamics, pharmacological, and toxicological studies (Gupta 2016). While some nutraceuticals enjoy the GRAS (generally recognized as safe) status from the US FDA, others pose a toxic threat to human and animal health (Gupta et al. 2018). Due to inadequate quality control, contamination of nutraceuticals with metals, mycotoxins, and inherently toxic plant alkaloids and adulteration with drugs of abuse not only compromise their quality but raise serious health concerns, in addition to giving a bad image to the nutraceutical industry. Patients receiving nutraceuticals also consume therapeutic drug(s), and with the increasing polytherapy trend, adverse interactions and outcomes ensue due to metabolic perturbances from food–nutraceutical–drug interactions (Doorman et al. 2016; Gupta et al. 2018). Furthermore, in many cases, claims for nutraceutical use are either exaggerated or asserted without sound scientific merit.

Nutraceuticals are primarily derived from biological (plants, invertebrate and vertebrate animals, fish, and birds) sources and are well characterized for chemical constituents and biological and pharmacological properties. But, unlike pharmaceuticals, nutraceuticals lack unremitting efforts for the basic core scaffold, mechanism of action (essential and adverse pathways), bioinformatics, pharmacovigilance, structure–activity, dose–response, temporal relationships, and clinical studies.

Unlike modern medicines, nutraceuticals are not strictly regulated in any country. In the USA, the only major regulation related to nutraceuticals is the 1994 passage by the US Congress of the Dietary Supplement Health Education Act. Based on this loosely regulated act, dietary supplements are classified as foods, not dugs, allowing them to be sold without proof of safety and effectiveness (US FDA 1994). However, unlike food, nutraceuticals are not generally recognized as safe, nor can one assume that they are all safe (Gupta et al. 2018). As of now, the FDA's position is clearly asserted that this act does not apply to animals, and the American Veterinary Medical Association (AVMA) does not believe that the act should be modified to include animals (Burns 2017). In the European Union, current regulations require evidence that herbal medicinal products meet acceptable standards of quality, safety, and efficacy before a product license can be issued. Quality control and regulatory guidelines for nutraceuticals, from production, distribution, and national and international trade up to end-user level, appear to vary widely from country to country, and currently they are not strictly adhered to as for pharmaceuticals.

At recent national and international conferences (American Veterinary Medical Association, International Veterinary Congress, World Veterinary Association Congress, European nutraceuticals, and many others), a large number of veterinarians, nutritionists, food scientists, and animal health professionals recognized the importance of nutraceuticals for animal health and diseases. Accordingly, *Nutraceuticals in Veterinary Medicine* has been prepared to meet the challenges of today's veterinarians, pet lovers, animal health professionals, farm animal producers, and the veterinary nutraceutical industry. The book contains more than sixty chapters, arranged under seven sections. Each chapter is prepared using a very user-friendly format to provide scientific insight for academicians and veterinary practitioners with an interest in animal nutrition, complementary veterinary medicine, and nutraceutical product development and research.

The factual statements are substantiated with pertinent references for further reading. Some chapters are prepared from the one health perspective, encompassing animal and human health and experimental studies.

Following a brief introduction, the book begins with Section I on common nutraceuticals that are used in the formulations of hundreds of nutraceutical products. This follows Section II on prebiotics, probiotics, synbiotics, enzymes, antibacterial alternatives, and feed additives. The bulk of this book (20 chapters) lies in Section III that deals with nutraceuticals in organ/system-related diseases and disorders. Section IV covers chapters devoted to nutraceuticals for specific species including cattle, equine, camelids, and poultry. This follows Section V on safety and toxicity evaluation of nutraceuticals and functional foods using *in vitro*, *in vivo*, and other models, biomarkers for selected foods and nutraceuticals, and toxic interaction of nutraceuticals with foods and pharmaceuticals. Section VI deals with newer trends in nutraceutical research and product development covering chapters on proteomics and foodomics, nanoparticle-based bioavailability of nutraceutical ingredients and nanosupplements, and veterinary nutraceuticals stability testing. Lastly, Section VII extensively covers chapters on regulatory aspects of nutraceuticals in different continents and countries, including North America, the European Union, India, China, Australia, New Zealand, Turkey, the Philippines, and South Africa. *Nutraceuticals in Veterinary Medicine* is the most comprehensive book in the field of veterinary nutraceuticals, and it offers many chapters on novel topics that are not

covered in any previously published book. This book will serve academia, industry, and government sectors alike.

The editors remain grateful to the contributors of this book from many countries (the USA, Australia, Canada, China, India, Philippines, Russia, Saudi Arabia, South Africa, Turkey, and the UK) for their hard work and dedication. These authors are highly qualified and trained in diverse disciplines (veterinary medicine, nutrition, food science, animal science, pharmacology, toxicology, molecular biology and technology, omics, chemistry, biochemistry, and others), who shaped this book using a framework of integrative approach. The editors would like to thank Ms. Annette Klaus, associate editor, Mr. Bibhuti Sharma, project coordinator (Springer Nature), and Ms. Krithika Shivakumar, project manager, for their untiring support in the production of this book. Last but not least, the editors would also like to thank Ms. Robin B. Doss for critically checking the text and references.

Part I

Common Nutraceuticals

Standardized Turmeric and Curcumin

Naresh Chand

Abstract

Turmeric root is an ancient Ayurvedic herb, and it is used as a spice, and in very low doses, it may modulate immune-inflammatory diseases of the gut, joints, brain, and body in turmeric-consuming part of the world. Turmeric contains more than 235 active ingredients including essential oils, curcuminoids (>89), and turmerosaccharides as well as curcuminoid-free ingredients and fiber. These phytochemicals and fiber as well as their metabolites and products of microbial degradation may act in additive or synergistic fashion as a modulator of persistent dysregulated chronic immune inflammation and pain in horses, pets, and people. The limited preclinical data support that low doses of turmeric or its active ingredient (curcumin/curcuminoids) may have modulatory applications in preventing or treating immune-inflammatory diseases of the eyes, brain, joints, and gut in pets and people. The standardized turmeric (ST) is a novel concept; it is based on a recently filled patent. ST may reduce the need for analgesics (opiates), antidepressants, steroids, and anticancer medications. Using the latest drug-targeted delivery and reliable clinical trial strategies, ST may be considered for R&D for the prevention and treatment of OA, dementia, and other age-related diseases of the eyes, brain, gut, and joints in pets and humans. The consumers need to be aware of the adulterations of turmeric and its extracts.

Keywords

Standardized turmeric · Curcumin · Modulator of persistent dysregulated chronic immune inflammation and pain · Pets

N. Chand (✉)
ADRx Synergy, North Potomac, MD, USA

1 Introduction

Turmeric is the dried rhizome (root) from three major varieties of the *Curcuma longa* plant—*Curcuma aromatica* (wild turmeric, South Asia), *Curcuma wenyujin* (China), and *Curcuma domestica* (Thailand). It is an herbaceous perennial plant which belongs to the ginger family, *Zingiberaceae*. Turmeric is native to Southeast Asia particularly to the Indian subcontinent. It is cultivated in India, China, Thailand, Indonesia, Japan, and other tropical regions including Africa (Gopinath and Karthikeyan 2018). More than 133 different species of turmeric have been identified (Prasad and Aggarwal 2011). The composition of turmeric has been summarized in Table 1. Turmeric root contains curcuminoids, curcumin-free ingredients, essential oils, water-soluble turmerosaccharides, and fiber. The amount of medicinal ingredients such as curcumin/curcuminoids in turmeric powder may vary considerably from region to region (Ashraf et al. 2015). This may depend on the species, phylogenetic and epigenetics of the turmeric plant, cultivation practices, soil nutrition, rainfall, and sun exposure, as well as different extraction methods. Native turmeric's more than 235 complex phytochemicals naturally assemble in the roots and may exert additive or synergistic health beneficial effects (Aggarwal et al. 2013; Javeri and Chand 2016; Li et al. 2011). Turmeric may be considered the "poor man's aspirin" as it is available in every Indian home and is affordable as food (spice).

Pulverized turmeric root is an ancient Ayurvedic herb (spice) often used for cosmetic, religious, and spiritual festivities as well as for flavoring and coloring foods in traditional cooking. It is also used as a traditional herbal medicine since ancient times in India and other turmeric-consuming parts of the world. In addition, small quantities of turmeric are used two or three times a day as a flavoring spice in the Indian subcontinent and Southeast Asia. Turmeric alone, or in combination with other herbs, is seasoned by frying in cooking oil or ghee (clarified butter) before

Table 1 Composition of turmeric and major curcuminoids

Turmeric constituents		Curcuminoids	
	% (w/w)		%
Curcuminoids	1.4–5[a]	Curcumin	60–70
Essential oils	3–7	Demethoxycurcumin	20–27
Fiber	2–7	Bismethoxycurcumin	10–15
Minerals	3–7		
Fat	5–10		
Protein	6–8	Turmerosaccharide	10
Carbohydrate	60–70		
Moisture	6–13		

Modified after Nelson et al. The essential medicinal chemistry of curcumin. Mini-perspective. J Med Chem 60, 1620–1637
[a]Ashraf et al. (2015)

adding beans, grains, rice, and vegetables. This method is part of the lipidation (solubilization), activation, and stabilization of turmeric's active ingredients. It is used as food, and it may offer some health benefits in early stages of chronic diseases. This ancient formulation method (may resemble to nanotechnology of the modern era) is used in traditional Indian kitchens. It may improve the bioavailability of phytochemicals in turmeric. The traditional Indian kitchen is a living and functional polypharmacy. Turmeric use has been described to prevent food and lung allergies, aches, pain, flu, common cold, skin wounds, and digestive and other disorders; it has been used to overcome the effects of concussions (TBI) and has been used in many herbal formulations (>800) in dietary supplements for prevention of a wide variety of diseases (Gopinath and Karthikeyan 2018). The safety and efficacy of these combinations (nutraceuticals or dietary supplements on the market) have not undergone rigorous testing in animals and people suffering with immune-inflammatory diseases of the joints, gut, and brain.

The health benefit of turmeric or its active ingredients, such as curcumin, may be more pronounced during early disease states (Javeri and Chand 2016; Sundaram et al. 2017; Kumar et al. 2018). Therefore, turmeric or curcuminoids and other ingredients are likely to be part of the preventive strategies rather than a cure. Standardized turmeric (meaning containing 1.4, 3, 5% curcumin, Chand 2018) and other ingredients at low doses may be used as an adjunct therapy in the management of dysregulated persistent chronic immune-inflammatory diseases of the musculoskeletal, gastrointestinal (digestive), pulmonary, cardiovascular, and nervous systems.

Ayurveda is an ancient art of restoring "homeostasis" under early disease states. It proposes that the amount of spice or its active ingredient(s) does not follow a perfect relationship to effectiveness (pharmacokinetics/pharmacodynamics (PK/PD) modeling)—meaning that more is not better. Preclinical studies in Alzheimer's mouse models support this concept (Lim et al. 2001; Begum et al. 2008). In fact, the opposite situation may occur at higher doses, meaning higher dose may negate its own health benefits (Dr. Frautschy UCLA; personal communication). One of the Ayurvedic medicine's basic principles is that efficacy cannot be related to plasma levels of a major ingredient in a spice (herb), and the whole herb is often more efficacious than its individual ingredients. In most preclinical studies, the distribution of active ingredient(s) of turmeric to site of action (inflammation or disease states) is not carefully investigated. The active ingredients of turmeric seem to be preferentially delivered to the site of inflammation (personal observation) and the brain of mice with progressive Alzheimer's disease state (Begum et al. 2008).

Curcumin, chemically known as (1*E*, 6*E*)-1,7-bis (4-hydroxy-3-methoxyphenyl) hepta-1,6-diene-3,5-dione, is a highly pleiotropic natural polyphenolic chemical (Fig. 1). Recently, Kumar et al. (2018) summarized the potential use of curcumin in aging-related diseases. Curcumin is one of the active ingredients in the spice turmeric—a routinely used spice in traditional Indian cuisine. Curcumin is known to exert numerous in vitro and in vivo pharmacological activities in experimental animals often at relatively high doses (concentrations). The broad pharmacological profile of curcumin in experimental animals tends to suggest that it may exert health beneficial effects; however, clear clinical evidence of efficacy in any disease state is still lacking.

Over the past decade, the field has made enormous progress in improving the bioavailability of curcumin (Gopi et al. 2017). In addition to improvement of curcumin's bioavailability (pharmacokinetics), high doses of curcumin were utilized in most clinical trials conducted so far. Neither improvement of bioavailability nor increased dose improved curcumin's efficacy in Alzheimer's disease in humans (Mazzanti and Di Giacomo 2016). This is in agreement with the Ayurvedic principle—more of one active ingredient is not better (Begum et al. 2008; Chand 2018).

The chemical structure of major curcuminoids—curcumin, demethoxycurcumin, and bisdemethoxycurcumin—and major metabolites of curcumin is shown in Fig. 1.

Curcumin is an unstable, reactive, and non-bioavailable physiochemical, and therefore it is not a lead candidate for R&D. This concept is likely to be true when high "astronomical" doses of curcumin are utilized in animals or patients, but low doses of standardized turmeric or curcumin may present R&D opportunities which should be explored. In this book chapter, I (as a lifelong Ayurvedic scholar and an R&D pharmacologist since 1981) take a different perspective on this subject matter of great economic and healthcare importance for aging populations. Standardized turmeric (containing 3, 9, 27, or 81 mg curcuminoids) taken with

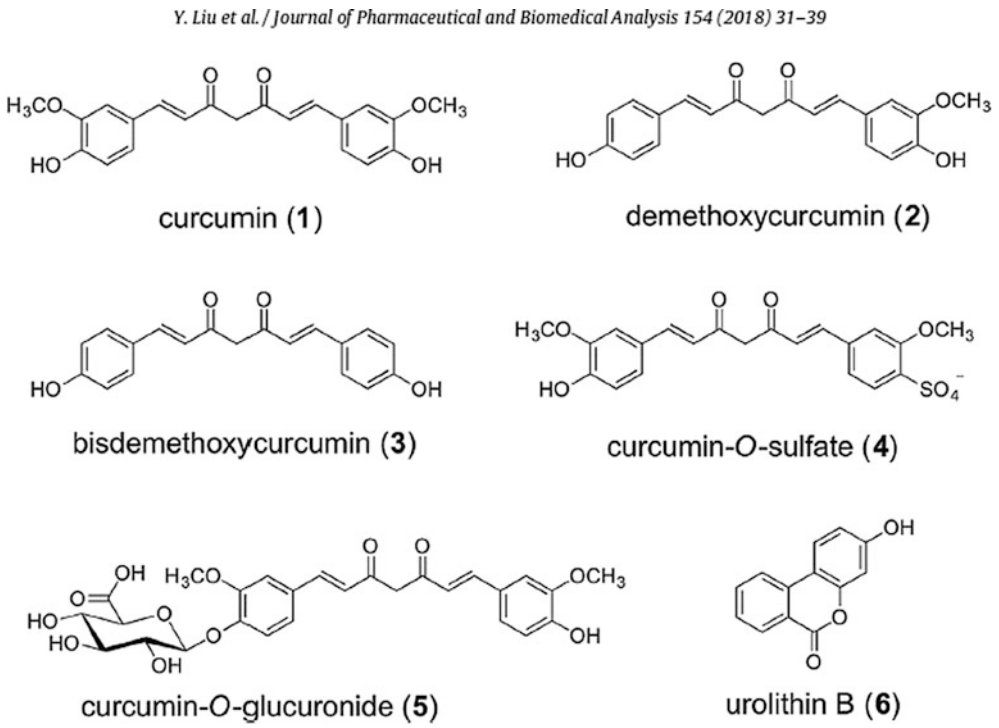

Fig. 1 Chemical structures of curcumin (**1**), demethoxycurcumin (**2**), bisdemethoxycurcumin (**3**), curcumin-*O*-sulfate (**4**), curcumin-*O*-glucuronide (**5**), and the internal standard, urolithin B (**6**)

food two to three times a day for life may have some long-term potential for slowing the age-related progression of chronic diseases in pets, including horses, and people. This chapter described the effects of turmeric or low doses of curcumin in animals, which may have some clinical relevance in the prevention of chronic illnesses of the joints, digestive system, eyes, brain, etc.

Curcumin may act as an immune modulator (Mollazadeh et al. 2017). Low doses of standardized turmeric or curcumin (curcuminoids) taken as a dietary supplement (as food/spice) for long duration (lifelong exposure) may exert modulation of immune inflammation in many chronic disease states including chronic pain, inflammatory bowel disease (IBD), osteoarthritis, and Alzheimer's disease (Javeri and Chand 2016; Lim et al. 2001; Begum et al. 2008; Sundaram et al. 2017). Furthermore, turmeric, which contains diverse and complex phytochemicals (>235; 69 curcuminoids), may serve as a preventive (modulatory) agent or as an adjunct therapy. It may reduce the need for medications such as opiates, NSAIDs, steroids, antiarthritic, or anti-gout, as well as anticancer agents. In other words, low doses of ST, especially when taken as a spice (herb in low doses) added to foods on regular basis—rather than in a pill (capsule)—may act as an adjunct therapy in many diseases with underlying dysregulated persistent chronic immune inflammation in aging pets, horses, and people.

The products of bioactive degradation and microbial metabolism of curcuminoids, polysaccharides, curcumin-free phytochemicals, and fiber in the digestive system may exert regulatory effects on genetics, epigenetics, protostomes, and function of microbiota in the digestive system. The photochemical metabolites from the liver and microbiota processing may exert additive or synergistic activity in modulating the gut-immune-brain axis, the colon and its surroundings—permeability and barrier functions of epithelium in immune-inflammatory diseases of the gastrointestinal tract and infections, constipation, and diarrhea. In Ayurvedic medicine, mild laxative effects of turmeric or ST and its interaction with microbiota in the digestive system have been suggested to improve gut-brain functioning (Shen et al. 2017).

Low doses of turmeric (~200–300 mg, once a day, BID) and curcumin (~3–30 mg once a day, BID, in foods) are often considered safe. In addition, many people in non-turmeric-consuming nations may be using too much of these dietary supplements—curcumin (curcuminoids) and turmeric alone or in combination with other dietary supplements and medications. They may not be benefiting from using these higher doses, and in fact, some may face adverse consequences, especially among seniors taking three to ten medications. Such drug-drug interactions remain to be evaluated. The efficacy and safety of standardized turmeric (ST) in disease states in pets and people taking various other medications or supplements is warranted. The level of various ingredients at the inflammatory site or brain or in cancer tissues in the disease states in dogs, cats, or horses may

offer better understanding of the absorption, distribution, metabolism, and excretion (ADME; pharmacokinetics—PK) and drug delivery issues in using herbs (nutraceutical "dietary supplements") in foods as well as adjunct medicine. The long-term use of low doses of ST as an oral supplement or as nanoparticles in disease states in pets and people may help in lowering the doses of medications such as NSAIDs, opiates, steroids, anticancer, anti-gout, anti-RA, and CNS-acting drugs. Thus, ST and other formulations of curcumin (curcuminoids, turmerosaccharides, curcumin-free phytochemicals) may exert sparing effects on morphine, steroids, and other medications.

2 Chemical Composition

Jia et al. (2017) reviewed and offered details about the chemical constituents of turmeric. It contains curcuminoids, steroids, terpenoids, flavonoids, and phenylpropene derivatives and alkaloids. The major curcuminoid (curcumin) has been extensively studied in preclinical animal models. In addition to turmeric's three major curcuminoids, there are several minor curcuminoids, which may exert significant bioactivities. They identified 89 curcuminoids in the turmeric samples using ultrahigh-performance liquid chromatography—quadrupole time-of-flight tandem mass spectrometry. Ashraf et al. (2015) demonstrated that content of curcuminoids in turmeric varies significantly from region to region of India (1.4–5.0%).

Commercially available curcumin contains at least three curcumin compounds including curcumin, demethoxycurcumin (DMC), and bisdemethoxycurcumin (BDMC) in a ratio of 66, 23, 11, respectively.

3 Turmeric Consumption

Prasad and Aggarwal (2011) summarized multiple uses of turmeric in Asian cuisine and its consumption. It is used as a preservative and antimicrobial agent and is used in making pickles (mango, limes, lemons, and others) and savory and sweet dishes and is widely used in Eastern cooking specialties. The consumption of turmeric in Asian countries in humans is in the range of 200–1000 mg/day (160–440 g/person/year, often costing less than $1 dollar). Intake in urban areas is lower (200 mg/day/person) than in rural areas (600 mg/day/person). This information may be used in translational sciences, meaning the consumption of curcumin from turmeric in Asian countries in humans is in the range of 2.8–30 mg/day (average of 15 mg/day; Chand 2018). In the USA, most people (healthy enthusiasts) are using 1–5 g of turmeric every day which is >5–25 times of that used in India. High doses of herbs often act as prooxidant and pro-inflammatory. Because of high consumption and demand for turmeric in Western countries, the adulteration with lead and other products has become a common practice.

3.1 Safety

Turmeric use (low dose) as a spice in food is safe for human consumption. However, high doses may alter taste and disturb gastrointestinal functions leading to nausea, diarrhea, and vomiting. Gupta et al. (2013) summarized that curcumin is safe in rodents, primates, horses, rabbits, cats, and humans. Curcumin inhibits the activity of drug-metabolizing enzymes such as cytochrome P450, GST, and UDP-glucuronosyltransferase in vitro and in animal models. Therefore, the possibility exists that drug-drug interaction in patients taking medications such as acetaminophen, digoxin, and morphine may increase the plasma concentrations after curcumin dosing. This may lead to potential drug safety concerns. Curcumin is an active iron chelator and induces anemia in mice fed iron-poor diets. These possibilities such as GI effects—nausea, diarrhea, and vomiting—anemia, and bleeding, under some circumstances, need to be kept in mind while advancing the R&D on standardized turmeric and curcumin (Gupta et al. 2013; Chand 2018).

It remains to be explored if standardized turmeric (containing >235 phytochemicals, essential oils, and fiber) offers better efficacy and safety than curcumin alone.

4 Pharmacokinetics

Despite a vast amount of publications on curcumin, detailed oral pharmacokinetic studies using turmeric and curcumin/curcuminoids (many formulations and brands) are still lacking. Following the latest PK/PD modeling and analytical techniques, detailed oral pharmacokinetic studies using turmeric or curcumin/curcuminoids (many formulations and brands) in the blood (cells) and tissues of cats, dogs, and horses living with chronic immune-inflammatory diseases are warranted. Such investigations would help in finding safe, effective, preventive, and therapeutic nutraceuticals for many diseases of pets and people.

Curcumin is insoluble in aqueous media; is unstable under conditions of ambient light, room temperature, and basic pH; and is readily metabolized or degraded upon oral dosing (Matabudul et al. 2012). Limited pharmacokinetic studies in mice (Begum et al. 2008), rats (Suresh and Srinivasan 2010), dogs (Bolger et al. 2017, 2018; Matabudul et al. 2012), and human (Schiborr et al. 2014; Small et al. 2017; Bolger et al. 2018) have been reported. Matabudul et al. (2012) studied

PK profiles following prolonged intravenous infusion of curcumin (10 mg/kg lipocurc™, either over 2 h or over 8 h) in dogs. The ratio of tetrahydrocurcumin (THC)/curcumin was highest in hippocampus > brainstem > striatum > spleen. Based on the data obtained in this study, they raised the possibility that this formulation may facilitate distribution into tissues via a transporter-dependent mechanism and that elevated tissue concentrations of curcumin may inhibit or saturate a putative reductase enzyme converting curcumin to THC in the body.

Bolger et al. (2017) investigated the distribution of curcumin (Lipocurc™) and its major metabolite tetrahydrocurcumin (THC) in dog (Beagles) and human red blood cells, peripheral blood mononuclear cells (PBMC), and hepatocytes. They observed a good correlation between the species differences of red blood cell metabolism of curcumin to THC and in vivo plasma levels of curcumin and THC from clinical studies. They found that curcumin's distribution into, and metabolism by, red blood cells significantly impacts the ADME (pharmacokinetics) of curcumin. They reported many species-related differences in distribution of curcumin and THC in dogs and humans. The metabolism of curcumin to THC was similar. Curcumin distribution into PBMC from patients with chronic lymphocytic leukemia (cancer) was higher compared to PBMC from healthy individuals. The greater distribution of curcumin into PBMC in patients with cancer may have therapeutic advantage (Bolger et al. 2018).

Suresh and Srinivasan (2010) studied pharmacokinetics following oral administration of piperine (170 mg/kg) and curcumin (500 mg/kg) in rats. The tissue concentrations of curcumin and piperine were determined by HPLC. Curcumin's bioavailability was 63.5% with a C_{max} at 1 h (intestine) and 6 h (blood) and remained at significantly higher level even at 24 h. Only a small portion of curcumin (0.2%) was excreted in urine. Concomitantly oral administration with piperine improved curcumin's intestinal absorption and stayed significantly longer in the body tissues. Curcumin was detected in the brain at 24, 48, and 96 h with a maximum at 48 h. They concluded that curcumin could be traced in the brain following its oral administration, and its bioavailability can be improved by co-administration with piperine. The long-term clinical studies using turmeric or curcumin at low doses are needed in pets, horses, and people.

Schiborr et al. (2014) conducted a randomized small crossover study in healthy subjects (13 women, 10 men). A single oral dose of 500 mg curcuminoids as native powder, micronized powder, or liquid micelles was utilized. Blood and urine samples were collected for 24 h, and total curcuminoids and safety parameters were quantified. In the area under the plasma concentration-time curve (AUC), micronized curcumin indicated 14-, 5-, and 9-fold and micellar curcumin 277-, 114-, and 185-fold better bioavailable than native curcumin in women, men, and all subjects, respectively. Curcumin was better absorbed in women than men. Both the micronized powder and, in particular, the liquid micellar formulation of curcumin significantly improved its oral bioavailability without altering safety parameters. The liquid micellar formulation of curcumin or nanoparticle may be well suited to deliver curcumin in human intervention trials. All safety parameters remained within the reference ranges following the consumption of these formulations. The observed differences in curcumin absorption (pharmacokinetics) warrant further ADME investigation in pets and horses of both genders.

5 Mechanism of Action

The precise mode of action for turmeric and curcumin (curcuminoids) remains unknown. Javeri and Chand (2016) and Kumar et al. (2018) summarized that curcumin may act via multiple modes of action. It may act as modulator of dysregulated immune inflammation. Curcumin is well known to influence many genes, epigenetic steps, enzymes, and pathways. This profile may be relevant to its broad spectrum of pharmacology (Javeri and Chand 2016; Cavaleri 2018; Kumar et al. 2018; McCubrey et al. 2017).

Colitti et al. (2012) evaluated the effects of dietary curcumin (CurcuVet, 4 mg/kg BID for 20 days, $n = 6$) and compared it with NSAID (firocoxib, 5 mg/kg BID for 20 days, $n = 6$) in dogs suffering with osteoarthritis (OA). This small clinical trial was designed to study the effects of NSAID or dietary administration of curcumin on canine transcriptome using circulating leukocytes. This study highlights the complexities of mode of action of curcumin on gene level using a chronic disease model. At the end of the treatment on day 20, a reduction of pain and a partial recovery of articular function were observed by the veterinarians. On day 20, these investigators discovered that curcumin treatment reduced 228 downregulated genes to 110 and reduced 271 upregulated genes to 31. Treatment with curcumin (CurcuVet, 4 mg/kg BID for 20 days, $n = 6$) altered gene expression, inhibited macrophage proliferation, downregulated genes involved in inflammatory response (TNFα, TLR4, IL8, IL18, and MAPK14), and upregulated Ikβ in the TNRF1 signaling pathway (improving communication between immune cells), as well as activated genes involved in fibrinolysis. However, NSAID upregulated genes (TNFα, TLR4, IL8) but did not influence genes (IL18 and Ikβ) in the TNRF1 signaling pathway. These findings show differential modulation of genes by curcumin and NSAID. A long-term large clinical trial is warranted in aging cats, dogs, horses, and people suffering with OA and other dysregulated chronic immune-inflammatory diseases of the joints, brain, eyes, and digestive system. In this study, the effect size was highly variable. These investigators

concluded that due to the small number of dogs (six) in the study and highly variable clinical effect size, the clear proof of clinical efficacy could not be established.

In the brain, diverse mechanisms of action may involve modulation of transcription pathways, protostomes, neurogenesis, and the hypothalamic-pituitary-adrenal axis as well as immune inflammatory pathways (Seo et al. 2015). The potential antiarthritic effects of turmeric or its extracts may be related to the establishment of equilibrium between catabolism and anabolism of joint cartilage as well as its well-known broad spectrum of anti-inflammatory activities. In 2016, de Oliveira et al. provided evidence that curcumin improves mitochondrial dynamics—mitochondrial biogenesis and mitophagy (a key step in keeping the cell healthy). They also elegantly summarized curcumin biosynthesis, source, bioavailability, and metabolism.

The long-term effect of turmeric- or curcumin-containing dietary supplements (nutraceuticals) and medications using wide dose ranges and longer duration of treatment on gene transcription (expression and function in circulatory leukocytes or at the site of inflammation such as the joints or the brain) in horses, pets, and patients living with specific diseases may offer reliable, reproducible, and viable biomarkers of clinical efficacy and safety. This knowledge may help the R&D experts in discovering and formulating safer and effective combination(s) of herbs or their active ingredients.

6 Digestive System

Inflammatory bowel disease (IBD), a chronic immune disorder of the digestive system, is very common in cats and humans. IBD can be divided into two subgroups: Crohn's disease (CD) and ulcerative colitis (UC). The current pharmacological approaches for treating IBD are generally not curative and are often associated with serious side effects. The disease-altering medications, such as thiopurines, methotrexate, tacrolimus, thalidomide, cyclosporine, and infliximab, are expensive. Brumatti et al. (2014) and Neto et al. (2018) have reviewed and summarized the pathogenesis of IBD and its current therapeutic approaches and potential therapeutic utility of curcumin. Often there is a strong relationship between nutrition and IBD pathogenesis. Therefore, developing new dietary strategies using turmeric or its active phytochemicals such as curcumin may open a door for finding an affordable adjunct therapy and prevention approach for the early stages of IBD. They concluded that it is necessary to find the suitable dose of curcumin and optimal duration of treatment for preventing or treating the recurrence of IBD. Turmeric or its active ingredients may act by decreasing the mucosal immune inflammation and dysbiosis in acute and chronic IBD.

Turmeric has been used in Ayurvedic and traditional folk medicine in the management of inflammatory disorders including IBD. Therapeutic concentration of turmeric and its active ingredients such as curcumin may be achieved in the gastrointestinal tract after oral dosing. This may make it a good candidate for the prevention and treatment of IBD (Hanai et al. 2006; Brumatti et al. 2014; Lang et al. 2015; Neto et al. 2018; Bastaki et al. 2016; Yang et al. 2018). Poor aqueous solubility, poor absorption, bio-distribution, rapid metabolism, and fast elimination of curcumin may cause limitations in its clinical development (Brumatti et al. 2014; Javeri and Chand 2016). However, this profile may be desirable for R&D for IBD. It remains to be discovered if standardized turmeric may overcome such challenges in treating digestive diseases (IBD and diarrhea) in cats, dogs, and people.

Bastaki et al. (2016) evaluated the effect of turmeric on colon histology, body weight, ulcer, IL_{23}, MPO, and glutathione in acetic acid-induced IBD in rats. Turmeric powder (1, 10, and 100 mg/kg/day) was administered orally for 3 days before or 30 min after the induction of IBD. This treatment was found to reduce macroscopic and microscopic ulcers, IL_{23}, myeloperoxidase, and GSH (reduced glutathione peroxidase). The lowest dose of turmeric (1 mg/kg) caused a significant decrease in mean macroscopic ulcer and score after day 7, when compared to untreated groups. Interestingly a high dose (100 mg/kg) also caused a significant (~50%) reduction after 2 days. High dose had no significant effect on mean macroscopic ulcer and score after 4 and 7 days of IBD. They also observed that this treatment increased body weight and reduced colitis-related oxidative stress. The 10 mg/kg dose appeared to be the ideal dose in rat IBD model. These investigators suggested a possibility of developing *C. longa* (turmeric) as a safe and potent anti-inflammatory and antioxidant herbal remedy in the management of IBD.

Hanai et al. (2006) studied the effect of curcumin on ulcerative colitis (UC). Patients suffering with UC were given sulfasalazine (1.0–3.0 g/day) or mesalamine (1.5–3.0 g/day) plus 2 g curcumin (1 g taken after breakfast and 1 g after the evening meal), or placebo, for 6 months. Patients were then followed for an additional 6 months, during which either SZ or mesalamine was continued. All medications except SZ or mesalamine were discontinued 4 weeks before starting this study. Eight of 39 patients in the placebo group relapsed, whereas 2 out of 43 patients on curcumin relapsed during the 6 months of therapy. These authors concluded that curcumin may be a safe and effective medication for maintaining remission in patients with Crohn's disease or UC. In another study, IBD patients were given curcumin (360 mg/dose) three to four times a day for 3 months. This treatment significantly reduced clinical relapse in patients with quiescent IBD. The inhibitory effects of curcumin on inflammatory mechanisms like NF-κB, COX_2, LOX, and TNFα and its safety profile suggest that

curcumin or turmeric may have some prospects in the treatment of IBD. They recommended that randomized controlled clinical investigations in large cohorts of patients are warranted to fully evaluate the clinical potential of curcumin (Hanai and Sugimoto 2009). Similar well-designed long-term clinical studies using turmeric or its active ingredients need to be conducted in cats and dogs suffering from digestive diseases such as diarrhea and IBD.

Later, Lang et al. (2015) demonstrated that the addition of curcumin to mesalamine was superior to the combination of placebo and mesalamine in inducing clinical and endoscopic remission in patients with mild-to-moderate active UC. Patients received 1 month of add-on therapy of 3 g oral capsules of curcumin or an identical placebo in two divided doses daily (consisting of three capsules twice a day before meals). This addition did not produce any apparent adverse effects. They concluded that curcumin may be a safe and effective agent for the management and treatment of UC.

Shen et al. (2017) evaluated the effects of oral curcumin administration on the gut microbiota of C57BL/6 mice. Curcumin significantly affected the abundance of several representative families in gut microbial communities including Prevotellaceae, Bacteroidaceae, and Rikenellaceae. Dou et al. (2018) studied the effect of curcumin (100 mg/kg/day PO for 14 days) on collagen-induced arthritis (CIA) in rats. They demonstrated that curcumin attenuates CIA through modulating the function of the cholinergic system in the gut-brain axis.

Yang et al. (2018) administered curcumin or tetrahydrocurcumin orally (0.1 or 0.25 mmol/kg daily) for 7 days before and together with dextran sulfate sodium (DSS administration, 3% in tap water) in mice. Oral dosing of curcumin significantly reduced the severity of DSS-induced colitis. This treatment also reduced the activation of NF-ϰB and STAT3 as well as expression of COX-2 and inducible nitric oxide synthase. Tetrahydrocurcumin exerted weak inhibitory effects. This group of scientists concluded that oral administration of curcumin inhibits experimentally induced murine colitis. This effect was associated with inhibition of pro-inflammatory signaling mediated by NF-ϰB and STAT3.

Ohno et al. (2017) studied the effect of nanoparticle curcumin on the development of DSS-induced colitis in mice. The rodent diet was mixed with nanoparticle curcumin (0.2%). The administration of nanoparticle curcumin was started 7 days before DSS administration. This treatment significantly improved mucosal permeability and reduced body weight loss, disease activity index, and histological colitis score. This treatment significantly reduced NF-κB activation in colonic epithelial cells and mucosal mRNA expression of inflammatory mediators and increased the abundance of butyrate-producing bacteria and fecal butyrate level. This was accompanied by increased expansion of CD4 + Foxp3+ regulatory T cells and CD103+ CD8α− regulatory dendritic cells in the colonic mucosa. They concluded that nanoparticle curcumin may be a promising candidate as a therapeutic option for the prevention and treatment of IBD.

McCann et al. (2014) demonstrated that turmeric, partly due to its curcumin content, exerts a beneficial effect on two gene variants linked to IBD severity. Turmeric reduces the abnormal transport function of the SLC22A4 503F variant (authenticated cell lines Flp-In™ 293 (Flp293) and 293/TLR4-MD2-CD14). It also increases the activity of the IL_{10} promoter variant, which was reduced in IBD. They suggested that IBD sufferers with the defective gene variants may benefit from turmeric consumption. These in vitro observations suggest a need for conducting long-term clinical studies using standardized turmeric and/or other curcumin formulations in pets, horses, and people suffering with IBD.

Bland et al. (2017) studied the effects of liposomal curcumin on five opportunistic bacterial strains in the equine hindgut. Horses often suffer gastrointestinal (GI) tract illnesses such as colic, enterocolitis, diarrhea, and inflammatory bowel disease. The intestinal tract in horse is sensitive and contains a highly complex microbial population. Infections, immune inflammation, and colic may occur as a result of a shift in the microbial population, or dysbiosis. The use of nutraceuticals in the equine industry is on the rise, and curcumin possesses antimicrobial properties that may help in minimizing the proliferation of opportunistic bacteria. *C. perfringens*, *C. difficile*, *E. coli* in general and K-12, and *Streptococcus bovis/equinus* complex (SBEC) are common opportunistic bacteria found in the hindgut of horses. Liposomal curcumin at higher doses has the potential to increase the concentration of opportunistic bacteria, which would contribute to microbial dysbiosis rather than mitigate it. The use of standardized turmeric or its active ingredients as nanoparticles, and a wide range of low doses with a longer treatment period, may restore homeostasis in the gastrointestinal system during disease states such as enterocolitis, diarrhea, and inflammatory bowel disease and dysbiosis. It may exert antimicrobial properties without adversely affecting cecal characteristics.

Turmeric, or its curcuminoids (curcumin) and other active ingredients, may slow the progression of dysregulated persistent chronic immune inflammation in the wall of the intestine if the treatment is started in the early stages of IBD. The regular use of low doses of turmeric or its extracts as dietary supplement or as spice (as food) may also reduce the need for disease-altering medications in the gastrointestinal tract. Clinical long-term studies using a wide dose range of turmeric or curcumin in pets, horses, and people living with mild-to-moderate IBD are warranted.

In conclusion, curcumin, or its novel nano-formulations, or standardized turmeric (containing >235 phytochemicals, fiber, and their degradation products by the gut microbiota)

may alter permeability and epithelial barrier function of the gastrointestinal (GI) tract by altering the macro- and micro-environment in IBD (UC and CD) in cats, dogs, and people. Turmeric, or its active ingredients' broad spectrum of the mechanism of action, especially under immune inflammatory states in the gastrointestinal tract, may restore homeostasis and may slow the progression of IBD, if treatment is started in the early stages.

7 Common Cold and Infections

Cats and dogs often suffer from ear, skin, urinary, and bladder infections and common cold. The anti-inflammatory, antibacterial, and antiviral activities of turmeric and curcumin may help in preventing or treating infection in pets and people. Kennel cough (common cold) is common in cats and dogs. There is a need for finding natural products or extracts to deal with the emergence of drug-resistant influenza viruses and the threat of pandemics in pets and people. Turmeric and curcumin may act in additive or synergistic fashion with anti-infective agents.

The three new chemical entities and ten known curcuminoids isolated from a methanol extract of turmeric strongly inhibited neuraminidases from two influenza viral strains, H1N1 and H9N2. This inhibition was noncompetitive with IC_{50} values ranging from 6.18 ± 0.64 to 40.17 ± 0.79 μg/ml and 3.77 ± 0.75 to 31.82 ± 1.33 μg/ml, respectively. Three compounds (4, 5, and 13) also exhibited significant inhibitory activity against the neuraminidases from novel influenza H1N1 (WT) and oseltamivir-resistant novel H1N1 (H274Y mutant) expressed in 293T cells. These findings suggest that turmeric or its curcuminoids may have preventive and therapeutic potential in the prevention and treatment of diseases caused by influenza viruses.

Recently, Han and his team (2018) demonstrated that daily oral dose of curcumin (100 mg/kg for 7 days) inhibited influenza A virus (IAV) in vitro and reduced the severity of the disease in mice. Curcumin was found to trigger expression of heme oxygenase-1 in vivo and attenuate IAV-induced lung injury. Furthermore, curcumin regulated immune response following IAV infection through inhibiting production of local inflammatory cytokines and NF-κB signaling in macrophages and by enhancing IκBα and AMPK. These data suggest that turmeric or its extract may have promising efficacy in viral pneumonia.

Nonsurgical traumatic wounds lead to bacterial infections. These infections can be a life-threatening medical situation, especially those caused by multidrug-resistant (MDR) bacteria with limited therapeutic options. The antimicrobial activity of polymyxin B and curcumin, alone and in combination, was determined to be effective against MDR bacterial isolates associated with traumatic wound infections. In the presence of curcumin, the minimum inhibitory concentrations of polymyxin B were significantly reduced by a factor of 3- to 10-fold, and it reduced the cytotoxicity of the antibiotic. These findings demonstrate that curcumin exerts antibiotic-sparing effects and this combination acts in a synergistic fashion (Betts et al. 2016). These studies suggest the developing combination formulations containing turmeric or curcumin with antibiotics. This approach may help to reduce the prevalence of multidrug-resistant (MDR) bacteria in hospital settings.

8 Osteoarthritis (OA, Degenerative Joint Disease)

The most common aging-associated diseases in pets and people include dysregulated and persistent chronic immune inflammation, osteoarthritis, rheumatoid arthritis, diabetes, obesity, atherosclerosis, neurodegenerative diseases, hypertension, ocular diseases, osteoporosis, cancer, cardiovascular diseases, and chronic kidney diseases, as well as infections. A vast body of literature on turmeric and its active ingredient, curcumin, shows that they have potential for preventive medicine in aging-associated diseases. Dende et al. (2017) demonstrated that nano-formulated curcumin has a better therapeutic index than the native form of curcumin. Kumar et al. (2018) reviewed the potential role of curcumin and nanocurcumin with improved stability and oral bioavailability and its putative mechanism of action and recent advances in the management and treatment of aging-associated diseases.

Aging horses exhibit chronic, low-grade inflammation, which is often associated with many afflictions including laminitis and osteoarthritis. Nonsteroidal anti-inflammatory drugs (NSAIDs including flunixin, meglumine, and phenylbutazone) are effective in treating acute inflammatory conditions. The chronic long-term treatment with NSAIDs may result in negative side effects. Curcumin (20 μg/ml) was found to inhibit lymphocyte pro-inflammatory cytokine production in aging horse in vitro (Siard et al. 2016). The long-term preventive and therapeutic effect of standardized turmeric, curcumin, and nanocurcumins (targeted drug delivery technologies) on aging-associated diseases in aging pets, horses, and people are warranted.

In dogs, osteoarthritis (OA) is one of the most common causes of lameness. OA is caused by a deterioration of cartilage in the joints. It leads to inflammation, loss of range of motion of the joint, and pain. More than ten million dogs suffer from OA in the USA alone. Repeated traumatic insults to the joints (hip or elbow), joint dysplasia, aging, obesity, and excessive jumping or running or playing or hunting or

other genetic risk factors may result in osteoarthritis in dogs. It is a multifactorial disease of the joints. Akuri and his associates (2017) summarized the pathophysiology of OA. A series of biomechanical and pathophysiological events perpetuate structural degenerative changes in the joint, which often leads to crippling pain, long-term disability, and poor quality of life. Good nutrition, functional foods, caloric restriction, exercise, and herbs (dietary supplements as food) may reduce the need for pain medications (opiates) and anti-inflammatory agents (NSAIDs and cortisone) in pets and people suffering with OA. For preventive strategies, early diagnosis and intervention of OA and comorbidities is absolutely necessary. Besides preventive strategies (proper nutrition, exercise, weight loss, caloric restriction), Ayurvedic herbal supplements in oils (emu oil, coconut oil, hemp oil, or fish oil, omega-3) may offer promise in managing chronic OA.

Analgesics (opiates), NSAIDs, and cortisone are often used in managing OA in aging pets and people. Their clinical utility is limited by adverse effects, low systemic absorption, and high costs. It remains to be discovered if curcumin or turmeric would reduce the need for NSAIDs, cortisone, and opiates in managing OA.

The pathogenesis of osteoarthritis involves processes such as inflammation, osteoclastogenesis, and proteolytic degradation of cartilage. Turmeric and its extracts (curcumin or curcuminoids and non-curcumin turmeric ingredients) have a broad-range pharmacological profile that can modify many aspects of OA and may slow the progression of OA by reducing inflammation and cartilage and bone destruction, especially in the early stages of OA. The vast literature summarized in this review suggest that curcuminoids in turmeric may have potential to benefit patients suffering with osteoarthritis (Akuri et al. 2017). Canine natural osteoarthritis is a realistic model for finding safe and effective doses of dietary supplements as nutraceuticals and/or prescription-grade nutraceuticals for veterinary and human use.

Innes et al. (2003) studied the effect of P54FP (an extract of Indian and Javanese turmeric). Each capsule contained 20 mg curcuminoids (curcumin and desmethoxycurcumin, 50 mg *C. xanthorrhiza* volatile oil, and 150 mg *C. domestica* essential oil), and dogs were treated twice daily for 8 weeks. They reported that this treatment produced a remittance of pain and a recovery of articular movement in dogs.

Zhang et al. (2016) investigated the effect of curcumin using destabilization of medial meniscus (DMM) osteoarthritis mouse model. Immediately after DMM, mice were treated orally with 50 mg/kg curcumin dissolved in corn oil or vehicle (corn oil only) for 8 weeks. The topical application of curcumin nanoparticles or vehicle control (coconut oil) on the skin, within a 5 mm^2 area directly above the DMM operated knee, once daily for 8 weeks. The data obtained in this study demonstrated that oral and topical curcumin administration slows the progression of OA in this post-traumatic osteoarthritis mouse model. This may be translated into an oral human equivalent dose of curcumin of ~4 mg/kg/day for 8 weeks or longer. The delivery of low doses of turmeric or curcuminoids using nanotechnology or target-specific drug delivery may offer affordable, safe, and effective strategies or adjunct therapy for the long-term management and treatment of OA and other chronic inflammatory diseases of the joints, gut, brain, and body.

Jeengar et al. (2016) reported that topical application of curcumin with emu oil inhibited carrageenan-induced rat paw edema and Freund's complete adjuvant-induced arthritis in rats. This combination was effective in bringing significant alterations in the functional, biochemical, histopathologic, and radiologic parameters in rat paw. Their outstanding findings suggest that that topical application of curcumin with emu oil may offer noninvasive intervention for the treatment of inflammatory arthritis in pets and people.

A polar extract of turmeric produced a dose-dependent decrease in monosodium iodoacetate-induced osteoarthritis in rats. This activity was correlated by upregulating type II collagen gene (COL2A1) as well as downregulating MMP-3 and MMP-7. The beneficial effects of polar extract of turmeric may be related to the establishment of equilibrium between catabolism and anabolism of joint cartilage (Murugan et al. 2017; Velusami et al. 2018).

Curcumin (CurcuVetR containing 20% curcuminoids) was found to reduce PMA-induced stimulation of sheep neutrophils and increased spontaneous apoptosis and inhibited both IL8 and Bcl2A1 expression cultured cells within 22 h (Farinacci et al. 2009). They suggested that curcumin may limit the early phases of neutrophil infiltrations, and such an effect may have potential clinical application in the management of ruminant inflammatory disorders. In addition, Colitti et al. (2012) studied the effect of dietary curcumin (CurcuVetR at 4 mg/kg BID for 20 days) on the gene expression of peripheral white blood cells in dogs suffering with OA. They used a 44K oligo microarray technique. This treatment was found to alter the molecular target of inflammatory response. Specific molecular targets of curcumin were inhibition of macrophages proliferation and downregulation of TNFα, TLR4, IL8, IL18, and MAPK14, as well as activation of fibrinolysis. From a mechanistic point of view, these findings suggest good support for OA treatment with low dose of curcumin. They suggest that for drawing a definitive conclusion from this study, a large number of patients (pets and people) are required to validate the use of curcumin for the treatment of OA in dogs.

Recently, Liu et al. (2018a, b) reviewed the vast literature on the efficacy and safety of dietary supplements for patients with osteoarthritis. Seven supplements (pycnogenol, passion fruit peel extract, *Curcuma longa* extract, L-carnitine, *Boswellia serrata* extract, curcumin, and MSM) were found to exert large and clinically significant effects on physical function in the short term in patients living with OA. Del

Grossi Moura et al. (2017) concluded that good-quality clinical research is still lacking and it does not support the use of curcumin and herbal medicines in treating OA. Poor patient adherence and compliance make it very difficult in finding the short-term or long-term efficacy of dietary supplements as with pharmaceutical medications (Liu et al. 2018a, b).

Recently, Haroyan et al. (2018) studied the effects of CuraMed® 500 mg capsules (333 mg curcuminoids) and Curamin® 500 mg capsules (350 mg curcuminoids and 150 mg boswellic acid), taken orally three times a day for 12 weeks, in 201 patients living with OA. This combination appeared to exert synergistic efficacy in 40- to 70-year-old patients suffering with OA. These studies suggest that the long-term use of turmeric and/or its major ingredients as dietary supplement or as foods may slow the progression of OA in pets and people.

9 Pain

Several complementary and integrative approaches including physical activity, exercise, herbs (turmeric, hot peppers, etc.) or their ingredients (curcumin, capsaicin, etc.), vitamin D, omega-3 fatty acids, lipoic acid, acupuncture, yoga, aquatic yoga, meditation, and mindfulness meditation may play important roles in managing chronic pain in people. The high interindividual variability between patients is expected in responses to these pain management modalities (Wojcikowski et al. 2018). The herbs or their extracts (ingredients such as curcuminoids), vitamin D, omega-3 fatty acids, emu oil, and lipoic acid as oral or topical application may be utilized as veterinary nutraceuticals and dietary supplements for chronic pain management.

Curcumin has been reported to exert analgesic effect in animal models and in humans (Cheppudira et al. 2013; Lin et al. 2011; Motaghinejad et al. 2015; Gaffey et al. 2015; Zhu et al. 2014). It may be acting as a transient receptor potential vanilloid-1 (TRPV1) receptor antagonist (Nalli et al. 2017; Zhi et al. 2013; Yeon et al. 2010).

Jhi et al. discovered that curcumin (4 mg/kg/min IV for over 3 min) caused a marked and rapidly reversible inhibition of colorectal distension-induced visceromotor responses (VMRs) in anesthetized rats. In the mouse jejunum, the mesenteric afferent nerve response to ramp distension was attenuated by curcumin (3 and 10 μM). In addition, curcumin (1–30 μM) inhibited the afferent responses to capsaicin in a concentration-dependent manner. Trinitrobenzene sulfonic acid-induced hypersensitivity of jejunal afferents was also attenuated by curcumin. Curcumin potently inhibited capsaicin-induced rise in intracellular calcium and inward currents in mouse or rat dorsal root ganglia (DRG) neurons. These studies demonstrate that curcumin inhibits visceral nociception via antagonizing transient receptor potential vanilloid-1 (TRPV1) receptor TRPV1. This suggests that curcumin or turmeric may help in the treatment of gastrointestinal diseases such as hypersensitive esophagus and heartburn.

Cheppudira et al. (2013) reviewed the effects of curcumin on various pain and wound-healing models in preclinical studies. Patients suffering with peripheral neuropathy (PN) frequently experience sharp spontaneous pain, allodynia, and hyperalgesia. Opioids, anticonvulsants, and tricyclic antidepressants are often used to treat neuropathic pain. These medications are often unsatisfactory because of limited efficacy and adverse side effects. There is unmet medical need for finding novel chemical entities or dietary supplements (nutraceuticals) to manage chronic pain and wound healing in pets and people. The preclinical studies summarized below suggest that turmeric or curcumin may have some potential to treat both pain and wounds. The oral use of curcumin, alone, or as an adjunct therapy, may be useful in the management of postoperative pain and neuropathic pain (Cheppudira et al. 2013; Zhu et al. 2014).

Lin et al. (2011) demonstrated that morphine injections (10 mg/kg, sc) for 7 days produce tolerance in mice. Morphine tolerance is attenuated by co-administration of low-dose curcumin (25 mg/kg, ip) for 7 days. On the other hand, morphine tolerance is aggravated by chronic high-dose curcumin (400 mg/kg/day for 7 days). The acute low-dose curcumin did not enhance morphine's analgesic activity. These observations tend to suggest that high doses of curcumin may be pro-inflammatory and may act by negating other beneficial effects such as inhibiting the expression of antiapoptotic cytokines and neuroprotective factors.

Zhu et al. (2014) summarized the results of many previously published preclinical studies. In a chronic constriction injury (CCI) model of neuropathic pain in rats, single dosing with curcumin did not influence mechanical and thermal hyperalgesia, but repeated curcumin treatment progressively and completely reversed CCI-induced hypersensitivity. The daily curcumin dosing reverts streptozotocin-induced diabetic neuropathy. However, acute curcumin treatment reduces formalin-induced defensive behaviors, visceral pain as measured by acetic acid-induced writhing response, capsaicin-induced thermal hyperalgesia, and reserpine-induced fibromyalgia-like behaviors. They also demonstrated that a surgical incision on the right hind paw of rats induces a sustained mechanical hyperalgesia. It lasted for 5 days. Curcumin (10–40 mg/kg administered by the mouth) apparently in dose-dependent fashion reversed mechanical hyperalgesia in rats. In addition, repeated curcumin treatment facilitated the recovery from surgery. The repeated treatment with curcumin before surgery did not impact the postoperative pain threshold and recovery rate. However, the repeated

treatment with curcumin after surgery reduced postoperative pain threshold and improved recovery rate. The oral use of curcumin, alone or as an adjunct therapy, may be useful in the management of postoperative pain (Zhu et al. 2014).

Motaghinejad et al. (2015) demonstrated that curcumin attenuates morphine withdrawal syndrome. The antinociceptive activity of curcumin in a mouse model of visceral pain is mediated by opioidergic and serotonergic systems. They suggested that curcumin may be effective in attenuating pain during the opioid withdrawal period.

Gaffey et al. (2015) reviewed the effects of curcumin on musculoskeletal pain. Curcuminoids found in turmeric were effective in enhancing wound healing and in the treatment of burn pain and diabetic neuropathic pain. The use of curcuminoids to treat pain associated with knee osteoarthritis showed greater reductions of pain as compared with a placebo, and the efficacy was comparable to the use of ibuprofen. A significant efficacy was found with the use of turmeric extract in combination with other nutraceuticals (devil's claw and bromelain) to treat acute and chronic osteoarthritis pain. A proprietary lecithin formulation of curcumin exerted significant reduction of delayed onset muscle soreness, and the efficacy was comparative to a standard dose of acetaminophen in the treatment of acute pain.

The prolonged use of opioids for the treatment of chronic pain induces opioid-induced hyperalgesia (OIH). It is one of the major clinical problems. A newly developed PLGA-curcumin nano-formulation (PLGA-curcumin) administered intrathecally or orally significantly attenuated hyperalgesia in mice with morphine-induced OIH. This was associated with the suppression of chronic morphine-induced CaMKIIα activation in the superficial laminae of the spinal dorsal horn. These data suggest that PLGA-curcumin may reverse OIH possibly by inhibiting CaMKIIα and its downstream signaling (Hu et al. 2016).

Earlier, Agarwal et al. (2011) reported that curcumin (500 mg capsule every 6 h for 3 weeks) improved postoperative pain and fatigue in patients undergoing postoperative recovery. The effect was more pronounced on days 7 and 14. Furthermore, oral administration of curcumin significantly reduced progression of osteoarthritis (OA) in destabilization of the medial meniscus mouse model. However, it did not influence pain. In addition, topical application of nanoparticles (curcumin) not only reduced pathogenesis of OA but also relieved OA-related pain. Nanoparticles reduced tactile hypersensitivity and improved locomotor behavior. Gera et al. (2017) reviewed the field of curcumin's nanoformulations. These novel formulations of turmeric or curcumin may be an emerging paradigm shift for improved remedial applications in nutraceutical and pharmaceutical settings.

The effect of repeated daily oral doses of curcuminoids (*C. longa* extract, CLE, at 5, 20, or 80 mg/kg/day) was evaluated in hot-plate test in mice. On day 11, all animals were subjected to foot-shock stress triggered by a hyperthermia test and day 12 to a tail suspension test for antidepressants. CLE produced dose-dependent analgesic activity. Interestingly, only low doses of CLE were effective in relieving central pain (Verma et al. 2017).

Bethapudi et al. (2017) evaluated the analgesic effect of turmerosaccharides rich fraction (NR-INF-02) on monosodium iodoacetate-induced OA pain in rat model that mimics human OA. The oral administration of turmerosaccharides rich fraction at 45 and 90 mg/kg was found to decrease OA pain at 1, 3, 6, and 24 h posttest administration on day 5. The effect of turmerosaccharides rich fraction on OA pain was superior to turmerosaccharides less fraction.

Dry socket (alveolar osteitis) is a painful dental condition that happens after a permanent adult tooth extraction when the blood clot at the site of the tooth extraction fails to develop or it dislodges or dissolves before the wound has healed. In a recent study, Lone et al. (2018) demonstrated a significant reduction in mouth pain, inflammation, and discomfort after turmeric dressing in 178 patients diagnosed with dry socket syndrome. Wound healing progressed faster than dressing with ZOE dressing. These studies suggest that the effect of curcumin (curcuminoids) may depend on the time of initiation of treatment, duration of treatment, dose of curcumin, etc. Double-blind placebo-controlled clinical studies are warranted in pets and people suffering with NP, OA, and postsurgical pain.

Curcumin (nanoparticles) may represent a novel topical antimicrobial (antibacterial, antiviral, and antifungal) and wound healing adjuvant for infected burn wounds and other cutaneous and muscle injuries and related pain conditions (Krausz et al. 2015; Gera et al. 2017). Long-term clinical studies are needed to establish analgesic activity of turmeric or curcuminoid nanoparticles (low doses and long duration of treatment in pain-related conditions).

10 Sports Medicine

Traumatic muscular injuries (soft tissue trauma, bruises, and contusions) are too common in dogs and horses. Dietary supplementation with ST or curcumin and other strategies to reduce muscle soreness and to improve muscle (physical) recovery are of great interest to athletes and to people caring for horses and dogs. ST or curcumin may be a suitable alternative to nonsteroidal anti-inflammatory medications for the management of diseases of the musculoskeletal systems such as muscle soreness and OA (Heaton et al. 2017).

Tanabe et al. (2015) studied the effect of 150 mg of curcumin (taken by mouth before and 12 h after each exercise session in a randomized, crossover design study in 14 untrained young men). This treatment reduced maximal voluntary contraction (MVC) torque, and muscles recovered

faster (e.g., 4 days postexercise $-31 \pm 13\%$ vs. $-15 \pm 15\%$); peak serum creatine kinase (CK) activity was less for those treated with curcumin than with placebo ($P < 0.05$). The researchers concluded that theracurmin ingestion may reduce some aspects of muscle damage.

McFarlin et al. (2016) evaluated the effect of curcumin supplementation (Longvida®; 400 mg/day). It reduced CK (a biomarker of muscle injury) by 48% after subjects consumed curcumin for 2 days before and 4 days after a high-intensity muscle damage-inducing protocol. They concluded that consumption of curcumin reduced a biomarker of muscle injury, but not quadriceps muscle soreness or inflammatory biomarkers, during recovery after exercise-induced muscle damage. The observed reduced biomarker of muscle injury may translate to faster recovery and improved functional capacity during subsequent exercise sessions. This conclusion needs to be explored using a large number of sports participants.

Heaton et al. (2017) reviewed nutritional strategies for muscle regeneration, muscle fatigue, physical and immune health, and preparation for subsequent training sessions in sports medicine. They concluded that the anti-inflammatory and anti-oxidative activities of turmeric and its active ingredients suggest that these agents at low appropriate doses may have a role in sports medicine, especially in preventing the consequences of concussions and muscle injuries.

Curcumin or turmeric may provide some recovery benefit or reduced muscle damage during the intense sport activities. Therefore, clinical research using wide doses of ST or curcumin is warranted prior to incorporating supplemental dosages into the athlete's diet or into pet supplements.

11 CNS Effects

Sarker and Franks (2018) reviewed published preclinical and clinical studies related to efficacy of curcumin for age-associated cognitive decline. Ramkumar et al. (2018) summarized the antioxidant, anti-inflammatory, neuroprotective, and antiproliferative activities of curcumin, demethoxycurcumin (DMC), and bisdemethoxycurcumin (BDMC). DMC may have better anticancer and anti-inflammatory activity as compared with curcumin. Recently, DMC (5, 10, and 20 mg/kg, i.p., for 7 days) was shown to abrogate rotenone-induced dopamine depletion and motor deficits by its anti-oxidative and anti-inflammatory properties in parkinsonian rat model. They concluded that DMC may be a promising therapeutic lead for the treatment of neurodegenerative diseases including Parkinson's disease.

12 Diabetes

In developing countries, about 80% of people depend on traditional herbal medicine to meet their healthcare needs. Turmeric has been used for the management of diabetes in Ayurvedic and traditional Chinese medicine. Curcumin reduces glycemia and hyperlipidemia in rodent models of diabetes (Zhang et al. 2013). Dietary curcumin relieves stress in metabolic tissue, leading to improvements in diabetes and associated disease complications in rodent models and in clinical studies. New improved methods of curcumin delivery (nanoparticles and lipid/liposome formulations) may help in cell-directed targeting, and it may offer improved therapeutic outcomes in diabetes (Maradana et al. 2013). In addition, curcumin or curcuminoid supplementation has been reported to be effective in lowering the fasting blood glucose concentrations in people with prediabetes, diabetes, or metabolic syndrome. Curcumin produced significant decrease in HbA_{1c} as compared to placebo. de Meloa concluded that curcumin supplementation may be an adjuvant aid in the management of dysglycemic patients.

Recently, Yang et al. (2018) studied the effects of curcumin on retinal damage in STZ-induced diabetic rats. Curcumin (100 and 200 mg/kg, PO, daily for 16 weeks) was found to reduce diabetes-induced body weight loss, blood glucose, and retinopathy. This activity may be attributed to the hypoglycemic, antioxidant, VEGF-downregulating, and neuroprotection properties of curcumin. They suggested that curcumin may have a potential in the treatment of diabetic retinopathy.

Curcumin suppresses activities of gluconeogenic enzymes and increases glycogen storage in the liver and reduces blood glucose in db/db mice (Fujiwara 2000). Wickenberg demonstrated that 6 g of turmeric taken by mouth increased postprandial insulin levels in healthy subjects. The increased insulin response may be due to the stimulation of β-cell function by curcumin. In addition, oral administration of 10 mg of curcumin (twice a day for 28 days) lowered LDL levels and increased HDL levels in patients with atherosclerosis (Ramirez et al. 2000). In this study, the low dose of curcumin seems to be relevant to what people get while taking low dose of ST or turmeric in the turmeric-consuming nations.

Inhibition of enzymes such as α-amylase could play a key role in the control of diabetes by slowing starch digestion. The inhibitors of pancreatic α-amylase may be of great therapeutic importance in treating diabetes mellitus. Bisdemethoxycurcumin (BDMC) inhibits porcine and human pancreatic α-amylase with an IC_{50} value of 26 and 25 μM, respectively. This may impart antidiabetic activity of turmeric and its metabolites in pets and people. BDMC could be a good drug candidate to reduce postprandial hyperglycemia (Ponnusamy et al. 2012).

Arun and Nalini (2002) studied the effect of turmeric and curcumin on diabetes mellitus in alloxan-induced diabetes in rats. Administration of turmeric or curcumin reduced the blood sugar and glycosylated hemoglobin levels as well as the activity of sorbitol dehydrogenase, which catalyzes the conversion of sorbitol to fructose. Curcumin was more effective than turmeric in attenuating diabetes mellitus-related changes. These results suggest that curcumin may be effective in attenuating diabetes mellitus-related changes.

Normal and diabetic rats were treated with curcumin (90 mg/kg/day) incorporated in yogurt. After 15 days of treatment, the glucose tolerance and the insulin sensitivity were significantly improved in diabetic rats. This improvement may be associated with an increase in the AKT phosphorylation levels and GLUT4 translocation in skeletal muscles. They suggested that curcumin metabolite(s) may be responsible for the antidiabetic activity (Gutierres et al. 2015).

ST, curcumin, and other ingredients present in turmeric and their metabolites may exert antioxidant and anti-inflammatory properties, which may assist in alleviating the complications in diabetes (Gutierres et al. 2015). In addition, curcumin exerts retina-protective effects (Xu et al. 2018; Yang et al. 2018).

13 Metabolic Syndrome

Curcumin is well known to exert an anti-inflammatory effect through downregulation of inflammatory cytokines, transcription factors, protein kinases, and enzymes that promote inflammation and participate in the development of chronic diseases. Such a multitude of effects of curcumin on gut permeability and barrier function, gut-brain axis, genes, epigenetic and molecular targets in mitochondria, and disease-specific target tissues may offer some health benefits in chronic disease states including metabolic syndrome (Shehzad et al. 2017; Ghosh et al. 2018).

Di Pierro et al. (2015) showed the ability of curcumin (complexed with phosphatidylserine in phytosome form or with pure phosphatidylserine) to reduce weight and omental adipose tissue in overweight people with metabolic syndrome in a preliminary clinical study. At the end of the first 30 days of lifestyle intervention, overweight participants were randomly assigned to one of the two groups for the 30-day treatment phase. Twenty-two of the participants were supplemented twice a day for 1 month with a nutritional supplement formulated to be enteric-coated and containing 800 mg/dose/day of *Curcuma longa* extract (95% curcumin), complexed with sunflower phospholipids (20% phosphatidylserine) and blended with 8 mg/dose/day of piperine from *Piper nigrum* extract (Bioperine). After 60 days, the collective weight loss was 6.7%, the BMI decrease was 8.4% with the percentage of fat reduced by more than 9%, and more than 6 cm was lost in waistline and 3 cm lost in hip circumference. These interesting preliminary observations by Di Pierro et al. (2015) suggest that long-term large randomized double-blind placebo-controlled clinical trials using a wide range of doses and formulations of turmeric and curcumin in overweight dogs, cats, and people are needed.

Sohrabi et al. (2018) summarized that pro-inflammatory cytokines such as interleukin-17F (IL-17F) has an association with induction of tissue inflammation and obesity. IL-17F is produced by T-helper (Th) 17 cells, natural killer cells, γδ T cells, CD4+, and CD8+ T cells. High-fructose consumption often increases body weight and serum level of IL-17. Cinnamon and curcumin supplementation decreases IL-17F under the standard diet. Feeding with cinnamon and turmeric (water-soluble extract) caused a decline in body weight but, surprisingly, increased IL-17F in rats on a high-fructose diet (Sohrabi et al. 2018).

A high-fat diet leading to postprandial hyperlipidemia and inflammation appears to be the key etiologic factor contributing to the development of atherosclerosis and subsequent coronary artery disease (Alipour et al. 2007). Acute supplementation with resveratrol (200 mg and curcumin 100 mg) did not modify high-fat diet-induced postprandial circulating inflammatory markers (C-reactive protein, IL-6, IL-8, monocyte chemoattractant protein-1), adhesion molecules (soluble E-selectin, soluble vascular cell adhesion molecule-1 (sVCAM-1)), or soluble intercellular adhesion molecule-1 in older adults with abdominal obesity (Vors et al. 2018). This study suggests that as-needed intake of dietary supplements (PRN basis) may not offer the desired efficacy in most clinical setting in pets and people. Long-term clinical studies are warranted to examine the dose response and newer formulations of curcumin and turmeric, alone or in combination, with other phytonutrients.

Intragastric administration of curcumin at 250 mg/kg daily for 8 weeks was found to decrease the level of free fatty acid and TNF-α in serum of type II DM rats. This treatment also improved the metabolic disorder of glucose and lipid, enhanced the sensitivity to the insulin, and ameliorated the resistance to insulin in rats (Su et al. 2017).

Mantzorou et al. (2018) reviewed recent, well-designed clinical studies and showed that curcumin appears to offer some health benefits against obesity, metabolic syndrome, and diabetes. Furthermore, curcumin may exert a heath beneficial effect in people suffering with arthritis, skin diseases, gut inflammation IBD, UC, cancer, fatty liver disease, depression, and symptoms of premenstrual syndrome. The concrete and precise recommendation cannot be made with respect to dose, formulations, and duration of treatment. They suggested that large- prospective studies are needed using well-designed clinical trials with proper considerations with respect to follow-up times, dosage, formulation, and duration of curcumin or ST supplementation, medication adherence, and patient compliance. Furthermore, a careful consideration

is needed for confounders in each specific chronic disease of pets and people.

Recently, Jin (2018) reviewed curcumin's complex mechanistic approach to drug discovery in metabolic disorders. Curcumin was shown to improve insulin signaling.

Dexamethasone injection induces insulin resistance, while concomitant curcumin gavage improves insulin tolerance (Tian et al. 2015). Insulin resistance attenuating effect of curcumin appears to be dissociated from its anti-inflammatory effect. In the long term, this protective effect may be attributed to its anti-inflammatory, anti-oxidation, and body weight-lowering effects (Jin 2018).

14 Retinopathies

Peddada et al. (2018) reviewed the etiology of eye diseases and mechanism of action for curcumin in eye diseases. They reviewed literature on the potential therapeutic of curcumin in major retinal pathologies. The retina has a rich blood supply and numerous mitochondria and is consistently exposed to pollutants and ultraviolet light (sun exposure, photons of light), which strikes its surface making the retina at high risk of developing ocular pathologies, particularly in aging populations. Oxidative stress and immune inflammatory pathways are well known to contribute to retinal pathology. Curcumin is known to possess anti-inflammatory, antitumor, antioxidant, and VEGF inhibition properties through modulation of numerous biochemical and transcription processes. Curcumin has been reported to slow, and in some cases even reverse, age-related macular degeneration, diabetic retinopathy, retinitis pigmentosa, proliferative vitreoretinopathy, and retinal cancers. The authors concluded that curcumin exerts limited efficacy, mostly in experimental animal studies.

The use of standardized turmeric as orally administered dietary supplement may slow the progression of age-related eye illnesses. Targeted drug delivery of novel formulations of turmeric or curcuminoids in the eye may reduce immune inflammation (HKH syndrome, uveitis). Oral or topical application of turmeric or its curcuminoids may reduce the need for steroids in treating ocular inflammatory conditions in pets and people.

15 Allergy

Allergic asthma is a complex, multifactorial, chronic immune-inflammatory disease of the airways. The allergic responses in the lungs are mediated via multiple complex pathways leading to release of a number of inflammatory mediators (histamine, cytokines, and enzymes) by activated mast cells, eosinophils, and T lymphocytes. Subhashini et al. (2013, 2016) briefly summarized the pathophysiology and treatment strategies of allergic asthma. The available medications (steroids and bronchodilators) are associated with limitations such as serious side effects. The studies summarized here suggest that turmeric and curcumin may have potential therapeutic utility in modulating (preventing and treating) lung allergy (asthma).

Kurup and Barrios (2007) demonstrated that orally administered curcumin suppressed latex allergen-induced Th2 response in mice. The suppression of Th2-mediated allergic responses was evident by reduced IL-4 and IL-13 production, as well as reduced infiltration of eosinophils in the lungs and reduced expression of molecules such as matrix metalloproteinase (MMP-9), thymic stromal lymphopoietin (TSLP), and ornithine aminotransferase (OAT). They concluded that curcumin may have potential therapeutic utility in lung allergy (asthma).

Subhashini et al. (2013) conducted an elegant preclinical study using curcumin in a mouse model of allergic airway inflammation (asthma). Curcumin was dissolved in dimethyl sulfoxide (DMSO) and administered an hour before every ovalbumin challenge (days 19–22). They discovered that intranasal curcumin application (2.5 and 5 mg/kg) was readily absorbed from airway mucosa and was effective in suppressing airway inflammation and allergic asthma.

Intranasal curcumin significantly inhibited leukocytes and eosinophil recruitment to the lungs and decreased eosinophil peroxidase and histamine levels in bronchoalveolar lavage fluid. These observations may suggest that curcumin (intranasal drop or spray) may reduce the need for inhaled or oral steroids and β-agonists by reducing chronic allergic airway inflammation in pets and people. Later these investigators demonstrated that intranasal curcumin (2.5 and 5.0 mg/kg) reduces airway inflammation and bronchoconstriction by modulating cytokine levels (IL-4 and IL-5 and IFN-γ and TNF-α) and sPLA2 activity and by inhibiting PGD2 release and COX-2 expression. Curcumin's anti-allergic (antiasthma) activity is mediated by the suppression of p38 MAPK, ERK 42/44, and JNK54/56 activation during allergic response in the lung. They suggested that curcumin may offer an alternative for the development of nasal formulations and inhalers for asthma management (Subhashini et al. 2016).

Shin et al. (2015) immunized mice with intraperitoneal injection of ovalbumin (OVA) and alum. The OA-sensitized mice were challenged orally with 50 mg OVA and treated with turmeric extract (100 mg/kg) or curcumin (3 mg/kg or 30 mg/kg) for 16 days. Food allergy symptoms were decreased, as were rectal temperature, diarrhea, and anaphylaxis. Turmeric extract significantly decreased food allergy symptoms (decreased rectal temperature and anaphylactic response). However, curcumin treatment showed little improvement. Turmeric extract also inhibited IgE, IgG1, and mMCP-1 levels. Turmeric extract reduced type 2 helper cell (Th2)-related cytokines and enhanced Th1-related cytokines. Turmeric extract ameliorated OVA-induced food

allergy in mice by restoring Th1/Th2 balance. They concluded that turmeric extract significantly ameliorated food allergic symptoms in this mouse model of food allergy through promoting Th1 responses over Th2-dominant immune responses. The orally administered turmeric extract including various components may be useful to ameliorate Th2-mediated allergic disorders such as food allergy, atopic dermatitis, and asthma.

Interleukin-10 (IL-10) is a pleiotropic anti-inflammatory and immunosuppressive cytokine that is produced by innate and adaptive immunity cells including macrophages, dendritic cells, mast cell, natural killer cells, eosinophils, neutrophils, B cells, CD8+ T cells, and TH1, TH2, TH17, and regulatory T cells. CNS, astrocytes, microglia, and neurons are the major sources of IL-10 production. The major source of IL-10 in the periphery is macrophages. Curcumin has been reported to enhance IL_{10} release. This mechanism may play a role in curcumin's actions—managing or treating immune inflammatory conditions of the gut, joints, lungs, heart, blood vessels, and brain (Mollazadeh et al. 2017).

16 Psoriasis

Dendritic cells (antigen-presenting cells) play a critical role for initiating the activation and differentiation of T cells in inflammatory diseases including psoriasis. Diarylheptanoid from *C. kwangsiensis* (DCK) modulated multiple functions of dendritic cells in the immunopathogenesis of psoriasis. Many steps were modified by DCK including antigen uptake, maturation, migration, and pro-inflammatory cytokine production, and it also decreased proliferation and differentiation of Th1 and TH17 and their effector cytokine production. These mechanisms in part may contribute to turmeric efficacy in treating psoriasis (Liu et al. 2018a, b).

17 Kidney Stones

Bas et al. (2009) administered curcumin orally at 75 mg/kg/day dissolved in 10% ethyl alcohol for 6 days (1 day before and 5 days after shock-wave lithotripsy, SWL) in rats. This treatment produced significant differences in histological changes under light microscope ($P < 0.02$) between SWL and control groups on days 7 and 35. This treatment was found to reduce tissue fibrosis, expressions of iNOS and p65, and serum nitric oxide levels and also prevented interstitial, glomerular, tubular epithelial, and endothelial cellular injuries. They suggested that curcumin may be used as a protective anti-oxidative agent to prevent SWL-induced renal injury.

In another study, curcumin (60 mg/kg body weight) was orally administered once daily for 28 days in rats. The calcium and oxalate levels in urine and kidney tissue homogenate were measured, and kidney histopathological examination was performed. Curcumin treatment inhibited the development of kidney stones but failed to reverse the changes caused by the kidney stones (Ghodasara et al. 2010). Herbal extract of turmeric (curcumin), among many other plants' extracts, was found to inhibit struvite formation (Das et al. 2017). Dietary polyphenols, including curcumin, may be promising dietary supplements for the prevention of urolithiasis (Nirumand et al. 2018). This limited research suggests that curcumin may slow the progression of kidney stone formation and fibrosis and may also exert protective effects in the kidneys.

18 Cancer

Cancer is one of the most common causes of death worldwide. There appears to be a link between cancer and diet. The dietary modulation of gut microbiota and miRNAs may play an important role in cancer development and prevalence. Various dietary components such as turmeric (curcumin), fatty acids, resveratrol, and isothiocyanate are often utilized in cancer prevention and treatment; dietary components and fiber serve as probiotics and alter miRNA expression. This vital interaction of functional foods, herbs, fiber, and dietary supplement modulates the vital pathways involved in metastasis, invasion, apoptosis, tumor growth, and cell proliferation (Riaz Rajoka et al. 2018).

Curcumin could enhance the effect of radiation therapy, inhibit angiogenesis and cell proliferation by suppressing NF-κB and its target genes in colon cancer cells, and inhibit cell growth by modulating Akt/mTOR pathways via the downregulation of EGFR. In addition, pancreatic cells treated with curcumin resulted in the downregulation of 18 miRNAs and upregulation of 11 miRNAs; the upregulation of miR-22 led to the suppression of ESR-1 (estrogen receptor 1) and SP1 transcription factors.

Glioma is the most aggressive, lethal, and most prevalent of primary brain tumors. Glioblastoma (glioblastoma multiforme) is a malignant glioma that is almost impossible to cure because of poor drug transportation across the blood-brain barrier (BBB) and the existence of glioma stem cells. Recently, Zhao et al. (2018) discovered that curcumin-loaded RDP-modified liposome (RCL) inhibited glioma cell proliferation and tumor growth using an intracranial glioma mouse model. RCL prolonged the survival time of the glioma-bearing mice from 23 to 33 days; the inhibition mechanism of RCL on glioma cells may involve cell cycle arrest at the S phase and induction of cell apoptosis. This study provides

evidence that nanotechnology (delivery of curcumin to brain cancer cells) has potential for the treatment of human malignant gliomas.

19 Translation from Population Epidemiology and Clinic to Bench

The average estimated daily human consumption of turmeric (ST) in India is approximately 200–600 mg for life (~1–3 mg/kg, BID, TID). This may be translated into curcuminoids estimated daily human dose of ~3–30 mg for life. This consumption of a low dose of turmeric and its active ingredients may explain the low prevalence of Alzheimer's disease (AD) in India (1/4th of USA) and subsequent low cost of healthcare in India. Traditionally, turmeric powder is first seasoned in oil or ghee until it is brown for 1–2 min before it is used in beans, whole grains, rice, or vegetables (personal observation of Indian cooking during childhood). This method may be a reflection of the ancient art of nanoformulation and activation of >235 ingredients in turmeric and other species.

In non-turmeric-consuming nations, including the USA, many people are using higher doses of dietary supplements (curcumin or turmeric) as recommended by the nonscientist and nonbeliever in Ayurveda. High doses may negate its own beneficial health effects. Therefore, there is a need for developing low-dose formulations consisting of turmeric or curcumin/curcuminoids alone or in combination with other herbs or medications. Such novel combinations need to be clinically evaluated in aging dogs, cats, and people suffering with osteoarthritis, pain, and/or mild-to-moderate cognitive deficits (AD) and comorbidities, such as depression. However, such clinical studies require funding and the incentive to pursue this long course for finding an affordable herb for the prevention of chronic inflammatory diseases of the joints, gut, brain, and skin.

As an example, aspirin (81 mg daily for decades) lowers the risk of heart attack and stroke. Looking at aspirin's pharmacology, no one could have predicted such a great clinical outcome. A combination of salicylic acid (and other tricarboxylic acids) and turmeric at low doses used over decades in mid-age may reduce the progression of AD and OA in high-risk populations and pets.

20 Translation: Preclinical to Clinic

Preclinical data from earlier research from UCLA clearly demonstrate that curcumin at low doses has selective distribution in the brain. This finding may have great clinical implications in terms of its nonconventional PK and efficacy. The low (500 ppm) and high (2000 ppm) dose of curcumin in the feed for 6 months increases plasma level in dose-related fashion in mice, yielding 35 ± 14 and 171 ± 19 ng/ml, respectively. However, the brain level of curcumin following low and high dose was 469 ± 22 and 525 ± 125 ng/g, respectively. The brain-to-plasma ratio was 13.4 at low dose and 3 at high dose. Curcumin's half-life is >10 days in the brain and less than 7 h in the plasma (Dr. S. Frautschy, UCLA, personal communication). Long half-life suggests that active ingredients (curcumin and others) will accumulate in the brain and other fatty tissues over days or weeks.

These data may suggest that there is dose-related PK in the plasma, but not in the brain. The pGp transporters in the BBB may be activated by high plasma levels leading to promotion of curcumin's efflux from the brain. This phenomenon may explain the lack of efficacy in clinical trials using "industrial" doses of curcumin. The efficacy of 160 ppm and 500 ppm in feed for 6 months offered almost similar efficacy in a mouse model of Alzheimer's disease (references). Increasing the dose to 2000 or 5000 ppm did not yield better efficacy in mouse model. The translation effort from mice to human has failed in developing curcumin as a potential therapy for Alzheimer's disease. However, the failure in human clinical trials may help us in developing safer and more effective turmeric formulations for veterinary use, particularly for osteoarthritis and cognitive decline (dementia) in aging dogs and cats.

In depression, AD, pain, and ocular inflammation in animal model demonstrate that the low dose of turmeric or curcumin in feed or foods, for the duration of life, may offer an affordable way to reduce the burden of chronic inflammatory disease in aging pets and people. Along with lifestyle changes—exercise and healthy eating—a low dose of turmeric (ST) may reduce the need for opiates and other medications.

21 Gaps and Opportunities

- Recently, Cavaleri (2018) elegantly discussed and summarized the gaps, challenges, and opportunities in making turmeric or its major phytochemicals (e.g., curcumin, curcuminoids) and their active metabolites effective and safe dietary supplements (nutraceuticals) and medications.
- The purity, adulteration, heavy metal lead contamination, stability, and shelf-life of turmeric (standardized turmeric) and its major components in dietary supplements need to be kept forefront in R&D.
- The content of phytochemicals in turmeric may vary drastically from region to region within a country or around the world. This variation may contribute to the differences

in efficacy of many herbal dietary supplements (such as nutraceuticals, including standardized turmeric and its major components). Therefore, standardization of turmeric preparations (combinations) is not only desirable but is warranted.

- Tissue distribution studies (ADME, PK) following chronic administration of therapeutic (low) doses of turmeric (standardized turmeric) and its major components at steady state after 3, 7, or 30 days of dosing in chronic disease states need to be evaluated in dogs, cats, horses, and zoo animals.
- The in vitro and in vivo activities of curcumin in various experimental models so far have not been reproducible in clinical settings. The study of larger populations of cats, dogs, and horses living with natural progression of chronic dysregulated age-related diseases, and a longer duration of treatment with a wide range of doses of ST and varied formulations of curcumin, may offer more reliable data, which may have a better predictive value in the design of long-term clinical trials in pets and people.
- The use of standardized turmeric and its major components, alone or at various doses, in long-term clinical studies is warranted in aging pets and horses.
- The neuroprotective effects of IV, nasal, or oral formulations of ST or curcumin in stroke and concussion and in PTSD victims need to be evaluated.
- Standardized turmeric and its major components may be preferentially distributed to the therapeutic site (immune inflammation) and may serve a preventive (modulatory) role in aging pets and horses.
- Dogs, cats, and horses, as well as zoo animals, suffering with OA, age-related chronic dysregulated immune inflammation, and AD-type conditions are natural disease models. The efficacy of standardized turmeric and its major components needs to be established in aging pets and horses. Such studies are warranted for establishing more reliable and reproducible changes in the biomarkers of diseases over time.
- Long-term studies using turmeric (standardized turmeric) and its major components, alone or in combination, with other nutraceuticals (herbal supplements) and medications in pets, farm, and zoo animals suffering with chronic dysregulated immune inflammatory conditions are warranted. The long-term treatment with turmeric (standardized turmeric) and its major components would produce significant alterations (up- and downregulation of transcription and translation of genes and epigenetic mechanisms, proteins, mRNAs, and enzymes and their receptors and pathways). These kinds of precision clinical medicine studies are still lacking. This therapeutic approach in R&D may offer better and more reliable biomarkers of disease modification in the saliva, lymphocytes, blood, brain, joints, and eyes of dietary supplement-treated and placebo (vehicle)-treated animals and people.
- The aging people and pets at high risk of AD, OA, and other immune inflammatory conditions may be getting little or no amount (and sometimes too much) of standardized turmeric and its major components. Prevention studies are warranted in these high-risk populations to identify appropriate doses and duration of treatment.
- Population-based, broad dose-response, and PK/PD modeling in the presence and absence of medications for pain, depression, and other common illnesses in aging populations is needed. There is potential activation of drug transporters (Pgp) in target tissues such as the BBB and the gastrointestinal system and in joints while using a high dose of turmeric (standardized turmeric) and its major components. This field needs to be further explored.
- The use of turmeric (standardized turmeric) may be an affordable preventive approach for slowing the progression of aging-related chronic diseases. Its lifetime use as a food, rather than a pill or capsule, may be a viable approach to reduce the need for expensive medications with serious side effects in pets and people. Turmeric (standardized turmeric) and its major components may serve as an adjunct therapy in treating diseases of the digestive system, brain, joints, eyes, and body in aging pets and people.
- Nanotechnology and other medication delivery systems in aging pets may offer new approaches in veterinary practice.

22 Concluding Remarks and Future Directions

Turmeric is the dried rhizome (root) of *Curcuma longa* or *Curcuma aromatica* (wild turmeric), *Curcuma wenyujin* (China), and *Curcuma domestica* (Thailand). It is a rhizomatous herbaceous perennial plant belonging to the ginger family, *Zingiberaceae*. More than 133 different species of turmeric have been identified. It is native to the Indian subcontinent and Southeast Asia. Turmeric contains more than 235 active ingredients naturally packed into its root, optimistically in appropriate proportions. These complex phytochemicals (>235), including essential oils, curcuminoids (>89), and turmerosaccharides, as well as curcuminoid-free ingredients, fiber, and their metabolites and products of microbial degradation of standardized turmeric, may act in additive or synergistic fashion as a modulator of dysregulated chronic immune inflammation and pain in disease states in people, pets, and horses.

The average human consumption of turmeric in India is approximately 81 mg twice or three times a day for life (~1–3 mg/kg, BID, TID). This may be translated into curcuminoids' estimated human dose of ~3–15 mg BID, TID for life. The consumption of low dose of turmeric in foods may be responsible for low prevalence of AD in India (one-fourth of USA). A caution must be exercised when statistics and epidemiological data are being considered for possible translation from one culture or nation to others.

One of the Ayurvedic medicine's basic principles is that efficacy cannot be related to plasma level of a major active ingredient in a spice or an herb, and the whole herb is often more efficacious than its individual ingredients. Contrary to this basic principle, R&D teams over the past decades drastically improved the bioavailability of curcumin, turmeric's major active ingredient. Besides improving curcumin's pharmacokinetics, researchers also increased the dose of curcumin in most clinical trials conducted so far without improving its efficacy in cancer and AD.

Standardized turmeric containing curcumin (3, 9, 27, or 81 mg once a day or BID or TID) could achieve steady-state therapeutic level within 3–10 days in the brain of patients or pets suffering with AD or other persistent dysregulated chronic immune inflammatory conditions. This concept may be explored in aging dogs, cats, and horses living with OA and mild dementia. This concept is based on published preclinical studies—similar effects of aspirin and curcumin in vitro and in vivo. Twenty to thirty years ago, it was unforeseeable that 81 mg aspirin could reduce the risk of stroke and heart attack.

Low dose of standardized turmeric (3–4 mg/kg, BID, TID) blended in coconut oil or fish oil may tame age-related, persistent, dysregulated chronic immune inflammation in the brain, eyes, skin, muscles, gut, and other internal organs in pets. It may slow the progression of cognitive decline disorder (CCD) in dogs and cats. Low dose of standardized turmeric may serve as an adjunct therapy in managing many disease states in aging pets—in dogs and cats as well as in horses. The ingredients in turmeric may restore homeostasis in the brain, joints, gut, and other tissues only under disease states acting via many interrelated mechanisms of action.

In non-turmeric-consuming nations, including the USA, many people and pets may be using higher doses of dietary supplements containing curcumin or turmeric. This may negate its own beneficial health effects. Therefore, there is a need for developing low-dose formulations consisting of turmeric or curcumin/curcuminoids, alone or in combination with other herbs or medications. Such novel combinations need to be clinically evaluated in aging dogs, cats, horses, and people suffering with osteoarthritis and/or with mild-to-moderate dementia/Alzheimer's disease and comorbidities.

Standardized turmeric's novel formulations at low doses may exert mild-to-moderate beneficial effects on osteoarthritis, pain, depression, and neurodegenerative diseases. It may reduce the need for analgesics (opiates), antidepressants, anti-AD, steroids, and anticancer medications. The possibility that many active ingredients in turmeric formulations may be acting in additive or synergistic fashion needs to be explored and addressed. The preclinical data support such a concept. Using the latest drug-targeted delivery (nanotechnology) and reliable clinical trial strategies, standardized turmeric may be considered for R&D for the prevention, and possibly for the treatment, of OA and dementia and other aging-related diseases of the eyes, brain, gut, and joints in pets and humans.

Fenugreek in Health and Disease

Dinesh Kumar, Ramdas Singh Wangkheirakpam, Anu Rahal, and Jitendra K. Malik

Abstract

Fenugreek is an herb which has been used in traditional medicines for centuries in wound healing, as an aphrodisiac, for promotion of lactation, etc. The consumption of the seeds as a spice results in different medicinal effects such as hypocholesterolemic, antidiabetic, hepatoprotective, antibacterial, anthelmintic, anticancer, and galactogogue. Flavonoids, saponins, pyridine alkaloids, and steroidal sapogenins are some of the phytochemicals present in the plant. The plant is also embraced for its high content of important vitamins, minerals, protein and amino acids, and fibers making it a nutritious fodder for livestock. Extracts of the leaves and seeds of fenugreek are considered safe and are found to have potential therapeutic explicabilities in the treatment and/or management of diabetes, cancer, toxicities, cardiovascular diseases, physical injuries, and hormonal imbalances. The seeds and leaves of this plant are now being incorporated into animal, bird, and fish foods to increase feed intake, to promote weight gain, and to decrease the feed conversion ratio. The addition of fenugreek in the drinking water of poultry reduces stress, and this can be an important strategy to replace the use of antibiotics such as enrofloxacin as an anti-stress agent, and thus the issues of antibiotic residues in meat, as well as widely developing antibiotic resistance, would be less.

Nutraceutical · Fenugreek (*Trigonella foenum-graecum*) · Phytochemicals · Sapogenins · Trigonelline · Diosgenin · Galactomannan

1 Introduction

Fenugreek (*Trigonella foenum-graecum* L.) is an annual forage aromatic leguminous herb. The plant was once native to the Mediterranean region, India, China, Northern Africa, and Ukraine but is now cultivated widely in many parts of the world. It is about 30–60 cm tall with smoothed erect untoothed stipulate and 2–2.5-cm-long leaflets. There are 1–2 flowers which are axillary and sessile. Calyx-teeth is linear and pods measure about 5–7.5 cm in length with a long persistent beak often falcate with 10–29 small size seeds without transverse reticulations (Kirtikar and Basu 2002). The seed is 4.01–4.19 mm long, 2.35–2.61 mm wide, and 1.49–1.74 mm thick (Altuntaş et al. 2005). The leaves and seeds of the plant are used as an herb and the seeds are used as a spice. India leads among the countries which produce fenugreek by sharing 70–80% of the global export (Edison 1995).

Fenugreek is also considered as one of the oldest known medicinal plant in recorded history (Lust 1986). This medicinal plant is used in various traditional medicines including Indian Ayurvedic, traditional Chinese medicines, and Egyptian medicine for wound healing, as an aphrodisiac, for promotion of lactation, and many more (Tiran, 2003). Phytochemicals like flavonoids, saponins, steroidal sapogenins, amino acids, and alkaloids are some of the important constituents found in the extracts of leaves, stem, and seeds of *Trigonella foenum-graecum* L. (fenugreek). The consumption of the seeds as a spice results in different medicinal effects such as hypocholesterolemic (Mathern et al. 2009), antidiabetic (Ajabnoor and Tilmisany 1988), hepatoprotective (Pribac et al. 2009), antibacterial (Sharma

et al. 2017), anthelmintic (Khadse and Kakde 2010), anticancer (Alsemari et al. 2014), and galactogogue (Betty 2008). These phytochemicals also now serve as raw materials for the manufacture of various therapeutic and hormonal drugs (Priya et al. 2011). Fenugreek is also a good source of dietary fiber where the proportions of soluble and insoluble fibers present in its seeds are 13% and 32%, respectively (Roberts 2011).

The antidiabetic and hypocholesterolemic effects of fenugreek are attributed to multiple components. However, these effects, especially the hypoglycemic effect, may partly be secondary to the fiber content which is known to affect gastric emptying and subsequently decreasing the postprandial glucose level in blood (Srinivasan 2006; Benzie and Wachtel-Galor 2011).

Scientific Classifications

Kingdom:	Plantae
Subkingdom:	Tracheobionta
Super-kingdom:	Spermatophyta
Division:	Magnoliophyta
Class:	Magnoliopsida
Subclass:	Rosidae
Order:	Fabales
Family:	Leguminosae/Fabaceae
Genus:	*Trigonella*
Species:	*T. foenum-graecum* (Kirtikar and Basu 2003; Dymock et al. 2005)

2 Phytoconstituents

2.1 Leaves

The green leaves of fenugreek contain numerous phytochemicals, including various nutrients and vitamins. The fresh leaves are used as vegetables in diets mainly for their rich content of vitamins and minerals, and they have also been used as green fodder for livestock. The moisture, nutrient, and mineral contents in fenugreek leaves are shown in Table 1. Ascorbic acid and β-carotene contents in the fresh leaves of fenugreek are about 220.97 mg and 19 mg/100 g of leaves, respectively (Yadav and Sehgal 1997). Minerals like zinc, iron, phosphorous, calcium, etc. and vitamins like riboflavin, carotene, thiamine, niacin, vitamin C, etc. are also present in the leaves (Rao 2003) (Table 2).

2.2 Seeds

Phytochemical constituents in the seeds, husk, and cotyledons of fenugreek differ. The endosperm shows the highest saponin and protein content, while the husk shows a higher polyphenols content. The mature seeds contain about 0.1–1.5% of diosgenin (a steroidal sapogenin) and are extracted commercially (Saxena et al. 2013). Volatile and fixed oils are also present in fenugreek seeds in small amounts (Sowmya and Rajyalakshmi 1999). Among multiple flavonoid glycosides isolated from the seeds of fenugreek, isoorientin has been found in significant amount (Luan et al. 2018). Tables 3 and 4 show the list of chemicals present in fenugreek seeds.

Other constituents of the seed extracts include fibers, gum and neutral detergent fiber (Yadav et al. 2011), and lipids, triacylglycerols, diacylglycerols, monoacylglycerols, phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, free fatty acids (Chatterjee et al. 2010), and many others. The chemical structures of some of the bioactive phytochemicals present in fenugreek are shown in Figs. 1 and 2.

3 Uses of Fenugreek

Food is a major determinant for the health of animals including birds and fish. It not only helps in maintaining normal body functioning and metabolic status, but also the various constituents in feeds such as antioxidants, minerals, vitamins, fibers, etc. aid in disease prevention.

3.1 Ethnohistorical Uses of Fenugreek

Fenugreek is one of the oldest medicinal plants used for many ailments. The plant was traditionally used as galactogogue in Indian subcontinent (Betty 2008), as an analgesic in labor/delivery in ancient Rome, as a health tonic, and in treatment of edema and leg weakness in traditional Chinese medicine (Yoshikawa et al. 2000). The leaves and seeds are used as vegetable or green fodder for livestock (Ahmad et al. 2016) and as a spice (Wani and Kumar 2016), respectively, in many parts of the world.

3.2 Fenugreek Uses in Animal Health

Extracts of the seeds, shoots, roots, and leaves of fenugreek have shown multiple pharmacological properties, such as antimicrobial (Wagh et al. 2007; Norziah et al. 2015; Adil et al. 2015), antifungal (Haouala et al. 2008), anticancer (Raju et al. 2004; Shabbeer et al. 2009; Alsemari et al. 2014), hepatoprotective (Pribac et al. 2009), antidepressant (Kalshetti et al. 2015), antidiabetic (Sauvaire et al. 1998; Naicker et al. 2016), antiulcerogenic (Pandian et al. 2002), hypotensive (Moradi and Moradi 2013), anti-inflammatory, antipyretic, and analgesic (Malviya et al. 2010).

3.2.1 Diabetes

Diabetes, a group of metabolic disorders, is not limited to humans. Many animals, including pets, birds, and wild animals, also suffer diabetes naturally or by other influences. The hypoglycemic effect of fenugreek seeds in the human patient, as well as in chemically induced diabetic animals (rats, dog), has been described by many researchers. Decoction and ethanol extract of fenugreek seeds produced anti-hypoglycemic effects in alloxanized mice in a dose-dependent manner (Ajabnoor and Tilmisany 1988). This effect on blood glucose level in part has been attributed to the presence of steroids, saponins, alkaloids, and fiber content in the seeds. Soluble dietary fiber (SDF)—galactomannan of the plant—can improve glucose homeostasis in type I and type II diabetes by delaying carbohydrate digestion and absorption and enhancing insulin action. The viscous and gel-forming properties of SDF prevent macronutrients absorption, reduce postprandial glucose response, and beneficially affect certain blood lipids (Ou et al. 2001). Trigonelline, a pyridine alkaloid, apart from its antioxidative effects, can alter the activities of enzymes involved in glucose metabolism, β-cell regeneration, and insulin secretion (Zhou et al. 2012). The treatment of alloxan-induced diabetic rats with fenugreek seed powder modulated key enzymes like glycolytic, gluconeogenic, and NADH-linked lipogenic enzymes in the liver and kidney necessary for normalizing glucose level (Raju et al. 2001). Furostanol, a saponin constituent of fenugreek extract, increases feed intake and weight gain in diabetic rats (Petit et al. 1995). Saponins also modulate the disaccharidase and glycogen enzyme activities in the intestine, which results in increased hepatic glycogen content and suppression of blood glucose level. Diosgenin, a

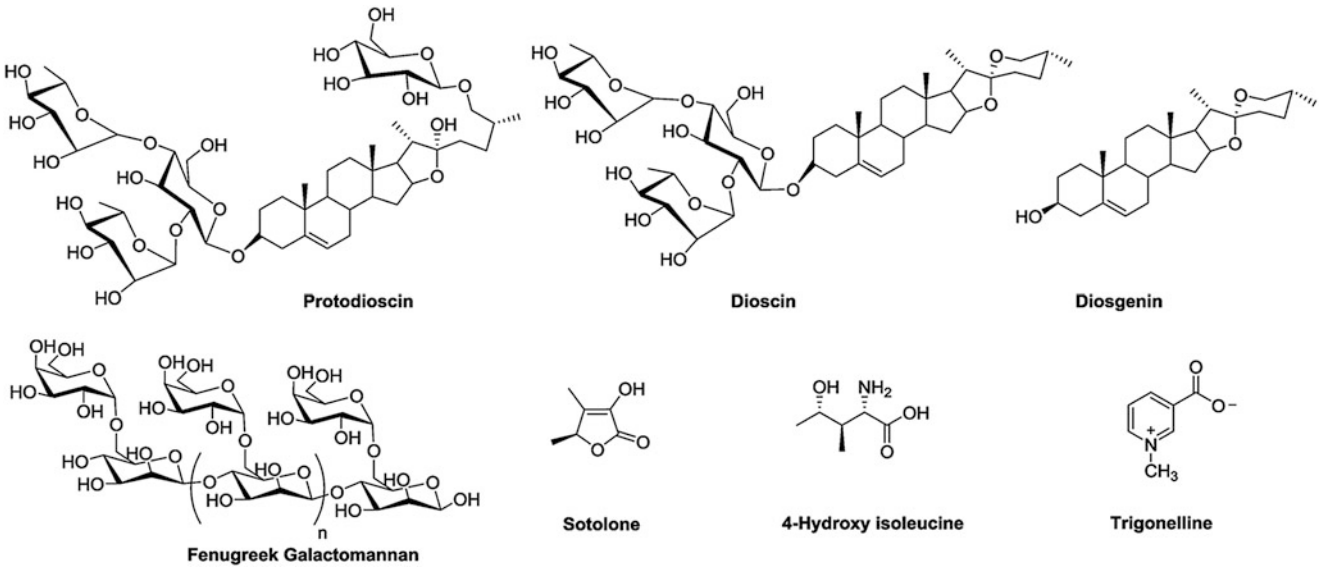

Fig. 1 Structures of some of the important phytochemicals present in fenugreek. Source: Review article of Venkata et al. (2017)

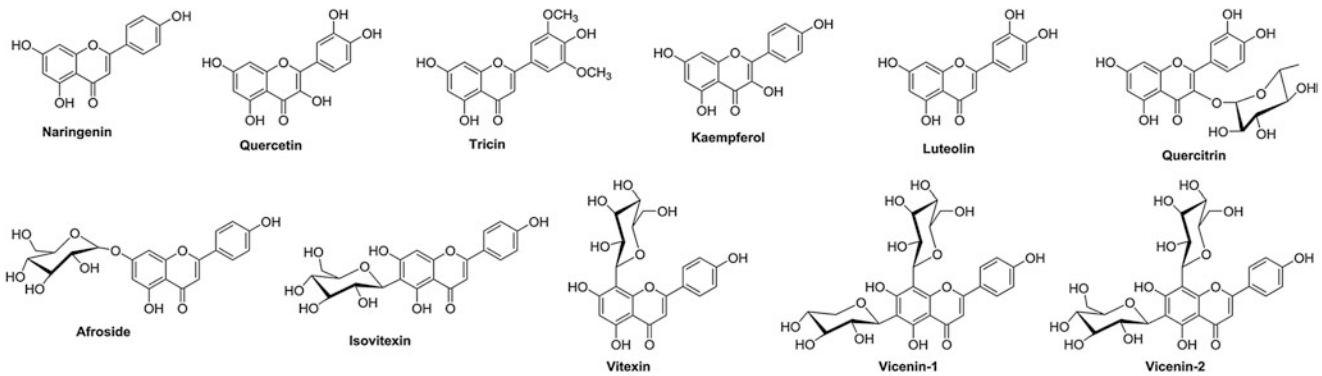

Fig. 2 Flavonoids and their derivatives present in fenugreek. Source: Review article of Venkata et al. (2017)

bioactive steroidal sapogenin belonging to the triterpene group, is a product of the hydrolysis of saponins. Diosgenin content in fenugreek seeds is higher than in its aerial parts (Dangi et al. 2014). This compound is a precursor for several hormones and is extracted commercially for producing sex hormones and other important steroidal drugs. The antidiabetic potential of diosgenin may be attributed to its multiple effects including renewal of pancreatic β-cells, stimulation of insulin secretion, antioxidative effects, stimulation of differentiation of adipocytes, and enhancement of insulin-dependent glucose uptake (Son et al. 2007; Uemura et al. 2010; Kalailingam et al. 2014). Diosgenin also exhibits renal protection in diabetic rats through its anti-inflammatory and antioxidative actions (Kanchan et al. 2016). Subsequent reduction of lipid peroxidation in the liver of diabetic rats after treating with fenugreek has also been attributed to its antioxidative actions (Jin et al. 2014). A nonprotein amino acid, 4-hydroxyisoleucine (4-HIL), is one of the extensively studied phytochemicals present in fenugreek which has insulin-like action and can stimulate insulin production, thereby controlling blood sugar levels in diabetic patient as well as in vitro studies (Gupta et al. 2001). This unusual amino acid is even safer and more effective than many of the current medications available for the treatment of type 2 diabetes mellitus (Zafar and Gao 2016).

The neurological consequences associated with this metabolic disease in the CNS are now receiving considerable attention (Kamboj et al. 2009). Oxidative stress has been implicated in the pathogenesis of many neurodegenerative diseases (Chen et al. 2012). Hyperglycemia generates many free radicals in the diabetic patient, ultimately leading to increased damage of plasma membranes and simultaneous reduction in antioxidant levels (Preet et al. 2005). There is also an increase in Ca^{2+} levels concomitantly with free radicals, which actually correlates to the increase in cellular lipid peroxidation of the synaptosomal membrane and

inhibition of Ca^{2+}ATPase activity (Pekiner et al. 2005; Kamboj et al. 2009). Administration of fenugreek also reduces some of the aberrations that occur in the brain during diabetes, mainly due to its antioxidative activities and neuroprotective effects.

3.2.2 Cholesterol Lowering and Cardiovascular Protection

Cardiovascular diseases (CVD) are the leading cause of human death and morbidity globally (Mendis et al. 2011). Proper management of the cholesterol level in the hypercholesterolemic patient is essential to prevent cardiovascular diseases. Statins alone or in combination with some other drugs are commonly used for controlling increased cholesterol levels. Hundreds of plant-based medicines are also used either singly or in combinations in traditional systems of medicine for the treatment of coronary heart diseases (Mahady 2009). Fenugreek seeds lower serum cholesterol, triglyceride, and low-density lipoprotein in hypercholesterolemic and diabetic patients (Sharma et al. 1996; Mathern et al. 2009) and animals (Sauvaire et al. 1991; Boban et al. 2009). Administration of fenugreek in obsessed rats also reduces triglyceride accumulation in liver while increasing the fecal bile and cholesterol excretion (Rashmi and Rahul 2011). This increased excretion of bile and cholesterol is considered to be a consequence of the reaction between bile acid and fenugreek-derived saponins in the gut causing formation of large micelles which cannot be absorbed easily from the gut (Olaiya and Soetan 2014). The cholesterol-lowering potential of fenugreek is also attributed to its high fiber content. Soluble fiber from fenugreek seemed to reduce reabsorption of bile constituents in the small intestine through binding cholesterol and bile acids and disruption in the enterohepatic cycle in vivo. This enhances utilization of cholesterol in bile acid biosynthesis, subsequently reducing its level (Muraki et al. 2011).

3.2.3 Cancer

Many constituents in fenugreek have shown to exhibit antitumor or anticancer activities in vivo and in vitro. Some of these important constituents include diosgenin (Raju et al. 2004), trigonelline (Bhalke et al. 2009), and flavonoids (Ahmed et al. 2017). Phytoestrogens and saponins present in fenugreek extracts are found to possess anticancer activity in vitro (Raju et al. 2004). Saponins in the extracts not only selectively inhibit cell division in tumor cells but also can initiate apoptosis of the cells (Francis et al. 2002). Diosgenin, a steroidal saponin, has shown antitumorigenic activities in colorectal cancer, osteosarcoma, hepatocellular carcinoma, breast cancer, and leukemia. The effects of diosgenin are mediated through various pathways such as the STAT pathway (Li et al. 2010), activation of p53 and caspase-3 (Liu et al. 2005), and the induction of the tumor necrosis factor-related *apoptosis*-inducing ligand (TRAIL) death receptor DR5 (Lepage et al. 2011). A study in rats revealed the anticancer activity of diosgenin from its ability to inhibit the formation of aberrant crypt foci (ACF), which are clusters of abnormal tube-like glands in the lining of the colon and rectum and can be observed as preneoplastic lesion (Raju et al. 2004). Diosgenin suppressed the expression of bcl-2, a proapoptotic protein, and increased the expression of caspase-3, an anti-apoptotic protein (Raju et al. 2004). Cytokine TNF-α is known to promote cell proliferation, an event common in the initiation and promotion of malignant disease. Diosgenin may also act against bone cancer through the inhibition of TNF-α, thus suppressing proliferation and development of bone cells (Shishodia and Aggarwal 2006). The effectiveness of the fenugreek plant was also seen in colon cancer through the modulation of β-glucuronidase and mucinase activities (Devasena and Menon 2003). Limiting the activities of β-glucuronidase and mucinase in the colonic mucosa may enhance the effectiveness of chemotherapy in colon cancer. The increased activities of β-glucuronidase promote the release of free carcinogens from carcinogen-glucuronide conjugates by enhancing the process of hydrolysis within the colonic lumen, and mucinase assists by hydrolyzing the protective mucin in the gut (Beaud et al. 2005; Booupathy et al. 2016). Fenugreek can decrease the activities of both β-glucuronidase and mucinase in colonic mucosa and may subsequently prevent free carcinogens from acting on the colonocytes (Devasena and Menon 2003).

3.2.4 Antibacterial and Antifungal Effects

The antibacterial and antifungal activities of fenugreek have been reported by many investigators in recent years. The examination of methanol, acetone, and aqueous extracts of fenugreek leaves, seeds, and stems against *E. coli* and *Staphylococcus* isolated from spoiled cabbage revealed the antibacterial property of the herb. The methanol extract of the leaves demonstrated the highest effect, while the aqueous extracts showed the least (Sharma et al. 2017). Mercan et al. (2007) reported an interesting finding that honey samples with the highest antibacterial activity against several bacteria such as *Staphylococcus aureus*, *Escherichia coli*, and *Pseudomonas aeruginosa* displayed maximum pollens from fenugreek as compared to other plants. The extracts were also effective against *Helicobacter pylori* (Randhir et al. 2004).

Fenugreek extracts are also effective against several fungal strains including *Fusarium graminearum*, *Rhizoctonia solani*, *Botrytis cinerea*, *Alternaria* sp., and *Pythium aphanidermatum* (Haouala et al. 2008). However, the potency of the extracts varies with different parts of the fenugreek plant and also the species of fungus. Defensins are small cysteine-rich cationic proteins and function as host defense peptides. A defensin-like peptide, Tf-AFP, with a molecular mass of 10.3 kDa is present in fenugreek and was

isolated from fenugreek seeds by Oddepally and Guruprasad (2015). These defensins are active against bacteria, fungi, and many viruses (Kagan et al. 1990).

3.2.5 Cutaneous Wound Healing

Many herb and spice extracts contain numerous constituents which enhance cutaneous wound healing. Antioxidant activity is one of the major effects of such bioactive constituents which can eventually reduce excessive or chronic inflammation during injury and subsequently promote wound healing. Topical application of 10 % fenugreek seed ointment promoted formation of cellular fibrous connective tissue, granulation tissue, and early maturation of fibrous connective tissues and thus enhanced wound healing in rabbits (Muhammed and Salih 2012). In another study in rats, topical or oral administration of the fenugreek seed suspension quickened contraction and epithelization of the cutaneous wound (Sumitra et al. 2000). Apart from its antioxidative actions, several other constituents present in the extracts are capable of modulating the different phases of healing, which include inflammation, cell proliferation and migration, angiogenesis, and maturation. Antioxidative and antibacterial activities exerted by several constituents of fenugreek extracts are considered important factors augmenting the healing processes (Muhammed and Salih 2012; Ktari et al. 2017). Moreover, fatty acids present in fenugreek seed help in building collagen and consequently promote wound healing and maintenance of skin elasticity (Dixit et al. 2005).

3.2.6 Toxicity Amelioration

Fenugreek is hepatoprotective (Kaviarasan and Anuradha 2007). The antioxidative (Reddy and Srinivasan 2011), anti-radical, and iron metabolism normalizing effect of fenugreek are thought to impart hepatoprotection (Kaviarasan et al. 2007). Incorporation of fenugreek seeds powder (FSP) (5%) in pelleted diet ameliorated chronic liver injury induced by $AlCl_3$ in Wistar rats (Belaïd-Nouira et al. 2013a). The altered liver enzymes and protein levels returned to normal after feeding FSP. Moreover, fenugreek could reduce nephrotoxicity (Belaïd-Nouira et al. 2013b). Fenugreek has shown effectiveness in preventing liver cell necrosis in primary rat hepatocytes culture against *N*-methyl- *N*-nitro-*N*-nitrosoguanidine (MNNG) toxicity in vitro (Khader et al. 2007). Furthermore, the plant has potential for initiating regeneration of hepatocytes during injury. Kaviarasan et al. (2006) reported that in ethanol-induced liver damage, protection of hepatocyte structure and function by fenugreek seed aqueous extract occurred in a dose-dependent manner. Ethanolic extract of fenugreek seed reduced dimethoate (an OP compound)-induced pancreatic damage (Mesallam et al. 2018). Nevertheless, fenugreek extracts were found to potentiate apoptosis of cells induced by radiation, and this cytotoxicity was pronounced in T cells of humans. The cytotoxic potentiative effect of this extract can be of great use in cancer research and treatment by reducing unwanted side effects in those patients who are more sensitive to radiation. However, more in vivo and in vitro studies are needed to support these findings for final validation of effects (Tavakoli et al. 2015).

3.2.7 Gastroprotection

The aqueous extract of fenugreek seeds and a gel fraction isolated from the seeds have ulcer protective potential when compared with omeprazole on ethanol-induced gastric ulcer in experimental rats (Pandian et al. 2002). A similar result was observed on aspirin-induced gastric ulcer in rats using ranitidine as the standard drug (Thirunavukkarasu and Anuradha 2007). This cytoprotective effect was not only due to anti-secretory action of the seed but also attributed to the effects on mucosal glycoproteins. Development of a mucin-like gel layer of galactomannan on the surface of the gastric mucosa forms a barrier, protecting the mucosa from ulcerogenic agents as well as from the gastric juice pepsin in the stomach (Madar and Shomer 1990). Moreover, the antioxidative actions of the seed extract may also contribute to diminishing mucosal injury (Narender et al. 2006). Figer et al. (2017) demonstrated that fenugreek aqueous extract at different concentrations significantly inhibited cell death better than misoprostol sodium against ethanol-induced damage in human gastric carcinoma epithelial cell line in vitro. Higher concentrations beyond 5.0 μg/ml resulted in a decrease in activity. In silico analysis revealed a remarkable degree of interaction of flavonoid constituents with H^+/K^+ ATPase receptor binding sites demonstrating the promising therapeutic potential of fenugreek seed extract as gastroprotective (Figer et al. 2017).

3.2.8 Other Benefits of Fenugreek

Apart from the uses discussed above, fenugreek is well known for its multiple pharmacological actions. Changes in hepatic lipid metabolism can result in development of chronic liver disease (Corey and Cohen 2015). Fenugreek can lower hepatic lipids in the body because of its potential to modify the activities of several enzymes including enzymes related to glucose and lipid metabolism (Madar and Shomer 1990).

Fenugreek is anthelmintic as it causes the evacuation of parasitic intestinal worms. Alcoholic extract of fenugreek seeds has shown anthelmintic activity against earth worm comparable to albendazole in vitro (Khadse and Kakde 2010). However, the aqueous extract was less potent than albendazole (Buchineni and Kondaveti 2016). The effectiveness of the extracts is also reported against *Hymenolepis nana*, *Syphacia obvelata*, and *Moniezia expansa* (Ghafagaai et al. 1980).

Fenugreek is a potent immunostimulant which can stimulate both humoral (Tripathi et al. 2012) and cell-mediated

immune mechanisms (Anarthe et al. 2014). The immunomodulatory effect has been reported by many investigators (Bin-Hafeez et al. 2003; Tripathi et al. 2012; Meghwal and Goswamy 2012; Wani and Kumar 2016). The extract increased phagocytic index, phagocytic capacity of macrophages, as well as lymphoproliferation which strongly suggest its stimulatory effect on immune functions in mice (Bin-Hafeez et al. 2003).

The neuroprotective action of fenugreek has also been reported (Moghadam et al. 2013; Hamden et al. 2010; Ahmed et al. 2017). The powder made from this herb has shown neuroprotective effect in aluminum chloride-induced Alzheimer's disease in rats which might be the result of synergistic activities of several constituents present in the seed powder. This effect resulted in attenuation of AlCl3-induced memory deficits, amyloid and tau pathology, oxidative stress, and inflammation in Alzheimer's disease in rats (Prema et al. 2017).

4 Fenugreek in Animal, Poultry, and Fish Feeds

The use of antibiotics, hormones, and many more chemicals as feed additives in livestock, poultry, and fish productions is usually associated with many untoward effects, as well as residue issues in meat, milk, eggs, and fish for human consumption. Many natural materials like medicinal plants/herbs could be used as feed additives in animal, poultry, and fish diets to increase feed utilization efficacy and production performance. Herbs or spices have been reported to have the potential of enhancing various physiological functions like appetite stimulation, growth, anti-stress, immune functions, and so on. Incorporation of 10% of an extract of a mixture of herbal plants including fenugreek seeds in animal feed reduced the production of aflatoxin by *Aspergillus flavus* by about 85–90% (El-Shayeb and Mabrouk 1984). Fenugreek stimulates bile secretion by increasing the conversion of cholesterol to bile salts (Bhat et al. 1985). Improvement in feed intake after incorporation of fenugreek seed in the diet has also been reported in rats (Petit et al. 1993).

4.1 Poultry Production

Incorporation of many herbs or spices in feeds improves digestibility, nutrient absorption, and even elimination of pathogens from the GI tract, and this in return enhances growth and productivity in poultry. Supplementation of broiler chick feed with fenugreek increased feed intake and body weight gain and decreased the feed conversion ratio (Elbushra 2012). Beside these, there was also a reduction in the mortality rate of poultry (Alloui et al. 2012). Fenugreek can also be added to drinking water as an anti-stress agent. This would be an important step in replacing the use of an antibiotic like enrofloxacin (Saber et al. 2017).

The inclusion of fenugreek seeds in broiler diet is not only economical by increasing the feed conversion ratio, but it also contributes to reduced abdominal fat deposition in the birds (Yesuf et al. 2017). This is an important finding which would be of great benefit for lean broiler meat production.

4.2 Livestock Production

Fenugreek produces high quality forages in all growth stages. It has a high content of many nutrients as well as phytochemicals (diosgenin) which promote growth and milk production in livestock. (Acharya et al. 2007; Żuk-Gołaszewska and Wierzbowska 2017). The nutritive value of the forage in all growth stages is comparable to early-bloom alfalfa (*Medicago sativa* L.) (Mir et al. 1998). The incorporation of fenugreek in cattle diets resulted in improvement of milk quality parameters and animal metabolism (Rjat and Taparia 1990). Fenugreek seed in buffalo diet improves total dry matter and daily consumption of concentrates thereby increasing milk production (Degirmencioglu et al. 2016). Fenugreek insignificantly affects milk constituents such as SNF, proteins, somatic cell count (SCC), fats, etc. (El-Nor et al. 2007; Degirmencioglu et al. 2016). However, a slight reduction in milk fat content as reported by some researchers might be related to increasing milk yield (Degirmencioglu et al. 2016). The enhanced performance of sheep after addition of fenugreek seeds in their feed has also been reported (Ismail 2000).

4.3 Fish Production

Fish are considered one of the best and least expensive sources of lean meat. In a study from 2010, 16.7% of animal protein and 6.5% of all protein consumed globally comes from fish (Barik 2017). In commercial fish production, antibiotics and hormones are increasingly added to the fish diet for a faster growth rate and other purposes. However, strict regulations on the application of antibiotics and chemotherapeutics in aquatic feeds exist due to concern for bioaccumulation (Lim et al. 2013). Hence, replacement of such chemicals with many natural materials such as herbs/spices which have medicinal value should be encouraged and practiced. The addition of different percentages of fenugreek seed meal (FSM) in the diet of common carp fingerlings has resulted in a decrease in the feed conversion ratio and a faster growth rate (Roohi et al. 2017).

5 Toxicology and Safety Profile

The various extracts of fenugreeks have been used since ancient times in different medical conditions of humans and animals and are generally considered safe. The acute and subacute toxicity studies of fenugreek in rats (up to 5g/kg body weight) and mice (up to 2g/kg body weight) did not produce significant toxicity in either sex (Narasimhamurthy et al. 1999). The LD_{50} of the aqueous extract of fenugreek in mice is 10 g/kg body weight p.o. (Abdel-Barry et al. 1997). Administration of a glycosidic extract orally to mice for 28 days has a lower LD_{50} (4.25 g/kg body weight) (Kandhare et al. 2015). Recent evidence suggests that fenugreek may have neurodevelopmental, neurobehavioral, and neuropathological side effects, and therefore its consumption should be avoided during pregnancy and lactation (human, rodent, rabbit, and chick data reviewed in Ouzir et al. 2016).

6 Concluding Remarks and Future Directions

Studies conducted over the last few years on fenugreek revealed its varied nutritive and medicinal values. Fenugreek, a rich source of protein, fiber, vitamins, and minerals, can be offered to animals, birds, and fish as a feed supplement for improving their health and performance. Antidiabetic, hypoglycemic, hypocholesterolemic, antioxidative, antiulcerogenic, antimicrobial, anticarcinogenic, and neuroprotective activities are some of the major medicinal effects exhibited by fenugreek. Replacement of harmful antibiotics and hormones with fenugreek and/or other medicinal plants/herbs in animal, bird, and fish feeds has shown definite benefit in the attempt to improve livestock, poultry, and fish production quantity and quality. Additionally, the issues of drug residues in meat, milk, fish, and eggs and their products for human consumption as well as development of antibiotic resistance which occur mainly due to indiscriminate use of antimicrobial agents may be able to be resolved to a certain extent. However, current knowledge on the molecular mechanisms involved in exhibiting the various pharmacological effects of most of the bioactive phytochemicals in fenugreek extracts is limited, and further research is needed for scientific validation of the multiple effects as well as to explore any other distinct therapeutic potentials of the herb.

Acknowledgments The authors are thankful to all the scientists, scholars, and staff of the Division of Pharmacology and Toxicology, Indian Veterinary Research Institute (IVRI), Izzatnagar, Bareilly, India, for their support and cooperation in completion of this book chapter.

Neem Extract

Anu Rahal, Dinesh Kumar, and Jitendra K. Malik

Abstract

Neem has become a cynosure of modern lifestyle and finds extensive use in Ayurvedic, Unani and homoeopathic medicine. It elaborates a vast collection of bioactive compounds that are chemically diverse and structurally complex which exhibit immunomodulatory, anti-inflammatory, antihyperglycaemic, antiulcer, antimalarial, antifungal, antibacterial, antiviral, antioxidant, antimutagenic and anticarcinogenic properties. The leaves are a habitual feed for ruminants in arid lands; the seeds are a rich source of fatty acids and proteins but remain largely unexploited owing to the bitter toxic principles present in it. If the bitters can be substantially reduced, the toxicity of neem parts can be overcome, and its different parts may be fully utilized as an excellent nutraceutical. Its bioactivity, livestock safety and ecofriendly temperament is quite encouraging to prospect its bright future in the field of nutraceuticals.

Neem · Leaves · Seed kernel · Neem oil · Animal feed · Safety

1 Introduction

Neem (*Azadirachta indica*; family, Meliaceae; subfamily, Meliodeae; order, Meliales) is a nonleguminous evergreen tree native to the Indian subcontinent. It grows widely on almost all kinds of soils including saline and alkaline and other wastelands in several countries of Asia, Australia, Africa and Central and South America. It is, therefore, often used in afforestation programmes, especially in semiarid regions, and grows as boulevard, ornamental and agroforestry plantation or as roadside shade. It is a quick-growing tree, sometimes up to 100 feet high, with luxuriant spreading branches, and remains green throughout the year. At an age of 2–3 years, it bears white flowers, which smell like honey, and then fruits 1–2 years later. Fruits are green when raw, turning yellow after it ripened and aromatic with garlic-like odour. The ripe fruit is yellow drupes that are ellipsoid and glabrous, 12–20 mm long. Fresh leaves and flowers come in March–April. Fruits mature between April and August depending upon the environmental factors.

Neem is commonly known as village dispensary of India. It holds high value owing to its medicinal and insecticidal properties in Ayurvedic and Unani systems of medicines. Every part of neem (leaf, flower, fruit, seed, kernel bark, root, wood, twig and oil) and its fractioned products possess curative properties and find place in traditional remedies. United Nations has declared neem tree as the "Tree of the 21st century", while in a report published in 1992, the US National Academy of Science has designated it as "Neem: A tree of solving global problems". The European literature "Materia medica" has also regarded neem as "Panacea of all Disease". Neem finds varied use in ecological, medicinal and agricultural sectors, including animal feed, medicines, soap industry, nitrification inhibition, slow nutrient release manure, fuel, energy, pest control, etc. A large number of neem-based pest control and healthcare products have developed in the international market. Neem plant contents are effective bioinsecticide and are useful in the control of many insect species of medical and veterinary importance like head lice and *Anopheles* mosquito. Owing to their features of diverse activity and relative safety to non-target organisms, today, neem is being recognized as the single most important source of biopesticides and allied products. has focused, of late, on its applications as a spermicide and a treatment for scabies, although anticarcinogenic properties of the tree have also received attention.

2 Extracts of Neem

Diverse chromatographic techniques such as simple column chromatography, preparative thin-layer chromatography, vacuum liquid chromatography and reverse phase medium- or high-pressure preparative liquid chromatography have been described in literature for isolating bioactive principles from neem on an industrial scale. Depending upon the final use, different types of extraction procedures are taken up for different parts of the plant. The choice of solvent and the method depends on the compound to be concentrated. Technologies for the preparation of azadirachtin concentrates of varying strengths have been developed for both household and industrial use. The indigenous methods include aqueous extraction, cold maceration, steam distillation, and organic solvent extraction. Maceration is a cold extraction process for defatted kernels by soaking in methanol with intermittent stirring for 3 days, after which it is filtered and the solvent evaporated under vacuum to obtain the dried crude extract. In batch stirring extraction, a magnetic pellet is dropped in the flask, and the mixture is stirred for 8 h on a magnetic stirrer plate followed by vacuum drying to obtain crude extract.

A single seeded mature neem fruit contains 23.8% skin, 47.5% pulp, 18.6% shell and 10.1% kernel. The depulped and decoated seed yields about 26% kernel, which gives 45–50% oil leaving the rest as neem kernel cake (NKC). NKC is prepared by soaking the dried neem fruits in water for 3–4 days and depulping using depulper machine. The seeds are then dried for 7 days before being decorticated using a winnowing machine and then crushed after further drying for 3 days (Bawa et al. 2007). NKC can also be prepared by spreading the neem fruit in the sun for 15 days and then soaking in water for 3 days followed by depulping. The depulped seeds are washed and sun-dried for a period of 10 days. The dry seeds are decorticated, further dried for 5 days and crushed followed by manual removal of oil to produce the neem kernel cake (Aruwayo 2011).

Another method of preparing NKC is by spreading the seeds in the sun to obtain a constant weight. The dried seeds are soaked in water in an open basin for 72 h. The seeds are placed into a jute bag to drain the water and later sun-dried to constant weight. Then, the water soaked and untreated seeds are milled separately for oil extraction. Cake obtained from the oil extraction is then ground in a hammer mill.

NKC is unpalatable in calves (Bedi et al. 1975), crossbred bulls (Ananthasubramainiam et al. 1979) and sheep (Gupta and Bhaid 1980) owing to its bitter taste and pungent odour but possess antiparasitic (Ogbuewu et al. 2011a), insect repellent, antifeedant, growth inhibitors and other insecticidal properties. The bioactive principles are slightly hydrophilic but freely lipophilic and highly soluble in organic solvents like hydrocarbon, alcohols, ketones and esters (Schmutterer 1995; NRC 1992). There are various methods of removing the oil from the neem seed cake. For the expeller NKC, the crushed kernel is steamed, and the oil is pressed out using expeller machine. The NKC processing by hydraulic press is devoid of heat. The milled kernel is cold-pressed using the hydraulic press machine until the oil content of the residue (cake) is minimal. The NKC can be further defatted using hexane.

To facilitate acceptance of NKC as animal feed, the removal of bioactive bitters from neem kernels is essential and can be made using simple techniques like

- *Water extraction*: This is the simplest technique to crush or grind the kernels and extract them with water. They may be steeped overnight in a cloth bag suspended in a barrel of water, or water can be poured into the bag, and extract can be collected as it emerges. By using water extraction, it has been estimated that 20–30 kg neem seeds can normally treat one hectare of land.
- *Hexane extraction*: Kernels are grated and steeped in the solvent hexane to extract only oil. The residue left after extraction with hexane still contains limonoid active ingredients, and subsequent water or alcohol extraction yields clean limonoids uncontaminated by oil.
- *Alcohol extraction*: It is the shortest process for generating neem-based pesticides in concentrated form. Limonoids are highly soluble in alcohol. The grated kernels are soaked in ethanol usually, but sometimes methanol is also used. It extracts the active ingredients to the range of 0.2–6.2%.

In addition to these techniques, further attempts can be made to remove the bitter principles of the cake for improved palatability. The oil from the crushed NKC can be extracted using organic solvent of high polarity mixed with water. Other methods include alcohol treatment and alkali treatment (0.8% sodium hydroxide, w/w) along with aqueous boiling (in the ratio 1:2.5w/v) of cake followed by water washing and draining off. Out of these several methods used to detoxify NKC, water washing is most effective despite the loss of 22% dry matter. To avoid this dry matter loss from water washing, alkali-treated (20 g sodium hydroxide/kg cake, w/w) NKC without washing is also quite palatable to adult cattle and buffaloes (Katiyar et al. 1993), promising future in the feeding of buffalo calves, Uda lambs and rams (Aruwayo 2011).

3 Phytoconstituents

Neem is a source of several bioactive triterpenoids including azadirachtin, nimbin, nimbinin, nimbidin, 6-desacetylnimbin, salannin and beta-sitosterol (Dasgupta et al. 2004). The most biologically active compound is azadirachtin, which is actually a mixture of seven isomeric compounds labelled as azadirachtin A–G, of which azadirachtin E is most effective (Verkerk and Wright 1993). Other compounds that have a biological activity are salannin, volatile oils, meliantriol and nimbin (NRC 1992).

Neem kernels contain 30–50% of oil rich in triterpene or limonoids mainly used by the soap, pesticide and pharmaceutical industries (Djenontin et al. 2012). The four best limonoids compounds are azadirachtin, salannin, meliantriol, and nimbin. Limonoids contain insecticidal and pesticidal activity. The seed also contains tignic acid responsible for the distinctive odour of the oil (Sharma et al. 2011).

The bark powder contains proteins, sugar, amino acids and oil (Subramanian and Lakshmanan 1996). Bark extract is also rich in phenols, unsaturated sterol, triterpene (including diterpenoids, limonoids, cseco-meliacins, cseco-limonoids, etc.) and saponin. Polysaccharides such as arabinofucoglucanes and fucogalactoglucoarabinanes have also been isolated (Fujiwara et al. 1984). Flavonoids, flavonolglycosides, dihydrochalcones, tannins and others are also important constituents of bark, leaves, fruits and flowers of neem.

4 Medicinal Uses

Indigenous literature indicates applications of various parts of neem as feed and in a large number of prescriptions and formulations to provide health cover to livestock in various forms. Pandava brothers Nakul and Sahadev used neem to treat sick and injured horses and elephants using poultices prepared from neem leaves and oil, during the battle of Mahabharata. Various neem preparations have been standardized in the form of powders, oils, liquids and liniments. Various preparations obtained from different parts of neem have been found to exert antibacterial, antiviral, antimalarial, antioxidant, antifungal, antimutagenic, anticarcinogenic, anti-inflammatory, contraceptive and antiulcer activities (Subapriya and Nagini 2005). Azadirachtin disrupts the metamorphosis of insect larvae and is thus used as a feeding deterrent (NRC 1992). Nimbidin is quite effective in the treatment of skin conditions such as eczema, furunculosis, arsenical dermatitis, scabies and seborrheic dermatitis (Dasgupta et al. 2004). Extracts from neem leaves, seeds, and bark also act as nitrification inhibitors (Abbasi et al. 2011).

4.1 Bacterial Diseases

Neem oil is effective against a wide spectrum of bacteria such as *Staphylococcus aureus*, *Bacillus cereus*, *Bacillus pumilus*, *Escherichia coli*, *Pasteurella vulgaris*, *Mycobacterium tuberculosis*, *Klebsiella pneumoniae*, *Salmonella typhi*, *Salmonella dysenteriae*, *Enterococcus faecalis*, *Streptococcus mutans*, *Streptococcus salivarius*, *Streptococcus mitis*, *Streptococcus sanguis* and even streptomycin-resistant strains (SaiRam et al. 2000; Prashant et al. 2007; Mehrotra et al. 2010; Sarmiento et al. 2011; Maragathavalli et al. 2012; Vinoth et al. 2012; Chava et al. 2012; Rosaline et al. 2013). It is a conventional precautionary measure against leptospiral epidemics in tropics, especially in waterlogged areas. It acts as an impermeable antibacterial film on skin coat that prevents the portal entry of bacteria. Moreover, when it is mixed with water, the neem oil, even in lower concentrations, becomes acidic and may turn leptospiricidal.

The bark extract is immunomodulatory. Extracts from bark, leaves, fruits, oil and root are used to control leprosy, intestinal ulcers and respiratory disorders (Ketkar and Ketkar 1995; Kartikar and Basu 1935). Anthraquinone fraction of leaf, dried flower and fruit is taken orally for leprosy. Tricyclic triterpenoids, margolone, margolonone and isomargolonone inhibit the growth of *Klebsiella*, *Staphylococcus* and *Serratia* species. Chloroform extracts of neem inhibit the growth of *Listeria monocytogenes*, while ethanolic extracts inhibit *Staphylococcus aureus* (Mahfuzul et al. 2007). Even extracts of neem cake, a waste by-product of oil extraction, can inhibit *Campylobacter jejuni* (Del Serrone and Nicoletti 2013).

Aquaneem, an emulsified product from neem kernels, inhibits pathogens of fish (*Aeromonas hydrophila*, *Pseudomonas fluorescens* and *Escherichia coli*) (Das et al. 1999). Neem leaf extract reduces bacterial load of *Streptococcus* sp., *Aeromonas hydrophila*, *Enterobacter* sp., *Escherichia coli*, *Pseudomonas* sp., *Proteus* sp., *Vibrio* sp. and *Yersinia enterocolitica* in marine decorative fishes (Dhayanithi et al. 2010). It inhibits the formation of biofilm in *Pseudomonas aeruginosa* (Harjai et al. 2013). Sulfonoquinovosyldiacylglyceride, a water-soluble glycolipid isolated from the leaves of neem, inhibits *Salmonella typhi*, *Shigella dysenteriae*, *Escherichia coli*, and *Vibrio cholerae* (Bharitkar et al. 2014).

4.2 Viral Diseases

An aqueous extract of tender leaves protects against vaccinia (viral disease in cattle), variola (smallpox), fowlpox and Newcastle diseases, while its paste is used for ulcerative lesions of cowpox. It inhibits poliovirus, herpes infectious virus, coxsackie B group virus and dengue virus at an early

step of viral genome replication (Badam et al. 1999; Parida et al. 2002; SaiRam et al. 2000). This is possibly by virus inactivation, in addition to interfering at an early event of its replication cycle. The bark extract also significantly blocks herpes simplex virus type 1 (HSV-1) access into cells at concentrations 50–100 μg/ml (Tiwari et al. 2010). Inhibition of HSV-1 glycoprotein-mediated cell fusion and polykaryocytes formation indicates an additional role of the extract at the viral fusion step, opening new prospectives for the development of bark extract as a novel anti-herpetic microbicide.

4.3 Fungal Diseases

Nimbidin inhibits the growth of *Tinea rubrum*, while gedunin can treat a range of fungal infections including *Aspergillus fumigatus*, *Aspergillus flavus*, *Aspergillus niger*, *Candida albicans*, *Microsporum gypseum*, *Microsporum canis*, *Trichophyton rubrum*, *Trichophyton mentagrophytes*, *Fusarium oxysporum*, *Cladosporium* sp., *Penicillium notatum* and *Penicillium citrinum* (SaiRam et al. 2000; Asif 2012; Al-Samarrai et al. 2012). The cyclic trisulfides and tetrasulfides of steam distillate of mature leaves can be used against *Trichophyton mentagrophytes* (Pant et al. 1986).

4.4 Ulcer, Oxidative Stress and Inflammation

The aqueous extract from bark is an astringent tonic used for relieving fever, thirst, nausea, vomiting and skin diseases. It also blocks gastric ulcer due to stress, indomethacin and ethanol effectively. Increased lipid peroxidation, increased protein carbonyl content and decreased level of endogenous GSH are the characteristic features of oxidative damage of the gastric mucosa during ulceration (Bandyopadhyay et al. 2000) which are effectively reverted by the bark extract. The antisecretory and antiulcer activity is due to its phenolic glycoside and is superior to that of other natural antioxidants such as vitamin E and ascorbate and the physiological antioxidant, melatonin (Bandyopadhyay et al. 2000). Nimbidin suppresses basal as well as stimulated gastric acid release along with blockade of histamine H_2 receptors. It shows potent antioxidant activity by directly scavenging free radicals and associated DNA damage, which is observed in apoptotic cell death in gastric mucosal cell injury. It also protects the mucosa by preventing depletion of the mucus adhering to it (Wallace and Grangers 1996). Ethanol leaf extract also inhibits the proliferative phase of inflammation (Chattopadhyay 1998). Methanol extract of bark and leaves is antipyretic at a slightly higher dose. Its ether-soluble fraction is a good analgesic in acute inflammatory pain (Tandan et al. 1990). The bark extract also shows an antithrombotic effect in mice (Olajide 1999).

4.5 Cancer

Neem can prevent or reverse carcinogen-induced accumulation of reactive oxygen metabolites, which play a pivotal role in carcinogenesis (Androutsopoulos et al. 2009). A 5-day pretreatment with leaf extract decreased the formation of lipid peroxides and enhanced the levels of antioxidants and detoxifying enzymes in the stomach, the liver and circulation (Arivazhagan et al. 2000). Azadirachtin and nimbolide show concentration-dependent antiradical scavenging activity and reductive potential in the order: nimbolide > azadirachtin > ascorbate. Furthermore, azadirachtin and nimbolide inhibit the development of DMBA (7,12-dimethylbenz(a)anthracene)-induced hamster buccal pouch carcinomas through prevention of procarcinogen activation and oxidative DNA damage and upregulation of antioxidant and carcinogen detoxification enzymes (Priyadarsini et al. 2009).

The ethanolic extract of neem leaf inhibits the growth of cancerous cells in a dose- and time-dependent manner. It does not affect the viability of lymphocytes significantly indicating its selective cytotoxicity towards the cancer cells and, thus, providing a rationale for development of neem as a biosafe chemopreventive agent (Sharma et al. 2014). This antiproliferative action is associated with the downregulation of cyclin D1expression in cancer cells (Kumar et al. 2010; Priyadarsini et al. 2010; Gunadharini et al. 2011) and upregulation of the proapoptotic genes and proteins including p53, Bax, Bcl-2-associated death promoter protein (Bad) caspases, phosphatase and tensin homolog gene (pTEN) and c-Jun N-terminal kinase (JNK) (Arumugam et al. 2014). Ethanolic extract at EC_{50} doses causes a significant time-dependent increase in the Bax gene expression.

In murine sarcoma, neem leaf glycoprotein causes alteration in cytokine profile in the tumour microenvironment, i.e. from interleukin (IL)-10 and transforming growth factor (TGF)-β. IL-6-rich type 2 characters were switched to type 1 microenvironment with dominance of interferon (IFN) γ secretion (Barik et al. 2013). $CD8^+$ T cell population gets fairly increased with a higher expression of cytotoxicity-related molecules, perforin and granzyme B along with a low expression of $FasR^+$ cells symbolizing prevention from activation induced cell death.

4.6 Reproductive Health and Fertility

Contraceptive activity of neem extracts in male as well as female animals and human beings is well known. It reduces

the weight of the ovaries and uterus along with increase in the incidence of structural changes of metaphase chromosomes. A phytoconstituent of the extract probably interferes with DNA to yield chromosome strand breakage or produced spindle disturbances, inducing genotoxic effects. In a subchronic dose, the leaf powder causes a decrease in total sperm count and in sperm motility in rats with an increase in the relative percentage of abnormal sperm which could be reversed by simultaneous administration of testosterone, suggesting that the effects are due to an androgen deficiency, thereby affecting the physiological maturation of sperm (Aladakatti et al. 2001). Extracts of bark, flower and seed oil induce reversible infertility in male rats such as decrease in spermatid number. The alcohol extract of leaves reduces the sperm count and increases the frequency of spermatozoa with abnormal head morphology (Awasthy 2001).

The volatile fraction of steam-distilled neem oil is spermicidal. A minimum concentration of 0.25 and 25 mg/ml causes dose-dependent inhibition of spermatozoal motility in rat and human semen, respectively, which remains unaffected by the presence of vaginal or cervical mucus. A dose of 15 mg/kg neem extract delays reproduction in male rats up to 60 days (normal reproduction cycle is 20–23 days). At a dose of 25 mg/kg extract, 50% mortality was seen along with reversibly delayed reproduction (up to 3 months) in the remaining animals. Histological studies of testes indicated aberrations in spermatogenesis and sperm production in some of the seminiferous tubules. In vivo vaginal lubrication of neem oil prior to coitus is 100% effective in preventing pregnancy (Jacobson 1995). In rats, disruption of oestrous cycle leading to partial block in ovulation takes place after treatment with alcoholic extract of neem flower (Gbotolorunet al. 2008).

A highly safe and efficacious intravaginal contraceptive formulation has been developed from neem for rabbits and monkeys. Its minimum effective spermicidal concentration is 25% with complete immobilization of sperm within 20 s (Garg et al. 1994). In pregnant rats, the formulation caused complete resorption of the developing embryos on day 15 of pregnancy. The effects were reversible and animals regained fertility.

4.7 Miscellaneous Uses

Neem trees with rich water supply exude a sap which forms the stem tip. The sap is a coolant tonic and particularly useful in skin diseases, indigestion and general debility. The bark exudes a bright and amber-coloured gum which is a powerful stimulant, demulcent and tonic and is used in catarrhal and other infections. Hot water extract of the bark is an oral tonic and emmenagogue for adult female, while flower and leaf if taken orally work as an antihysteric remedy and externally to treat wound. The dried flowers are helpful orally in diabetes, while hot aqueous is used for piles, skin disease and ulcers. The fruit is a tonic, emollient, purgative and an anthelmintic. The dry fruit is mashed in water to treat skin diseases. Leaves are carminative and assist digestion. The tender leaves are used along with *Piper nigrum* Linn. to remove intestinal helminthiasis. The leaves are also effective in treating snake poisons and insect bites due to anti-clotting phytoconstituents. Hot water extract of the entire plant is an efficacious anthelmintic, an insecticide and purgative.

Neem induces radiosensitization radiotherapy (Veeraraghavan et al. 2011). The aqueous leaf preparation has been shown to prevent the cyclophosphamide-, cisplatin- and 5-fluorouracil-induced haematological complications (Ezz-Din et al. 2011). Sodium nimbidinate further produces diuresis facilitating the drug clearance. The aqueous leaf extract normalized gross appearance and histopathological changes of the liver in paracetamol-treated rats along with a reduction in serum levels of aspartate aminotransferase (AST), alanine aminotransferase (ALT), and γ-glutamyl transpeptidase (Bhanwra et al. 2000). Subchronic administration of leaf extract is more effective than seed oil in controlling blood sugar levels in normal and diabetic rabbits (Khosla et al. 2000b).

Neem oil contains vitamin E and many other essential amino acids which help to restore moisture and elasticity to the skin. Neem can be used against midges, lice, mites and flies, for minor wounds, scar reduction and hair regrowth. On minor wounds, it promotes healthy, new skin development and reduces scar tissue. To make a rinse solution or spray, neem oil can be diluted by adding a small amount of a mild detergent along with water. A dilution of 1:20 is suggested for a fly spray. Neem oil can be rubbed directly onto the problem area, up to twice a day to soften and remove the scabs (without shampooing), to soothe and to kill the bacteria. The aqueous leaf extract of neem has acaricidal proficiency at par to ivermectin (Seddieket al. 2013), but the antinematodal activity varied with the season and composition (protein content) of diet offered better results in rainy season in comparison to dry season (Chagas et al. 2008).

In vitro both the oil and the aqueous extracts from seeds produce concentration-dependent sterilization and disturbed development of larval ticks, *Boophilus microplus*, *Hyalomma excavatum anatolicum* and *Amblyomma variegatum*. At a concentration of 10,000 ppm, azadirachtin and other limonoids disrupt reproduction of *Rhipicephalus microplus* females. At a dose of 1000 mg/kg body wt, neem extract checks parasitaemia levels, prevents weight loss and extends the lifespan of the host at par to suramin, a well-known trypanocidal drug. It has been suggested that neem leaf extract (125 mg/kg body wt) potentiates, synergizes and increases the half-life of diminazene diaceturate (7 mg/kg) and quickly removes *Trypanosoma brucei brucei* and prevents relapse (Omoja et al. 2011). The methanolic extracts of seed are superior prophylactically.

Azadirachtin, present in neem, is a primary as well as secondary antifeedant for Lepidoptera insects in the concentration of 1–50ppm. It also downregulates haemolymph ecdysteroid level in larval insects by blocking the release of prothoracicotropic hormone from brain-corpus cardiacum complex leading to disordered growth like disrupted moulting, growth inhibition and malformation leading to mortality.

5 Neem as Livestock Feed

5.1 Neem as Animal Feed

A major obstacle to ruminant livestock production in most tropical ecosystems is seasonal fluctuation in forage availability and quality due to the diverse rainfall patterns. For cultivated as well as natural pastures, forage biomass yields and quality decline drastically in the dry season. For example, low crude protein content (5–7%) has been reported for forage legumes during the dry season (Peters et al. 1997). Similarly, decline in crude protein and rise in neutral detergent fibre of leguminous forage crops occur with a change in season (Fujihara et al. 2004). Reproductive losses, together with reduced growth during the arid spell, adversely affect their productivity. This may be overcome by supplementation of ruminant diets, especially during the arid period with high crude protein constituents that can sustain production (Adjorlolo et al. 2016).

Exploitation of tree leaves for animal feeding is an antique practice. The crude protein of grasses becomes a major limiting factor in ruminant diet during the arid weather; tree leaves, with high crude protein content, has given some encouraging results in grazing ruminants (Ansah and Nabilla 2011). Leaves of leguminous plants are of particular significance owing to their higher crude protein content as compared to other vegetation (Adjorlolo et al. 2016). However, their utilization as fodder is also affected by their comparative digestibility, palatability and drought tolerance, which determines its forage biomass availability during the patchy season.

5.1.1 Leaves

Neem ranks high amongst fodder trees in India. A mature neem tree produces 3–4 quintals leaves per annum, which are fed to goats routinely and to cattle during famine. Neem leaves are acceptable to sheep (Chandrawathani et al. 2006) and goats (Seresinhe and Marapana 2011). In the Talensi-Nabdam District of Ghana, approximately one-fifth of farmers use neem leaves and fruits as fodder (Ansah and Nagbila 2011). Neem leaves high in crude protein ranging 17.5–18.7% have been reported (Bhowmik et al. 2008) as compared to 10–15% in leaves of nonleguminous fodder trees. They contain minerals and adequate amount of trace minerals except zinc and alleviate copper deficiency in animals that are stallfed on straw and dry fodder. Neem leaves incorporated into ruminant feeds can facilitate the utility of the plant and help alleviate the severe feed inadequacy experienced in the dryer tropics during the dry season. They have low crude fibre content (11.3%) (Bhowmik et al. 2008) along with 38.0% neutral detergent fibre (NDF) and 27.0% acid detergent fibre (ADF) levels (Ramana et al. 2000). These are quite low compared with NDF and ADF ranges of 27.40–55.23 and 18.87–46.30, respectively, for most of the tropical fodder trees (Kumar and Sharma 2003). Low fibre content of neem, coupled with the reported high nitrogen-free extract up to 53.9% (Bhowmik et al. 2008), makes it an important source of readily fermentable carbohydrates in ruminant feed. Goat and camel enjoy chopped neem leaves even as sole feed. A sole diet of neem leaves to goats increases the voluntary intake of feed up to 3.12% of body weight. Cattle are usually fed twigs and leaves mixed with other feeds.

Several anti-nutritional factors such as tannins, phenolic compounds and oxalates have been identified in neem leaves, but their concentrations are similar to that reported for other ligneous fodder species. The lignin content falls within the range of 4.2–11.7 as reported for Leucaena (Garcia et al. 1996). The bitterness in leaves is conferred by the presence of triterpenoids, mainly azadirachtin, but the concentration varies with season and ecotypes (Dhaliwal et al. 2004). However, ruminants, especially goats, can tolerate bitter taste owing to their ability to detoxify secondary plant compounds through allelochemical-type reactions that take place within them.

Neem leaves as feed supplement, to basal diets of crop residues, improve feed utilization and animal performance in ruminants. Replacement of 30% of mustard straw with neem leaves increases both dry matter and crude protein intakes with a concomitant increases in volatile fatty acid production (Raghuvansi et al. 2007), indicating that neem leaves supply critical nutrients needed to augment ruminal microbial growth and fermentation of feed. Neem leaves can replace up to half of soybean meal in ruminant diets with no negative effects on feed intake, dry matter and fibre digestibility as well as body weight gain (Paengkoum 2010). The improvement in performance of ruminants fed with neem leaves is partially attributable to the antiparasitic effects of the bioactive compounds in the leaves on intestinal parasites like *Haemonchus contortus* (Chandrawathani et al. 2006; Tiwary and Pandey 2010). In addition, hormone-mimicking action of neem extracts causes interference with the parasitic life cycle, thereby inhibiting their nutrition intake as well as the hatching of eggs (Kumar and Navaratnam 2013).

5.1.2 Seed

Several plants seeds have been tried as a protein source in animal feed (Gowda and Sastry 2000; Aruwayo et al. 2011; Ogbuewu et al. 2011a). The seeds can be used as seed meal, seed kernel cake or even as fruit cake. Neem seed is readily available in Northeast India and, perhaps, most parts of Asia and northern part of Nigeria, Australia, Africa and Central and South America, the home to the largest number of ruminants in the country. Neem seed cake, with an approximately 0.9 million tons availability in India (Singh 1993), is an excellent source of protein (30–40%) for livestock. It contains all essential and non-essential amino acids including sulphur-containing amino acids but with small amounts of valine and tryptophan. The sulphur content is 1.07–1.36% which is more than other cakes. The nitrogen content varies from 2 to 3%. Its balanced amino acid and mineral profile (Gowda and Sastry 2000) in respect to other plant seeds carry tremendous potential to compensate protein supplement shortages in the livestock industry. The only concern in this regard is its acceptability owing to its pungent smell and bitterness caused by the presence of bitter and toxic triterpenoids, mainly nimbin, nimbidin, azadirachtin and salannin which impart unpleasant taste or smell to meat (Clausen et al. 1985). Removal of these bitter phytoconstituents through solvent extraction, water washing, alkali soaking and urea ammoniation has achieved appreciable success in improving the livestock acceptability (Gowda and Sastry 2000).

The palatability of the neem seed cake can be improved by removing the bioactive principles or by feeding along with barley, molasses and peanut meal, but reduced consumption (from 79 to 39%) of concentrate mixture may result when neem seed cake levels are increased from 59 to 90% (Bhandari and Joshi 1974). Yearling sheep can completely utilize concentrate mixture having 75 parts of neem seed cake and 25parts of maize, but their feed consumption reduces to one-third if neem seed cake is fed alone (Gupta and Bhaid 1980). Buffalo calves accept readily 5–15 parts of neem seed cake when fed along with 7 parts of molasses and 20 parts of peanut meal, but the overall feed consumption reduces to half following the withdrawal of molasses. In addition, the keeping quality is good with a long shelf life.

5.1.3 Neem Oil

Debitterized neem oil is quite useful as animal feed. It is rich in long chain fatty acids and contains azadirachtin, meliantriol and salannin. Deoiled seeds find use as fertilizer in the agriculture sector. The palatability and utilization of such alternative feedstuffs can be further improved by incorporating them in complete diets and processing into pellets (Reddy and Reddy 1999).

5.2 Neem as Poultry Feed

Neem oil is used in poultry rations. The proximate composition of neem leaf meal indicates it as a good source of protein for poultry as well. Principally, unprocessed neem is not suitable for poultry feeding, because of its toxicity and the presence of bitter compounds that impair feed intake (Gowda and Sastry 2000; Uko and Kamalu 2008). Improvement in performance after supplementing neem leaves is also reported for poultry. Specific properties of these active compounds make it potentially interesting in veterinary medicine, e.g. against external parasites. Similarly, neem seeds or extracts could be used at low incorporation rates in feeds as replacement of antibiotics (Landy et al. 2011). The maximum tolerance levels of neem leaf meal as a protein source described in literature are 10% in starter broilers (Obikaonu et al. 2012*)* and 15% in laying birds (Esonu et al. 2006) and rabbits (Ogbuewu et al. 2010a, b, 2011b), as it contains several bioactive compounds (azadirachtin, nimbin, salannin, limonoids and tannin) that may affect nutrient utilization. The bioactive toxic principles may be reduced by sun-drying (Obikaonu et al. 2012*;* Esonu et al. 2006; Ogbuewu et al. 2010a, b, 2011a).

When used raw, neem seeds or oil meal decreases feed intake and broiler performance (Gowda and Sastry 2000). Soaking, cooking, alkaline or acid treatments and extraction with one or several solvents have been investigated (Gowda and Sastry 2000) to improve the overall acceptability. Some acceptable results at relatively low incorporation rates are also observed. Treatment with alkali or urea maintains reasonable performance at 13% incorporation (Nagalakshmi et al. 1996, 1999). Similarly, toasting or autoclaving alleviates the negative effects of neem (Uko and Kamalu 2008). Overall, neem is not recommended in broiler feeding. However, it could be used with caution at an incorporation rates below 5% with rigorous detoxification protocol.

Raw neem oil meal reduces feed intake and laying performance when used at 15 or 20% in layer diets, while at 10% performance remains unaffected (Gowda et al. 1998). Neem should be used with caution in layers, given the possible long-term effects on health. In male or female breeders, neem should be strictly avoided because of its potential effects on reproduction (Gowda and Sastry 2000). In growing quails, incorporation of 5–10% dehulled oil meal (solvent extracted) decreases slightly growth performance while inducing mild pathological effects (Elangovan et al. 2000b). In laying quails, performance was maintained with 5–10% oil meal in diet but with reduced feed efficiency (Elangovan et al. 2000a).

5.3 Neem as Fish Feed

Neem leaves supplemented diet is an immunostimulant for fish (Talpur and Ikhwanuddin 2013) due to hundreds of bioactive compounds, with proven anti-inflammatory, anti-arthritic, antipyretic, hypoglycaemic, antiulcer, antimicrobial and diuretic properties (Girish and Shankara 2008). It produces both cell-mediated and humoral responses during immunostimulation. There is an increased level of phagocytic activity, which is a module of non-specific immune system in fish (MacArthur and Fletcher 1995). The plant extract is antioxidant and forages superoxide anion which scavenges reactive radicals effectively to provide a possible protection against autotoxicity and fatality (Nya and Austin 2009; Kim et al. 2007).

5.4 Nutritional Quality of Neem Seed Cake

Neem seed cake (NSC) is a nonconventional feed ingredient with great potential for livestock feeding (Bawa et al. 2005). Chemical composition of NSC and neem seed meal (NSM) varies considerably depending on the method of processing. It is a rich protein source with 34–38% crude protein (CP) (Bawa et al. 2007) and 33.20% and 32.90% for alkali-treated neem seed cake (ATNSC) and NSC, respectively (Aruwayo 2011). It is balanced in Ca, P but exceptionally high iron content. Neem cake is a rich source of essential and non-essential amino acids including sulphur-containing ones, with little histidine, lysine and tyrosine (Gowda and Sastry 2000). The undecorticated NSC contains 6.5–11.6% digestible CP (Ananthasubramainiam et al. 1979). The raw neem seed meal has highest CP (23.19%), followed by solvent extracted NSC (23.06%), hydraulic press NSC (22.69%) and expeller NSC (22.5%)(Bawa et al. 2007), and the quality is comparable to that of peanut meal (PNM) (Gowda and Sastry 2000). Much higher CP is present in ATNSC (33.76%) and urea-treated neem seed cake (UANSC) (40.91%) (Katiyar et al. 1993). Therefore, ATNSC can be considered as a wholesome substitute for PNM in terms of performance.

Highest crude fibre content (40.50%) is seen in full fat NSM (FFNSM) (Salawu et al. 1994), while the lowest value is reported in NSC with 11.40% (Reddy et al. 1988). The ether extract (EE) is 0.38% in deoiled NSC (Garg 1989) and 27% in FFNSM (Salawu et al. 1994). The nitrogen-free extract was the lowest in FFNSM (Fajinmi et al. 1989) with 14% and highest in NSC (Bedi et al. 1975) with 52.52%. Amongst all, UANSC seems to be the best because of high crude protein of 40.91% and relatively low crude fibre of 11.43%.

Urea ammoniated neem seed meal (UANSM) has proved to be a satisfactory, economical and wholesome substitute for complete replacement of traditional protein supplement, deoiled groundnut cake (DGNC), in rations of growing goats (Anandan et al. 1996) on the basis of nutritive value, biochemical parameters and feeding economics. Dietary deviation did not significantly influence the efficiency of dry matter (DM) (8.7 vs. 9.1 g), protein (1.2 vs. 1.2 g CP) and metabolic energy (22.9 vs. 22.8 kcal ME) utilization per unit gain. The total body weight gain (kg), average daily gain (g), feed conversion efficiency (feed/gain) and feed cost (Rs.) per kg gain in the UANSM group were 5.6 ± 0.59, 31.0 ± 3.25, 9.1 ± 0.57 and 25.6 ± 1.62, respectively, as compared to the corresponding values as 6.0 ± 0.56, 32.8 ± 3.20, 8.7 ± 0.55 and 29.8 ± 1.83, respectively, in the DGNC group. The haematobiochemical profile (haemoglobin, glucose and urea nitrogen) and the activity of various enzymes (transaminases and alkaline phosphatase) showed insignificant variation, but the feed cost per kg gain of the UANSM diet is cheaper than the DGNC diet by 14.2%. The feeding cost per unit weight gain and overall average daily gain were slightly better in males compared to females.

6 Neem as Nutraceutical

The neem leaf accounts for a wide range of pharmacological activities, including antibacterial, anticarcinogenic, antifungal, antihyperglycaemic, anti-inflammatory, antimalarial, antimutagenic, antioxidant, antiulcer, antiviral and immunomodulatory (Subapriya and Nagini 2005), and in addition, chewing fresh leaves acts as a sedative and relaxant. Aqueous extract of neem leaves has noteworthy antiulcer activity and causes reduction in severity of gastric injury and prevents mast cell degranulation and mucus depletion. Neem leaves are quite prosperous in nutritious elements as compared to any other similar vegetation that has been subjected to chemical analysis earlier. Neem leaf chutney was a regular feature of Mahatma Gandhi's everyday diet. A nutraceutical neem tea would indisputably have been Gandhi's favourite drink. Neem can also be blended with green or black tea. The leaf extract has also been reported to be advantageous in the treatment of carbon tetrachloride-induced liver damage (Mujumdar et al. 1998).

In Ayurveda, neem is always mixed with other herbs to augment its efficacy and to turn the taste to a more favourable side. Herbs good for the pitta dosha such as licorice, honey, sugar, lemon juice and/or spices like cardamom can be used to amplify the efficacy or to reduce the side effects. The bitterness can also be counterbalanced with herbs and spices like cinnamon, orange peel, licorice root and fennel seed. Neem is indicated in contemporary Ayurveda for diabetes mellitus, perhaps, by enhancing the insulin receptor sensitivity. Oral administration of leaf extract significantly reduces insulin requirement for non-insulin-dependent diabetes

patients. Nimbidiol present in root and bark of neem tree can inhibit intestinal glucosidases thus helpful in control of diabetes (Mukherjee and Sengupta 2013). Fresh mature leaves, along with the seeds of *Psoralea corylifolia* and *Cicer arietinum*, are effective in leucoderma. Tender leaves, along with black pepper, are effective in intestinal helminthic infections (Kumar et al. 2016).

With a ban on four commonly used feed antibiotic growth promoter (monensin, salinomycin, avilamycin and flavophospholipol) by European Commission, neem leaf meal (NLM) can be harnesses as an ingredient in diet of broilers owing to its therapeutic and dietary importance (Bonsu et al. 2012), but the inclusion level varies with the age and physiological status. Neem has been shown to exert their antioxidant properties by decreasing tumour necrosis factor-α, increasing interferon-γ and modulating antioxidant enzymes such as glutathione S-transferase (GST) and certain hepatic cytochrome P450-dependent monooxygenases (Manikandan et al. 2008; Kusamran et al. 1998; Schumacher et al. 2011; Vasenwala et al. 2012). It induces apoptosis via both the intrinsic and extrinsic pathways and stimulates cell cycle arrest via p53-dependent p21 buildup and downregulation of the cell cycle regulatory proteins cyclin B, cyclin D1, p53 and propagating cell nuclear antigen (Kumar et al. 2010; Priyadarsini et al. 2010).

Neem, in combination with tulsi leaves extract, activates the cell-mediated immune response and, therefore, creates an enhanced response to any future challenges occurred by disease organisms. So, the feeding neem and tulsi leaves to immunosuppressed poultry birds increase their humoral and cell-mediated immune responses. Low dose of neem leaf extract has an inhibitory action on wide spectrum of microorganisms. Infusion (4%) of neem leaves at a concentration of 50 ml/l of fresh drinking water could be effectively used as a potential natural growth promoter and as immune stimulant contributing to better body weight gain, feed conversion ratio, gross return, lower mortality and higher antibody titre against infectious bursal disease (Durrani et al. 2008; Kumar et al. 2016).

6.1 Efficacy as Nutraceutical

Neem leaves can be eaten on a regular basis. Neem is a potent blood purifier and detoxifier in the Ayurveda. Neem leaves can treat symptoms coupled with viral infections like fever, common cold, herpes, influenza and chicken pox. They contain phospholipase A_2inhibitor which can be used as a snake venom inhibitor (Mukherjee et al. 2008).

Poultry birds supplemented with neem and tulsi leaf extract (1–3 ml/kg poultry ration) show a significant beneficial effect on body weight, weekly gain in weight, feed consumption and feed efficiency (Prasannabalaji et al. 2012). These effects may be due to their antimicrobial and antiprotozoal properties (Kale et al. 2003), which help in reduction of the microbial load of birds and resulted in better absorption of the nutrients present in the gut and finely leading to improvement in feed conversion ratio of the rations.

Fusarium is a filamentous fungus widely distributed in soil and produces mycotoxins such as trichothecenes and zearalenone in cereal crops used as animal and poultry feed and can affect human and animal health once they enter the food chain. Zearalenone triggers reproduction disorders including hyperestrogenic syndromes and tumour production, while trichothecenes are sesquiterpenoid epoxides that act as potent inhibitors of eukaryotic protein synthesis. Neem oil extract decreases zearalenone production at a 0.1–0.5% concentration, but maximum inhibition (59.05%) occurs at 0.1% (Geraldo et al. 2011).

Neem flowers contain compounds capable of inducing monofunctional phase II enzyme and repressing monooxygenases, especially those involved in the metabolic activation of chemical xenobiotics. Feeding diets containing 12.5% neem flowers for 2 weeks strongly enhance GST activity by almost 2.7-fold and a marked reduction in the levels of phase I reactions, thereby increasing the overall xenobiotic toxicity threshold (Kusamran et al. 1998).

Neem is being used profitably in aquaculture systems to control fish predators (Dunkel and Ricilards 1998). Martinez (2002) reported that aqueous extract of neem leaves and other neem-based products are effective alternatives for the control of fish parasites and fish fly predators such as dragonfly larvae in fish farms. Although neem extract is considered for low toxicity towards non-target aquatic life, water extracts of the bark of the neem plant caused respiratory problems in *Tilapia zillii* (Omoregie and Okpanachi 1997), while long exposure to low concentrations of the crude extract delayed the growth of this cichlid fish (Omoregie and Okpanachi 1992).

7 Safety

Neem has attracted worldwide distinction due to its vast range of medicinal properties like antibacterial, antiviral, antifungal, antiprotozoal, hepatoprotective and various other properties without showing any adverse effects (Kale et al. 2003). Its widespread conventional use confirms the safety. Over 75% Ayurvedic remedies contain neem, usually in the form of leaf (or extract), sometimes the bark/fruit/flowers, and almost never the oil. The majority of scientific neem studies have been conducted with neem leaf or leaf extracts. Neem leaves taken internally on a regular or daily basis are considered safe unless any physiological stress is indicated. In millennium indigenous use, no reports of negative side

effects from neem leaves have been acknowledged. Although neem has been found adequately safe for use as an insecticide, animal studies suggest that persistent ingestion of neem oil might generate toxic effects. However, comprehensive safety evaluation of the different formulations of neem has also not been accomplished (Kumar et al. 2016). Formal safety testing has been done only for neem oil, it being an important insecticide product. In addition, whole neem extract may produce genotypic damage on prolonged use or at higher doses (Badam et al. 1999; Awasthy 2001). For all these reasons, use of neem is not advocated in young, pregnant or nursing animals or animals with severe liver or kidney disease. In rats, administration of neem oil during the first few days of pregnancy is abortifacient, and the activity reduces with the advancement of gestation. At a dose of 6ml/kg body wt, even mortality may be seen up to 25% (Lal et al. 1987). Administration of oil increased tail flick reaction time and reduced induced writhing (Khosla et al. 2000a). In normal and hyperglycaemic rats, administration of oil causes a lowering of the blood glucose.

At the higher oral dose (100 mg/kg body wt for 20 days), neem leaf extract decreased serum triiodothyronine (T_3) and increased serum thyroxine (T_4) concentrations but produced no such changes at the lower oral dose (40 mg/kg body wt for 20 days). This indicates that high concentrations of neem extract can be inhibitory to thyroid function, particularly in the conversion of T_4 to T_3, the major source of T_3 generation (Panda and Kar 2000). A concomitant increase in hepatic lipid peroxidation and a decrease in glucose-6-phosphatase activity in the higher dose group also indicated the adverse effect of neem extract despite an augmentation in the activities of defensive enzymes, superoxide dismutase (SOD) and catalase. Thus, it appears that the neem extract in higher dose may show symptoms of thyroid function and lipid peroxidation.

8 Toxicity

The toxicological data of different neem-based preparations have been recently reviewed by Kumar et al. (2016). The daily oral administration of petroleum ether extract of neem whole seed (566 mg/kg body wt) and husk (360 mg/kg body wt) for a period of 60 days produced no alteration in haemoglobin, packed cell volume, leukocyte count and mean corpuscular haemoglobin and blood glucose, but AST and ALT were decreased. Serum protein, serum cholesterol, plasma total lipids and GST were increased, while plasma phospholipids and erythrocyte acetylcholinesterase were decreased (Gupta et al. 2001). Gandhi et al. (1988) reported dose- and time-dependent effects on motor activity, respiration and on the orientation within the cage after ingestion of the neem oil by rats and rabbits. The animals had diarrhoea, tremors and convulsions. The median lethal dose (LD_{50}) was 14 ml/kg body wt for rats and, showing similar symptoms, 24 ml/kg body wt for rabbits.

The tail flick reaction time increased while induced writhing reduced in rats after administration of leaf extract. Naloxone pretreatment partially reversed the effects. The effects of the leaf extract were more pronounced than those of the seed oil (Khosla et al. 2000a). The body weight of goats and guinea pigs was decreased upon addition of leaves to their drinking water. Both acute and chronic toxicities were evident through signs of weakness, loss of condition and depression. Decreases in heart, pulse and respiratory rates were observed, and diarrhoea, tremors and ataxia occurred in some animals. Total erythrocyte count, packed cell volume and haemoglobin decreased slightly, whereas the activities of AST, sorbitol dehydrogenase and the concentrations of cholesterol, urea, creatine and potassium increased. The liver and kidney were most affected (Ali 1987). However, treatment of rats with leaf extract resulted in decreases in total testosterone, total bilirubin and potassium in serum. There was increase in packed cell volume, mean corpuscular haemoglobin concentration, red blood cell, white blood cell and lymphocyte counts, but no cytotoxic effects were observed (Parshad et al. 1994).

The effects of aqueous extracts are ambiguous. Many of the studies do not report dose-effect relationships. Mostly positive effects are mentioned, even after administration of high doses, but toxic effects are observed at concentrations of 200 mg/kg body wt resulting in death of treated goats (Ali 1987). Effects on reproduction are only indirectly mentioned as a decrease in testosterone (Parshad et al. 1994). The most relevant no observed adverse effect level (NOAEL) is 30 mg/kg body wt/day at which there is no modulation of the immune responses (Ray et al. 1996).

The nonaqueous extracts are more repellent than the powders. Acute toxicity of acetone leaf extract caused a decrease in spontaneous activity, respiratory rate and body and limb tone in mice along with decreased responses to the environment, piloerection and a dose-dependent hypothermia (Singh et al. 1987). Two fractions of an acetone leaf extract showed central nervous system depressant activity in mice as evidenced by a reduction in locomotor activity. Both fractions caused reductions in blood pressure and heart rate in rats without showing diuretic activity. Acute toxicity of petroleum ether extract of leaves was evident on the motor activity, on orientation, a reduced reaction to pain and convulsions in mice with an oral LD_{50} of 22g/kg body wt (Koley et al. 1994).

Ethanol leaf extract induced dose-dependent mitotic chromosome abnormalities in bone marrow cells of mice. Gross type abnormalities appeared even at the lowest dose and remained unchanged in frequency at higher doses. The extract caused increase in the incidence of structural changes of metaphase chromosomes. A constituent of the extract

probably interferes with DNA to yield chromosome strand breakage or produced spindle disturbances, inducing genotoxic effects (Awasthy et al. 1999). Ethanol leaf extract in itself had no effect on peripheral utilization of glucose (Chattopadhyay 1996). At doses higher than 50 mg/kg body wt, the extract decreased the blood sugar level. The LD_{50} value in mice was 4.6 g/kg body wt (Chattopadhyay 1999). Ethanol leaf extract did not alter the hepatic glycogen content in normal rats, but in glucose fed rats or in combination with insulin, it reduced the hepatic glycogen content (Chattopadhyay et al. 1993). Examination in rodents previously treated with seed extracts revealed complete resorption of embryos on day 15 of pregnancy (Mukherjee et al. 1996). Hexane seed extract, in contrast to ethanol and water extracts, completely abrogated pregnancy. Restoration of fertility was observed in subsequent cycles, and no further toxic effects were found (Mukherjee et al. 1999).

9 Concluding Remarks and Future Directions

Neem is currently one of the world's most scientifically exploited trees. The domestic, commercial and industrial prospects of neem are unlimited and exciting. It can help the mankind to solve comprehensive health and ecological concerns. It has been widely used in Chinese, Ayurvedic and Unani medicines worldwide especially in Indian subcontinent in the treatment and prevention of various diseases through its role in the scavenging of free radical production and preclusion of initiation of disease pathogenesis. It is drought tolerant with rich forage even during the dry season. Today's reducing growth in animal feed resources is posing a serious concern for livestock health and productivity. In this scenario, neem leaves may be fed as a supplement during the dry season to increase feed intake as well as diet quality. Research on neem leaves as fodder should therefore be given adequate attention to find ways to utilize this abundant resource especially in the low rainfall areas of the subregion where dry season feeding remains a major challenge. Its kernel cake is also quite palatable to adult cattle and buffaloes even without washing, promising future in the feeding of buffalo calves, lambs and rams. For enhanced utilization, decortication of neem seeds can be done effectively at industrial level with maximized oil recovery. The processed proteinaceous kernel by-product carries the potential for a cheaper unconventional protein supplement. However, further research is needed for scientific validation of the multiple effects as well as to explore any other distinct therapeutic potential of the extracts to optimize their utilization.

Nutraceutical Potential of Ginger

Krishnamoorthy Srinivasan, Pratik Adhya, and Shyam Sunder Sharma

Abstract

In recent years, most people throughout the world have become health conscious, and recently countries have even been ranked on the basis of how health conscious their citizens are. According to the 2018 best countries ranking, Sweden is perceived to be the most health conscious country in the world. People throughout the world would like to live healthy lifestyle and do not want any disease that could should create distress in their life. In order to improve their health, people have started consuming food supplements or nutraceuticals which have many health benefits for the prevention of disease. Dietary fibers, probiotics, prebiotics, polyunsaturated fatty acids (PUFA), antioxidants, vitamins, polyphenols and spices are all being used as nutraceuticals. Ginger is one such spice used all over the world for culinary purposes and also for its health benefits in both animals and humans. The rich phytochemical composition of ginger makes it effective against a wide spectrum of chronic disorders. Phytoconstituents in ginger provide health benefits not only by modulating various intrinsic antioxidant systems of the body but also by acting as free radical scavengers themselves. The nutraceuticals properties of ginger include antioxidant, anti-inflammatory, gastroprotective, immunomodulatory, neuroprotective, cardioprotective to chemopreventive, and antidiabetic. In fact, the beneficial effects of ginger have propelled its study in various clinical trials in different countries to test its efficacy in various disease conditions. Even different formulations with a ginger extract or its constituents, like gingerol, are commercially available for improving the health of both humans and animals. In this chapter, we have reviewed evidence of the beneficial effects of ginger as a dietary supplement, together with scientific studies in animals and humans proving its benefits in the improvement of health.

Keywords

Veterinary nutraceuticals · Ginger

1 Introduction

Ginger (*Zingiber officinale*, Family: Zingiberaceae) is a tropical, flowering plant, and its roots or rhizome have been widely used as a spice worldwide for culinary purposes especially for its characteristic aroma and pungency (Kubra and Rao 2012). The generic name, *Zingiber*, is derived from the Greek word "zingiberis" which itself has come from the Sanskrit name of the spice "*singabera*". The Sanskrit name, singabera, means "shaped like a horn" because of its root's resemblance to a deer's antler (Sharma 2017). Specifically, ginger is widely regarded as a plant of potent medicinal value in many ancient systems of medicine including Chinese medicine, Tibb-Unani herbal medicine, and Ayurvedic medicine. In fact, ginger is depicted as *Mahaoushadha* (great medicine) in Indian traditional medicine because of its wide medical benefits. Traditional medicinal systems have used the rhizome of ginger in its fresh or dried form for the treatment of various disease conditions like nausea, vomiting, loss of appetite, stomach cramps, heartburn, flatulence, indigestion, common cold, influenza, cough, catarrh, nervous diseases, gingivitis, toothache, asthma, stroke, constipation, diabetes, arthritis, rheumatism, migraines, headaches, cardiac palpitations, hypertension, and impotence (Ali et al. 2008; Kubra and Rao 2012). It may also aid in preventing numerous ailments like coronary artery disease, ulcers, cancer, and various inflammatory disorders. The lifestyle of human beings has changed tremendously over the last few decades because of industrialization and change in work culture which has led to a culture of fast-food eating. These meals

R. C. Gupta et al. (eds.), *Nutraceuticals in Veterinary Medicine*, https://doi.org/10.1007/978-3-030-04624-8_4

are instant and more tasty, but they have little nutritional value. This has led to increase in the incidence of various chronic and lifestyle diseases like diabetes, obesity, cancer, cardiovascular, and neurodegenerative diseases and immune dysfunction. Hence, there has been an increasing global interest for health-promoting food products, so-called nutraceuticals, by consumers all over the world. Nutraceutical is the new hybrid term between nutrient and pharmaceutical as coined by Dr. Stephen L. DeFelice in 1989 (Prabu et al. 2012). Numerous in vitro, in vivo experimental and clinical validation studies have substantiated the various pharmacological effects of ginger and its safety (Semwal et al. 2015; Srinivasan 2017). Certain bioactive molecules and active principles have also been identified as being responsible for its activity. Apart from its therapeutic indications, ginger and its phytochemical constituents can be used for multiple health-promoting benefits encompassing prevention and treatment of diseases in humans as well as in animals (Srinivasan 2017). This book chapter describes the evidence of the health-promoting benefits of dietary ginger on a pharmacological basis and its potential to be labeled a nutraceutical in the near future.

2 Phytochemical Composition of Ginger

The occurrence, cultivation, harvest, morphological characteristics, and chemical constituents of ginger have recently been described (Sharma 2017). The chemical constituents of ginger rhizomes are numerous, and the amount of such constituents depends on the place of origin and the condition of rhizomes (fresh or dry) (Ali et al. 2008; Kubra and Rao 2012). Broadly, the chemical constituents in ginger can be classified into four categories as listed in Table 1. It is reported that the rhizome contains 3–6% fatty oil, 9% protein, 60–70% carbohydrates, 3–8% crude fiber, about 8% ash, 9–12% water, and 2–3% volatile oil. The odor of ginger is mainly due to its volatile oil. To date, over 70 components of the oil have been reported and characterized, and these can be classified into two groups: monoterpenoids [β-phellandrene, (+)-camphene, cineole, geraniol, curcumene, citral, terpineol, borneol] and sesquiterpenoids [α-zingiberene (30–70%), β-sesquiphellandrene (15–20%), β-bisabolene (10–15%), (E-E)-α-farnesene, arcurcumene, zingiberol]. Among which zingiberol is principally responsible for the distinct aroma of the ginger rhizome (Ali et al. 2008; Baliga et al. 2011).

Table 1 Phytochemical constituents of ginger

Category	Components
Monoterpenoids	Geraniol, curcumene, β-phellandrene, (+)-camphene, 1,8-cineole, citral, terpineol, borneol, linalool, neral
Sesquiterpenoids	Zerumbone, α-zingiberene, β-sesquiphellandrene, β-bisabolene, (E, E)-α-farnesene, arcurcumene, zingiberol
Nonvolatile pungent components	Gingerols, shogaols, paradols, zingerone, dehydrozingerone
Miscellaneous	Zingibain

Ginger also has nonvolatile pungent components, including gingerols, shogaols, paradols, zingerone, and dehydrozingerone, which have potent biological activities as shown in Fig. 1.

Of these components, gingerols (1-(30-methoxy-40-hydroxyphenyl)-5-hydroxyalkan-3-ones) are the most important phytoconstituents and are responsible for its spicy flavor and various pharmacological properties. Among the gingerols, 6-gingerol ([5]-hydroxy-1-(4-hydroxy-3-methoxy phenyl) decan-3-one) is the most abundant (Baliga et al. 2012; Kubra and Rao 2012). Other nonvolatile more pungent components present in lower concentrations in ginger are the shogaols (phenylalkanones) which have wide pharmacological utility. Shogaols come from dehydration of gingerols, and their concentration increases during drying and storage (Baliga et al. 2012; Haniadka et al. 2013). Gingerols are thermally labile because of the presence of a β-hydroxy keto group and readily undergo dehydration to form the corresponding shogaols (Semwal et al. 2015). These shogaols can be further converted to paradols by hydrogenation. Other compounds, such as gingediols, gingediacetates, gingerdione, and gingerenones, are also reported to be present in the pungent fraction of ginger in varied concentrations. Some other constituents reported to be present in the ginger rhizome in minor quantities include zingibain (potent proteolytic enzyme), capsaicin, gingediol, galanolactone, gingesulfonic acid, galactosylglycerols, gingerglycolipids, diarylheptanoids, phytosterols, vitamins, and minerals (Baliga et al. 2011; Haniadka et al. 2013). Nutraceutical compounds which claim to have medicinal value include gingerols, shogaol, gingerdiols, eugenol, paradols, and zingerone. Of these, gingerols are thought to be the most pharmacologically active components (Mekuriya and Mekibib 2018).

3 Pharmacological Profile of Ginger

3.1 Potential Benefits in Gastrointestinal Disorders

Ginger has been widely used since ancient times to ameliorate certain gastrointestinal symptoms such as dyspepsia and gastrointestinal hemorrhage; it is mainly used in indigestion as it adsorbs and neutralizes certain toxins in the stomach and improves the production and secretion of bile from the liver and gall bladder. Bile aids in the digestion of fats which in turn helps to lower cholesterol levels. Ginger has been used

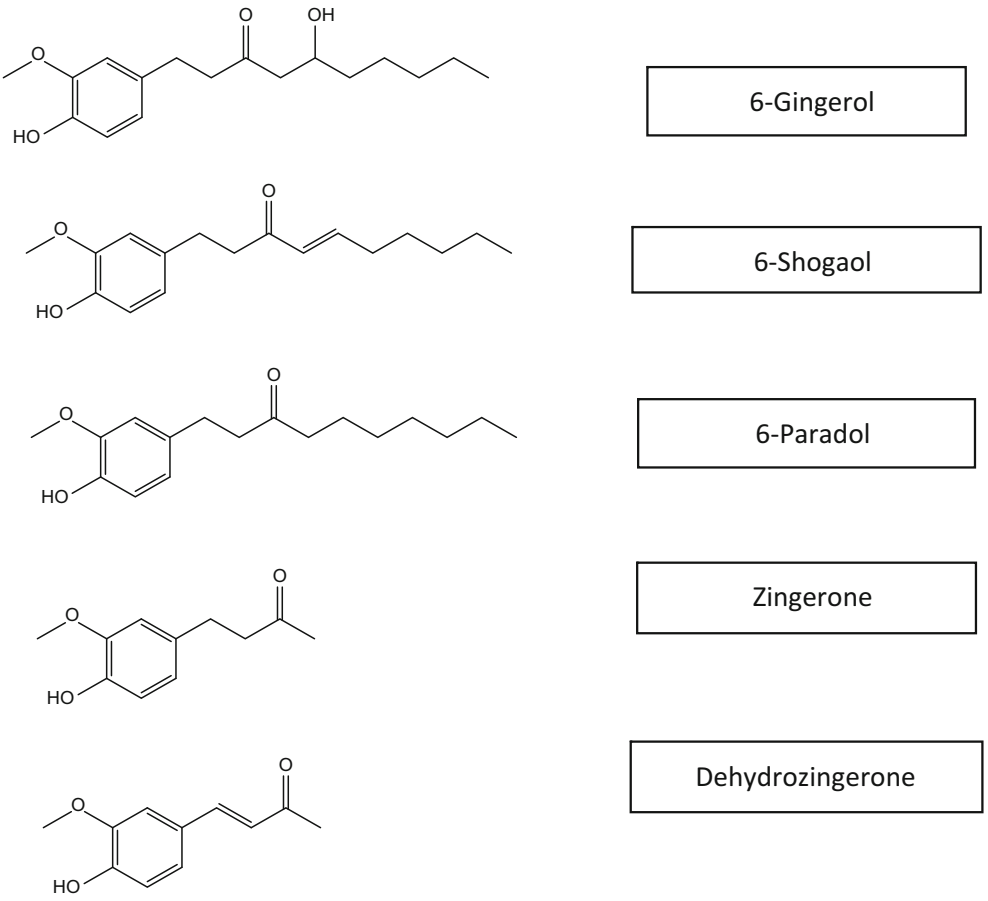

Fig 1 Phytochemical constituents of ginger with pharmacological properties

as carminative to enhance digestion and reduce gastrointestinal gas and flatulence (Qin and Xu 2008; Sharma 2017). Gastric complications like constipation, dyspepsia, belching, bloating, gastritis, epigastric discomfort, gastric ulcer, indigestion, nausea, and vomiting have been effectively mitigated with ginger extract in various preclinical and clinical studies (Haniadka et al. 2013; Keng-Liang et al. 2008). Ginger extract, [6]-gingerol, and zingerone have been shown to inhibit ACh-induced contractions of rat intestine and hypermotility-induced diarrhea, supporting its clinical application of ginger in gastrointestinal motility disorders (Chatturong et al. 2018; Iwami et al. 2011). Mechanistically, the effects of zingerone as a prokinetic agent have recently been attributed to inhibition of pacemaker potentials of interstitial cells of Cajal (ICCs) (responsible for slow waves in the gastrointestinal (GI) tract) via nitric oxide/cyclic guanosine monophosphate (NO/cGMP)-dependent adenosine triphosphate (ATP)-sensitive K^+ channels through mitogen-activated protein kinase (MAPK)-dependent pathways in vitro (Kim et al. 2018).

Ginger is also widely reported to possess powerful antiemetic properties in hyperemesis gravidarum, motion sickness, cancer chemotherapy, postoperative nausea, and vomiting and pregnancy-associated vomiting (Ali et al. 2008). Researchers also reported the beneficial effect of ginger extract in cisplatin (a chemotherapeutic agent)-induced emesis and delayed gastric emptying (Sharma et al. 1997). Notably, it was determined that the acetone alcoholic extract of ginger is effective rather than the aqueous extract (Sharma and Gupta 1998; Sharma et al. 1997). However, in clinical studies conducted in cancer patients receiving chemotherapeutic agents (cisplatin, doxorubicin), ginger powder extract showed no significant efficacy, which may be due to the use of a water extract in such patients (Arslan and Ozdemir 2015; Li et al. 2018a; Lua et al. 2015). Ginger extract and its essence is reported to be effective in pregnant women undergoing cesarean section (Zeraati et al. 2016), with postoperative nausea and vomiting associated with nephrectomies (Hosseini and Adib-Hajbaghery 2015) and with antiretroviral-induced nausea and vomiting (Dabaghzadeh et al. 2014) signifying a different mechanism for vomiting stimuli in different settings. Some clinical trials over efficacy of ginger on GI disorders have been and are being undertaken in different countries as shown in Table 2. The extracts of ginger have been reported to increase digestion efficiency by enhancing the activity of pancreatic lipases and amylases. Ginger also improves the overall health of the gastrointestinal tract via its gastroprotective actions and by

Table 2 Clinical trials on ginger (2011–2018)

Condition/ disease	Title of study	Sponsor	Study design	Outcome	References
Gastrointestinal disorders					
Nausea and vomiting	Efficacy of ginger on intraoperative and postoperative nausea and vomiting in elective cesarean section patients (2013)	New York Methodist Hospital, Brooklyn, NY 11215, USA	239 women were divided into 2 groups: dry powder ginger ($n = 116$) and placebo group ($n = 123$). Each were given 1 g capsule before induction of spinal anesthesia	Dry ginger powder group reported reduced number of episodes of intraoperative nausea but not postoperative nausea as compared to placebo group	Kalava et al. (2013) ClinicalTrials.gov Identifier: NCT01733212)
	The effect of ginger on the incidence of postoperative nausea and vomiting (2017)	The University of The West Indies, Kingston, Kng 7, Jamaica	110 female patients were divided into 2 groups : placebo and 0.5 g ginger powder, given 2 h before gynecological surgery	Results not published	ClinicalTrials.gov Identifier: NCT03626441
	Effect of ginger on nausea and vomiting during acute gastroenteritis in children (2016)	University of Naples Federico II, Italy, 80131	150 children, below the age of 10, were administered ginger extract in acute gastroenteritis	Results not published	ClinicalTrials.gov Identifier: NCT02701491
	Efficacy of ginger as an adjunctive prophylaxis for chemotherapy-induced nausea and vomiting (2015)	Mahidol University, Thailand	34 participants were divided into 2 groups: placebo capsule and ginger capsule (500 mg) taken orally twice a day during the first 5 days of chemotherapy cycle	Results not published	ClinicalTrials.gov Identifier: NCT02390648
	A study to assess the antiemetic efficacy of ginger in children and adolescents receiving chemotherapy (2009–2011)	All India Institute of Medical Sciences, New Delhi, India	32 children receiving highly emetogenic chemotherapeutic agents were administered ginger root powder capsule of different dose at 1 h, 3 h, and 8 h after chemotherapy. Their effect was compared to placebo capsule	The ginger root powder was reported to be effective in reducing the severity of acute and delayed chemotherapeutic-agent-induced nausea and vomiting, but it did not eliminate completely	Pillai et al. (2011) ClinicalTrials.gov Identifier: NCT00940368
	Efficacy study of ginger (*Zingiber officinale*) extract "Ginpax" to manage nausea in cancer patients receiving high emetogenic treatments and standard anti-emetogenic therapy (2013)	Istituto Nazionale dei Tumori, Milan, Italy	250 participants were randomized to receive 2 soft gel capsules of ginger extract per day during two cycles of cisplatin within 28 days	Results not published	ClinicalTrials.gov Identifier: NCT01887314
Abdominal distention	Efficacy of ginger in the prevention of abdominal distention in post-cesarean section patient (2016)	Chulalongkorn University, Thailand	178 participants were divided into 2 groups: placebo capsule and ginger capsule (500 mg) taken orally, 2 capsules after each of three meals for 3 days	Results not published	ClinicalTrials.gov Identifier: NCT02809027
Non-alcoholic fatty liver disease	The effects of ginger on nonalcoholic fatty liver disease (2014)	Shiraz University of Medical Sciences, Iran	90 adult patients were divided into 2 groups, viz., placebo and ginger group (500 mg capsule) and were administered this capsule for 3 months	Results not published	ClinicalTrials.gov Identifier: NCT02289235
	Effect of ginger supplement on nonalcoholic fatty liver (2015)	National Nutrition and Food Technology Institute, Iran	60 adult patients were randomly divided into 2 groups: placebo capsule and ginger capsule (500 mg) three times daily for 3 weeks	Results not published	ClinicalTrials.gov Identifier: NCT02535195

CNS Disorders					
Migraine	Double-blind placebo-controlled randomized clinical trial of ginger (*Zingiber officinale* Rosc.) addition in migraine acute treatment (2018)	Federal University of Minas Gerais, Brazil	60 patients were given 400 mg ginger extract capsule, in addition to an intravenous drug (100 mg of ketoprofen), and result was compared to placebo-controlled group	The study showed that the addition of ginger extract to intravenous ketoprofen may contribute to the treatment of migraine attack	Martins et al. (2018) ClinicalTrials.gov Identifier: NCT02568644

Condition/ disease	Title of study	Sponsor	Study design	Outcome	References
CVS disorders					
Antiplatelet activity	The effect of drinking ginger daily on platelet function in the Saudi population (2013)	King Abdullah International Medical Research Center, Saudi Arabia	40 individuals were randomly divided into 2 groups and administered 4 g of ginger powder once or twice for 5 days	Results not published	ClinicalTrials.gov Identifier: NCT02882776
Cardiovascular disease markers	Acute effects of ginger extract consumption on risk markers of cardiovascular disease (2014)	University of Reading, UK	22 male volunteers were divided into 2 groups: placebo drink group and ginger drink group (300 mL) with breakfast on 2 visits separated by 2 weeks	Results not published	ClinicalTrials.gov Identifier: NCT02735486

Condition/ disease	Title of study (year)	Sponsor	Study design	Outcome	References
Inflammatory diseases					
Inflammation	The effects of ginger supplementation on inflammation in exercising individuals (2017)	Loma Linda, California, USA	12 individuals were divided in 2 groups: exercising group and non-exercising group. Both group received 3 g of ginger extract three times weekly, for 8 weeks	Results not published	ClinicalTrials.gov Identifier: NCT03219463

Disease	Title of study (year)	Location	Study design	Outcome of study	References
Cancer					
Colorectal cancer	Pilot clinical study of the effects of ginger root extract on eicosanoids in colonic mucosa of subjects at increased risk for colorectal cancer (2015)	University of Michigan Medical School, USA	21 patients who are at increased risk of colorectal cancer were administered 2 g of encapsulated ginger root extract daily for 28 days, and effect was compared with placebo	Ginger is reported to have chemopreventive effects and is both tolerable and safe	Zick et al. (2015) ClinicalTrials.gov Identifier: NCT01344538

enhancing the growth of beneficial bacteria in the intestines (Butt and Sultan 2011; Haniadka et al. 2013). Ginger exhibits anti-ulcerogenic properties in the animal models of gastric ulcers induced by ethanol, nonsteroidal anti-inflammatory drugs (NSAIDs), and hydrochloric acid (Liju et al. 2015; Salah Khalil 2015). In addition, it also inhibits the growth of *Helicobacter pylori*, a major ulcerogenic, and the associated inflammatory lesions, thereby protecting the gut (Gaus et al. 2009; Mahady et al. 2003). In addition, ginger volatile oil and gingerols were shown to be effective in different animal models of colitis or ulcerative colitis (Fig. 2) (Rashidian et al. 2014; Zhang et al. 2017).

Ginger not only improves functionality of the gastrointestinal tract, but it also gives a major boost to liver health as well

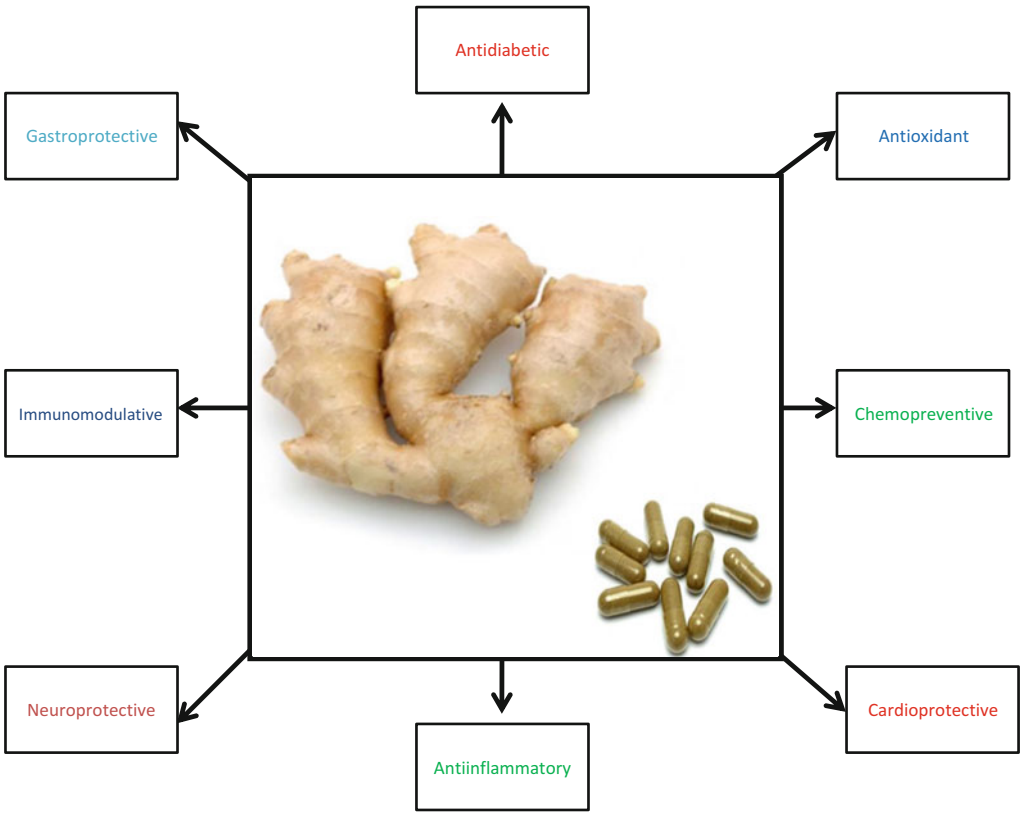

Fig. 2 Various pharmacological effects of ginger

(Abdulaziz Bardi et al. 2013; El-Sharaky et al. 2009; Emrani et al. 2016). It is reported to possess nutraceutical value in preventing hepatic fibrosis (Motawi et al. 2011), nonalcoholic fatty liver disease (Lai et al. 2016; Sahebkar 2011), and alcohol induced liver cirrhosis (Zhuang et al. 2015). It has also been reported to possess an anti-hepatotoxic property in various chemical induced-hepatotoxicity preclinical models (Abdulaziz Bardi et al. 2013; Baiomy and Mansour 2016; Sabina et al. 2011).

3.2 Potential Benefits as Antioxidant

Redox reactions are constantly going on inside each and every living tissue to provide energy. Consequently, such reactions are liberating free radicals like reactive oxygen species and (ROS) reactive nitrogen species (RNS). It is reported that increased generation of such free radicals gives rise to a condition known as oxidative stress, which is cytotoxic and mutagenic to the cells. In normal circumstances antioxidant enzymes of the cells like superoxide dismutase (SOD), glutathione peroxidase (GPx), and catalase (CAT) help in maintaining normal oxidant homeostasis. During increased free radical generation and oxidative stress, however, such enzyme activity is reduced, requiring antioxidant supplementation through the diet (Ali et al. 2008; Chandel and Schieber 2014).

Various studies have reported the strong antioxidant properties of ginger extract and its phytochemical constituents (Ahmad et al. 2015; Mashhadi et al. 2013). Ginger exerts antioxidant effects against all oxidative stress induced by the different agents, ranging from chemical to biological agents and to radiation (Jeena et al. 2016; Saberi et al. 2017). For example, ginger has been reported to alleviate oxidative stress and organ damage induced by chemical agents like carbon tetrachloride (Ali et al. 2008), malathion, lindane (Butt and Sultan 2011), lambda cyhalothrin (Al-Amoudi 2018), hydrogen peroxide (Peng et al. 2015), chlorpyrifos (Abolaji et al. 2017), mercuric chloride (Al Hroob et al. 2018; Joshi et al. 2017), sodium arsenite (Chakraborty et al. 2012), sulfite (Afkhami Fathabad et al. 2018), lead acetate (Mohamed et al. 2016), carbendazim (Salihu et al. 2017), and aflatoxin B_1 (Vipin et al. 2017). It also has antioxidant properties against drug-induced toxicities like acetaminophen (Abdel-Azeem et al. 2013; Sabina et al. 2011), vancomycin (Kandemir et al. 2018), piroxicam (Badawi 2018), gentamicin (Hegazy et al. 2016), and cisplatin (Ali et al. 2008; Alibakhshi et al. 2018) in

various organs of experimental animals. Hyperglycemia (Al Hroob et al. 2018)-, ethanol (Akbari et al. 2017; Heshmati et al. 2018; Shirpoor et al. 2017, 2018)-, lipopolysaccharide (Li et al. 2012a)-, lipids (Si et al. 2018)-, interleukin-1β (Hosseinzadeh et al. 2017)-, and ischemia (Jittiwat and Wattanathorn, 2012; Li et al. 2017)-associated oxidative damages are also ameliorated by ginger extracts. Therefore ginger has antioxidant properties in several organs from the brain to the testes in experimental animals, signifying its nutraceutical value in combating oxidative stress induced by several agents. In fact, the oxidative stress-reducing property of ginger is comparable to that of chemical antioxidants and free radical scavengers like butylated hydroxyl toluene (BHT) and butylated hydroxyl anisole (BHA) (Kubra and Rao 2012). The antioxidant property of ginger extract and its phytoconstituents is attributed to the enhancement of antioxidant enzymes (SOD, catalase, GPx), free radical scavenging action, and reduction of lipid peroxidation (Butt and Sultan 2011; Kubra and Rao 2012; Zhuang et al. 2015). The other molecular mechanisms underlying the antioxidant properties of ginger include the activation of nuclear factor erythroid 2-related factor 2 (Nrf-2) and heme oxygenase-1 (HO-1) pathway (Peng et al. 2015; Zhu et al. 2016).

3.3 Potential Benefits as Anti-inflammatory and Immunomodulatory

Inflammatory disorders and related diseases like rheumatic conditions have been treated with ginger or ginger-derived formulations for ages worldwide because of its broad anti-inflammatory actions. Experimentally, ginger and its constituents exhibited anti-inflammatory effects in various models of acute and chronic inflammation (Banji et al. 2014; Mashhadi et al. 2013; Song et al. 2016; Xie et al. 2014). For instance, zerumbone is reported to inhibit endotoxin-induced lung inflammation in mice (Ho et al. 2017), while 6-shogaol reduces neuroinflammation associated with cognitive impairment (Moon et al. 2014) and Parkinson's disease by inhibiting the plasma level of tumor necrosis factor-α (TNF-α) (Park et al. 2013) (Luettig et al. 2016). Ginger suppresses prostaglandin synthesis through the inhibition of cyclooxygenase (COX)-1 and COX-2. It also suppresses leukotriene biosynthesis by inhibiting 5-lipoxygenase (5-LOX). This pharmacological property distinguishes ginger as a dual inhibitor of COX and 5-LOX from nonsteroidal anti-inflammatory drugs which may have a better therapeutic profile with fewer side effects. Ginger extracts have been shown to inhibit the induction of several genes encoding for cytokines, chemokines, and the inducible COX-2 involved in the inflammatory response (Grzanna et al. 2005). Immunomodulation refers to a process and a course of action in which an immune response is altered to a desired level. Herbs exhibit an array of diverse biological activity such as anti-stress, adaptogenic, antiaging, and immunomodulatory activity (Mahima et al. 2012). Ginger has an excellent immunomodulatory property in many experimental settings induced by infectious agents, allergies, drugs, inflammation, and cancer (Carrasco et al. 2009). It was indicated that the alcohol extract of *Z. officinale* also improved the immunological functions in the tumorous mice of immune inadequacy. In contrast, it was also reported that ginger inhibited lymphocyte proliferation and suppressed interleukins (IL-2 and IL-10) production in human lymphocytes (Wilasrusmee et al. 2002b). Moreover, ginger may inhibit both mitogen- and alloantigen-stimulated lymphocyte proliferations in mice (Wilasrusmee et al. 2002a). The effects of the volatile oil of ginger on the immune response were also evaluated in vitro and in vivo in mice, and the underlying mechanism of its anti-inflammatory activity was explored. Ginger extract reduces the expression of IL-17 and IL-23 and also modulates the expression of chemokines CCL20 and CCL22 and their receptors (CCR6 and CCR4) in the central nervous system (CNS) of mice with experimental autoimmune encephalomyelitis (Jafarzadeh et al. 2015, 2017b). [6]-Gingerol and [6]-shogaol, active ingredients of the traditional Japanese medicine hangeshashinto, relieve oral ulcerative mucositis-induced pain via action on Na^+ channels (Hitomi et al. 2017).

3.4 Potential Benefits in Diabetes

Diabetes mellitus (DM) is one of the major chronic metabolic disorders, and there are currently more than 420 million people living with diabetes (IDF 2017). Presently available allopathic medicines for diabetes are limited and further associated with adverse effects. The antidiabetic activity of ginger powder has been recently promoted, with the recommendation that it be included as one of the dietary supplements for diabetic patients (Bi et al. 2017; Medagama and Bandara 2014). It may be helpful in reducing the dosages of antidiabetic medications and associated side effects via its antidiabetic and antioxidant effects. Data from in vitro, in vivo, and clinical trials have demonstrated the antihyperglycemic effect of ginger. Preventive and protective properties of ginger in diabetes mellitus, diabetic complications, and associated lipid and other metabolic disorders were also reported (Li et al. 2012c). Multiple mechanisms have been proposed underlying the antidiabetic effects of ginger which are due to its insulinotropic, insulin-sensitizing actions including enhancing glucose uptake via cell surface glucose transporter 4 (GLUT4), and restoration of altered carbohydrate and lipid metabolism. It also includes the inhibition of several transcriptional pathways at the molecular level, lipid peroxidation, carbohydrate-metabolizing enzymes, increase in adenosine monophosphate kinase

(AMPK) phosphorylation and 3-hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase, and the activation of antioxidant enzyme capacity and low-density lipoprotein receptors (Akash et al. 2015; Li et al. 2012b; Rani et al. 2012).

Aqueous ginger extract administered orally (daily) in three different doses (100, 300, 500 mg/kg body weight) for a period of 30 days improved carbohydrate metabolism in STZ-induced type 1 diabetic rats through its effects on the glycolytic enzyme activities (Abdulrazaq et al. 2012). Ginger exhibited inhibitory actions on gut α-glucosidase and α-amylase that help in ameliorating hyperglycemia (Rani et al. 2011, 2012). Administration of ginger extracts significantly improved hyperglycemia and hyperlipidemia, as well as the impaired kidney function and hemogram in alloxan-induced type 1 diabetic rabbits (Elkirdasy et al. 2015). Polyphenol extracts of ginger rhizome have exhibited amelioration of pancreatic and renal derangements in STZ-induced diabetic rats (Kazeem et al. 2015). Since oxidative stress is involved in the pathophysiology of diabetes, the effect of ginger on oxidative stress markers was investigated on STZ diabetic rats. Ginger significantly increased antioxidant effects as compared to glibenclamide (Ahmadi et al. 2013). In another study, the combination of gelam honey and ginger significantly ameliorated oxidative stress and metabolic profile in STZ type 1 diabetic rats (Sani et al. 2014).

[6]-Gingerol, a major constituent of ginger, has been reported to ameliorate hyperglycemia in Lepr (db/db) type 2 diabetic mice. Endocrine signaling involved in insulin secretion is perturbed in these diabetic mice. Four-week treatment of [6]-gingerol led to significant increase in glucose-stimulated insulin secretion and improved glucose tolerance involving glucagon-like peptide (GLP)-1-mediated insulin secretion pathway (Samad et al. 2017). 6-Paradol and [6]-gingerol supplementation significantly reduced plasma glucose, alanine aminotransferase, aspartate aminotransferase, advanced glycation end products (AGEs), and insulin levels in mice on high-fat diet (Sampath et al. 2017; Wei et al. 2017).

3.5 Potential Benefits in Diabetic Complications

Ginger has been reported to offer health benefits in certain micro- and macro-vascular diabetic complications related to the kidney, liver, peripheral nerve, and cardiovascular systems (Li et al. 2012c). Recent investigations have revealed that ginger alleviates hyperglycemia-induced oxidative stress, inflammation, and apoptosis and protects rats against STZ-induced diabetic nephropathy (Al Hroob et al. 2018). Ginger extract and zingerone were shown to exert nephroprotective effects by ameliorating various biochemical parameters and pathological injuries of the kidneys in different animal models of diabetic nephropathy (Ramudu et al. 2011; Rehman et al. 2018; Cui et al. 2018). Chronic treatment with 50 mg daily dose of ginger extract intragastrically for 6 weeks significantly reduced heart structural abnormalities in diabetic rats, and this suggested that these effects might be associated with improvements in serum apo, leptin, cathepsin G, and homocysteine levels (Ilkhanizadeh et al. 2016). Ginger hydroalcoholic extract and zerumbone, a phytochemical of subtropical ginger, alleviated diabetic retinopathy through reducing arginase I activity, blocking the AGEs/RAGE/NF-κB (nuclear factor- κB) pathway in the retina, and also through anti-inflammatory and antiangiogenic actions (Dongare et al. 2016; Lamuchi-Deli et al. 2017; Tzeng et al. 2016). Antiglycating potential of ginger and delay of diabetic cataract in rats have also been reported (Saraswat et al. 2010). Zingerone ameliorates enhanced vascular contraction in diabetic aorta which may be mediated by its vasodilator effect through NO- and guanylate cyclase stimulation (Ghareib et al. 2016). This is of significant importance for therapeutic interventions in complementary treatment/management of diabetes-related complications. Treatment with ginger ingredients like zingerone, geraniol, and 6-gingerol in doses of 20, 200, and 75 mg/kg, respectively, alleviate diabetic prostatic complications through suppressing oxidative stress and tissue fibrosis (Eid et al. 2017). The combination of ginger and cinnamon has significant beneficial effects on sperm viability and motility, serum total testosterone, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and serum antioxidant levels in diabetic animals (Khaki et al. 2014). Treatment with ginger extracts caused alleviation of the testicular lesions in diabetic mice suggesting that the intake of ginger roots as a drink may be useful for diabetic patients who suffer from sexual impotency (Shalaby and Hamowieh 2010).

3.6 Clinical Studies

Some clinical studies have reported and substantiated the health benefits of ginger in diabetic patients. A randomized, double-blind, placebo-controlled trial demonstrated that daily consumption of three 1 gram capsules of ginger powder for 8 weeks is useful for patients with type 2 diabetes due to fasting blood sugar (FBS) and HbA1c reduction and improvement of insulin resistance indices such as QUICKI index (Mozaffari-Khosravi et al. 2014). Ginger improved insulin sensitivity and some fractions of the lipid profile and reduced CRP and PGE_2 in type 2 diabetic patients (Arablou et al. 2014). Ginger exhibited ameliorative effects on glucose control, insulin sensitivity, and lipid profile and proved to be a promising adjuvant therapy for T2DM and metabolic syndrome (Makhdoomi Arzati et al. 2017; Zhu et al. 2018). Three-month supplementation of ginger improved glycemic indices, total antioxidant capacity, malondialdehyde (MDA), C-reactive protein (CRP), and serum paraoxonase (PON-1)

activity in patients with T2DM (Shidfar et al. 2015). Daily administration of 1000 mg ginger reduces serum fasting glucose, which is a risk factor for hyperinsulinemia, dyslipidemia, peritoneal membrane fibrosis, and cardiovascular disease in patients on peritoneal dialysis (Imani et al. 2015). Patients with type 2 diabetes are prone to cardiovascular disease (CVD) due to inflammation process and oxidative stress. ADMA (asymmetric dimethylarginine) and ICAM-1 (intercellular adhesion molecule-1) play an important role in CVD pathogenesis. Ginger as an antioxidant and anti-inflammatory agent has been shown to have an effect on these biomarkers (Zarezadeh et al. 2018). Ginger supplementation improved insulin sensitivity and some fractions of lipid profile in T2DM patients. Therefore, it may be considered as a useful remedy to reduce the secondary complications of T2DM (Mahluji et al. 2013). Functional foods like ginger can be effective in the prevention of metabolic syndrome and subsequently the onset of cardiovascular diseases and T2DM as seen from human interventional trials (van den Driessche et al. 2018). The study also revealed the effect of ginger herbal spray on reducing xerostomia in patients with T2DM (Mardani et al. 2017).

3.6.1 Potential Benefits in Obesity

Obesity is a complex, multifactorial, and largely preventable disease, affecting over a third of the world's population today. If secular trends continue, by 2030, an estimated 38% of the world's adult population will be overweight and another 20% will be obese (Hruby and Hu 2016). Obesity, which describes the condition of an abnormal accumulation of body fat mass, is directly related to an increased risk of several chronic diseases, including glucose intolerance, cardiovascular disease hypertension, hyperlipidemia, hemostatic variables, and increased insulin resistance. Ginger provides anti-obesity effects by accelerating weight loss and metabolism. The beneficial effects of ginger on obesity and metabolic syndrome have been recently reviewed (Ebrahimzadeh Attari et al. 2018; Wang et al. 2017). Most preclinical studies have supported the weight-lowering effect of ginger extract or powder in obese animal models. Ginger may modulate obesity through various mechanisms including increasing thermogenesis, increasing lipolysis, suppression of lipogenesis, inhibition of intestinal fat absorption, and by controlling appetite (Ebrahimzadeh Attari et al. 2018). Rats fed a high-fat diet supplemented with 5% ginger powder exhibited a significantly greater ability to reduce body weight without inhibiting pancreatic lipase level, or affecting bilirubin concentration, with positive effect on increasing peroxisomal catalase level and HDL cholesterol as compared to orlistat supplementation (200 mg/kg diet) (Mahmoud and Elnour 2013). de Las Heras et al. (2017) recently investigated the molecular factors involved in the anti-obesity and hypolipidemic effects of a hydroethanolic ginger extract in HFD-fed rats. The hypolipidemic and insulin-sensitizing effects of ginger extract were associated with higher liver expression of transcription factors peroxisome proliferator-activated receptor (PPAR)α, PPARγ, GLUT-2, and collagen at molecular levels and the enhancement of plasma adiponectin levels (de Las Heras et al. 2017). The ameliorative potential of gingerol via modulating inflammatory factors and enzymes involved in cholesterol metabolism and targeting of the AMPK-NF-κB pathway through elevation in sirutin (SIRT)-6 and reduction in resistin levels has been demonstrated in HFD-induced obese rats (Brahma Naidu et al. 2016; Hashem et al. 2017). The plasma cholesterol-lowering activity of gingerol- and shogaol-enriched extract was also demonstrated in a hamster model which was mediated by enhancing the excretion of fecal cholesterol and bile acids via upregulation of hepatic CYP7A1 and downregulation of mRNA of intestinal Niemann-Pick C1-like 1 protein (NPC1L1), acyl CoA:cholesterol acyltransferase 2 (ACAT2), and microsomal triacylglycerol transport protein (MTP) (Lei et al. 2014). Gingerenone A, yet another polyphenol present in ginger, has been shown to mitigate obesity and adipose tissue inflammation in HFD-fed mice (Suk et al. 2017).

3.6.2 Potential Benefits in Cancer

Despite tremendous advancement in the last two decades in cancer research, cancer remains the second leading cause of death globally after heart ailments and has been responsible for an estimated 9.6 million deaths so far in 2018. Globally, about one in six deaths is due to cancer. Epidemiological studies report that Asians have a lower incidence of cancer than Western countries, which may be due to consumption of a diet rich in plants among the Asian population (Prasad and Tyagi 2015). A wide variety of phenolic compounds derived from spices possess potent antioxidant, anti-inflammatory, antimutagenic, and anticarcinogenic activities. The protective and therapeutic potential of ginger extract and various other constituents of ginger against different types of cancer have been reviewed and are shown in Table 3 (de Lima et al. 2018; Poltronieri et al. 2014; Prasad and Tyagi 2015; Shukla and Singh 2007).

The anticancer properties of ginger and its constituents have been reported to be associated with antioxidant, anti-inflammatory, and antimutagenic properties, as well as other biological activities as shown in Table 3. [6]-Gingerol is the major pungent principle of ginger, with numerous pharmacological properties. The proposed mode of molecular actions of gingerol include but is not limited to: (1) decrease in iNOS and TNF-α expression, (2) NF-kB nuclear translocation, (3) the release of cytochrome c, (4) caspases activation, and (5) increase in apoptotic protease-activating factor-1 (Apaf-1) as a mechanism of apoptosis induction. Further, 6-gingerol also stimulates apoptosis through upregulation of NSAID-activated gene-1 (NAG-1) and by modulating β-catenin, protein kinase C (PKCζ), and GSK-3β pathways (Lee et al.

Table 3 Anticancer property of ginger

Cancer type	Models	Compounds	Outcome	References
Colorectal cancer	HT-29 cell line	6-Shogaol	6-Shogaol chemo-preventive potential for colorectal cancer	Li and Chiang (2017)

	BxPC-3 and MIA PaCa-2 cell lines	Zerumbone	It is reported to exhibit anticancer activity by inhibiting angiogenesis	Shamoto et al. (2014)
	PANC-1 and BxPC-3 cell lines	6-Shogaol	It acts as an important adjuvant by inhibiting the growth of human	Zhou et al. (2014)

(continued)

Table 3 (continued)

Cancer type	Models	Compounds	Outcome	References
			pancreatic tumors and chemo-sensitize them to gemcitabine treatment	
Cervical cancer	HeLa, CaSki, and SiHa cells	6-Gingerol	It is shown to inhibit proliferation of the HPV positive cervical cancer cells through proteasome activation	Rastogi et al. (2015)
	HeLa cell line	Essential oils of ginger	Along with mitomycin C has reported enhanced cytotoxicity and apoptosis in cervical cancer	Al-Otaibi et al. (2018)
Oral cancer	Oral squamous cell carcinoma (OSCC) cell lines	Zerumbone	Effective in OSCC by inhibiting cell proliferation, migration, and invasion	Zainal et al. (2018)
	Golden Syrian hamsters age 8–10 weeks. Cancer has been induced by paint with 7, 12-dimethylbenz[a] anthracene (0.5%) in liquid paraffin using a No. 4 sable brush, three times per week for 16 weeks on right buccal pouches of hamsters	6-Shogaol	Ameliorated DMBA-induced inflammation and cell proliferation-mediated tumorigenesis	Annamalai et al. (2016)
Skin cancer	B16F10 mouse melanoma cells	6-Shogaol	Inhibited melanogenesis in melanoma cells by ERK activation	Yao et al. (2013)

2008). Recently, the new gingerol derivatives were evaluated for their cytotoxic activities against human cancer cells (Li et al. 2018b). Taken together, the chemopreventive potentials of [6]-gingerol present a promising future alternative to therapeutic agents that are expensive, toxic, and possibly even carcinogenic (Oyagbemi et al. 2010). Recently, [6]-gingerol aspirinate as a novel chemopreventive prodrug of aspirin for colon cancer was investigated in vitro and in vivo that showed enhanced anticancer properties along with gastroprotective effects (Zhu et al. 2017). The use of nanotechnology for drug delivery has shown great promise for improving cancer treatment. However, potential toxicity, hazardous environmental effects, issues with large-scale production, and potential excessive costs are challenges that confront their further clinical applications. Edible ginger-derived nanoparticles have been reported as a novel therapeutic approach for the prevention and treatment of inflammatory bowel disease and colitis-associated cancer. Further, a nanovector made from ginger-derived lipids as a delivery platform for the therapeutic agent doxorubicin to treat colon cancer has also been reported (Zhang et al. 2016a, b).

3.7 Potential Benefits in CNS Disorders

Ginger extract is also reported to be effective in various CNS disorders like age-related neurodegenerative disorders (Alzheimer's disease, Parkinson's disease) (Choi et al. 2018), multiple sclerosis (Sapkota et al. 2018), experimental autoimmune encephalomyelitis (Jafarzadeh et al. 2015, 2017a), cognitive dysfunction (Wattanthorn and Sutalangka 2017), neuroinflammation (Ho et al. 2013), and migraine (Choi et al. 2018; Maghbooli Mehdi et al. 2013), as well as diabetes-induced CNS changes (Shanmugam et al. 2011). It has been experimentally demonstrated that ginger and its constituents, such as 6-gingerol, 6-shogaol, 6-paradol, zingerone, and dehydrozingerone, are effective for ameliorating the neurological symptoms and pathological conditions of age-related neurodegenerative disorders through modulating cell death or cell survival signaling molecules (Choi et al. 2018). [6]-shogaol has significant protective effects in various neuronal and astrocyte cell culture models via induction of heat shock protein 70 (HSP70), histone deacetylase (HDAC) inhibition (Shim et al. 2011) and upregulation of neurotropic factors (Kim and Kwon 2013) in vitro. Apart from its anti-inflammatory and antioxidant actions, 6-shogaol is also shown to have anti-amyloidogenic activity. This activity of 6-shagaol ameliorates Alzheimer's disease via cysteinyl leukotriene 1 receptor (CysLT1R)-mediated inhibition of cathepsin B and activation of sortilin-related receptor 1, resulting in enhanced neuronal cell survival through the inhibition of Aβ production (Na et al. 2016a, 2017).

6-shogaol has been shown to attenuate brain damage in ischemic stroke after middle cerebral artery occlusion in mice (Na et al. 2016b). Delayed administration of zingerone mitigates the behavioral and histological alteration via repression of oxidative stress and intrinsic programmed cell death in focal transient ischemic rats (Vaibhav et al. 2013). Ginger extract and its contituents have displayed neuroprotective properties and improved cognitive functions in different preclinical models of cognitive impairment (Lim et al. 2014;

Moon et al. 2014). Recently, ginger fermented with *Schizosaccharomyces pombe* alleviates memory impairment via protection of the hippocampal neuronal cells in amyloid β_{1-42} plaque injected mice (Huh et al. 2018). Ginger extract also has an anti-addictive property against morphine in preclinical settings. In migraine, the efficacy profile of ginger extract is comparable to that of the standard prescribed drug sumatriptan, although it had less side effects that sumatriptan in 100 Iranian patients. However, the chemical constituent responsible for its anti-neuroinflammatory property is still debatable. Some researchers attribute it to 6-shogaol (Sapkota et al. 2018; Ha et al. 2012), but others attribute it to 10-gingerol (Ho et al. 2013). Thus, ginger extract has the potential to be used for various CNS disorders; however, much research still needs to be undertaken before it can be used.

3.8 Potential Benefits in Cardiovascular Disorders

The beneficial effect of ginger as a nutraceutical is also reported in cardiovascular complications. Cardiovascular disease is reported to be the leading cause of death in the world (Aimin Shi et al. 2016). Ginger extract is reported to halt and treat such events together with that of lifestyle and dietary modifications. The aqueous extract of ginger has an antihypertensive effect (Akinyemi et al. 2014; Liu et al. 2013a). Ginger also has antiplatelet (Lee et al. 2017; Nicoll and Henein 2009), antithrombotic (Nicoll and Henein 2009), and lipid-lowering properties in dyslipidemic patients (El-Seweidy et al. 2015; Khosravani et al. 2016; Pourmasoumi et al. 2018). Ginger confers significant protection from stroke and heart attack due to its ability to help prevent blood clotting. It has also been reported to possess a positive inotropic effect (Nicoll and Henein 2009) and therefore may be very effective in mitigating congestive heart failure in preclinical studies.

Ginger extract's beneficial role in the heart, combined with that of its potent anti-inflammatory and antioxidant properties, make it a very useful nutraceuticals in alleviating cardiovascular complications (Nicoll and Henein 2009). [6]-shogaol exerts its antiproliferative effect of vascular smooth muscle cells through accumulation of cells in the G0/G1 cell-cycle phase associated with activation of the Nrf2/HO-1 pathway which helps in alleviating the pathogenesis of certain cardiovascular disease (Liu et al. 2015). In fact, recent clinical studies conducted in Iran have shown that dietary ginger supplementation has been able to lower the plasma level of triglycerides and low-density lipoprotein cholesterol (LDL-C), thereby reducing the risk of atherosclerosis (Pourmasoumi et al. 2018). Indeed, such reports are well aligned to previous preclinical findings in various animal models (El-Seweidy et al. 2015; Elseweidy et al. 2015; Khosravani et al. 2016). Moreover, ginger extract also provided protection from myocardial damage induced by isoproterenol in rats (Amran et al. 2015).

The cardioprotective effect of ginger extract in cardiovascular complications is reported to be attributed to different phytochemical constituents. For example, its antiplatelet activity is reported to be due to zingerone (Lee et al. 2017), while its blood pressure-lowering effect is attributed to 6-gingerols and 6-shogaols (Akinyemi et al. 2014; Liu et al. 2013a). In fact, 6-gingerol is also depicted to possess potent (angiotensin) AT_1 receptor blocking activity in in vitro cell lines (Liu et al. 2013a). Furthermore, the lipid-lowering activity of ginger extract is considered to be due to 10-dehydrogingerdione (El-Seweidy et al. 2015). A cross-sectional study revealed that daily ginger consumption has a potential preventive property against some chronic diseases, especially hypertension and coronary heart diseases, as well as an ability to reduce the probability of illness (Wang et al. 2017). Recent systematic review and meta-analysis suggests that ginger has a favorable effect on triacylglycerol and LDL-C. This review also revealed that a low dose of ginger ($\leq$2 g/day) had a greater lowering impact on triacylglycerol and total cholesterol (Pourmasoumi et al. 2018). Thus, ginger supplementation has beneficial effects in almost all facets of cardiovascular complications.

4 Veterinary Use of Ginger

Ginger has been used in veterinary medicine for thousands of years for various GI disorders of animals. It has been used in treatment of constipation, food poisoning, diarrhea, eye diseases, hematuria, to improve stamina, indigestion, tympany, dysentery, stomachache, and skin diseases (Tiwari and Pande 2010). Some clinical investigations have experimentally validated its use.

Cattle Ginger products are used in veterinary medicine for the treatment of digestive problems in cattle. The beneficial effect of ginger is likely due to an elevated synthesis of bile acids in the liver and their excretion in bile resulting in an increase in digestion and absorption of lipids. It also helps to increase the absorption of essential nutrients and to increase stability of feed and beneficially influence the gastrointestinal ecosystem through inhibition of pathogenic microorganisms growth (Mekuriya and Mekibib 2018). In the last 10 years, researchers in the field of animal science have used alternative natural materials such as medical herbs in feeding dairy cattle to substitute or minimize the use of chemical compounds like antibiotics. These chemical compounds may cause unfavorable side effects and be hazardous to animals and humans (Al-dain and Jarjeis 2015). Apart from

the prokinetic action of ginger demonstrated in laboratory animals and humans, the effect of a hydroalcoholic extract of ginger was also evaluated on contraction and motility of the reticulum and rumen of ruminants. The results of an in vitro study indicated that hydroalcoholic extract of ginger contained spasmogenic and spasmolytic constituents where an in vivo study presented evidence that the extract may have a stimulant effect on reticulorumen motility in a 40 mg/kg concentration (Mamaghani et al. 2013). Recently, the ameliorative effect of ginger powder was demonstrated against experimentally induced arsenic toxicity in calves (Biswas et al. 2017). Ginger provided in vivo anthelmintic activity in sheep, thus justifying the age-old traditional use of this plant in helminth infestation (Iqbal et al. 2006).

Equine The effects of ginger extract were studied on the physiological response to exercise as well as markers of muscle damage and mRNA expression for the inflammatory cytokines TNF-α, interferon(IFN)-γ, and IL-6 after an exhaustive bout of exercise in horses. Ginger extract was shown to reduce cardiovascular recovery time in horses completing a short, strenuous bout of exercise. Ginger extract's positive effect on recovery time may make it a useful tool for horses competing in endurance, jumping or racing events. However, further analysis of the compounds present in ginger extract is needed to determine whether those compounds would be picked up by drug tests often done at competition (Liburt et al. 2009). The anti-inflammatory effect of a single dose of ginger has also been demonstrated in the horse post-exercise (Williams and Lamprecht 2008). In current veterinary practice, many professionals and horse owners prefer herbal preparations, including ginger, to treat ulcer cases as compared to allopathic medicine.

Dog The use of nutraceuticals is gaining interest in veterinary medicine for pets. Nearly 30% of pet owners have used or considered the use of novel ingredients like nutraceuticals and herbs/botanicals in their animals (Boothe 2014). Like in humans, the use of ginger (e.g., gingersnap cookies, ginger ale) appears to have some benefit against motion sickness in the dog (Mowrey and Clayson 1982; Plumb 2015).

Poultry Nutritionists have found herbs to be one of the alternatives following the European Union ban on the use of antibiotic feed additives as growth promoters. Powdered rhizome of ginger is one such potential herb with a wide range of medicinal effects. In broilers and layers, this plant has been used in different forms, doses, and durations. Feeding of ginger promoted growth performance and weight gain in broilers and egg-laying characteristics in hens and also enhanced gut function and anti-oxidation in poultry. There were improvements in semen quality, sperm fatty acids, and reproductive performance in aged Cobb 500 breeder roosters fed diets containing dried ginger rhizomes (Akhlaghi et al. 2014). Dietary supplementation of ginger powder exhibited improved laying performance, improved serum and egg yolk antioxidant status, and lowered egg cholesterol in a dose-dependent manner. The optimum supplementation rate of ginger powder in the diet of laying hens is 10–15 g/kg of diet (Akbarian et al. 2011; Zhao et al. 2011). Dietary supplementation with either ginger or probiotics showed a significant influence on birds' immune response, probably because ginger has a strong antioxidant activity and the probiotics stimulate the production of natural antibodies (Qorbanpour et al. 2018).

Fish In order to avoid emergence of antibiotic-resistant bacteria and the generation of toxicants following the extensive use of antibiotics in aquaculture, the use of natural alternative feed additives like ginger has gained attention for disease control strategies. The application of ginger in aquaculture is advocated as an innovative approach to enhance the health of fish and to prevent diseases. A dose of 0.50 g/kg feed significantly reduced mortality associated with enhancement of growth rate, feed conversion, and protein efficiency (Mekuriya and Mekibib 2018). It provides protection against invading microorganisms, including *E. coli* and *Staphylococcus aureus* (a common cause of skin infections), and fungi, including *Candida albicans*. Ginger is a strong antioxidant substance and may either mitigate or prevent generation of free radicals that alleviate putrefaction/rancidity of fish and increase its consumability and marketability.

5 Safety Profile of Ginger

Recently, there has been increased usage of medicinal plants for the prevention and treatment of various diseases. Though their efficacy is proven in preclinical studies, a thorough scientific profile emphasizing the risk and benefit ratio is needed (Talalay and Talalay 2001). Currently, there is a growing interest among people to take ginger not only as a spice but also as a dietary supplement for preventing chronic diseases (Ali et al. 2008). Although ginger is considered to be safe with an LD_{50} of 10.25 g/kg and 11.75 g/kg of its methanolic and aqueous extract, respectively, in mice administered orally (Li et al. 2012c), still some countries do not recommend its use for the prevention of nausea and vomiting associated with pregnancy. A study conducted in France has reported that ginger root is safe and efficacious at a dose of 1 g/day for 4 days and has no risk to either fetus or mother (Stanisiere et al. 2018). In fact, the recommended safe value of ginger metabolites like 6-gingerol and 6-shogaol in

Table 4 Some of the available commercial products of ginger

Product name	Manufacturer	Nutraceutical value
Focalgin B	Method Pharmaceuticals, LLC, USA	Alleviates nausea and vomiting
B-Nexa	Upsher-Smith Laboratories, USA	Nausea and vomiting
Ginger Root	Gaia Herbs, India	Circulatory tonic and warming agent
Ginger Supreme	Gaia Herbs, India	Aids in digestion, supports heart health, and alleviates nausea
Macao Boost-Cacao-Ginger	Gaia Herbs, India	Aids in digestion
Jarrow Formulas Ginger	Jarrow Formulas, USA	Improves gastrointestinal health and antioxidant property
Now Ginger Essential Oils	Now Foods, USA	Nausea and vomiting
Sunthi(Ginger)	The Himalaya Drug Company, India	Anti-nausea in humans
Dabur Honey-Ginger	Dabur India Ltd.	Cough and cold in humans
Turmeric-Curcumin and Ginger with Bioperine	Vimerson Health, USA	Improves skin, brain, digestion, and immune health
Sea-Band Anti-Nausea Ginger Gum	Sea-Band, USA	Relief of nausea
Daily digestion (Ginger and Mint)	Animal Essentials, USA	Improves digestion in dogs and cats

healthy humans is up to 2000 mg (Zick et al. 2008), and its LD_{50} values are 250 and 687 mg/kg, respectively (Li et al. 2012c). However, high dose of ginger extract can cause various gastrointestinal disturbances, central nervous system depression, cardiac arrhythmias, and bleeding due to its potent antiplatelet property (Gunathilake and Rupasinghe 2015). Furthermore, there is also the risk of herb-drug interactions in clinical settings (Agbabiaka et al. 2017). Thus, a detailed scientific study verifying ginger's mechanism of action and safety is needed before it can be safely taken to prevent or protect against pathologic conditions (Bode and Dong 2011).

6 Concluding Remarks and Future Directions

Ginger powder, ginger root extract, and standardized ginger extract (5–7% gingerols) available in various formulations (tablet, capsule, syrup) and strengths (30, 280, 500, and 1000 mg or more) is available as a dietary supplement on the market for improving various disease conditions (Table 4). A considerable number of the aforementioned scientific studies suggest its nutraceutical value. Apart from gastrointestinal disorders, ginger is shown to have health benefits in cancer, diabetes, coronary heart disease, obesity, osteoporosis, and neurodegenerative diseases. The beneficial pharmacological effects of ginger in these disease conditions may be attributed to activation of antioxidant defenses, signal transduction pathways, cell survival-associated gene expression, cell proliferation and differentiation, and preservation of mitochondrial integrity. It appears that these properties play a pivotal role in the protection and providing health benefits. The majority of preclinical studies in disease models indicate the beneficial role of ginger. Several clinical studies have also been carried out on healthy volunteers and in patients using ginger and its formulations. Although several clinical studies have shown beneficial effects, some have shown mixed results, and results of some clinical studies have yet to be published. To enhance the health benefit of ginger, there is a need for further investigation of the beneficial effect of ginger with other nutraceuticals. More focused scientific efforts are required to explore the true nutraceutical value of ginger.

Berberine

Ajay Srivastava, Anita Sinha, Rajiv Lall, and Ramesh C. Gupta

Abstract

Berberine (BBR) is an isoquinoline alkaloid that can be obtained from many plants of genus *Berberis*, *Hydrastis*, *Coptis*, and *Argemone*. Common plants that are sources for BBR include *B. vulgaris* (barberry), *B. aristata* (tree turmeric), *B. aquifolium* (Oregon grape), *B. thunbergii*, *C. chinensis* (*Coptis* or Chinese goldthread), *C. trifolia* (American goldthread), *C. japonica*, *H. canadensis* (goldenseal), *Argemone mexicana* (prickly poppy), and *Thalictrum lucidum*. Following the oral administration, BBR is unstable in the GI tract and poorly bioavailable. It has wide pharmacological and therapeutic applications because of its multiple mechanisms and target effects. The therapeutic use of BBR has been described in obesity, type 2 diabetes, hyperlipidemia, hypertension, congestive heart failure, neurodegenerative diseases, hepatic diseases, chronic trachoma, and cancer. This chapter describes pharmacokinetics, pharmacological and therapeutic applications, and safety and toxicity assessment of BBR and its major metabolites.

Keywords

Berberine · Dihydroberberine · Thalifendine · Jatrorrhizine · Type 2 diabetes · Hypertension · Cognitive disorder syndrome · Obesity · Chronic trachoma · Bacterial diarrhea

1 Introduction

The use of berberine (BBR)-containing plants dates back 3000 years in the Ayurvedic and Chinese medicinal systems. BBR is an isoquinoline alkaloid (2,3-methylenedioxy-9,10-di-methoxyprotoberberine) naturally found in the roots, rhizomes, and stem barks of plants including *Berberis vulgaris* (barberry), *B. aristata* (tree turmeric), *B. aquifolium* (Oregon grape), *Hydrastis canadensis* (goldenseal), *Coptis chinensis* (Chinese goldthread), *C. trifolia* (American goldthread), *C. japonica*, *Argemone mexicana* (prickly poppy), *Thalictrum lucidum*, and others. It has a chemical formula of $C_{20}H_{18}NO_4^+$ with a molecular weight of 336.361. The chemical structure of BBR is shown in Fig. 1.

BBR is used singly or in combination with other supplements/drugs in various ailments, including cognitive impairment, type 2 diabetes, metabolic syndrome, cardiac arrhythmia, congestive heart failure, hyperlipidemia, bacterial diarrhea, obesity, chronic trachoma, and cancer. Since BBR exerts antimicrobial activity, it is considered to be antibiotic. Preclinical studies have well established its potent antimicrobial, antiprotozoal, antifungal, antioxidant, anti-inflammatory, antitumor/anticancer, immunomodulatory, neuroprotective, hepatoprotective, nephroprotective, carminative, uterotonic, and antipyretic properties. Recent in vitro studies suggest the possibility for berberine to be used in osteoarthritis (Liu et al. 2015). BBR exerts its therapeutic effects via multiple pharmacological mechanisms by targeting various receptors, transmitters, enzymes, and other significant biomolecules. Doses for therapeutic efficacy and safety of BBR can vary depending on the disease and animal species. This chapter describes various aspects of BBR including pharmacokinetics, pharmacology, therapeutics, and toxicity and safety assessment.

2 Pharmacokinetics and Pharmacodynamics

The oral bioavailability of BBR is low (<1%) due to its poor aqueous solubility, first-pass elimination, interaction with P-glycoprotein, and dissolution (Pan et al. 2002; Chen et al. 2011; Fratter and De Servi 2014; Imenshahidi and Hosseinzadeh 2015; Liu et al. 2015). Kheir et al. (2010) noted a significant difference in bioavailability between the different routes of administration (oral, intravenous, and intraperitoneal). Following oral administration, BBR is usually converted in the gut to dihydroberberine (dhBBR), which is five times more absorbable (Feng et al. 2015). BBR and its 14 metabolites are shown in Fig. 2.

With a single oral dose of BBR (200 mg/kg) in rats, Tan et al. (2013) observed that BBR was quickly distributed in the liver, kidneys, muscle, lungs, brain, heart, pancreas, and fat in descending order of amount. The pharmacokinetic profile indicated that BBR's level in most of the studied tissues was higher than in plasma at 4 h post-administration. Major metabolites of BBR are thalifendine, berberrubine, jatrorrhizine, and demethyleneberberine. In rat plasma, these metabolites can be present as free and glucuronide conjugates (Zuo et al. 2006). Following oral administration of BBR, the highest concentrations of BBR and its metabolites are found in the liver, the site for cholesterol, triglycerides and glucose production and metabolism and pharmacological effects.

In a rat noncompartmental model, unbound BBR is transported to the bile through active transport, and it is metabolized by a cytochrome P450 enzyme system in the liver, with phase I demethylation and phase II glucuronidation (Tsai and Tsai 2003). BBR has four main metabolites identified in rats (berberrubine, thalifendine, demethyleneberberine, and jatrorrhizine), all of which have glucuronide conjugates. Following an oral dose of BBR chloride (0.9 g/day for 3 days) in healthy adults, three sulfate metabolites (jatrorrhizine-3-sulfate, thalifendine-10-sulfate, and demethyleneberberine-2-sulfate) were identified in the urine (Qiu et al. 2008). These authors also identified six additional metabolites (jatrorrhizine-3-*O*-*β*-D-glucuronide, thalifendine-10-*O*-*β*-D-glucuronide, berberrubine-9-*O*-*β*-D-glucuronide, 3,10-demethylpalmatine-10-*O*-sulfate, columbamin-2-*O*-*β*-D-glucuronide, and demethyleneberberine-2,3-di-*O*-*β*-D-glucuronide) following BBR administration in rats (100 mg/kg, p.o.) and humans (300 mg, p.o.). Oral administration of BBR at 200 mg/kg dose in rats resulted in excretion of BBR and its metabolites in the bile, urine, and feces with a total recovery rate of 22.83% BBR (19.07% of prototype and 3.76% of its metabolites) within 48 h (reviewed in Kumar et al. 2015). The maximum amount of BBR (84%) and its metabolites were excreted in the feces. Approximately 83% of BBR was excreted in the bile, and 78% of urinary excretion was thalifendine and berberrubine (Ma et al. 2013).

Pharmacokinetic studies have been conducted with BBR in dogs following oral or intravenous administration (Shen et al. 1993; Feng et al. 2018). Feng et al. (2018a) studied the pharmacokinetics of BBR and its active metabolites in Beagles after single (50 mg/kg) or multiple doses (50 mg/kg/day) for 7 days. These investigators measured dhBBR, butyrate, and BBR, as well as its phase I and phase II metabolites. Results showed that dhBBR was not detected in dog plasma but was excreted in small amounts in the feces on days 3 and 7. Eleven metabolites were detected in plasma and feces after BBR administration, of which eight metabolites were phase I and three metabolites were phase II. The pharmacokinetic profile indicated that the concentration of BBR in the plasma was low, with a C_{max} of 36.88 ± 23.45 ng/mL. The relative content of glucuronic acid conjugates was higher than those of other metabolites in the plasma. In dog feces, BBR was detected with high concentrations on day 3 (2625.04 ± 1726.94 μg/g) and day 7 (2793.43 ± 488.10 μg/g). In rat, hamsters, and dogs, the gut microbiota has been shown to regulate pharmacokinetics of BBR and its metabolites (Zuo et al. 2006; Gu et al. 2015; Feng et al. 2018a).

Intestinal bacterial flora plays a role in enterohepatic circulation of BBR and its conjugated metabolites, while a very small amount of unchanged BBR is eliminated in the urine. Zuo et al. (2006) emphasized that rat intestinal flora may not exert significant metabolic activity against BBR and its metabolites, but it may play a significant role in the enterohepatic circulation of metabolites. The liver and intestinal bacteria participate in the metabolism and disposition of BBR in vivo.

In an in vitro study, Fratter and De Servi (2014) described a novel oral delivery system containing a chitosan-*N*-acetylcysteine salt capable of interacting with *P*-glycoprotein, partially inhibiting the BBR chloride extruding process. D-α-tocopheryl polyethylene glycol 1000 succinate (TPGS) has also been reported to inhibit P-glycoprotein (Dintaman and Silverman 1999). Chen et al. (2011) demonstrated that 2.5% TPGS improved peak concentration and area under the curve of BBR by 2.9 and 1.9 times, respectively, due to its ability to inhibit the activity of P-glycoprotein, thereby reducing the excretion of absorbed BBR into the intestinal lumen of rats.

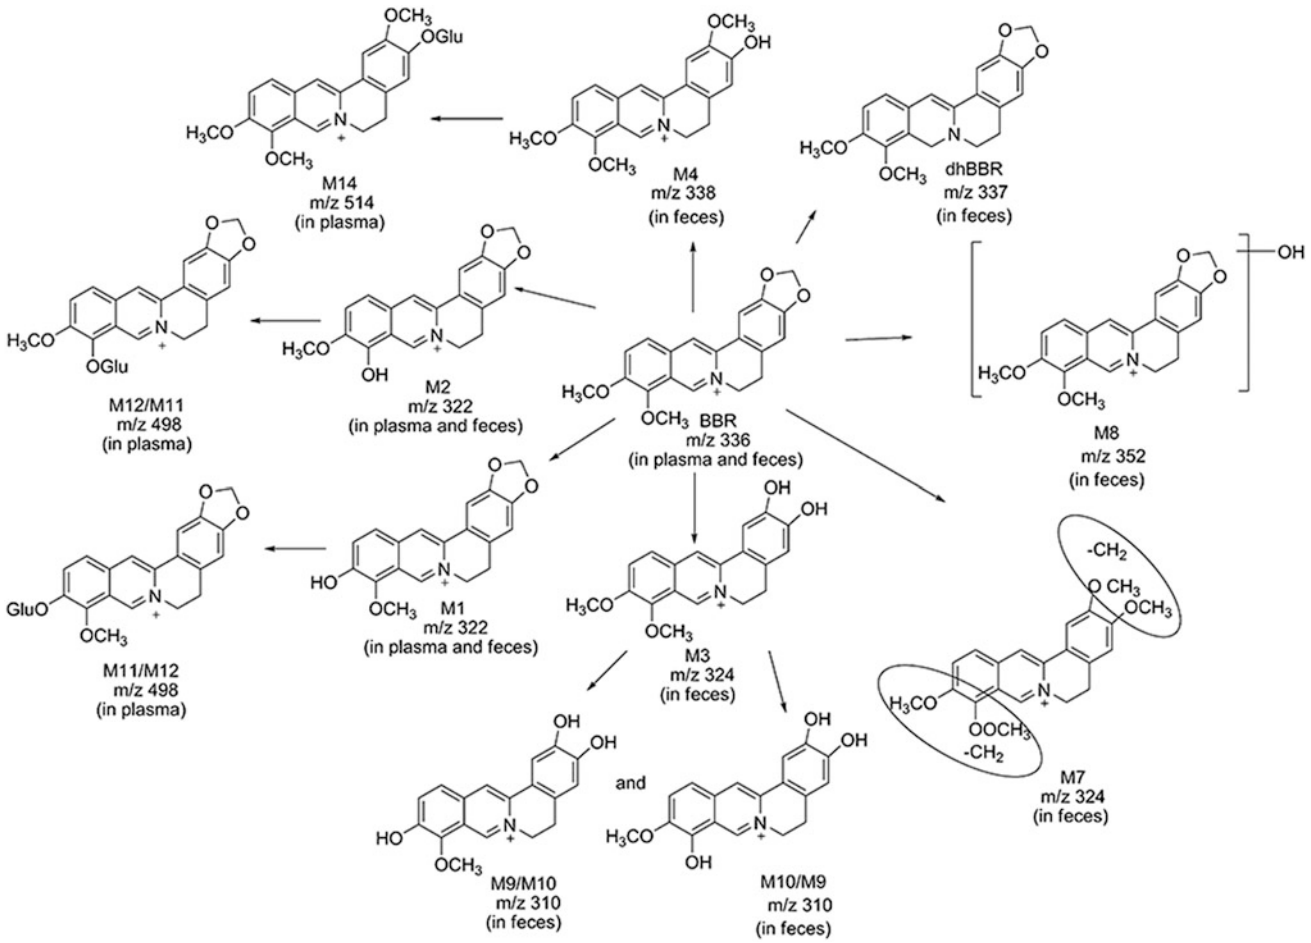

Fig. 2 Berberine and its 14 metabolites in dogs (Courtesy of Feng et al. 2018)

In a number of reports, BBR and its metabolites have exhibited anticancer properties (Li et al. 2015b; Bhattacharyya et al. 2017; Wang et al. 2017). Wang et al. (2017) prepared polyethylene glycol-modified long-circulating BBR liposomes and evaluated their efficacy and safety as potential antitumor agents. Results revealed that BBR liposomes may provide a safe form of intravenous drug therapy for strengthening the antitumor effects of BBR.

3 Pharmacological and Therapeutic Potential of BBR

Berberine is known to exert multiple pharmacological effects by having antioxidative, anti-inflammatory, and microsomal drug-metabolizing enzyme inhibitory properties. Its therapeutic potential has been recognized in a number of diseases and syndromes. The application of berberine in some health conditions has been described in brief.

3.1 Neurodegenerative Diseases

The use of BBR has been implicated in Alzheimer's disease (AD), Parkinson's disease (PD), anxiety, depression, and epilepsy (Peng et al. 2007; Ye et al. 2009; Kumar et al. 2015 also reviewed in chapter on "Cognitive dysfunction"). Although the bioavailability of BBR is poor, it crosses the blood–brain barrier (BBB) in adequate concentrations and accumulates in the hippocampus, where it provides potassium channel blocking, antiapoptotic, and neuroprotective effects (Wang et al. 2004, 2005, 2009; Ye et al. 2009). In addition, BBR exerts other pharmacological and biological actions, such as antioxidant, anti-inflammatory, analgesic, anxiolytic, and immunomodulatory actions, thereby providing preventive and therapeutic effects in neurological conditions (Kumar et al. 2015; Hussein et al. 2018).

BBR has been reported to improve learning and memory and to protect neurons from death by inhibiting AChE (Bhutada et al. 2011; Abd El-Wahab et al. 2013) and

normalizing ChAT, SOD, and MAO-B activities and cytokines, MDA, and neurotransmitters (norepinephrine, dopamine, and 5-HT) in discrete brain regions (Kulkarni and Dhir 2008a, b; Zhang et al. 2009; Kumar et al. 2015). Zhu and Qian (2006) demonstrated that BBR treatment (50 mg/kg, intragastrically once daily) for 14 days ameliorated spatial memory impairment in the rat model of AD. Kong et al. (2001) reported that BBR competitively inhibited MAO A in rat brain mitochondria, with an IC_{50} value of 126 μM. Yoo et al. (2006) found that BBR protects the hippocampal CA1 region from ischemic injury by inhibiting NMDA receptor 1 immunoreactivity in the ischemic gerbil brain.

BBR has also been shown to prevent or delay the process of AD by inhibiting the formation of $A\beta_{1-42}$, in addition to lowering oxidative stress and cholesterol (Abd El-Wahab et al. 2013; Cai et al. 2016). Asai et al. (2007) reported that BBR reduced Aβ levels by modulating amyloid precursor protein (APP) processing in human neuroglioma H4 cells. Additionally, quaternary protoberberine alkaloids, such as stepharanine, cyclanoline, and *N*-methyl stepholidine, from *Stephania venosa* were found to express AChE inhibitory activity (Ingkaninan et al. 2006). In the streptozotocin-induced diabetic rat model, BBR treatment (25–100 mg/kg, po, twice daily for 30 days) improved cognitive performance by normalizing AChE level and attenuating oxidative stress (Bhutada et al. 2011).

BBR appears to be a novel preventive and therapeutic modality for CDS in canine and felines.

3.2 Cardiovascular Effects

BBR has been extensively studied for its effects on the cardiovascular system (Lau et al. 2001; Affuso et al. 2010a; Xia and Luo 2015; Bagade et al. 2017). Xu et al. (1989) investigated the effects of BBR (5 mg/kg, IV) on ventricular tachyarrhythmias and electrophysiologic consequences in normal and ischemic myocardium in open-chest dogs subjected to programmed electrical stimulation (PES). The PES-induced ventricular tachycardia or ventricular fibrillation was prevented in four out of six BBR-treated dogs. BBR lengthened the QTc interval and the effective refractory period. These data suggest that BBR may be effective in preventing the onset of reentrant ventricular tachyarrhythmia and sudden coronary death after myocardial ischemic damage in dogs. In another study, Huang et al. (1992) reported that in dogs with ischemic left ventricular failure, BBR treatment (1 mg/kg IV bolus, followed by a constant infusion of 0.2 mg/kg/min for 30 min) improved left ventricular function by its positive inotropic effect and mild systemic vasodilation. BBR-treated dogs showed increased cardiac output and decreased left ventricular end-diastolic pressure and systemic vascular resistance. BBR increased coronary artery flow in anesthetized open-chest canines and isolated guinea pig hearts. A strong positive inotropic activity has been observed for BBR in dogs (Vik-Mo et al. 1983), rats, rabbits, guinea pigs (Sabir et al. 1978), and humans (Maroko and Ruzyllo 1983; Martin-Neto et al. 1988).

BBR can prolong the duration of ventricular action potential. In an in vitro study, Riccioppo (1993) demonstrated that BBR, in a concentration-dependent manner, increases the action potential (AP) duration in canine Purkinje and ventricular muscle fibers without affecting other parameters of the AP. BBR at 3–30 μM concentration produced a significant prolongation of AP duration in isolated guinea pig ventricular fibers without affecting the resting membrane potential and AP amplitude (Wang and Zheng 1997). Similar findings were observed in rats (Chi et al. 1996), cats (Sanchez-Chapula 1996), rabbits (Riccioppo 1993), and humans (Martin-Neto et al. 1988; Chi et al. 1996). BBR exerts class III antiarrhythmic and proarrhythmic actions in the cardiac muscle of the dog. Furthermore, spasms of isolated swine coronary arterial rings were prevented and treated effectively by BBR (Birdsall and Kelly 1997). BBR may exert its antiarrhythmic effect by acting as a Ca^{2+} agonist and/or a K^+ channel blocker. Cardiac ATP-sensitive K^+ (K_{ATP}) channels are considered potential targets for BBR's action. Lau et al. (2001) further reiterated that some of the cardiovascular effects of BBR and its derivatives are attributed to the blockade of K^+ channels (delayed rectifier and K_{ATP}) and stimulation of Na^+-Ca^{2+} exchanger. Evidence also suggests that BBR, by reducing tyrosine hydroxylase activity, has an inhibitory effect on catecholamine biosynthesis (Lee and Kim 1996).

The vasodilatory and hypotensive actions of BBR can be explained by several mechanisms. Ko and Lim (1980) reported that BBR caused hypotension in rabbits by blocking α-adrenoceptors. However, in dogs this effect appears to be due to the direct vascular action of BBR, which is independent of adrenergic, cholinergic, or histaminergic mechanisms (Sabir and Bhide 1971). BBR reduces blood pressure by competitively inhibiting vascular smooth muscle cells (VSMCs) α_1 receptors, thereby blocking the release of the enzyme adenylyl cyclase, which results in vasodilation and augmented acetylcholine activity (Zhang 2004). The hypotensive effect of BBR has been attributed to its inhibitory effect on acetylcholinesterase (Chun et al. 1979). BBR induces endothelium-dependent smooth muscle relaxation by increasing endothelial NO release (Ko et al. 2000). In a hypertensive rat model, Zhao et al. (2007) demonstrated that BBR at a dose of 5–10 mg/kg improved cardiac contractility, inhibited myocardial fibrosis, and reduced cardiac atrophy.

BBR is widely used for the treatment of congestive heart failure (CHF) (Martin-Neto et al. 1988; Zeng et al. 2003). Martin-Neto et al. (1988) examined the acute hemodynamic effects of intravenous BBR administration (0.2 mg/kg/min

for 30 min) in patients with CHF. A marked reduction in systemic and pulmonary vascular resistance, coupled with increased cardiac output, resulted in significant decreases in both systemic and pulmonary arterial pressures. Further evidence of improvement in cardiovascular function was shown by favorable BBR effects on several hemodynamic and echocardiographic indices of left ventricular performance. In another study, Zeng et al. (2003) treated CHF patients with BBR (1.2–2 g/day), in addition to conventional therapy (including ACE inhibitors, digoxin, diuretics, and nitrates), for 8 weeks. BBR-treated patients showed a significantly greater increase in left ventricular ejection fraction, exercise capacity, improvement of the dyspnea–fatigue index, and a decrease of frequency and complexity of ventricular premature complexes compared with the placebo group.

Hong et al. (2002) investigated the inhibitory effect of BBR on experimental cardiac hypertrophy in rats, which is regarded as a risk factor of chronic heart failure and other heart diseases. Cardiac hypertrophy was induced by suprarenal abdominal data constriction (banding). Rats were treated for 8 weeks with BBR (10 mg/kg body wt, po) and captopril (50 mg/kg body wt, po) beginning from 4 weeks after surgery. The findings revealed that (1) the elevated left ventricular and diastolic pressure was slightly decreased and (2) the maximum rates of contraction and relaxation ($\pm dp/dt_{max}$) were shortened, indicating that functions of the heart, both contraction and relaxation, were improved. Additionally (1) the whole heart and left ventricular weight and (2) cell size of the left ventricular myocardium were decreased compared with the banded rats. These data suggest that BBR can improve abnormal cardiac function and can prevent the development of left ventricular hypertrophy.

In conclusion, BBR exerts positive inotropic, negative chronotropic, antiarrhythmic, and vasodilator properties and can be used as a nutraceutical in hypertension, congestive heart failure, arrhythmias, and heart failure.

3.3 Antihyperlipidemic Effects

BBR has been shown to exert an antihyperlipidemic effect by lowering total cholesterol (TC), triglyceride (TG), and low-density lipoprotein cholesterol (LDL-C) levels in humans and animals (Kong et al. 2004; Bagade et al. 2017). BBR (500 mg) given twice daily for 3 months to hyperlipidemic patients significantly reduced total cholesterol by 29%, triglycerides by 35%, and LDL-C by 25% (Zhang et al. 2008). Dong et al. (2011) reported that BBR attenuates cardiac dysfunction in hypercholesterolemic and hyperglycemic rats. In atherogenic rats, BBR treatment (50–150 mg/kg) reduced total cholesterol by 29–33% and non-high-density lipoprotein (non-HDL) by 31–41%. Huang et al. (1992) found that BBR provided beneficial effects on hemodynamics during acute ischemic left ventricular failure in dogs. BBR, when combined with red yeast rice and policosanol, induced a positive effect on flow-mediated vasodilation in a double-blind, placebo-controlled trial on subjects with hypercholesterolemia (Cicero et al. 2007; Affuso et al. 2010b; Marazzi et al. 2011). Marazzi et al. (2011) observed statistically significant reduction in total cholesterol (−20%) and LDL-C (−31%) in elderly hypercholesterolemic humans or animals and suggested that this combined nutraceuticals is a better strategy for those who are statin-intolerant.

BBR can decrease cholesterol levels by multiple mechanisms, and some of these mechanisms may differ from those that are involved in statins (Kong et al. 2004). Statins upregulate the low-density lipoprotein receptor (LDLR) via inhibiting cholesterol synthesis. Statins inhibit the activity of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase. BBR induces downregulation of LDL-C by upregulation of LDLR expression. BBR stabilizes LDLR by an extracellular signal-regulated kinase (ERK)-dependent pathway and also by increasing transcriptional activity of the LDLR promotor via a c-Jun N-terminal kinase (JNK) pathway (Abidi et al. 2005; Choi et al. 2006; Lee et al. 2007; Tan et al. 2013; Xia and Luo 2015). Choi et al. (2006) reported that in 3T3-L1 cell leptin, transcription factors like sterol regulatory element-binding protein-1c (SREBP-1c) and CCAAT enhancer-binding protein-α (C/EBP-α), peroxisome proliferator-activated receptor-γ (PRAR-γ), fatty acid synthase, acetyl-coenzyme A carboxylase, acyl-CoA synthase, and lipoprotein lipase are reduced by BBR. BBR is also known to activate 5′-adenosine monophosphate (AMP) kinase (AMPK) while blocking the MAPK/ERK pathway, resulting in inhibition of lipid synthesis (Brusq et al. 2006; Xia and Luo 2015; Bagade et al. 2017). BBR is also reported to inhibit the differentiation of preadipocytes, reduce accumulation of lipid droplets, and lower triglyceride levels (Huang et al. 2006; Zhou et al. 2008).

Wang et al. (2014) reported that BBR produced a decrease in cholesterol levels by inhibiting cholesterol absorption (40–51%). BBR interfered with cholesterol micellarization and decreased cholesterol uptake by Caco-2 cells and permeability through Caco-2 monolayer. BBR also inhibited the gene and protein expressions of acyl-coenzyme A cholesterol acyltransferase-2 in the small intestine in rats and Caco-2 cells. In hyperlipidemic hamsters, Wang et al. (2010) found that the combined use of BBR and plant stanols has a greater synergistic effect on inhibiting cholesterol absorption than BBR or stanols alone. Furthermore, Li et al. (2015a, b) reported that hyperlipidemic hamsters treated with BBR (50 or 100 mg/kg) showed gradual decrease in liver

cholesterol levels and an increase in bile cholesterol levels, suggesting that BBR promotes excretion of cholesterol from the liver into the bile. In hamsters, Gu et al. (2015) demonstrated that orally administered BBR modulated the gut microbiota and BBR showed a significant inhibition of the 7α-dehydroxylation conversion of cholic acid to deoxycholic acid, indicating a decreased elimination of bile acids in the gut. In conclusion, BBR can be used as a nutraceutical in hyperlipidemia, hypercholesterolemia, and metabolic diseases.

3.4 Antihyperglycemic and Antidiabetic Effects

Type 2 diabetes mellitus is the most common form of diabetes. Alterations of endothelial homeostasis, due primarily to proinflammatory cytokines and reduced adiponectin secretion, appear to be two key events in insulin resistance and hyperglycemia. These conditions are associated with altered gene expression and cell signaling in the vascular endothelium, thereby affecting the release of endothelium-derived factors, activation of NADPH oxidase, uncoupling of endothelial NOS (eNOS), and expression of endothelin-1 (Bagade et al. 2017). This cascade of events often results in an imbalance between the production of vasodilator and vasoconstrictor mediators and the induction of adhesion molecules (Rask-Madsen and King 2007).

BBR has been found to be effective in type 2 diabetes. Chen and Xie (1986) reported that *Coptis chinensis* and BBR exert a hypoglycemic effect. In a meta-analysis, Dong et al. (2012) confirmed similar results. BBR produces antihyperglycemic effect in diabetes by multiple mechanisms:

1. Decreases glucose absorption by inhibition of α-glucosidase and reduces glucose transport through the intestinal epithelium (Pan et al. 2003)
2. Activates adenosine 5′-monophosphate-activated protein kinase (AMPK) (Lee et al. 2006; Yin et al. 2008a, b; Zhang and Chen 2012)
3. Induces glucose transport by enhancing GLUT1 gene expression (Kim et al. 2007)
4. Increases glucose uptake from blood to target organs, such as the skeletal muscle and adipose tissue (Zhang and Chen 2012)
5. Increases insulin receptor expression and improves insulin secretion and sensitivity and thereby reduces insulin resistance (Kong et al. 2009; Zhang et al. 2010a, b; Pérez-Rubio et al. 2013; Derosa et al. 2014; Xia and Luo 2015)
6. Directly inhibits gluconeogenesis in the liver (Xia et al. 2011; Zhang and Chen 2012)

Furthermore, Yin et al. (2008b) reported that BBR enhanced glucose metabolism by stimulation of glycolysis, which is related to the inhibition of glucose oxidation in mitochondria and consequently the induction of AMPK activation.

In an in vitro study, Wang et al. (2008) reported that BBR enhanced glucose-stimulated insulin secretion in rat pancreatic islets, and both mRNA and protein expressions of hepatic nuclear factor 4 alpha (*HNF4α*) were upregulated by BBR in a dose-dependent manner. Glucokinase activity was found to be increased accordingly. Recently, Bagade et al. (2017) further echoed on the underlying mechanism in BBR's effect on insulin sensitivity by increasing insulin receptor (*InsR*) expression in a dose- and time-dependent manner. This led to the promotion of glucose uptake in the presence of insulin. BBR induces *InsR* gene expression via transcriptional regulation through protein kinase C (PKC) (Zhang et al. 2010a). Additionally, BBR inhibits the intracellular accumulation of ROS, cellular apoptosis, and inflammation that characterize vascular injury, and these are mostly triggered by hyperglycemia (Affuso et al. 2010b; Bagade et al. 2017).

In a clinical study, BBR significantly lowered fasting blood glucose, hemoglobin A_{1c}, triglyceride, and insulin receptor expression in patients with type 2 diabetes (Zhang et al. 2010a, b). In a multicenter clinical trial, Li (2007) also reported that type 2 diabetic patients with dyslipidemia receiving BBR (1 g daily) for 3 months showed significantly reduced levels of blood glucose, hemoglobin A_{1c}, triglyceride, total cholesterol, and LDL-C compared to placebo. In another clinical study, BBR given three times a day at the dose of 500 mg to patients with type 2 diabetes caused significant reduction in hemoglobin A_{1c} (−2%), fasting plasma glucose (−44%), postprandial glucose (−45%), fasting plasma insulin (−28%), and homeostasis model assessment of insulin resistance index (44.7%) (Yin et al. 2008a). In an in vitro study, Hui et al. (1991) shown that BBR acts on both endothelial and underlying vascular smooth muscle cells to induce vasodilation via eNOS leading to NO production.

BBR has positive effects in treating diabetic nephropathy, diabetic neuropathy, and diabetic cardiomyopathy (Pang et al. 2015; Imenshahidi and Hosseinzadeh 2015). Diabetic nephropathy is a progressive kidney disease, which is pathologically characterized by thickened glomerular and tubular basement membranes, accumulation of the cellular matrix, and increased mesangial hypertrophy. The disease is induced by factors, such as dyslipidemia, hyperglycemia, hemodynamic abnormalities, and oxidative stress. Ni et al. (2015) suggested that by lowering blood glucose, regulating blood lipids, and reducing oxidative stress and inflammation, BBR has potential for treating diabetic nephropathy. In systematic reviews and meta-analysis, Zhang and Chen (2012) and Lan et al. (2015) found BBR to be highly effective in type 2 diabetes mellitus and diabetic complications with no serious side effects.

3.5 Hepatoprotective Effects

BBR has been found to be effective against hepatic disease and toxicity. Feng et al. (2010) determined the hepatoprotective effects of BBR on serum and tissue superoxide dismutase (SOD) levels and histopathology in carbon tetrachloride-induced liver injury in rats. The hepatoprotective mechanisms of BBR may be related to the elevation of antioxidative activity and attenuation of oxidative/nitrosative stress and free radical scavenging, as well as to the inhibition of TNF-α, iNOS, and COX-2 activities (Domitrovic et al. 2011). Li et al. (2014) showed that BBR ameliorated liver fibrosis in mice with carbon tetrachloride-induced liver injury and inhibited the proliferation of hepatic stellate cells in a dose- and time-dependent manner. BBR decreased the enzyme release of ALT, AST, and ALP in serum, elevated SOD, and reduced MDA content of liver. BBR treatment activated AMPK activity and decreased the protein expression of Nox4 and TGF-β1 and the phosphorylated Akt. BBR treatment also reduced the expression of smooth muscle actin (α-SMA), the marker of hepatic stellate cell. In another study, Janbaz and Gilani (2000) reported that pretreatment of rats with BBR (4 mg/kg, po, twice daily) for 2 days prevented the acetaminophen- or carbon tetrachloride-induced rise in serum levels of ALT, AST, and ALP, suggesting hepatoprotection. Furthermore, posttreatment with three successive oral doses of BBR (4 mg/kg every 6 h) reduced the hepatic damage induced by acetaminophen, while carbon tetrachloride-induced hepatotoxicity was not modified, suggesting a selective curative effect against acetaminophen.

Methotrexate, a commonly used anticancer and immunosuppressant drug, is known to cause hepatotoxicity. In a recent study, Mehrzadi et al. (2018) pretreated male Wistar rats with BBR (100 mg/kg body wt) for 10 consecutive days and treated rats with methotrexate (20 mg/kg, ip) on the ninth day. Rats were sacrificed on day 11, and the serum and liver were analyzed for various biochemical parameters. Results revealed that BBR might be useful for prevention of the hepatotoxicity induced by methotrexate via ameliorative effects on biochemical, inflammation, and oxidative indices.

Doxorubicin, an anthracycline anticancer drug, is extensively used in chemotherapy due to its efficacy in fighting a wide spectrum of malignancies. In addition to cardiotoxicity, doxorubicin causes hepatotoxicity in approximately 40% of patients. The main toxic effects on hepatocytes include (1) arrest cell cycle of hepatocytes (Kassner et al. 2008), (2) oxidative stress, and (3) disruption of electron transport chain (Zhao et al. 2012). Zhao et al. (2012) pretreated mice with BBR (60 mg/kg, ip) 1 h before doxorubicin (2.5 mg/kg, ip) on alternative days for 7 days. Findings revealed that BBR pretreatment significantly prevented doxorubicin-induced decline in body weight, increase in ALT and AST activities, and attenuated histopathological changes, such as vascular congestion, inflammatory cell infiltration, hepatocellular degeneration, necrosis, and fibrosis in the liver.

Metals such as mercury and lead induce hepatotoxicity by multiple mechanisms, including oxidative stress. Othman et al. (2014) reported that mice treated with mercuric chloride (0.4 mg/kg body wt) for 7 days caused oxidative stress by increasing lipid peroxidation and NO production with a concomitant decrease in glutathione and various antioxidant enzymes (SOD, catalase, glutathione peroxidase, and glutathione reductase). Liver enzymes and bilirubin were also found to be increased in serum. BBR (100 mg/kg body wt) treatment inhibited lipid peroxidation and NO production, restored antioxidant enzymes compared to control, and increased glutathione content. Histopathological examination of the liver revealed the protective effects of BBR against mercury-induced hepatotoxicity.

Laamech et al. (2017) investigated the protective effect of *B. vulgaris* aqueous extract against lead-induced hepatotoxicity in mice. Mice received lead acetate (5 mg/kg body wt) in water for 40 days. In another group, mice also received *B. vulgaris* extract (25, 50, 100, and 150 mg/kg body wt) daily for 30 days from day 11 after the beginning of lead acetate exposure. *B. vulgaris* treatment significantly prevented lead accumulation; increased ALT, AST, total bilirubin, and total cholesterol; inhibited lipid peroxidation and protein carbonyl formation; and normalized antioxidant enzymes (SOD, catalase, and glutathione peroxidase) and architecture of liver tissue.

In patients with nonalcoholic fatty liver disease (NAFLD), Yan et al. (2015) found that BBR (0.5 g three times a day) resulted in a significant reduction of NAFLD and related metabolic disorders. Recently, in an experimental study, Feng et al. (2018b) reported that rats treated with BBR (50 mg/kg body wt) plus curcumin (50 mg/kg body wt) exhibited lower body weight and fat weight compared with those treated with lovastatin (100 mg/kg body wt). Nutraceutical-treated group also showed lower levels of LDL-c, ALT, AST, ALP, MDA, and LSP compared with lovastatin group. Lower expression of SREBP-1c, pERK, TNF-α, and pJNK was also observed in BBR + curcumin group. Authors concluded that the combination of BBR and curcumin exhibited better ameliorative effects in treating NAFLD than lovastatin, and this enhanced effect is associated with oxidative stress, hepatic inflammation, and lipid metabolism.

3.6 Antimicrobial Effects

BBR has demonstrated significant antimicrobial activity against bacteria, fungi, protozoans, helminths, chlamydia, and viruses (Birdsall and Kelly 1997). Since BBR exerts

antimicrobial activity, it is considered to be an antibiotic. Its most common clinical uses have been for bacterial diarrhea, intestinal parasites, and ocular trachoma infections. BBR was shown to inhibit the intestinal secretory response due to cholera toxins. Using a ligated rabbit intestinal loop model, Sack and Froehlich (1982) demonstrated a significant suppression of the intestinal secretory response following exposure to *Vibrio cholerae* crude enterotoxin. It has been suggested that BBR may exert antidiarrheal effects by inhibiting the formation of certain organisms; inhibiting the formation of toxins, direct antagonism of the toxins; inhibiting intestinal ion secretion; and inhibiting smooth muscle contraction (reviewed in Birdsall and Kelly 1997). The antidiarrheal effects of BBR may also be mediated by its ability to delay intestinal transit time due to blockage of muscarinic acetylcholine (ACh) receptors, thereby inhibiting spontaneous intestinal peristalsis (Eaker and Sninsky 1989).

BBR sulfate has been reported to be effective against *Giardia lamblia*, *Trichomonas vaginalis*, and *Entamoeba histolytica* (Kaneda et al. 1991). The crude extract was found to be more effective than the BBR sulfate salt. In both rat and golden hamster models, BBR sulfate provided protection against *E. histolytica*-induced hepatic abscesses (reviewed in Birdsall and Kelly 1997). Ahuja et al. (1993) found BBR sulfate to be very effective against cutaneous leishmaniasis in domestic dogs when BBR sulfate (1%) was inoculated intralesionally. Ghosh et al. (1985) reported that golden hamsters infected with *L. donovani* showed parasite reduction up to 90% in the liver and spleen when treated with BBR (50 or 100 mg/kg i.p./day for 5 days).

3.7 Osteoarthritis

Osteoarthritis (OA) is a chronic debilitating disease affecting the entire joint, and its pathophysiology is very complex (reviewed in Gupta 2016; Gupta et al. 2019; Appleton 2018). One of the early triggers in development and progression of OA is synovial inflammation. Biochemical mediators found in OA synovial fibroblasts (OASFs) affecting the cellular functions of tissues include cytokines, chemokines, growth factors, and matrix metalloproteinases (MMPs). These mediators, such as interleukins (ILs) produced by OASFs, promote inflammation, neovascularization, and cartilage degradation, thereby contributing to joint destruction (Liu et al. 2015; Appleton 2018; Peffers et al. 2018; Watt 2018).

Connective tissue growth factor (CTGF, also known as CCN2) is an inflammatory mediator that is abundantly expressed in OA. IL-1β plays a pivotal role in OA pathogenesis. Liu et al. (2015) reported that CCN2-induced IL-1β expression is mediated by the activation of avβ3/avβ5 integrin-dependent ROS generation and subsequent activation of apoptosis signal-regulating kinase 1 (ASK1), p38/JNK, and NF-κB signaling pathways. The expression of IL-1β in OASFs has been reported to be attenuated by *N*-acetylcysteine (NAC), inhibitors of ASK1, p38, or JNK, or treatment with BBR. BBR has also been reported to reverse cartilage damage in an experimental model of collagenase-induced OA.

In in vitro and in vivo studies in rat OA model, Hu et al. (2011) demonstrated that BBR inhibited the expression of matrix metalloproteinases (MMP-1, MMP-3, and MMP-13) and increased the level of tissue inhibitor of metalloproteinase-1 at the mRNA level in a dose-dependent manner. In IL-1β-induced rat articular chondrocytes, BBR decreased IL-1β-induced glycosaminoglycan release and NO production, suggesting a chondroprotective effect. In high doses, BBR exhibited an anticatabolic effect in an IL-1-β-induced rat OA model. These findings suggest that BBR may play an anti-inflammatory, chondroprotective, and anticatabolic role in the development of OA, and BBR may be useful in the treatment of OA in animals.

4 Safety and Toxicity of BBR

In general, BBR shows very low toxicity and side effects (Pang et al. 2015; Imenshahidi and Hosseinzadeh 2015). Safety data of BBR reports its oral LD_{50} >29,586 and >15,000 mg/kg in mouse and rats, respectively. The LD_{50} of BBR in mice from intravenous (IV) and intraperitoneal (IP) injections is 9.03 and 57.61 mg/kg, respectively (Kheir et al. 2010). Following oral intragastric doses of BBR (10.4, 20.8, 41.6, and 83.2 g/kg), the LD_{50} could not be determined, although a 30% mortality rate was found among mice in the two highest dosage groups. In type 2 diabetics, humans have been given up to 1500 mg BBR (in three divided doses of 500 mg each) daily without any serious adverse effects. In high doses, BBR has been associated with arterial hypotension, dyspnea, flu-like symptoms, mild to moderate gastrointestinal discomfort, constipation, and cardiac damage (Imenshahidi and Hosseinzadeh 2008, 2015).

BBR has not been reported to produce genotoxic, cytotoxic, or mutagenic effects with its clinical doses (Birdsall and Kelly 1997). Berberine has been reported to cross the placenta and cause harm to the developing fetus. It has also been shown to exert a uterine stimulatory effect; therefore its use in pregnancy is cautioned. BBR can be transferred through breast milk; hence caution is required for BBR use while breastfeeding.

5 Concluding Remarks and Future Directions

BBR can be obtained from a number of plants of genus *Berberis*, *Hydrastis*, *Coptis*, *Argemone*, and *Thalictrum*. BBR has a strong potential for ameliorating chronic ailments,

such as neurodegenerative diseases, cardiovascular/metabolic disorders, type 2 diabetes mellitus, bacterial diarrhea, trachoma, gastroenteritis, etc., as it exerts multiple pharmacological actions. Although there is little concern about the side effects from BBR use, safety data from validated preclinical and clinical studies is warranted. Based on acute toxicity data, BBR can be classified as a nontoxic substance. Much of the literature is derived from in vitro studies and human clinical trials, while safety data based on animal studies are lacking. BBR should not be used by pregnant or lactating animals, as it may cause harm to the unborn or newly born.

Acknowledgment The authors would like to thank Ms. Robin B. Doss for her technical assistance in preparation of this chapter.

Sea Buckthorn and Apricot Based Nutraceuticals

Vijay K. Bharti, Sahil Kalia, Arup Giri, and Bhuvnesh Kumar

Abstract

A high-altitude environment is characterized by hypobaric hypoxia, extreme temperature variation, low humidity, intense ultraviolet radiation, low rainfall, and high wind velocity. These types of extreme climatic conditions can result in oxidative stress in animals. This stress leads to a marked increase in cellular dysfunction and a decline in the production of antioxidant defense molecules which affects health and productivity of livestock especially at high altitudes. Therefore, the veterinary clinician is required to induce an upregulation of antioxidants and in the immune system to ameliorate the oxidative stress. Currently, nutraceuticals are used in nutritional therapy to manage various disease conditions and to improve productivity of pets and livestock animals. Nutraceuticals refer to natural functional foods or bioactive phytochemicals that have health-promoting and disease-preventing properties. These nutraceuticals in general contain alkaloids, flavonoids, some vitamins, trace minerals, etc. Various studies have revealed that apricot seed cake, sea buckthorn leaves, fruit pomace, and fruit pulp are rich in phytomolecules which modulate the immune system and upregulate the antioxidant defense system in broiler chicken, sheep, and goats. This chapter discusses the value of nutraceuticals and the usefulness of apricot (*Prunus armeniaca*) and sea buckthorn (*Hippophae rhamnoides*) in broiler chicken health management and improvement of weight gain in high-altitude regions.

1 High-Altitude Environment

A high-altitude environment is characterized by hypobaric hypoxia, extreme temperature variation, low humidity, intense ultraviolet radiation, low rainfall, and high wind velocity. Physiologically, this environment is not suitable for good health and performance of animals and human beings. The growth performance of livestock animals that are raised in a cold, arid, high altitude is very poor due to the stressful environmental conditions. The climatic adversaries contribute to high-altitude oxidative stress, which ultimately hinders the growth rate of livestock by inducing their catabolic activities, thus producing a low financial return (Biswas et al. 2011; Kalia et al. 2017). The major consequence of oxidative stress is the marked increase in cellular dysfunction and the decline of the antioxidant defense system due to the increased generation of reactive oxygen species (Miller et al. 2013). Oxidative stress results from an excess generation of reactive oxygen species (ROS) like $O_2^{\cdot -}$, H_2O_2, and $ROO^{\cdot}$ that lead to cellular damage due to the interaction of ROS with cellular constituents. To maintain a healthy biological system, it is important to balance the presence of these species with antioxidant defense (Halliwell 1996; Valko et al. 2007). Antioxidants such as polyphenols are on the front line of investigation not only because of their natural origin but also their ability to act as free-radical scavengers, helping the endogenous antioxidant system (Katalinic et al. 2006; Ferreira et al. 2009). A whole range of plant-derived dietary supplements, phytochemicals, and provitamins that assist in maintaining good health and combating disease are now being described as functional foods and nutraceuticals (Bernal et al. 2011). Nutraceutical is a term coined in 1989 by

R. C. Gupta et al. (eds.), *Nutraceuticals in Veterinary Medicine*, https://doi.org/10.1007/978-3-030-04624-8_6

Stephen DeFelice. It is defined as a food or parts of food that provide medical or health benefits, including the prevention and treatment of disease. Nutraceuticals range from isolated nutrients, herbal products, dietary supplements, and diets to genetically engineered "designer" foods and processed products such as cereals, soups, and beverages. A nutraceutical is any nontoxic food extract supplement that has scientifically proven health benefits for both the treatment and prevention of disease. Nutraceutical also refers to natural functional/medical foods or bioactive phytochemicals that have health-promoting, disease-preventing, or medicinal properties. These nutraceuticals, in general, include vitamins, lipids, proteins, carbohydrates, minerals, and other necessary nutrients, depending on their emphases (Zeisel 1999; Whitman 2001). These nutraceuticals are used in nutritional therapy based upon their chemical structures and biological functions (Brower 1998). Phytomolecules such as polyphenols, flavonoids, vitamins, carotenoids, etc. are widely used as prophylactic and therapeutic agents in combating health problems associated with high altitude (Kala 2006). These phytogenic feed additives would be less toxic and ideal to replace antibiotic growth promoters in the broiler chick diet (Kalia et al. 2017, 2018).

This chapter describes the feed supplement of sea buckthorn and apricot plants on poultry for better health management and higher production levels at a high altitude.

2 Constraints and Prospects of Poultry Production at High-Altitude Region

Critical temperature is the temperature at which animals are properly sustained, and if the temperature varies slightly, then the animal may face difficulty. At higher altitudes the temperature significantly fluctuates throughout the year. As altitude rises then the partial pressure of oxygen is very low, and this causes significant effects on animal health as well as farming in the region. Poultry also face other problems related to low humidity, cold stress in winter, and high UV radiation. All these environmental factors are responsible for the poor sustainability of poultry farming in high-altitude regions. Unavailability of feed, lack of proper housing management, and unavailability of suitable germplasm are also critical factors in the regulation of poultry farming (Biswas et al. 2010; Kalia et al. 2017, 2018).

3 Important Diseases and Clinical Conditions of Poultry at High Altitude

The high-altitude environment is not suitable for livestock production, including poultry rearing, due to the harsh climate and the incidence of various physiological conditions, such as ascites, respiratory infection, impaction, coccidiosis, cannibalism, poor feed intake, stunted growth, extremely poor hatchability, cecal hemorrhage, etc. (Biswas et al. 2011).

4 Nonconventional Sources for Poultry Feeding at High-Altitude Cold Desert

High-altitude regions have no economic poultry feed available locally due to extreme climate and limited crop production. Therefore, poultry feeds are brought from other areas which are formulated based on nutrient requirements of chickens reared in specific areas such as the plains. Poultry raised at a high altitude require a special ration formulated specifically for those conditions. Unfortunately, there is very limited availability of this special ration. Therefore, farmers are supplementing poultry ration with antioxidants and other locally available feed resources like lucerne leaves, hydroalcoholic willow leaf extract, crushed oats, sea buckthorn fruit pomace and leaves, and apricot seed cake and seed extract (Biswas et al. 2011). These plant parts can be mixed with the existing poultry diet base as per palatability and acceptance. This feed supplementation with nutraceuticals improves poultry antioxidant defense and immune system requirements for amelioration of high-altitude stress prevalent in the region. Formulation of a nutraceutical-based poultry ration is greatly needed for high-altitude regions considering their nutrient requirements. This will improve health conditions and productivity of poultry in these regions.

5 Sea Buckthorn as a Source of Phytomolecules and Their Therapeutic Value

Hippophae rhamnoides (currently, *Elaeagnus rhamnoides*), also called sea buckthorn (SBT), belongs to the family *Elaeagnaceae* (Fig. 1). It is a significant herbal medicinal plant of the Trans-Himalayan cold desert and is commonly found at an altitude of 3000–4500 m above MSL (Saggu et al. 2007). It is a hardy plant which can tolerate extreme temperatures from −43 to 40 °C, and it contains barriers of different colors. Every part of the SBT plant is a good source of a large number of phytomolecules such as polyphenols, flavonols, flavonoids, proanthocyanidins, vitamins, carotenoids, organic acids, polyunsaturated fatty acids, and amino acids (Beveridge et al. 1999; Saggu et al. 2007; Ma et al. 2017; Puganen et al. 2018). In traditional Ayurvedic medicine, the extract of SBT fruits has been used for treatment of various kinds of health disorders (Saggu et al. 2007). Many bioactive phytomolecules such as *Hippophae*

Fig. 1 Sea buckthorn (*Hippophae rhamnoides*) plant with ripe fruit

cerebroside, vitamin C, vitamin E, gallic acid, kaempferol 3-*O*-sophoroside-7-*O*-rhamnoside, quercetin, etc. were identified in the berries of SBT which are responsible for its pharmacological properties (Chen et al. 2003; Zheng et al. 2009; Upadhyay et al. 2010). The leaves are a rich source of antioxidants including β-carotenoids, vitamin E, catechins, and folic acid and negligible amount of calcium, magnesium, and potassium (Upadhyay et al. 2010).

Various pharmacological activities of SBT, including antioxidative, immunomodulatory, anti-stress, anticancer, hepatoprotective, and radioprotective, have been reported in humans and livestock (Geetha et al. 2002; Goel et al. 2002; Yasukawa et al. 2009; Tulsawani 2010; Maheshwari et al. 2011; Olas et al. 2018). The seeds, leaves, and fruit of SBT are reported to be an ideal feeding material for livestock and poultry in the high-altitude Trans-Himalayan region (Biswas et al. 2011). Supplementation of SBT flavonoids in the diet of broiler chickens has shown a positive influence on their growth performance, fatty acid composition, and lipometabolism in the liver (Ma et al. 2015). Various studies report the usefulness of a sea buckthorn plant-based feed formulation in improving health conditions via modulation of various physio-biochemical indices. These studies are summarized in Table 1.

The potent hepatoprotective activity of SBT berry oils against aflatoxin B1 (AFB1) has been reported in broiler chickens (Solcan et al. 2013). Moreover, supplementation of SBT barriers in broiler chickens at different treatment concentrations improved their humoral and cell-mediated immune response against the adverse effects of T-2 toxin (Lavinia et al. 2009; Ramasamy et al. 2010). Similarly, the increased proliferative activity of chicken peripheral blood lymphocytes with the supplementation of SBT fruit extract has been reported in recent studies (Kalia et al. 2018). Supplementation of SBT as a feed additive in broiler chicken diet elevated the level of free-radical scavenging activity and decreased the level of lipid peroxidation in blood serum at higher altitudes (Kalia et al. 2018). These pharmacological activities of SBT in poultry may be due to the synergistic effect of certain bioactive phytomolecules present in SBT fruit (Table 1).

6 Apricot as Source of Various Phytomolecules and Their Therapeutic Value

Apricot, widely known as *Prunus armeniaca*, is an edible fruit that belongs to the family *Rosaceae* (Fig. 2), and it is grown in climates with very cold winters. Apricot can tolerate temperatures as low as −30 °C (Ahmadi et al. 2008). The major areas of apricot cultivation are in India and include the hilly areas of Himachal Pradesh, northeastern regions of Jammu and Kashmir, and the major growing area of Leh-Ladakh (Wani et al. 2015).

A large number of diverse bioactive phytomolecules such as polyphenols, flavonoids, carotenoids, vitamins, fatty acids, etc. have been found in the apricot, thereby giving this plant pharmacological antioxidative properties (Dragovic-Uzelac et al. 2007; Yigit et al. 2009; Kan et al. 2014). Apricot seeds are an abundant source of dietary proteins along with a significant amount of oil and fibers (Nout et al. 1995). Various pharmacological effects of the apricot have been reported, including antioxidant (Gomaa 2013), antimicrobial (Yigit et al. 2009), antitumor (Gomaa 2013), immunomodulatory (Tian et al. 2016), anti-inflammatory (Minaiyan et al. 2014),

Table 1 Effects of sea buckthorn (SBT) on poultry

No.	Experimental animal	Duration	Dose and route of administration	Effect	References
1.	Broiler chicken	42 days	3% flax oil and 3% dried SBT pomace in feed mixture	↓ Lipid oxidation, ↑ α-tocopherol, ↑ feed intake, ↑ feed conversion ratio (FCR), ↑ body weight, ↓ mortality, ↓ triglycerides, ↓ cholesterol, ↓ glucose, ↓ T3, ↓ T4	Orczewska-Dudek et al. (2018)
2.	Turkey poults	56 days	SBT leaf meal powder at 0.5% in feed mixture	↑ Body weight, ↑ feed conversion ratio (FCR), ↓ plasma uric acid, ↓ alkaline phosphatase, ↑ zinc	Sharma et al. (2018)
3.	Japanese quail	21 days	2% SBT leaf powder in drinking water	↓ Mortality, ↓ alanine aminotransferase (ALT), ↓ uric acid, ↓ cholesterol, ↑ total protein, ↑ albumin	Patial et al. (2015)
4.	Arbor Acres (AA) broilers	28 days	0.25%, 0.5%, 1% SBT powder in feed mixture	↑ Muscle inosine monophosphate, ↑ adenylosuccinate lyase	Zhao et al. (2012)
5.	Broiler chicks	49 days	5% SBT fruit residue in feed mixture	↑ Body weight, ↑ feed conversion ratio (FCR), ↓ mortality	Ben-Mahmoud et al. (2014)
6.	Broiler chicks	56 days	SBT seeds, leaves, and fruit residues in feed mixture	↑ Body weight, ↑ egg laying rate	Biswas et al. (2010)
7.	Broiler chicken	42 days	Group II diet contained 1000 ppm SBT leaf extract, group III contained 400 ppm of SBT pulp, and group IV contained 0.5 mL/kg SBT seed oil in feed	↑ Body weight, no changes in feed conversion ratio (FCR), carcass traits like chilled weight, breast weight, thigh weight, and drumstick weight were improved	Pathak et al. (2011)
8.	Arbor Acres male broilers	42 days	0.05%, 0.10%, and 0.15% SBT fruits in feed mixture	Improved average daily feed intake (ADFI), average daily gain (ADG), and final body weight (BW), ↓ abdominal fat percentage, ↑ intramuscular fat (IMF), ↑ thigh meat, ↑ breast muscle, quadratic effect on the abdominal fat percentage, ↓ levels of triglyceride, cholesterol, and low-density lipoprotein cholesterol	Ma et al. (2015)
9.	Laying hens	21 days	5% and 13% of SBT in feed mixture	↓ Egg productivity and egg weight, color of yolk increased significantly, feed consumption was the highest, no change in feed conversion	Pebriansyah and Silberov (2014)
10.	Isa Brown laying hens	322 days	SBT fruit residues in feed mixture	Total number of eggs laid and egg yolk color were detected, a nonsignificant effect of SBT was found on hen performance or egg quality including egg weight, yolk weight, eggshell strength, and shape index of egg, eggshell thickness, Haugh units, eggshell color and blood spot, albumen weight, proportion	Shaker et al. (2018)
11.	Poultry birds	28 days	Powdered SBT berries were added at 400 and 800 ppm	Significant increase in hemagglutination inhibition titer and total serum Ig	Ramasamy et al. (2010)
12.	RIR cross-bred broiler chickens	42 days	*H. rhamnoides* fruit extract in drinking water	↑ Body weight, ↑ feed conversion ratio (FCR), ↓ mortality, ↑ TAC, ↑ DPPH, ↓ LPO, ↑ total protein, ↑ albumin, ↑ globulin, ↓ cholesterol, ↓ triglyceride, ↑ HDL, ↓ LDL, ↓ glucose, ↑ creatinine, ↓ AST, ↓ ALT	Kalia et al. (2018)
13.	Peripheral blood lymphocyte	24 h	100 ng/mL–400 μg/mL extract	Reduced H_2O_2-induced oxidative stress in lymphocytes, stimulated PBL	Kalia et al. (2018)

↑ upregulation/increase/improvement, ↓ downregulation/decrease/deterioration, *ALP* alkaline phosphatase, *ALT* alanine transaminase, *AST* aspartate transaminase, *Zn* zinc, H_2O_2 hydrogen peroxidase, *LDH* lactate dehydrogenase, *LPO* lipid peroxidase, *MDA* malondialdehyde, *TAC* total antioxidant capacity, *HDL* high-density lipoprotein, *LDL* low-density lipoprotein, *DPPH* 2,2-diphenyl-1-picrylhydrazyl, *Ig* immunoglobulin

hepatoprotective (Yilmaz et al. 2015), radioprotective (Kurus et al. 2013), and cardioprotective (Parlakpinar et al. 2009).

Feeding of apricot seed cake to lambs under the high-altitude climatic conditions of Leh-Ladakh provided adequate nutrition to support normal body growth and had no adverse effects on performance (Jadhav et al. 2011). It has also been reported that supplementation of apricot kernel meal in broiler chicken diet produced a positive effect on the performance and intestinal microbiota (Samli et al. 2014). Furthermore, improved fatty acid composition in broiler meat was reported after administration of apricot without any deleterious effect on performance (Tekeli 2012).

Fig. 2 Apricot (*Prunus armeniaca*) plant at fruiting

Table 2 Effects of apricot on poultry

Experimental animal	Duration	Dose and route of administration	Effect	References
Broiler chickens	21 days	5%, 10%, and 20% apricot kernel meal	↑ Body weight, ↑ intestinal microbiota	Samli et al. (2014)
Broiler chickens	42 days	5, 10, and 15 g/kg apricot kernel oils	Increased the proportions of pentadecanoic acid, heptadecanoic (margaric) acid, heptadecanoic (margoleic) acid, linolenic acid, and eicosanoic acid	Tekeli (2012)
RIR cross-bred broiler chickens	42 days	Seed extract of 100, 150, 200, 300, 400, and 800 mg/kg body weight of chicken administered through drinking water	↑ Body weight, ↑ feed conversion ratio (FCR), ↓ mortality, ↑ TAC, ↑ DPPH, ↓ LPO, ↑ total protein, ↑ albumin, ↑ globulin, ↓ cholesterol, ↓ triglyceride, ↑ HDL, ↓ LDL, ↓ glucose, ↑ creatinine, ↓ AST, ↓ ALT	Kalia et al. (2018)
Peripheral blood lymphocyte	24 h	100, 200, 400, 800 ng/mL extract	Reduced H_2O_2-induced oxidative stress in lymphocytes, stimulated PBL	Kalia et al. (2018)

↑ upregulation/increase/improvement, ↓ downregulation/decrease/deterioration, *ALP* alkaline phosphatase, *ALT* alanine transaminase, *AST* aspartate transaminase, *Zn* zinc, H_2O_2 hydrogen peroxidase, *LDH* lactate dehydrogenase, *LPO* lipid peroxidase, *MDA* malondialdehyde, *TAC* total antioxidant capacity, *HDL* high-density lipoprotein, *LDL* low-density lipoprotein, *DPPH* 2,2-diphenyl-1-picrylhydrazyl, *Ig* immunoglobulin

Supplementation of apricot extract in broiler chicken diet stimulates increased digestion and metabolism of nutrients resulting in improved growth performance of broilers at a higher altitude (Kalia et al. 2017). Increased proliferative activity of chicken peripheral blood lymphocytes following supplementation with apricot extract has been reported (Kalia et al. 2017). Supplementation of apricot as a broiler feed additive also improved immunological, antioxidant, and blood biochemical profiles under high-altitude stress conditions (Kalia et al. 2017). These pharmacological activities in poultry may be due to the synergistic effect of certain bioactive phytomolecules present in the apricot (Table 2).

7 Mechanism of Therapeutic Value of Sea Buckthorn- and Apricot-Based Nutraceuticals

Some of the studies on feed supplements of sea buckthorn and apricot plant products indicate that growth performance, survivability rate, physio-biochemical indices, and economics are positively affected. But, the mechanism of action of these feed supplements has yet to be elucidated. Kalia et al. (2017) found that feeding an aqueous extract of *P. armeniaca* produced significantly higher total antioxidant capacity, free-radical scavenging activity, interleukin-2, total protein, albumin, and globulin levels as well as lower malondialdehyde, interleukin-6, glucose, cholesterol, triglyceride, ALT, and AST levels as compared to the control group. Another study found that *P. armeniaca* extract reduced the level of proinflammatory cytokine IL-6 in treatment groups. This reduction might be due to the anti-inflammatory activity of the polyphenolic compounds of *P. armeniaca* downregulating NF-kB signaling pathway via decreased phosphorylation of NF-kB. Moreover, *P. armeniaca* extracts stimulate the production of IL-2 via activation of the T helper cells 1 (Th1) and also play a central role in cell-mediated immunity. This suggests that *P. armeniaca* extract exerts immunomodulatory effects in broilers through mediating both cellular and humoral immunity. These same findings were also reported in the sea buckthorn feed supplements study on broiler chickens. Therefore, it may be concluded that both feed supplements have an immunomodulatory role along with antioxidative properties which ultimately lead to

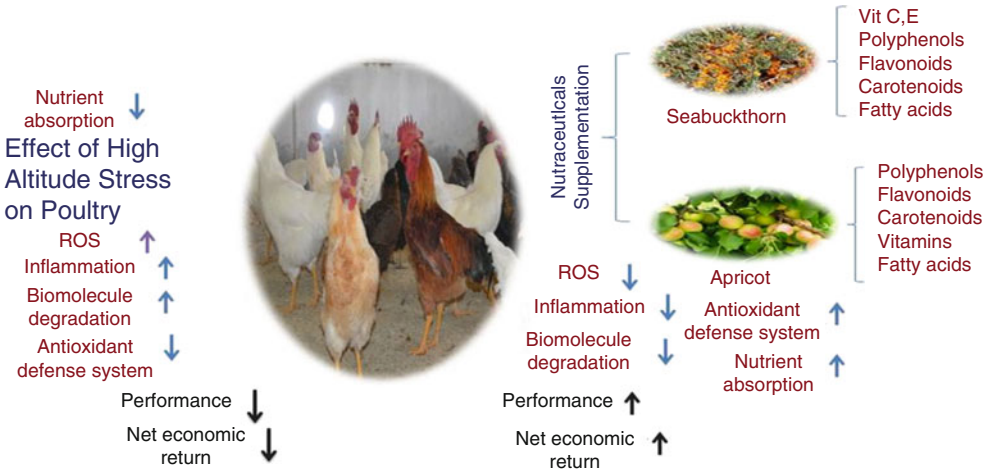

Fig. 3 Probable mechanism of therapeutic action of sea buckthorn- and apricot-based nutraceuticals

Table 3 Feed formulation based on sea buckthorn and apricot

Brand name	Composition	Manufacturer
Monosaturated sea buckthorn berry oil	Linoleic acid 4.7%, oleic acid 66.8%, unsaturated fatty acids 25.2%, phenolic 19%	Natures Natural India
Sea buckthorn oil	Linoleic acid, oleic acid, unsaturated fatty acids, etc.	Arian Enterprises
Sea buckthorn Omega7 oil	Omegas, flavonoids, omega-7	MNC Globle Multitrade
Apricot oil	Mixed fatty acids	Shri Hari Aromatics
Apricot oil	Oleic 64.2%, palmitic 5.0%, linoleic 28.3%, linolenic 0.2%, stearic 1.0%	Bo International
Apricot oil	Arginine, histidine, lysine, phenylalanine, valine, leucine, cystine and tryptophan, and methionine	Natural Cosmetic Supplies (Unit of Mother Herbs)

better growth performance and survivability (Tekeli 2012; Kalia et al. 2017, 2018). The most probable mechanism of action of feed the supplement of sea buckthorn and apricot is represented in Fig. 3.

8 Available Sea Buckthorn and Apricot Plant-Based Feed Formulation

Different types of feed formulations and herbal products have been developed by various institutions and private manufacturers for human and animal use. Scientists also developed a feed bolus (DB-LactoMax, a sea buckthorn and apricot preparation) for dairy cattle (90–100 g or 1 bolus daily/cow). It improves milk yield and body and reproductive condition. A liquid preparation (Immunobooster, 5–10 mL/100 birds) was developed for broiler chickens and layers that is comprised of sea buckthorn, apricot seed, and willow leaf extracts in preferable weight ratio. It enhances cytokines, immune status, and upregulation of antioxidant status in broiler birds under high-altitude stress conditions and thereafter improves overall health, growth performance (150 g in 42 days), and FCR. Bakery products like biscuits, buns, bread, cakes, jellies, health drinks, wine, food colorants, and yogurt have been made for human use also using sea buckthorn pulp and leaves. Some of these formulations are given in Table 3.

9 Concluding Remarks and Future Directions

This chapter describes the value of nutraceuticals and the therapeutic potential of sea buckthorn and apricot in poultry for improvement of their health and productivity in higher-altitude regions. Several research findings suggest the upregulation of cellular and extracellular antioxidant defense and the scavenging of free radicals. Recent findings indicate their immunomodulatory effect which may be beneficial in the control of immunosuppressive disease as well. These plant-based products may be useful in plain areas under different farm conditions. However, further studies are required to establish their dose regime. Moreover, continued research is needed to better understand the mechanisms and specific pathways involved in ROS-induced diseases and to determine the most rational and effective combination of antioxidants in veterinary clinical use for management of various disease conditions.

Abstract

The wide versatility of medicinal plants has made them of great interest all around the world. *Nigella sativa* (NS, commonly called black seed), a member of *Ranunculaceae* family, is one of the most important medicinal plants. NS is reported in the treatment of a wide variety of medical ailments due to its chemical constituents which may enhance the source of functional and nutritional foods. The constituents of NS have the competence to cure many biological ailments including, asthma, diabetes, digestive diseases, inflammatory diseases, and rheumatoid arthritis. Wide-ranging pharmacological activities including analgesic, antidiabetic, anticancer, anti-inflammatory, antimicrobial, immunostimulatory, bronchodilator, spasmolytic, antihistaminic, and hepatoprotective have been reported for the seeds and oil extract of NS. It affects the reproductive system, central nervous system, and immune system as anticonvulsant and wound-healing mediators. NS can be exploited for producing a series of drugs for the medication of numerous diseases. In the present chapter, we discussed the general introduction of NS and its geographical location followed by chemical constituents. Further, some crucial pharmacological activities and toxicological effects of NS are also described.

Keywords

Nigella sativa · Medicinal plant · Nutraceutical · Thymoquinone · Phytochemical

1 Introduction

Medicinal plants are a major source for treating human ailment throughout the world since ancient times. These plants are invaluable resources, useful in daily life as pigments, food additives, flavors, fragrance, and pharmaceuticals. Today scientists are interested in identification of their main constituents and elucidating their mechanism of action. Many studies have concluded that compounds such as phenolics, flavonoids, alkaloids, terpenoids, saponins, tannins, and anthraquinones have beneficial effects as antioxidant, anti-inflammatory, immunomodulatory, antimicrobial, anticancer, antidiabetic, etc. (Omojate et al. 2014). According to a study (Vuorelaa et al. 2004), in the last 20 years, more than 25% of drugs are directly isolated from plants, and the other 25% are obtained from their chemically derived products. The plant NS, locally known as "kalonji," is used as a traditional medicine to cure many diseases such as diarrhea, asthma, etc. (Tasawar et al. 2011; Gilani et al. 2001; Benhaddou-Andaloussi et al. 2011). The diverse chemical components of NS seeds provide excellent opportunity for development and innovation in the area of medicinal drug.

The seed of *Nigella sativa* (Ranunculaceae) has been used for many years as a spice, food preservative, and medicinal drug to cure many ailments (Abdulelah and Zainal-Abidin 2007; Goreja 2003). They are known as black seed because when they are exposed to air, they turn into black-colored seeds (Goreja 2003). It is an annual herb with an average height of about 20–90 cm. Its leaves are about 2.5–5.0 cm long and linear hastate-shaped. Its flowers are pale blue colored and seeds are black in color, usually flattened,

oblong, angular, funnel shaped with size of 0.2 cm long and 0.1 cm wide.

Seeds of NS contain various components such as protein (20–27%), fat (34.5–38.7%), carbohydrates (23.5–33.2%), crude fiber (8.4%), and ash (4.8%) (Babyan et al. 1978). These also contain many vitamins and minerals such as Zn, Cu, P, and F. Apart from this NS is also reported to contain carotene, which further converts into vitamin A in the liver (Ahmad et al. 2013). The seeds also contain many active compounds such as nogelleone, thymoquinone, and thymohydroquinone which are reported to provide beneficial activity such as antimicrobial, antitoxic, and other pharmacological activities (Forouzanfar et al. 2014).

NS seeds are reported to have 20% alcohol-soluble extractives, 15% water-soluble extractives, 25–32% total fixed oil, 0.42% volatile oil, and 3.91% organic matter (expressed as w/w) (Sharma et al. 2005).

2 Geographical Location

The origin of *Nigella sativa* is not well established. The plant was certainly under wide cultivation more than 3000 years ago. NS is inherent to Southeast Europe, North Africa, and Southwest Asia. It is cultivated in countries such as the Middle Eastern Mediterranean region, South Europe, India, Pakistan, Oman, Saudi Arabia, Israel, Syria, and Turkey (Fig. 1) (Gilani et al. 2004; Khare 2004).

3 Taxonomical Classification

The taxonomical classification of *Nigella sativa* is as follows: Kingdom, Plantae; subkingdom, Tracheobionta; superdivision, Spermatophyta; phylum, Magnoliophyta; class, Magnoliopsida; order, Ranunculales; family, Ranunculaceae; genus, *Nigella*; species, *sativa* (Fig. 2).

The NS is recognized as black cumin, black caraway, black seed, damascena, devil-in-the-bush, fennel flower, haba-al-barka, kalonji, kalajeera, nutmeg, and many more. It is an annually flowering plant that is characterized with finely divided petals (widely colored as pink, pale blue, purple, white, and yellow) and having 5–10 petals.

4 Chemical Constituents of NS

It has been found that essential oil of NS seed contains numerous chemical constituents, confirmed by GC and GC-MS techniques. Few compounds have been represented in Fig. 3. The extraction of essential oil from NS is done using Clevenger's apparatus. There are two types of extraction technique available using Clevenger's apparatus, one is microwave steam distillation 1 (MSD1) in which seeds are placed inside the oven apparatus, and the second is microwave steam distillation 2 (MSD2) in which seeds have been placed outside the oven apparatus (Akloul et al. 2014). Apart from this cryogenic grinding (CG) method was also used for the oil extraction. In CG methods the process is carried out by either MSD1-CG or MSD2-CG. Akloul et al. (2014) reported that essential oil contains more amount of oxygenated compounds and less amounts of monoterpene hydrocarbons extracted by using MSD1 and MSD2 than MSD1-CG and MSD2-CG. MSD1 oil extract contains comparative amount of ketones and alcohols than MSD2 oil extract, while MSD2 oil extracts contain more monoterpene hydrocarbons than MSD1 oil extracts. The amount of sesquiterpene hydrocarbons has approximately similar quantity in both. By using MSD1-CG and MSD2-CG, similar results have been observed. Some sesquiterpene hydrocarbons like longifolene, α-longipinene, and Z-γ-bisabolene have been reported in essential oil using MSD1 and MSD1-CG methods.

A qualitative assessment of NS seeds revealed the presence of triterpenes, sterols, flavonoids, tannins, alkaloids, cardiac glycosides, coumarins, saponins, volatile oils, volatile bases, anthraquinones, and glucosinolates (Al-Yahya 1986). It has been reported that seeds of NS contain more than 30% of fixed oil and 0.40–0.50% of volatile oil (w/w). Qualitative estimation of essential oil of NS seed by gas chromatography-mass spectrometry (GC-MS) technique has showed around 65–67 different chemical compounds. When

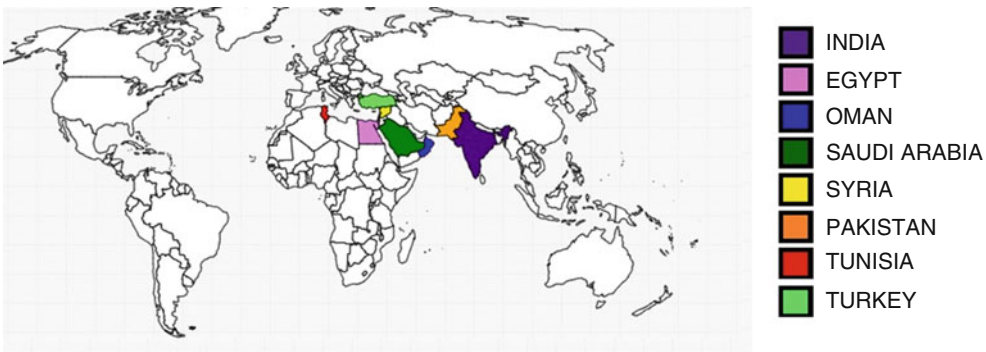

Fig. 1 Representation of geographical distribution of NS across the world

Fig. 2 Seeds of *N. sativa*

such compounds were subjected into various functional groups, the following results were obtained: carbonyl compounds (25%), phenols (1.7%), alcohols (0.9%), monoterpenes (46%), and esters (16%) (Aboutable et al. 1986). Approximately 18–24% thymoquinone and a total of 46% of various monoterpenes such as pinene and *p*-cymene were reported in volatile oil (El-Tahir et al. 1993).

Omar et al. (1999) provided a brief account about the presence of dithymoquinone, thymohydroquinone, thymoquinone, carvacrol, thymol, 6-methoxy-coumarin and 7-hydroxy-coumarin, oxy-coumarin, steryl-glucoside, and α-hedrin as well as enough amounts of tannins, essential fatty acids, flavonoids, ascorbic acid, amino acids, and few inorganic substances such as iron and calcium. As per the article of Weiss (2002), the seeds contain around 0.5% volatile oil that have seven main phyto-constituents, and their estimated proportions are as follows: thymoquinone (25%), *p*-cymene (31%), ethyl hexadecanoate (3%), α-pinene (9%), ethyl linoleate (9%), ethyl oleate (3%), and β-pinene (2%). Similarly Sharma et al. (2009) reported that thymoquinone was identified as the main component (up to 50%) alongside *p*-cymene (40%), pinene (up to 15%), fatty acid ethyl ester (10%), dithymoquinone, and thymohydroquinone. Other terpene derivatives were found only in trace amounts: carvacrol, carvone, limonene, 4-terpineol, and citronellol in the essential oil of NS (mean 0.5%, max. 1.5%). The conversion of thymoquinone to dithymoquinonene and higher oligo condensation products on storage results into the aromatic flavor of NS. Nickavara et al. (2003) from Iran used GC and GC-MS methods to investigate the chemical composition of the volatile oil of NS seeds and reported 32 compounds (86.7%). Among them, the major compounds were *trans*-anethole (38.3%), *p*-cymene (14.8%), limonene (4.3%), and carvone (4.0%). The GC and GC-MS results are given in Table 1 (Nickavara et al. 2003).

The main components of NS were *p*-cymene (33.8%) and thymol (26.8%), with only a small amount of thymoquinone (3.8%) reported by Moretti et al. (2004). Rajkapoor et al. (2002) reported the alkaloids present in the seeds to be nigellidine, nigellicin, tannin, steroid α-spinasterol, quinazoline, cholesterol, campesterol, stigmas 7-en-3-β-ol, stigmasterol, and flavonoids of trigillin quercetin-3-glucoside. Morikawa et al. (2004a, b) reported isolation of four dolabellane-type diterpene alkaloids from the seeds of NS. The active constituents, nigellidine and nigellone, were reported to contain an indazol nucleus (Rahman et al. 1995). Three flavonoid glycosides and triterpene saponins were also isolated and identified from NS together with four phospholipid classes: phosphatidylethanolamine, phosphatidylcholine, phosphatidylserine, and phosphatidylinositol (Merfort et al. 1997; Ramadan and Morsel 2002).

5 Pharmacological Studies

The extractives of NS showed many important pharmacological activities. The notability of the plant is due to its properties to cure many disorders. The detailed pharmacological studies of NS are given below:

5.1 Antioxidant Activity

NS essential oil has been found to possess great antioxidant activity. It has been observed that essential oil of NS affects the antioxidant enzyme status and myocardium of cyclosporine A-treated rats. It has also been reported that when pre-treatment with essential oil of NS was performed, it decreased the succeeding cyclosporine. Essential oil of NS showed antioxidant activity as it reduces the lipid peroxidation, development in antioxidant enzyme status, and cellular protein oxidation (Ebru et al. 2008). Essential oil of NS displayed many antioxidant activities verified by diphenylpicrylhydracyl. Thymoquinone (TQ) and other chemical components of NS like carvacrol, anethole, and 4-terpineol have radical scavenger property which is proved by using two TLC screening methods. These components have also been found to be effective OH radical scavenging agents,

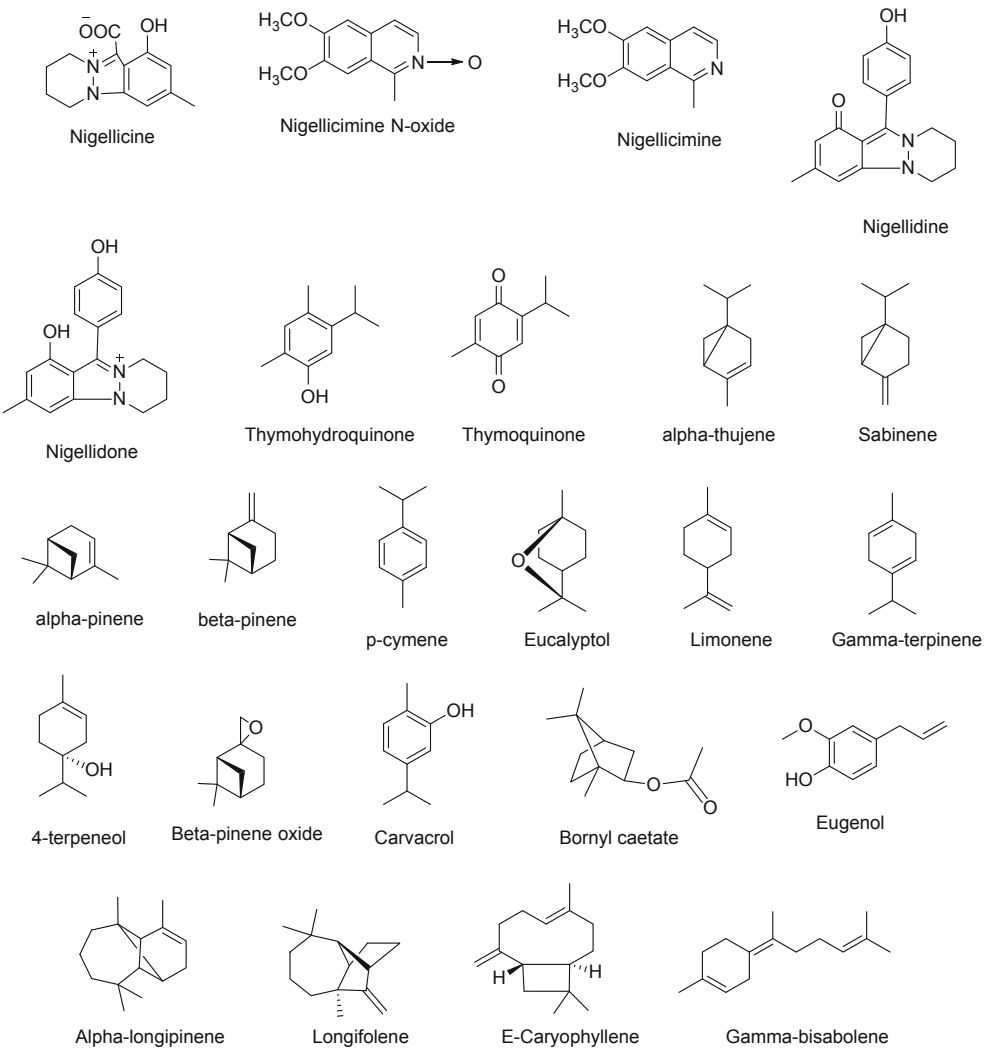

Fig. 3 Structures of chemical constituents of NS seeds

verified for nonenzymatic lipid peroxidation in liposomes and also deoxyribose degradation (Burits and Bucar 2000). The chemical constituents of NS like thymol, TQ, and dithymoquinone showed free-radical scavenging effect by attenuating reactive oxygen species (ROS) like hydroxyl radical, superoxide radical, and nascent oxygen, determined by chemiluminescence and spectrophotometric methods (Kruk et al. 2000). Due to the antioxidant activity of TQ, it showed protective effect against doxorubicin-induced nephrotoxicity (Badary et al. 2000) and doxorubicin-induced cardiotoxicity (Al-Shabanah et al. 1998; Nagi and Mansour 2000). It shows modulating effect and antitumor effect on bezo(a)pyrene-induced cancer in mice (Badary et al. 1999) and on 20-methylcholanthrene-induced fibrosarcoma tumor genesis (Badary and Gamal-el-Din 2001), respectively, due to antioxidant activity. NS seeds and their extracts have been reported to display antioxidant property, as they provide protection against damage caused by oxidation. Lado et al. (2004), Nagwa et al. (2006), and Adamu et al. (2010) have all observed that *Nigella* oils may be used as an antioxidant, while Musa et al. (2004) reported that the ethyl alcohol extract can also produce antioxidants and was able to extend the life span of mice. Recently, Ibraheem et al. (2010) reported that NS has antioxidant and calcium antagonist properties.

5.2 Antibacterial Activity

Essential oil extracted from NS seed by following various techniques, such as steam distillation (SD), dry steam distillation (DSD), hydrodistillation (HD), solvent extraction (SE), and supercritical fluid extraction (SFE-SD), has been reported to exert antibacterial activities (Islam et al. 2013). It has been found that the MIC (minimum inhibitory concentration) values of HD and SD extractives are 256 and 32 μg/mL, respectively, while for both SE-SD and SFE-SD, the value was 4 μg/mL. All NS essential oil samples have been observed to possess greater activity against gram-positive than gram-negative bacteria (Kokoska et al. 2008). The

Table 1 Chemical composition of the volatile constituents

Compound	%
1,3,5-Trimethyl benzene	0.5

Source: Malhotra (2012)

antibacterial activities of NS against clinical isolates of methicillin-resistant *Staphylococcus aureus* have been studied by Hannan et al. (2008). It has been found that different NS extracts show antibacterial activity against different bacteria. Different extracts of NS have shown antibacterial activity against 16 gram-negative and 6 gram-positive bacteria. It has been found that the most effective extracts for antibacterial activity are alkaloids and water extracts. Also, the gram-negative bacteria are more affected than gram-positive bacteria (Hanafy and Hatem 1991; Sokmen et al. 1997). The methanol extracts of seeds exhibit anti-plaque action by inhibiting *Streptococcus mutans*. Alcoholic extracts exhibit antibacterial activity against bacteria *Micrococcus pyogenes* var. *aureus*, *Shigella dysenteriae*, *S. sonnei*, *S. boydii*, *Vibrio cholera*, and *E. coli* (Ferdous et al. 1992). Alcohol extracts of NS seed showed inhibitory activity against the growth of *Staphylococcus aureus* at a conc. of 4 mg/disc with MIC ranges from 0.2 to 0.5 mg/mL (Hannan et al. 2008).

5.3 Antifungal Activity

The essential oil of NS seeds is reported to have appreciable activity against a large number of fungi (Agarwal et al. 1979; Bourrel et al. 1995; Aboul Ela et al. 1996). The inhibition of toxic substance named as "aflatoxin" formation by a number of medicinal plants including NS at different concentrations has been studied in the past. In one of these studies, the powdered seed and essential oil of NS efficiently inhibited the growth and production of aflatoxin from the toxigenic strain of *Aspergillus flavus* (El-Shayeb and Mabrouk 1984; El-Sayed et al. 1997; Ozcan 1998).

The aqueous extractives of NS seeds have inhibitory effect against candidiasis in mice (Bita et al. 2012). The ether extract of NS and TQ has been tested for the antidermatophyte activity against eight species of dermatophytes, in which four species are of *Trichophyton rubrum* and one each of *Trichophyton interdigitale*, *Trichophyton mentagrophytes*, *Epidermophyton floccosum*, and *Microsporum canis* using agar diffusion method (Ahmad et al. 2013). TQ and ether extracts of NS also show inhibitory activity against fungal strains (Aljabre et al. 2005). TQ exhibited high antifungal activity against *Aspergillus niger*, *Fusarium solani*, and *Scopulariopsis brevicaulis*, and the activity is found to be similar with that of drug amphotericin B (Aljabre et al. 2015a, b).

It is found that the MICs of the ether extracts of NS and TQ range between 10 and 40 mg/mL and 0.125 and 0.25 mg/mL, respectively (Aljabre et al. 2005). The NS seed oil has been found to possess antifungal activities against 20 fungi, including pathogenic and industrial strains. Many researchers have found that all the oil extracts of NS have antifungal activities, but a stronger and wider range of antifungal activities have been shown only by volatile oil. The MIC values of volatile oil of the NS seeds have been determined against three pathogenic fungi, and the lowest MIC has been found against *Aspergillus fumigatus* (Islam et al. 1989).

5.4 Anticancer Activity

There are a number of active chemical components that have been extracted from NS such as thymoquinone (TQ) and

alpha-hederin which possess anticancer activities (Aljabre et al. 2015a, b). Several experiments have been performed in mice and rats to explore the anticancer activity of NS. The anti-cancer activity of black seed was observed with activity of natural killer cells to 200–300% in patients with advanced cancer (Salim 2010). The essential oil ($IC_{50} = 0.6\%$ v/v) and ethyl acetate ($IC_{50} = 0.75\%$) extracts of NS have been found to be more toxic against the P815 cell line than their butanol extractives ($IC_{50} = 2\%$). It was found that tests on the BSR cell line manifest a higher cytotoxic effect of ethyl acetate extractive ($IC_{50} = 0.2\%$) than essential oil ($IC_{50} = 1.2\%$) (Ait et al. 2007). The ethyl alchol extracts of NS seeds have been reported for in vitro inhibition of cancer cells and endothelial cells progression (Medenica et al. 1997; Swamy and Tan 2000). The defensive effect of NS seeds against the oxidative stress and carcinogenesis induced by using methylnitrosourea in rats has been studied. Its protective ability is high (80%) against methylnitrosourea-induced oxidative stress and carcinogenesis (Mabrouk et al. 2002). The aqueous and alcoholic extracts, which are either alone or in combination with H_2O_2, were found to be effective in vitro in deactivating MCF-7 breast cancer (Farah and Begum 2003). So the above data elucidates the toxic effect of each extract against various types of tumor cell.

5.5 Antidiabetic Properties

The seeds and oil extracts of NS have been found to possess antidiabetic properties. The effects on oral glucose tolerance of the aqueous crude extract of NS have been investigated by using the electroshock technique. It has been found that the aqueous crude extract of NS directly inhibits the intestinal absorption. Therefore, the improvement of carbohydrate tolerance and body weight in experimental rats after oral intake of seeds authenticates the use of NS as antidiabetic agents (Meddah et al. 2009). Various HIV protease inhibitors such as nelfinavir and atazanavir (Fig. 4) have been exposed along with the NS seed extracts. The combination has been reported to decline the insulin secretion in rats. Due to reduced insulin secretion, there has been rapid decline in the mortality rate in the HIV-I-positive patients (Chandra et al. 2009).

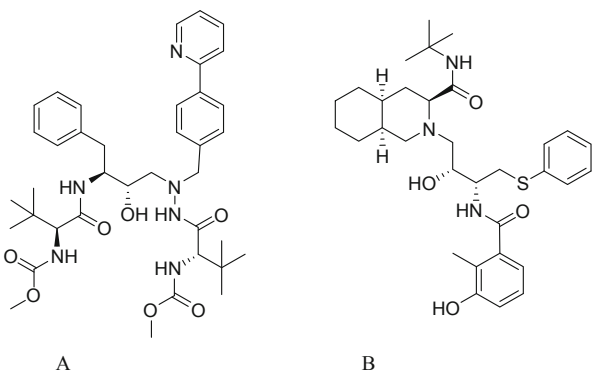

Fig. 4 Structure of atazanavir (**a**) and nelfinavir (**b**) as antidiabetic drugs, respectively

The defatted whole extracts of seeds have been evaluated for the insulin secretary effects in rats. The defatted extract has been divided into two subcategories as one with acidic and neutral molecules and the other with basic molecules. These subcategories have been tested in vitro in pancreatic islets of rats. The study revealed that the subcategories with basic molecules significantly enhanced the glucose-induced insulin release in rats indicating antidiabetic activity of the extract of NS (Rchid et al. 2004). Therefore, NS exhibits a protective effect in the diabetic rat by preserving insulin-producing pancreatic cells and inhibiting the oxidative stress in the cells (Kanter et al. 2004).

5.6 Antifertility Activity

A variety of reproductive responses of NS have been reported which include semen quality, follicle development, and effects related to pregnancy in both male and female individuals (Babazadeh et al. 2012). The seeds and extracts of NS have been used in albino rats to observe the effects on postmenopausal parameters. It has been found that the NS can be used for substituting the hormone therapy due to the presence of various beneficial effects (Parhizkar et al. 2016). The protein diet of Rahmani ewe lamb has been replaced with the protein diet rich in NS. It has been observed that the NS protein mixture has a wide range of beneficial role in altering the length of estrous cycle and conception rate (El-Harairy et al. 2006). Male lamb's performance has been found to be boosted when supplemented with NS (100–200 mg/kg body weight). The serum testosterone concentration was increased by NS. A group of broiler supplemented with the seeds and oil extracts of NS showed better semen characteristics which include increase in sperm mass motility, ejaculation volume, count, total sperm output, and viability percentage (Zanouny et al. 2013).

5.7 Anti-inflammatory Activity

TQ and other extracts of NS have significant anti-inflammatory activity. It has been studied that the ethanol extracts of NS seeds are used in the treatment of psoriasis, which is a general skin condition due to hyperproliferative, autoimmune skin disorder, and sometimes it is itchy and dolorous (Dwarampudi et al. 2012). Ahmed et al. (2014) reported that the ethanol extracts of NS showed anti-psoriatic effect. Also, NS oil is used generally in two forms which may be in balm and oral dosage form. The IC_{50} value of NS oil is

reported to be 23.9 μg/mL, which approximately equals to IC_{50} value of asiaticoside ($IC_{50} = 20.13$ μg/mL) (Jawad et al. 2014). NS oil is also used to cure acne vulgaris, which is the most common skin disease. Hadi and Ashor (2010) observed that using 20% NS oil extractives is better and less injurious in lotion formulation than using benzoyl peroxide. This is utilized in the treatment of mild to middle stage of acne vulgaris (Hadi and Ashor 2010).

5.8 Gastroprotective Properties

Wide-ranging gastroprotective activity of NS has been observed. The rats have been induced with gastric ulcer by using noxious chemical. The effects of aqueous extracts have been found to be significantly beneficial in the prevention of gastric ulcer and improving basal gastric secretion. The aqueous extract replenishes the depleted mucus content in the gastric mucosa indicating the gastroprotective activity of aqueous extract (Mofleh et al. 2008). Thymoquinone is examined against the noxious chemical-induced ulcer in rats and found to protect the gastric mucosa against the harmful effects of noxious chemical and support ulcer healing (Kanter et al. 2005; El-Dakhakhny et al. 2000). The aqueous extract of NS decreased the acidity in the gastric juice exhibiting gastroprotective activity in the acetyl salicylic acid-induced ulcer in rats (Akhtar et al. 1996).

5.9 Cardiovascular Activity

The seeds and extracts of NS have been employed to study the responses in the stimulation of cardiac activity. The seeds of NS have been administered orally to the normal rats to study their effect. The seeds enhanced the inherent contractile properties of the heart without increasing the cardiac workload (Al-Hariri et al. 2009; El-Bahai et al. 2009). The aqueous and macerated extracts from NS have been employed to examine their effects on heart rate and contractility of the heart. The powerful inhibitory effect on the heart rate and contractility has been noticed and found to be more effective than diltiazem (Fig. 5). The effect is attributed to calcium channel inhibition, and in plants it is due to the opening of potassium channels (Boskabady et al. 2005; Shafei et al. 2005).

Through the blockage of calcium ion channel, the active ingredient thymol is found to reduce the blood pressure (Gialni et al. 2001). Different doses of powdered seeds of NS have been administrated to albino rats to analyze the effect on the density of lipoprotein-cholesterol level. These powdered seeds lowered the level of low-density lipoprotein and enhanced the level of high-density lipoproteins which are essential for regular cardiovascular activities (Kocyigit et al. 2009).

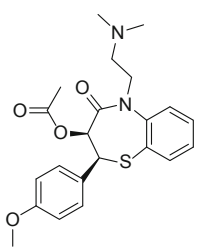

Fig. 5 Structure of diltiazem, anti-cardiovascular drug

5.10 Immunomodulatory Activities

Various synthetic antibiotics are used against various pathogenic organisms. Pathogenic organisms have been found to develop drug resistance against the administrated synthetic antibiotics. Therefore, compared to synthetic antibiotics, natural alternatives such as oil extracts and seeds of NS might be helpful. The seeds and purified constituents of NS have been used in the treatment of various diseases (Zeweil et al. 2008). Increased total plasma protein, albumin, and globulin were reported in rabbits upon supplementation with oil/extracts of NS (Tousson et al. 2011). The radioprotective activity of oil extracts of NS has been observed against hemopoietic harmful effect of gamma radiation. Before irradiation the oil extracts of NS were orally administrated which normalized the amplified concentration of malondialdehyde by decreasing the concentrations of catalase, plasma glutathione, and erythrocyte superoxide dismutase activities. Therefore, the oil extracts have been found to possess natural radioprotective activity and immunosuppressive effects on ionizing radiation (Assayed 2010). Significant declines in spontaneous motility, modification in general behavior, and normal body temperature were observed in methanol and aqueous extracts of oil suggesting depressant activity in the central nervous system (Khanna et al. 1993).

5.11 Memory and Learning Activities

In comparison with the other plant extracts, NS seed oil and its extracts are effective on the CNS and other actions related to spatial memory which involves special information, recognition, codifying, storing, and recovering by the brain (Kalat 2007). NS extracts are applied for acetylcholinesterase (AChE) activity inhibition.

The hydroalcoholic extracts of NS are involved in the central cholinergic enhancement against scopolamine-induced amnesia (Hosseini et al. 2015). The NS extractive oil shows mnemonic effect, cholinergic modulation, and oxidative stress mitigation (Raza et al. 2006). Khan et al.

(2008) reported that TQ of NS extract has neuroprotective properties on perceptional harm and other related dementias. It was also found that NS has antianxiety effect (Perveen et al. 2009). The hydroalcoholic extracts of NS have been reported to be useful in preventing the decadence of learning and memory activities shown in the pentylenetetrazole (PTZ)-induced epileptic model (Vafaee et al. 2015). The hydroalcoholic extracts of NS also reversed the harm of hypothyroidism linked with learning and memory in neonatal animals (Beheshti et al. 2016a, b). NS is also reported to affect the human mood, anxiety, and cognition (Sayeed Bin et al. 2014).

5.12 Anticonvulsant Activity

Since ancient times, epilepsy is one of the lethal disorders which is characterized by frequent seizures. In the treatment of epilepsy, the seeds and oil extracts of NS have been used since ancient times. In the tomb of Tutankhamun, it was selected as one of the entombed products as it was believed that it will cure cerebral malaria and epilepsy (Tahan and Bayram 2011; Mathur et al. 2011). The techniques such as maximal electroshock (MES) along with pentylenetetrazole (PTZ) have been used to determine the anticonvulsant activity of the seeds and oil extract of NS. Intraperitoneal insertion of thymoquinone has been found to diminish the duration of seizures (Yaman et al. 2010). Valproate (one of the major constituents among antiepileptic drugs) and oil extracts of NS were simultaneously tested for their ability to suppress the lethal and convulsive effects of PTZ in mice. The suppression activity has been found to be more pronounced in case of oil extract of NS than valproate in inhibiting PTZ-induced seizures (Abu-Zinadah 2009). Various constituents of NS like fixed oil, aqueous oil, and oil extracts have been investigated against MES- and PTZ-induced convulsion. It is observed that except the fixed oils, other constituents were found to be effective against PTZ convulsion (Ali and Meitei 2011).

6 Toxicological Properties

The seeds, extracts, and constituents of NS have been observed to have low toxicity. Intraperitoneal administrations of NS extract (50 mg/kg) to rats have been found to possess less significant effect on the activities of various enzymes (el-Daly 1998). The major constituent thymoquinone is characterized with very high lethal dosage value ranging between 1.52 and 3.77 g/kg (Badary et al. 1998). Supplementation of high dosage of NS extract causes hypoactivity and obstructed breathing. These high dosages declined the concentration of growth-stimulating hormone (GSH) in the liver, kidney, and heart. Due to the declined concentration of GSH in the kidney and liver, plasma metabolites and enzymes increased and caused damages in the organs (Badary et al. 1998). The rats have been treated with the NS fixed oil extracts to determine the toxicity level, and no significant effect was found in the levels of hepatic enzymes. However, the levels of thyroglobulin (TG), cholesterol, and glucose and count of leukocytes and platelets have been decreased. Therefore, the seeds and oil extracts of NS are of immense importance as they possess low level of toxicity (Zaghlol et al. 2012).

7 Concluding Remarks and Future Directions

The ethnobotanical and wide application of natural compounds especially plant derivatives have received great attention in recent years. The use of NS seeds and their constituents has been shown to exert multiple useful effects in the treatment of various ailments. It contains a wide range of pharmaceutical properties including antidiabetic, anticancer, immunomodulatory, gastroprotective, and many more. The seed oil/extracts of NS have been utilized as therapeutic agents since ancient times due to their least toxic effect. *N. sativa* has a great potential for nutraceutical and subject to further investigations.

Babool (*Acacia nilotica*)

Ramesh C. Gupta, Robin B. Doss, Rajiv Lall, Anita Sinha, Ajay Srivastava, and Jitendra K. Malik

Abstract

The importance of *Acacia* plants in animal nutrition and in the prevention and treatment of human and animal diseases has been recognized for centuries. Babool extract, obtained from *Acacia nilotica* (also known as gum Arabica tree), is very rich in secondary metabolites such as tannins, flavonoids, alkaloids, terpenes, fatty acids, etc. These compounds exert antioxidative, anti-inflammatory, anthelmintic, antidiarrheal, antispasmodic, antihypertensive, antibacterial, antifungal, antidiabetic, antiplatelet aggregatory, antiplasmodial, antimutagenic, anticancer, acetylcholinesterase-inhibiting, diuretic, antipyretic, analgesic, and many other effects. This chapter describes various aspects of babool with special emphasis on its nutritional value and applications in prevention and treatment of diseases in animals.

Keywords

Nutraceuticals · Veterinary nutraceuticals · Babool · Animal health

1 Introduction

Babool (*Acacia nilotica*) is a tropical tree, which can be 15–18 m high and 2–3 m in diameter. The tree is native to the Indian and African subcontinents. Other names for babool are babul, booni, babbula, Egyptian thorn, Egyptian acacia, Indian gum arabic, thorn mimosa, thorny acacia, prickly acacia, black piquant, kikar, sant tree, goma arabica, acacia de cayenne, gommier rouge, and many others. *Acacia nilotica* has several synonyms, such as *Acacia arabica* (Lam.) Wild, *Acacia arabica* var. *cupressiformis* J. Stewart, *Acacia arabica* var. Indica Benth., *Acacia arabica* var. *tomentosa* Benth., Acacia *benthamii* Rochebr., *Acacia nilotica* subsp. *adansonii* (Guill. and Perr.) Brenan, *Acacia scorpioides* (L.) W. Wight, *Acacia subalata* Vatke, *Acacia vera* Wild., and many others.

Babool has many chemical compounds, including tannins, flavonoids, alkaloids, terpenes, fatty acids, etc. These compounds exert antioxidative, anti-inflammatory, anthelmintic, antidiarrheal, antispasmodic, antihypertensive, antibacterial, antiviral, antifungal, antidiabetic, antiplatelet aggregatory, antiplasmodial, antimutagenic, anticancer, acetylcholinesterase inhibitory, diuretic, antipyretic, analgesic, and many other biological and pharmacological effects (Rather et al. 2015). Currently, many phytoconstituents of this plant are used as therapeutic drugs, while others are under investigation for novel uses. This chapter describes various aspects of babool, especially its nutritional value and biological and pharmacological effects in the health and diseases of animals.

2 Chemical Constituents in Babool

Babool (*Acacia nilotica*) is of significant nutritional, nutraceutical, and pharmaceutical importance. Abbasian et al. (2015) reported that mature and dry seeds of babool contain potassium, iron, zinc, copper, and manganese (2.1, 203.1, 108.7, 322.7, and 1.09 g/100 g, respectively). The oil, crude protein, and crude fiber contents in the seeds were found to be 4.1, 25.3, and 28.4% (fresh weight basis), respectively.

At least 66 chemical compounds have been identified in various parts of babool (Rather et al. 2015). The main

alkaloids and amines present include dimethyltryptamine, 5-methoxydimethyltryptamine, and N-methyltryptamine. The extract has *D*-pinitol, kaempferol, gallic acid, ellagic acid, (+/−) catechin, (−) epigallocatechin, and rutin. Babool extract has an anti-inflammatory compound, androstene steroid. In addition, the extract has cyclitols, fatty acids (palmitic acid, stearic acid, arachidic acid, oleic acid, linoleic acid, and coronaric acid), seed oils, nonprotein amino acids, terpenes (niloticane, lupenone, and lupeol), saponins, hydrolyzable tannins, flavonoids, and niloticane (Malviya et al. 2011). The extract also contains a total phenolic content ranging from 9.2 to 16.5% (Bushra et al. 2007) and tannins and gallic acid from 24 to 42% (Rahaman 2010). In some studies, tannin content in *A. nilotica* is reported at 18–27%, but in *A. nilotica* subsp. indica, the level could be as high as 50% (Kumari et al. 2014). Babool pods have been found to contain gallic acid, m-digallic acid, (+)-catechin, chlorogenic acid, gallolylated flaven-3, 4-diol robidandiol (7, 3, 4, 5-tetrahydroxyflavan-3,4-diol), kaempferol, umbelliferone, androstene steroid, D-pinitol, carbohydrate, and catechin-5-galloyl ester (Singh et al. 2009a, b; Prathapa Reddy et al. 2018).

The secondary metabolites described in *Acacia nilotica* Delile included naringenin, niloticane, and several galloyl and catechin derivatives isolated from the bark (Khalid et al. 1989; Malan 1991; Eldeen et al. 2010), an androstene steroid from the aerial parts (Chaubal et al. 2003), flavonol glycosides from the seeds (Chauhan et al. 2000), triterpenes botulin and β-amyrin from the roots (Prakash and Garg 1981), arabinobioses from the gum (Chalk et al. 1968), and acanilol A and acanilol B (Ahmadu et al. 2009), together with the known triterpene lupenone, from the stem bark. For further details on chemical constituents in different parts of babool, readers are referred to recent publications (Rana 2018; Prathapa Reddy et al. 2018).

3 Nutritional Value of Babool

In the subcontinents of India and Africa, and other tropical regions, babool (*Acacia nilotica*) is used as an inexpensive source of protein for livestock (Mlambo 2003; Mousa 2011; Paswan et al. 2016). Babool contains about 13% crude protein and about 87% or more organic matter. Bargali and Bargali (2009) found that babool fruit (pods and seeds) contained 12% protein, 2% fat, 15.36% crude fiber, 5.26% ash, 5.45% tannins, 0.26% phosphorus, 0.64% calcium, 0.13% magnesium, 1.28% potassium, 6.43% copper, 28.50 mg/kg zinc, 2650 mg/kg manganese, and 100 mg/kg iron. Recently, Abdullah et al. (2018) evaluated the effect of babool pods on nutrient digestibility, nitrogen balance, and rumen liquor parameters (pH, total protozoa count, protein concentration, and enzyme activity) in rams. The findings revealed that inclusion of babool pods at the rate of 1.5 or 3.0% of the concentrate (equivalent to a tannin concentration of 2.9 and 4.6 g/kg) for 3 weeks significantly improved the total feed intake and the digestibility of crude protein, while the digestibility of dry matter and crude fiber was significantly decreased. Values of nitrogen intake and nitrogen retained were significantly increased by babool supplement. Rams receiving babool showed low protozoa count, protein concentration, and enzymes (α-amylase, cellulase, and protease) in the rumen content, without any change in pH. It was concluded that babool supplement can be used as a natural protein protectant in ruminants by forming tannin-protein complexes in the rumen to maximize the availability of amino acids in the lower digestive tract. The significance of tannins from *A. nilotica* and other acacia plants in the ruminants ration is well documented (Mangan 1988; Scalbert 1991; Mlambo 2003; Mueller 2006). Also, babool pods at the rate of 1.5 or 3.0% can increase the protein digestibility as well as the nitrogen retained in the body. Abbasian et al. (2015) found significant levels of minerals in the seeds of babool. Therefore, babool pods/seeds can be recommended as a dietary supplement of high-protein content and trace and essential minerals to livestock.

4 Pharmacotherapeutic Effects

The leaves, roots, bark, flowers, pods/seeds, branches, and gum extracts of babool have been used in various Ayurvedic, Unani, Chinese, Egyptian, and other traditional medicines for centuries. In general, acacia plants are very rich in bioactive secondary compounds which can be indicated in the promotion of health and prevention and treatment of human and animal ailments. This fact can be substantiated with a few examples, such as triterpenoid and saponins in cancer; glucosides as diuretic and natriuretic; saponins, tannins, and flavonoids in digestive disorders; polyphenols as antioxidants; and tryptamine, tannins, saponins, and organic acids as antiplasmodial (Saini et al. 2008).

Although *A. nilotica* has many medicinal properties, some of them are described here in brief, while others are listed in Table 1.

4.1 Antioxidative and Anti-inflammatory

The extracts from various parts of babool contain many chemical constituents that possess metal chelation, free radical scavenging, and antioxidative properties. Antioxidative activity can be attributed to kaempferol, umbelliferone, and many phenolic compounds present in the babool extracts. In in vitro studies, Singh et al. (2008, 2010) demonstrated that kaempferol and umbelliferone exhibited antioxidative

Table 1 Phytoconstituents in babool (*Acacia nilotica*) and their biological and pharmacological properties

Biological/ pharmacological activity	Bioactive phytoconstituents	References

Metal chelation	Phenolic compounds	Singh et al. (2009a)

activity in a dose-dependent manner. Singh et al. (2009a) also reported free radical scavenging and metal chelation effects of babool's green pod extracts.

Babool pods and seeds are an easily accessible source of natural antioxidants, which can be used as supplement to aid the therapy of free radical-mediated diseases such as cancer, diabetes, inflammation, etc. (Amos et al. 1999; Pareek and Choudhry 2013). In several other studies, it was reported that the extracts of babool have strong free radical scavenging and antioxidative activities, which may be due to hydroxyl groups existing in the phenolic compounds (Kalaivani and Mathew 2010; Sultana et al. 2007; Singh and Arora 2007). Vadivel and Biesalski (2012) also found that the methanolic extract of *A. nilotica* seed materials contain a total free phenolic content of 14.57 ± 1.69 g catechin equivalent/ 100 g extract. The levels of ferric reducing antioxidant power (FRAP, 1840 mmol Fe^{2+}/mg extract), inhibition of β-carotene degradation (53.26%), and radical scavenging activity against DPPH (64.91%) and superoxide (53.23%) radicals were reported (reviewed in Pareek and Choudhry 2013). Some studies also provided evidence that among all extracts, the acetone extract exhibited the highest antioxidative activity, and this was related to total phenolic content (Sundaram and Mitra 2007; Rather et al. 2015).

Phytoconstituents, such as androstene, peltogynoids (acanilol A and acanilol B), and triterpene (lupenone), present in the stem bark of *Acacia nilotica* (L.) Delile are reported to exert anti-inflammatory activity (Ahmadu et al. 2009). Ahmadu et al. (2009) tested acanilol A and acanilol B as kinase inhibitors against CDK1, GSK3, CK1, and DYRK1A and found acanilol B as a DYRK1A inhibitor with an IC_{50} value of 19 μM. Eldeen et al. (2010) demonstrated that cassane diterpene niloticane from the bark extract exhibited COX-1 and COX-2 inhibitory effect with IC_{50} values of 3.6 μM and 189 μM, respectively. Chaubal et al. (2003) attributed anti-inflammatory activity to 3-β-acetoxy-17-β-hydroxyandrost-5-ene present in the aerial parts of babool. In in vivo studies, carrageenan- or formalin-induced paw edema model and cotton pellet-induced granuloma model in rats, *A. nilotica* extract significantly reduced the inflammatory reaction (Dafallah and Al-Mustafa 1996; Sokeng et al. 2013; Safari et al. 2016).

4.2 Antimicrobial

The leaves, flowers, pods/seeds, bark, and root of *A. nilotica* have been extensively studied for their antimicrobial (antibacterial, antiviral, and antifungal) activity. Banso (2009) reported that the stem bark extract of the plant possessed certain bioactive constituents including terpenoids, tannins, saponins, and glycosides. The antimicrobial activity of the extracts was assayed against *Streptococcus viridans*, *Staphylococcus aureus*, *E. coli*, *Bacillus subtilis*, and *Shigella sonnei*. The plant extract exhibited antimicrobial activity against all the test microorganisms. *B. subtilis* was found to be the most susceptible, and *Candida albicans* was the most resistant to the plant extract. The minimum inhibitory concentration of the extract ranged between 35 and 50 mg/ml, while the minimum bactericidal concentration ranged between 35 and 60 mg/ml. Fatima et al. (2012) assessed antibacterial activity of leaf bark and root extracts (aqueous and ethyl acetate) of *A. nilotica* (L.) Del. against *Xanthomonas malvacearum* bacteria and found that ethyl acetate extracts of the root seem to contain greater antibacterial components than the pure antibiotic (streptomycin or tetracycline), with a concentration of 500 μg/ml. Saini et al. (2008) reported that the methanolic extract of *A. nilotica* pods shows antimicrobial activity against *E. coli*, *S. aureus*, and *A. niger*.

Dev et al. (2014) examined antimicrobial activity of aqueous, chloroform, ethanol, and methanol extracts of different parts (stem, leaf, seed) of *A. nilotica* (L.) Del. against *E. coli*, *Agrobacterium tumefaciens*, *Bacillus aureus*, *Candida glabrata*, and *Aspergillus niger*. Only the methanolic extract showed good activity against all bacteria and fungi (except *A. niger*) due to the presence of alkaloids, saponins, flavonoids, tannins, and glycosides in the leaf extract. Rani and Khullar (2004) observed moderate antimicrobial activity of methanol and aqueous extracts of *A. nilotica* toward multidrug-resistant *Salmonella typhi*.

In some studies, antimicrobial activity of *A. nilotica* has been reported against pathogens involved in periodontitis (including *Streptococcus mutans*; Sharma et al. 2014a, b) and otitis (Pai et al. 2010).

Like some other plant products (Vanden Berghe et al. 1986; Vlietinck and Vanden Berghe 1991; Vlietinck et al. 1997), *A. nilotica* extract has been reported to exert antiviral activity against fowl pox, Newcastle disease, and hepatitis C virus (Hussein et al. 2000; Mohamed et al. 2010).

Antimicrobial activity of babool extracts appears to be due to hydrophilic compounds such as polyphenols, polysaccharides, terpenoids, tannins, alkaloids, saponins, glycosides, flavone, and quercetin 3-gallate. The antifungal activity may be attributed to polyphenols and nilobamate (Bhargava et al. 1998; Mbatchou and Oumar 2012; Rai et al. 2014).

A dental chew formulation ACANIL (Vets Plus Inc, Menomonie, WI, USA), which contains babool extract and white curcumin, showed a great effect on reducing halitosis in dogs. In in vitro studies, ACANIL has shown a zone of inhibition on microbial colonies, and the effect was comparable to chlorhexidine (data presented at the 26th American Dental Congress 2017, Philadelphia, PA, USA). In proof of concept clinical studies, ACANIL has been found significantly effective (unpublished).

It is suggested that babool extract can be used as an antimicrobial nutraceutical in humans and animals.

4.3 Antiplasmodials

A good number of plant extracts have been found to possess antiplasmodial activity (Ibrahim et al. 1991; El-Tahir et al. 1999; Alli et al. 2016). El-Tahir et al. (1999) reported that ethyl acetate extract of *A. nilotica*, by having tannins and terpenoids, exerted a very strong inhibitory potential (IC_{50} = 1.5 μg/ml) against *Plasmodium falciparum*. The methanol extract of *A. nilotica* seed exerted high activity with an IC_{50} value of 0.9 μg/ml. The husk also revealed highly potent antiplasmodial activity where the methanol extract and the water extract showed IC_{50} values of 4.9 and 7.5 μg/ml, respectively. Recently, Alli et al. (2016) demonstrated that a particular fraction (F-1 rich in alkaloids and phenolics) of *A. nilotica* root (50 and 100 mg/kg body wt) produced a significant and dose-dependent reduction in *Plasmodium berghei*-infected mice compared to the control and also significantly increased the survival time of the mice compared to the control group. The same fraction also ameliorated malaria-induced anemia by improving PCV in

treated mice. However, this fraction of *A. nilotica* could not reverse the reduced body temperature and weight loss associated with rodent malaria. In several other studies, roots, twigs, and other parts of *A. nilotica* extracts have shown strong antiplasmodial potential (Alli et al. 2011; Bapna et al. 2014). Taking all findings into consideration, *A. nilotica* extract (particularly Fraction-1) appears to be an alternative therapy to conventional drugs which have an issue of drug resistance.

4.4 Anticholinesterase

Eldeen et al. (2005) reported that *A. nilotica* possesses anticholinesterase properties. Krowch and Okello (2009) further demonstrated the activity of *A. nilotica* root in an aqueous extraction (IC_{50} 0.079 mg/ml) to be about tenfold more potent than with leaf (IC_{50} 0.7 and 0.5 mg/ml for ethyl acetate and ethanol extracts, respectively) and bark (IC_{50} 1.3 mg/ml ethyl acetate extraction). Acetylcholinesterase inhibition kinetics revealed a concentration-dependent mixed type inhibition (noncompetitive uncompetitive), similar to that found with galantamine. *A. nilotica* extract was found not to be as strong AChE inhibitor as galantamine. However, by having antioxidative, anti-inflammatory, and acetylcholinesterase (AChE) properties, *A. nilotica* could provide the basis as a novel poly-pharmacological treatment of chronic cognition syndrome in senior dogs and cats.

4.5 Anti-diabetic, Hypoglycemic, and Hypolipidemic

Currently, a variety of herbal treatments are recommended for the management of type 2 diabetes. Karau (2013) reported that the aqueous extract of *A. nilotica* exerts an antidiabetic effect which may be due to the release of insulin from pancreatic β-cells. Babool is known to have a very high content of tannins, and tannic acid stimulates the transport of glucose and inhibits adipocyte differentiation, thereby producing an antidiabetic effect (Liu et al. 2005; Kumari et al. 2014). In alloxan-induced diabetic rabbits, methanol extract of *A. nilotica* pods (400 mg/kg body wt) showed significant reductions in blood glucose, plasma total cholesterol, triglyceride, and low-density lipids. In a similar study conducted on alloxan-induced diabetic rats, methanolic extract of fruits of this plant did not significantly reduce serum glucose but did reduce serum levels of triglycerides and low-density lipoprotein cholesterol (Abuelgassim 2013a, b). However, in the streptozotocin-induced diabetic rat model, methanolic extract of *A. nilotica* pod extract (150 and 300 mg/kg body wt/day for 60 days) lowered blood glucose levels, restored serum urea, and creatinine levels as well as the normal histopathological architecture of the kidney (Omara et al. 2012). Asad et al. (2011) found that *A. nilotica* leaf extract (300 mg/kg body wt) produced hypoglycemic and antiplatelet aggregation effects in streptozotocin-induced diabetic rats.

Pareek and Choudhry (2013) assessed the effect of babool pods powder (2, 3, or 4 g/day) on blood glucose and lipid levels in type 2 diabetic subjects. After 4 weeks of treatment, the patients showed reduced fasting blood glucose (10–19%), postprandial (7–35%), triglyceride (6–18%), LDL (7–10%), total cholesterol (5–11%), VLDL (7–15%), HDL cholesterol (5–10%), and blood pressure (8–13%). Significant changes occurred in the postprandial glucose, triglyceride, VLDL cholesterol, and blood pressure of the subjects receiving 4 g/day dose. In several other studies, babool pod products have been found to exert antidiabetic, hypoglycemic, and hypolipidemic effects (Ahmad et al. 2008; Rahaman 2010; Roozbeh et al. 2017). The observed antihyperglycemic effect of *A. nilotica* extracts in diabetes may be due to multiple mechanisms: (1) increased insulin release from pancreatic β-cells, (2) antioxidative effect, (3) anti-inflammatory effect, and (4) increased glucose transport to tissues from circulation. In conclusion, it can be suggested that a diet supplemented with babool products will produce antidiabetic effects and reduce risk factors associated with cardiovascular and renal diseases.

4.6 Antipyretic and Analgesic

Alli et al. (2014) investigated the effect of an aqueous extract of *A. nilotica* root on pain and fever in rats. These investigators used Brewer's yeast suspension to induce pyrexia and the hot plate, tail immersion, and acetic acid-induced writhing tests as nociceptive models for the analgesic study. In a dose-dependent manner, the extract produced significant reduction in rectal temperature at 200 and 400 mg/kg body wt. At these dose levels, significant analgesic activities were observed in the hot plate, tail immersion, and acetic acid-induced writhing, and the effects were comparable to acetaminophen (150 mg/kg body wt). In a recent study, Safari et al. (2016) demonstrated antinociceptive (not dose-dependent), anti-inflammatory (80.07%), and antipyretic effects (98.89%) of aqueous extract of *A. nilotica* bark (150 mg/kg) in mice. These studies provided scientific support for the use of *A. nilotica* root and bark extracts for fever, inflammation, and pain.

4.7 Antihypertensive and Antispasmodic

Gilani et al. (1999) reported that a methanol extract of babool pods caused a dose-dependent (3–30 mg/kg) fall in arterial

blood pressure, and the observed effect was independent of muscarinic receptor stimulation or adrenoceptor blockage. In the in vitro studies, these investigators found that the plant extract produced a dose-dependent (0.3–3 mg/ml) inhibitory effect on force and rate of spontaneous contractions in guinea pig atria. Similarly, it inhibited the spontaneous contraction of rabbit jejunum in a concentration-dependent (0.1–3 mg/ml) manner. The extract inhibited K^+-induced contractions in rabbit jejunum at a similar concentration range, which suggests that the antispasmodic action of babool is mediated through calcium channel blockage, and this may also be responsible for the antihypertensive effect.

4.8 Antimutagenic and Anticancer

This antihypertensive effect appears to be independent of muscarinic acetylcholine receptor stimulation or adrenoceptor blockade. The same extract is also known to exert antispasmodic activity (Gilani et al. 1999). Lompo-Ouedraogo et al. (2004) demonstrated that an aqueous extract of babool stimulated milk production (59% greater) and prolactin release in female rats. This could consequently be helpful in lactating animals and women. In Africa, babool extract has been used for cough, asthma, diarrhea, dysentery, conjunctivitis, skin diseases, tumors, cancers, and leprosy treatment, and in Egypt for diabetes mellitus treatment.

In a recent study, Umaru et al. (2016) treated rats with babool pod aqueous extract (50, 100, 200, and 400 mg/kg) daily for 21 days and found that the extract had immunostimulatory and anti-hemostatic properties.

Other ethnopharmacological claims include antimicrobial (antibacterial, antifungal, antimalarial), antidiarrheal, antioxidant, antispasmodial, antihypertensive, antidiabetic, antimutagenic, anti-inflammatory, analgesic, antiplatelet, anticancer, and molluscicidal activities (Amos et al. 1999; Rajvaidhya et al. 2015). It has been used as an anthelmintic in ethnoveterinary medicine (Bachaya et al. 2009). A 50% ethanolic extract of the stem bark in a preliminary biological screening exhibited antiprotozoal activity against *Entamoeba histolytica* in dogs and cats.

5 Toxicity and Safety

Al-Mustafa (2000) found a low toxicity potential of babool extract in rats receiving 2% and 8% acacia diet for 2 and 4 weeks. There was no change in serum biomarkers for hepatic and renal functions, fasting glucose, and triglycerides. No histopathological changes in liver sections and no deaths in animals were noted. Alli et al. (2015) reported that the aqueous extract of *Acacia nilotica* root was found to be safe in a single acute dose (50, 300, and 2000 mg/kg body wt) in mice. The estimated oral LD_{50} in mice is 5000 mg/kg. The IP LD_{50} in mice was reported to be 500 mg/kg (Bhakuni et al. 1969). In a 28-day subacute study (125, 250, and 500 mg/kg babool extract) in rats, doses higher than 250 mg/kg body wt appeared to cause hepatotoxicity (Alli et al. 2015). There was no evidence of nephrotoxicity in the subacute toxicity study. These authors suggested NOAEL <250 mg/kg body wt.

6 Concluding Remarks and Future Directions

Babool has been widely used for multipurpose (nutritional, nutraceutical, and pharmacological) in human and animal medicine for centuries. Different parts of babool (bark, root, fruits/pods, leaves, and gum) have different chemical constituents, and accordingly their applications differ in disease conditions. The root portion of the tree is widely used in traditional treatment of diseases because of its wide margin of safety. Antioxidative and anti-inflammatory properties of *A. nilotica* play significant roles in ameliorating various diseases. Based on acute toxicity in mice, aqueous extract of babool root extract is safe up to a dose of 2000 mg/kg; and its NOEL in rats is reported to be <250 mg/kg/day. Repeat exposure at higher doses may cause hepatotoxicity.

Glucosinolates and Organosulfur Compounds

Karyn Bischoff

Abstract

Glucosinolates are compounds commonly found in plants of the Brassicaceae family. Many common edible plants, such as broccoli, cabbage, cauliflower, mustard, and horseradish, are members of the Brassicaceae family, and the strong flavors of these plants correlate with high glucosinolate concentrations. Recent studies have found beneficial effects of glucosinolates, including regulatory functions in inflammation, stress response, phase I metabolism, antioxidant activities, and direct antimicrobial properties. Future studies will no doubt find more benefits of these chemicals. However, feeding rations high in brassicae to livestock is likely to have adverse effects, some life-threatening, and may add unwanted flavors to animal products. The high sulfur content of many brassicas can cause trace mineral deficiencies and polioencephalomalacia. Therefore, while Brassicaceae-derived feeds can be a good source of nutrition, it's best to avoid overusing them.

Keywords

Glucosinolates · Brassica · Canola · Rapeseed · Erucic acid · Broccoli · Cabbage · Cauliflower · Mustard

1 Introduction

The first known glucosinolate was isolated in 1831 (Dinkova-Kostova and Kostov 2012). Glucosinolates and other organosulfur compounds are found in the Brassica family of plants, which includes the cruciferous vegetables: cabbage, broccoli, cauliflower, kale, mustards, etc. The Brassicaceae family also includes the important oil seed crop canola or rapeseed, *Brassica napus* (Burel et al. 2000). Many brassicas are late-season crops; thus they remain palatable after other plants have died (Burrows and Tyrl 2013). Glucosinolates are present in all species in the Brassicaceae family. Different species can typically produce up to at least 40 glucosinolates (Halkier and Gershenzon 2006). Concentrations of glucosinolates and related chemicals are dependent on portion of the plant (leaves, flowers, roots, stems, seeds, etc.), species and variety of plant, season, and environmental conditions. Hot, dry conditions are likely to increase plant glucosinolate concentrations (Tripathi and Mishra 2007). Glucosinolate concentrations in foliage can range from 1000 ppm to at least 3000 ppm, depending on the species. Concentrations in roots and seeds are often higher, up to 60,000 ppm in mustard seed (*B. nigra*). Glucosinolate metabolites, other sulfur-containing compounds, and erucic acid in *Brassica* are the defensive chemicals of plants (Cavaiuolo and Ferrante 2014; Vig et al. 2009). Consequently, these chemicals are bioactive and can have beneficial and harmful effects in people and domestic animals (Bischoff 2016).

Structurally, glucosinolates consist of a β-D-glycopyranose with a sulfonated oxime and an R-group (Tripathi and Mishra 2007; Dinkova-Kostova and Kostov 2012; Vig et al. 2009). The R-group is an amino acid (Collett et al. 2014). While the glucosinolates themselves are minimally biologically active, their metabolites are bioactive (Tripathi and Mishra 2007; Vig et al. 2009). Indole glucosinolates are metabolized to isothiocyanates, which are associated with bitter flavors (Halkier and Gershenzon 2006). The bitter flavors can decrease palatability when *Brassica* spp. are used in livestock feed, which can be associated with decreased gain (Woyengo et al. 2014). Additionally, dietary glucosinolates have been associated with off-flavors in milk and eggs (Bell 1984; Burrows and Tyrl 2013; Tripathi and Mishra 2007). Other glucosinolates disrupt iodine metabolism and thyroid function or have hepatotoxic or nephrotoxic effects (Tripathi and Mishra 2007).

Forage and by-products of the oil seed industries are the most common sources of glucosinolates in livestock diets

(Tripathi and Mishra 2007). Oil seed meals, such as canola, are a good source of protein, but the glucosinolate concentrations limit the amount that can be added to livestock diets. Pennycress is a common weed in North America that originated from Europe and Asia. Because it is about 36% oil, it has potential for use in biodiesel production, and high protein oil meals and cakes from pennycress have been proposed for use in animal feeds (Alhotan et al. 2017).

Varieties of oilseeds were bred to decrease glucosinolate concentrations. Low and very low glucosinolate varieties of canola (known as double-zero or double-low) produce a meal that can have less than a quarter of the glucosinolate concentrations seen in older varieties (Flachowsky et al. 2014; Tripathi and Mishra 2007; Olukosi et al. 2017). Additionally, higher protein, lower fiber canola meals have been developed to make them more suitable for animal feeds (Pedersen et al. 2016). Oil seed cakes have the advantage of higher residual oil than meals, making them suitable feed for some livestock species (Drażbo et al. 2018). Glucosinolate concentrations in oil seed meals vary based on extraction processes (Tripathi and Mishra 2007). Heat treatment decreases glucosinolate in seed meals, and wet heat and pressure decrease glucosinolate concentrations more than dry heating. Heat treatment also reduced the activity of plant myrosinase, the enzyme that metabolizes glucosinolates to more bioactive products (Alhotan et al. 2017). Storage conditions can also affect glucosinolate concentrations in cakes and meals, which can increase in the short-term but decrease in the long-term (Cavaiuolo and Ferrante 2014). Fermentation is documented to decrease glucosinolate concentrations in conventional canola meal and cake used for animal feed (Shi et al. 2015; Drażbo et al. 2018). Fermentation for 10 days can decrease glucosinolate concentrations by more than 40%, and fermentation for 30 days decreases glucosinolate concentrations tenfold in *Brassica napus* (Burrows and Tyrl 2013; Drażbo et al. 2018). This is most likely due to the utilization of sulfur groups in glucosinolates by microbial enzymes (Tripathi and Mishra 2007; Drażbo et al. 2018). Fermentation also increases the protein availability and promotes vitamin and antioxidant production (Drażbo et al. 2018).

2 Metabolism of Glucosinolates

Glucosinolates are bound to a sugar moiety and thus are glycosides. While glucosinolates in and of themselves are minimally biologically active, the aglycone metabolites (metabolites with the sugar removed) are unstable and often do have biological properties. The parent compounds are stored within cell vacuoles in the plant (Cavaiuolo and Ferrante 2014). Idioblasts, structures within plant cells, contain the enzyme myrosinase (Burel et al. 2000; Cavaiuolo and Ferrante 2014; Collett et al. 2014; Halkier and Gershenzon 2006; Vig et al. 2009). Damage to the cell releases the myrosinase which, at a neutral pH, causes hydrolysis of glucosinolates (Cavaiuolo and Ferrante 2014; Ahlin et al. 1994). This system has an important role in plant defense against fungi, bacteria, and insect pests and also prevents spoilage of harvested plants (Vig et al. 2009). Glucosinolate metabolism by plant myrosinase can occur in the rumen of ruminants and the intestinal tract of birds and other monogastric animals (Burrows and Tyrl 2013; Pekel et al. 2015; Tripathi and Mishra 2007). Additionally, common organisms of the gastrointestinal microflora can produce their own myrosinase (Tripathi and Mishra 2007; Kiebooms et al. 2014; Velayudhan et al. 2017). Consequently, antibiotic treatment in humans has been reported to decrease metabolism of glucosinolates (Dinkova-Kostova and Kostov 2012). Metabolites of glucosinolates include isothiocyanates, thiocyanates, nitriles, sulfates, and goitrins (Burel et al. 2000; Cavaiuolo and Ferrante 2014; Burrows and Tyrl 2013; Wight et al. 1987).

Glucosinolates and their metabolites are not known to accumulate in animal tissue, but can be found in milk and eggs, where they produce off-flavors (Bell 1984; Burrows and Tyrl 2013).

3 Important Glucosinolates

A few examples of relatively well-characterized glucosinolates are listed below. Metabolites of these include reactive isothiocyanates or mustard oils, which impart the pungent mustard or garlic-like odors associated with mustard and horseradish, and also include thiocyanates, nitriles, sulfates, and goitrins (Burrows and Tyrl 2013).

- *Glucobrassicin* (3-indolylmethyl glucosinolate), found throughout the Brassicaceae family, is hydrolyzed to an isothiocyanate. One metabolite is indole-3-carbinol, which inhibits nuclear factor κβ (Wagner et al. 2013).
- *Glucoraphanin* (4-methylsulfinylbutyl glucosinolate), found in broccoli and other vegetables, is hydrolyzed to an isothiocyanate, specifically sulforaphane (4-methylsulfonylbutyl isothiocyanate), which has tumor preventive and other properties. Sulforaphane blocks the cell cycle and promotes apoptosis (Halkier and Gershenzon 2006; Fimognari et al. 2012). Sulforaphane also induces mammalian cytoprotective proteins through the Keap1-NrF2-ARE pathway (Dinkova-Kostova and Kostov 2012).
- *Progoitrin*, found in rapeseed and a number of vegetables, is hydrolyzed to thiocyanate and goitrin (L-5-vinyl-2-thioöxazolidine), which is named for its antithyroid effects. Long-term ingestion is associated with goiter

formation. Thiocyanate inhibits sodium-iodide symporter, the transport molecule responsible for iodine uptake by the thyroid, mammary gland, and some other tissues (Flachowsky et al. 2014). Goitrin blocks tyrosine iodination and inhibits T4 formation (Burrows and Tyrl 2013).

- *Sinigrin* (prop-3-enyl glucosinolates), found in a number of vegetables and seeds, is hydrolyzed to allyl isothiocyanate, which is believed to inhibit expression of microRNA and activate the transcription factor Nrf2 (Fimognari et al. 2012; Wagner et al. 2013; Alhotan et al. 2017).

4 Effects of Glucosinolates

Glucosinolates are metabolized to isothiocyanates and related compounds. The effects of these metabolites are through interactions with cellular proteins, such as those involved in intracellular signaling (Fimognari et al. 2012). These biologically active compounds have a variety of known beneficial and detrimental effects.

Benefits Metabolites of glucosinolates protect the plant itself and prevent spoilage of harvested plants. They can have a variety of beneficial biological activities in humans and other animals (Vig et al. 2009).

Anti-inflammatory and immunomodulatory effects of glucosinolates have been reported. Isothiocyanates are able to inhibit cyclooxygenase-2, preventing inflammatory prostaglandin production (Fimognari et al. 2012). Isothiocyanates can downregulate vascular endothelial growth factor (VEGF), and sulforaphane can inhibit endothelial cell response to VEGF. These compounds can also downregulate proinflammatory cytokines such as interleukin (IL)-1β, IL6, granulocyte-macrophage colony-stimulating factor, tumor necrosis factor α, and macrophage migratory inhibitory factor (Dinkova-Kostova and Kostov 2012; Fimognari et al. 2012). Certain isothiocyanates are known to inhibit activity of the transcription regulator NF-κB, which is involved in stress response and inflammation (Wagner et al. 2013). Some activate nuclear factor (erythroid-derived 2)-like 2 factor (NFE2L2), which promotes synthesis of the regulatory protein Nrf2, important in phase II microsomal metabolism (Wagner et al. 2013; Cavaiuolo and Ferrante 2014; Vig et al. 2009).

Glucosinolates and isothiocyanates are considered indirect antioxidants (Vig et al. 2009). They can inhibit phase I metabolic (cytochrome P450) enzymes, which act on xenobiotics and endogenous compounds and generate reactive molecules. Sulforaphane and other isothiocyanates induce phase II metabolic enzymes, which deactivate the products of phase I metabolism and promote excretion, by increasing transcription of the antioxidant response element (ARE) sequence in the genome (Vig et al. 2009). Sulforaphane also induces other antioxidant enzymes via the Nrf-w pathway, including catalase, superoxide dismutase, glutathione peroxidase, glutathione reductase, glutathione *S*-transferase, and glutathione (Dinkova-Kostova and Kostov 2012; Fimognari et al. 2012). Sulforaphane also inhibited production of matrix metalloproteinases and increased antioxidant activity associated with osteoarthritis in vitro (Fimognari et al. 2012).

Antioxidant activities and phase II enzyme are one mechanism responsible for the anticarcinogenicity of glucosinolates and their metabolites (Vig et al. 2009). Isothiocyanates have been protective against carcinogenesis in rodent models, and protection was not organ specific (Dinkova-Kostova and Kostov 2012). There is a decreased risk of bladder cancer related to increased intake of raw cruciferous vegetables in humans (Dinkova-Kostova and Kostov 2012). There is also evidence that dietary cruciferous vegetables are protective against lung, colorectal, breast, prostate, and pancreatic cancer (Fimognari et al. 2012). Isothiocyanate inhibition of phase I enzymes prevents activation of procarcinogens (Dinkova-Kostova and Kostov 2012; Fimognari et al. 2012). Intake of glycoraphanin was associated with enhanced excretion of glutathione conjugates of aflatoxin and certain airborne pollutants in people (Dinkova-Kostova and Kostov 2012). Isothiocyanates are also reported to induce apoptosis in cancer cells, possibly through covalent binding to structural proteins leading to cell cycle arrest (Dinkova-Kostova and Kostov 2012; Fimognari et al. 2012). Epigenetic effects of isothiocyanates include inhibition of histone deacetylase, inhibition of DNA methylation, and inhibition of microRNA expression (Dinkova-Kostova and Kostov 2012; Wagner et al. 2013).

Isothiocyanates have direct antimicrobial effects (Cavaiuolo and Ferrante 2014). The antifungal function of isothiocyanates appears to be due to uncoupling of oxidative photophosphorylation in fungal mitochondria (Vig et al. 2009).

Isothiocyanates have antibacterial activity, though gram-negative bacteria are less susceptible than gram-positives (Vig et al. 2009). Borges et al. (2015) postulated that antibacterial effects are due to interactions with bacterial cell membrane molecules, leading to changes in membrane potential and hydrophobicity, and eventually to membrane disruption. A metabolite of sinigrin, 2-propenyl(allyl) isothiocyanate, has some antimicrobial activity in vitro against *E. coli* 0157:H7. Both benzyl isothiocyanate, a metabolite of glucotropaeolin (benzylglucosinolate), and 2-phenylethylisothiocyanate, a metabolite of gluconasturtiin (2-pheylethylglucosinoate), are effective, in vitro, against gram-positive and gram-negative bacteria at low concentrations. However the combination of 2-propenyl (allyl)isothiocyanate, benzyl isothiocyanate, and phenylethyl isothiocyanate is more effective than any one of the

isothiocyanates alone (Saavedra et al. 2012). Saavedra et al. (2012) also found that some of the metabolites of glucobrassicin, including indole-3-carbinol and indole-3-acetonitrile, had in vitro antimicrobial activity against gram-negative organisms, and ascorbigen had activity against gram-positive organisms, but only at high concentrations.

Sulforaphane has in vitro bacteriostatic and bacteriocidal activity against *Helicobacter pylori* (Dinkova-Kostova and Kostov 2012; Vig et al. 2009). In patients with chronic obstructive pulmonary disease and in animal models, sulforaphane enhanced resistance to pulmonary bacterial pathogens (Fimognari et al. 2012). Glucosinolates have been implicated in improvements in intestinal microflora in birds, as well as improved antioxidant status (Drażbo et al. 2018).

Isothiocyanates and nitriles are toxic to insects and some other invertebrates, which offer protection to growing plants. Proposed insecticide and anti-nematode mechanisms include uncoupling oxidative phosphorylation, binding to thiol groups, and alkylating DNA (Vig et al. 2009). Nitriles can act as insect growth regulators (Vig et al. 2009). Work in Atlantic salmon determined that sea lice infestations could be reduced by about 25% when fish fed diets containing an unspecified glucosinolate-containing plant from the Brassicaceae family (Holm et al. 2016). Possible causes of decreased parasite burden include direct toxic effects of glucosinolates on invertebrates, modulation of host immunity, and changes in the host's skin mucus, making it less attractive or less nutritious to the lice.

Glucosinolates have recently been investigated for their antimicrobial properties due to the increased concern about antibiotic resistance in zoonotic and food-borne pathogens, and some glucosinolate metabolites do have antimicrobial properties. Unfortunately, their cytotoxicity could preclude their use as antimicrobials in vivo (Borges et al. 2015). Isothiocyanate metabolites can react with sulfhydryl groups, for example, from glutathione, to produce dithiocarbamates, which promote oxidation (Nobel et al. 1997). These metabolites can react with sulfhydryl groups on proteins, leading to enzyme inhibition and cell death (Saavedra et al. 2012). Metabolites can react with amino acids to form reactive thiocyanate radicals (Borges et al. 2015). Borges et al. (2015) postulated that antibacterial effects are due to interactions with bacterial cell membrane molecules, leading to changes in membrane potential and hydrophobicity, and eventually to membrane disruption.

A metabolite of sinigrin, 2-propenyl(allyl)isothiocyanate, has some antimicrobial activity in vitro against *E. coli* 0157: H7. Both benzylisothiocyanate, a metabolite of glucotropaeolin (benzylglucosinolate), and 2-phenylethylisothiocyanate, a metabolite of gluconasturtiin (2-pheylethylglucosinoate) are effective, in vitro, against gram positive and gram negative bacteria at low concentrations. However the combination of 2-propenyl(allyl)isothiocyanate, benzylisothiocyanate, and phenylethylisothiocyanate is more effective than any one of the isothiocyanates alone (Saavedra et al. 2012). Saavedra et al. (2012) also found that some of the metabolites of glucobrassicin, including indol-3-carbinol and indole-3-acetonitrile, had in vitro antimicrobial activity against gram negative organisms, and ascorbigen had activity against gram positive organisms, but only at high concentrations.

Recent work suggests that, when used as livestock forage, lambs fed canola had faster growth rates compared to sheep on ryegrass, produced less methane, and their fecal and urinary waste produced less nitrogen dioxide pollution (Luo et al. 2014; Sun et al. 2015). Methane and nitrogen dioxide are important greenhouse gases, and ruminants are a significant contributor to total anthropogenic greenhouse gas production (Sun et al. 2015; Durge et al. 2016). The reduced methane production could be due to the rapid fermentation and increased digestibility of *Brassica* spp.-based feed concentrates, increased rumen pH, and consequent shift in microflora to propionate-forming bacteria, in lambs fed canola forage (Sun et al. 2015; Durge et al. 2016).

Adverse Effects Unfortunately, feeding an excess of *Brassica* vegetables and seed products is associated with toxic effects. Glucosinolates stimulate appetite at low concentrations and enhance the palatability of some foods, such as horseradish, mustard, and black pepper, to people (Burrows and Tyrl 2013). However, glucosinolates have also been associated with reduced palatability and feed consumption in livestock and, consequently, decreased growth rate and reproductive performance. Additionally, endocrine effects of glucosinolates are well known, and nitriles from *Brassica* can cause hepatic and renal dysfunctions (Tripathi and Mishra 2007; Pearson et al. 1983). Increasing dietary iodine and copper can decrease some of the adverse effects of dietary glucosinolates.

As potent electrophiles, isothiocyanates can be genotoxic (Fimognari et al. 2012). Bacterial assays with crude extracts of cruciferous vegetables have found genotoxic effects caused by glucosinolates (Fimognari et al. 2012).

Thyroid enlargement can occur with prolonged exposure to goitrin specifically, but thiocyanates can form thioureas with amino acids which affect thyroid uptake of iodide (Saavedra et al. 2012). Antithyroid effects of glucosinolates can result in goiter, but subclinical effects can include poor reproductive performance and decreased growth (Taljaard 1993). Rodent studies found fetal deaths associated with fetal thyroid follicular epithelial hypertrophy with decreased colloid present (Burrows and Tyrl 2013). Hypothyroidism was also reported in fish (Burel et al. 2000).

Brassicaceae overfeeding in livestock is commonly associated with Heinz body anemia, though the mechanism is slightly different between horses and ruminants. Glucosinolates directly cause Heinz body formation in horses, but the adapted rumen microflora is better able to degrade glucosinolates, decreasing ruminant susceptibility to direct Heinz body hemolysis (Burrows and Tyrl 2013; Cox-Ganser et al. 1994). However, dimethyl sulfoxides produced in the rumen by metabolism of Brassicaceae can also cause Heinz body formation and hemolysis (Taljaard 1993). Poultry are also susceptible to anemia caused by Brassicaceae in the diet (Woyengo et al. 2011).

Nitriles are hepatotoxic and have been associated with lesions including megalocytosis, hepatocyte necrosis, bile duct hyperplasia, and fibrosis (Collett et al. 2014). Serum chemistry in affected livestock will be consistent hepatocellular damage and bile stasis. Hepatic congestion and hemorrhage were reported in laying hens fed rapeseed meal (Wight et al. 1987). The hemorrhage most likely causes pressure necrosis of hepatic parenchyma (Martland et al. 1984). Megalocytosis has been reported in the kidneys (Collett et al. 2014).

The high concentration of sulfur in kale and other brassicas inhibits uptake of copper and selenium and causes deficiency in these trace minerals (Taljaard 1993). Excessive sulfur in ruminants is reported as a cause of polioencephalomalacia (Burrows and Tyrl 2013; Taljaard 1993).

Erucic acid is a monounsaturated fatty acid present in rapeseed, mustards (*B. napus*, *B. campestris*, *B. juncea*, *B. sarson*) and some related plants. Erucic acid is reported to cause cardiac injury in cattle and, experimentally, in rodents (Burrows and Tyrl 2013). Canola oil contains less than 5% erucic acid, but canola meal can contain high concentrations depending on the extraction method used in production (Burrows and Tyrl 2013; Woyengo et al. 2011).

Some other species-specific effects of *Brassica* spp. in the ration are noted below.

- *Swine*: Pigs are considered to be highly sensitive to dietary glucosinolates, and younger pigs are more susceptible than older swine (Tripathi and Mishra 2007). Glucosinolates in swine diets reduce gain in weanling pigs due to reduced palatability and thyroid effects (Woyengo et al. 2014). Currently, it is recommended that total glucosinolate concentrations in swine diets be below 2 μmol/g, dry matter (Kim et al. 2017; Tripathi and Mishra 2007). Higher dietary glucosinolate concentrations have sometimes been associated with thyroid hypertrophy due to reduced ability to uptake iodine (Pedersen et al. 2016). It is recommended that iodine be supplemented at a rate of 1000 μg/kg when using glucosinolate-containing feeds in the ration (Tripathi and Mishra 2007). Anemia and hepatic and renal damage have also been reported in swine fed glucosinolates (Velayudhan et al. 2017).
  It was discovered in Europe that thiouracil, a drug forbidden in meat-producing animals due to possible carcinogenic and teratogenic effects and increasing the water content of edible tissues, was detected in livestock fed canola or cabbage (Kiebooms et al. 2014). Thiouracil is produced from certain glycosinolates by the mature intestinal flora and occurs more commonly in older sows than in feeder pigs (Kiebooms et al. 2014).
- *Poultry*: Laying hens and turkeys are more susceptible to the adverse effects of *Brassica* spp. in the diet than broilers, and clinical effects included decreased growth and egg production and increased mortality (Tripathi and Mishra 2007). Decreased growth and reduced egg production are due to decreased feed intake and antinutritive factors including glucosinolates (Woyengo et al. 2011; Martland et al. 1984; Wight et al. 1987; Olukosi et al. 2017). Reduced growth in birds fed a diet containing 30% canola meal was more remarkable in chicks less than 3 weeks old compared to older broilers and was attributed to lack of thyroid development in young birds (Mushtaq et al. 2007). Pennycress cake containing 59 to 68 μmol/g sinigrin and 1.62–1.73% erucic acid caused reduced growth in chicks when fed at a rate of 5% to chicks less than 10 days of age or 8.5% of the diet for older chicks (Alhotan et al. 2017). There is some decrease in growth reported at feed glucosinolate concentrations greater than 2 μmol/g, and severe depression in growth is reported at dietary glucosinolate concentrations of 8 μmol/g and greater (Tripathi and Mishra 2007). Thyroid hypertrophy due to glucosinolates has been reported in poultry (Martland et al. 1984; Wight et al. 1987). When turkeys were fed conventional canola cake at 15% of the diet, those fed an unfermented cake had lower T4 concentrations than those fed a fermented cake (Drażbo et al. 2018). Hepatic enlargement has also been reported in broilers fed diets with high glucosinolate concentrations (Velayudhan et al. 2017). It is recommended that poultry feed contain less than 2.5 μmol glucosinolates per gram (Mushtaq et al. 2007; Pekel et al. 2015; Drażbo et al. 2018).
  Conventional canola meal was fed to ducks at a little more than 6% of the diet without adverse effects, but high glucosinolate products (7.57 μmol glucosinolates/g diet) had adverse effects on growth at lower concentrations (Qin et al. 2017). Adverse effects reported in ducks fed higher glucosinolate concentrations in the diet included decreased growth, impairment of feather growth, increased thyroid weight, and evidence of hepatic protein synthesis (Qin et al. 2017).
- *Horses*: Allyl isothiocyanates are direct gastrointestinal tract irritants, causing potentially lethal colic in horses

(Taljaard 1993; Mason and Lucas 1983; Woyengo et al. 2011).

- *Ruminants*: Ruminants are less sensitive to glucosinolates than other species due to ruminal digestion (Tripathi and Mishra 2007). Young animals are more sensitive than mature animals. Long-term use of glucosinolate-containing feeds, however, has been associated with goiter, decreased plasma thyroxin, poor reproductive performance in both cows and bulls, and decreased milk production in dairy cows (Tripathi and Mishra 2007). Goitrogen and thiocyanates from glucosinolates can also reduce milk iodine concentrations in dairy cattle through decreased iodide uptake by the mammary gland (Flachowsky et al. 2014). Conventional canola meal in dairy rations decreased the milk iodine concentration by half to three quarters, and this decrease was not prevented by adding more iodine to the diet. Glucosinolates in diets of dairy cattle also produced off-flavored milk (Tripathi and Mishra 2007). Though carcass quality is unaffected in ruminants fed glucosinolates, off-flavors have been reported in lambs fed canola meal (Tripathi and Mishra 2007).

  Severe irritant effects due to high dietary glucosinolates have been reported and can include sloughing of the ruminal epithelium. Symptomatic treatment, including pain control and a clean diet containing no *Brassica*, is the treatment for sever acute gastrointestinal signs (Burrows and Tyrl 2013).

  Interestingly, thiouracil, an illegal contaminant of animal products, was detected in cattle fed *Brassica* spp. Similar to swine, gastrointestinal microflora in cattle produced a myrosinase-like enzyme that leads to the formation of thiouracil from glucosinolates (Kiebooms et al. 2014).

  Ruminants can tolerate up to 4.22 μmol glucosinolates per gram of diet, though lambs fed glucosinolates at this rate developed evidence of iodine deficiency (Tripathi and Mishra 2007). Iodine supplementation can increase glucosinolate tolerance.
- *Rabbits*: Rabbits fed mustard meal had decreased feed intake and growth, and liver hypertrophy. Rabbits could tolerate less than 8 μmol glucosinolates per gram of feed, but feed concentrations above 17.6 μmol/g were associated with increased mortality (Tripathi and Mishra 2007). Decreased hematocrit was also reported in rabbits fed high glucosinolate diets (Velayudhan et al. 2017).
- *Fish*: Low dietary concentrations of glucosinolates were associated with reduced growth and thyroid lesions in rainbow trout, and the recommended maximum glucosinolate concentration in feed for fish is 1.4 μmol/g, which can still be associated with goiter (Tripathi and Mishra 2007).

5 Concluding Remarks and Future Directions

As more research is being conducted on the myriad of bioactive compounds in plants from the Brassicaceae family, more potential benefits are found. However, these compounds can also have adverse effects and lead to food taint when used in livestock rations. Interactions between glucosinolates and other plant compounds and biological processes in domestic animals are extremely complex and difficult to predict; thus more research is needed to determine the most beneficial ways to use glucosinolate-containing feeds in livestock diets to promote health and minimize risk.

Cannabis in Veterinary Medicine: Cannabinoid Therapies for Animals

Joshua A. Hartsel, Kyle Boyar, Andrew Pham, Robert J. Silver, and Alexandros Makriyannis

Abstract

The use of cannabis for animal species is an area of growing interest, largely due to the therapeutic benefits being observed for humans and animals in the era of cannabis legalization. The close relationship humans have with their pets and other veterinary species has led to a renewed interest in the possibility and promise of cannabis to treat similar health issues in the animal community. This chapter explores the literature available on cannabis, its interactions with the endocannabinoid system, and how animal species interact with various formulations and cannabis treatments. A brief overview of the biology, chemistry, and history of cannabis is discussed with the relevance to veterinary species in mind. The pharmacologically active components are discussed with both anecdotal and objective, evidence-based, and clinical data.

1 Introduction

The endocannabinoid system (ECS) has been identified in nearly all animals, from complex mammals like primates to phylogenetically primitive animals such as the cnidarians. The near universal presence and early emergence of the ECS, evolutionarily, is a strong indicator of its biological importance. Cannabinoid receptors are expressed in most animals, including vertebrates (mammals, birds, reptiles, and fish) and invertebrates (sea urchins, leeches, mussels, nematodes, and others). The most primitive animal an ECS has been observed in is the *Hydra* (*H. vulgaris*), a cnidarian in the class Hydrozoa, which is the first animal to develop a neural network. De Petrocellis et al. (1999) determined the major function of the ECS in the *Hydra* is to control the feeding response. It is evident from this data that all veterinary species contain an ECS. Therefore, an understanding of the ECS in these species is critical to the development of clinical applications for endocannabinoids and the phytocannabinoids derived primarily from *Cannabis sativa* L.

Clinical trials detailing the benefits and safety of phytocannabinoids in companion animals are finally being performed at academic institutions, after years of suppression of research due to the controversial status of cannabis. Public and commercial interest in this exciting and newly emerging therapy for animals has resulted in a number of studies and clinical trials being published or nearing publication. This chapter reports the findings of these studies that either have already been published, are in press, or are in their earlier stages; this chapter will provide personal communications with the principal investigators reporting on the results to date of their ongoing studies.

A thorough review of the literature reveals no published clinical trials prior to the studies reported in this chapter involving phytocannabinoids in dogs, cats, or horses. There are, however, quite a few studies in a laboratory setting using laboratory species to study the effects of phytocannabinoids, or to measure aspects of the ECS in a specific species.

R. C. Gupta et al. (eds.), *Nutraceuticals in Veterinary Medicine*, https://doi.org/10.1007/978-3-030-04624-8_10

In spite of the paucity of published controlled studies in veterinary species, animal caregivers have been using cannabis for their dogs, cats, and horses since before the legalization of medical marijuana in 1996 and likely much earlier. Observed benefits from the use of cannabis include the reduction of anxiety; relief of pain; improvement of mobility in animals with osteoarthritis; reduction in tumor size; improved appetite; improved control of type 2 diabetes, inflammatory conditions, and digestive issues; and improved control of epileptic seizures. These benefits have not been universal, and successful treatments are based on dosages relative to the type of condition, severity of condition, size and metabolism, and factors related to biochemical diversity and density and distribution of the ECS among members of the same species.

Veterinarians, veterinary researchers, and animal caregivers are all eager to adopt cannabis-based therapies and have been looking for the evidence to support the safe and effective use of cannabinoid therapies for their pets or their patients. We will focus on providing that data in this chapter.

2 *Cannabis sativa* L.: Food, Herbal Medicine, Pharmaceutical, and Nutraceutical

Many of the constituents of *Cannabis sativa* can be classified as either a pharmaceutical ingredient, a nutrient, a nutraceutical, or an herbal product. Nutraceutical is a term that was created in 1989 by DeFelice by joining the two words, "nutrition" and "pharmaceutical" (Kalra 2003). It has no legal definition but refers to those compounds that are neither nutrients nor pharmaceuticals. The North American Veterinary Nutraceutical Council in 1996 defined a veterinary nutraceutical as a "[non-drug] substance which is produced in a purified or extracted form and administered orally to a patient to provide agents required for normal body structure and function and administered with the intent of improving the health and well-being of animals (Booth 2009)."

2.1 Regulatory and Legal Considerations

The Center for Veterinary Medicine of the Food and Drug Administration (FDA-CVM) states that the Dietary Supplement Health and Education Act (1994), which regulates dietary supplements for humans, does not pertain to animals. This means that legally there are only two choices for regulating products which are similar to human dietary supplements under the law; based on the intended use and contents, products are either regulated as animal food or animal drugs. There is no other choice. The marketing of these animal food/feeds or animal remedy products may also occur on a state-by-state basis and as such may be subjected to regulatory approval by local State Feed Control Officials (FCOs).

The Association of American Feed Control Officials (AAFCO) has no regulatory powers, but it provides guidelines for individual states regarding animal nutrition products. Their guidelines are followed in most states although interpretations, especially of allowable claims, vary from state to state and individual to individual. If a nutritional product contains ingredients that are not approved as food ingredients by the FDA-CVM, or the claims are violative, the local State FCO can recommend a product not be sold or actually issue a stop sale notice or confiscation of the product from the supplier and retail outlets.

In 2000, Iowa FCOs began to pull nutritional products that contained unapproved ingredients from the shelves of veterinary offices because they did not have FDA-CVM approval. At that time a trade group was formed, the National Animal Supplement Council (www.NASC.cc) to work with the regulators at both the state and federal levels to develop workable guidelines for suppliers to follow that would satisfy the regulators' concerns about these products that were commonly referred to as nutraceuticals.

As a result of NASC's efforts, both products for health purposes are referred to as "dosage-form animal health products" and may be marketed under enforcement discretion provided companies act responsibly. The guidelines for company responsible behavior include but are not limited to labeling products properly; making claims that are not in violation of Sect. 201(g)(1)(b) of the Federal Food, Drug, and Cosmetic Act (FFDCA); following Good Manufacturing Practice Standards and implementing effective risk monitoring/management systems; ensuring product safety; and protecting both the health of animals and people which are always the most important consideration for any regulatory official (Fig. 1).

The FDA-CVM developed confidence in the work of the NASC when this trade group established a website for

Fig. 1 *NASC is an organization that* regulates the quality of animal-based nutritional supplements

veterinary nutraceutical adverse event reporting. This database, NAERS™, now contains risk management data, product labels, and statistical analysis on hundreds of nutraceutical and nutritional products and ingredients. NAERS contains many millions of recorded administrations and can accurately give the percent and type of adverse events recorded for a given material over this large number of animal administrations. The NASC Adverse Event Reporting System (NAERS™) is currently the most advanced data base in the world for dosage-form products for dogs, cats, and horses.

The NASC started with 18 members in 2001 and as of 2018 now has well over 175 members. Member companies must comply with cGMP standards, follow label template guidelines, and not make medical claims, but can use structure and function statements in their marketing materials and labels. Members must undergo regular audits by a third party that include random testing of their products to verify they meet label claims. Member companies who pass the audit are allowed to display the NASC seal on their bottles, or other marketing materials, which, for the consumer, has become a sign of quality, and many pet owners will select only those products that display this seal.

The FDA-CVM tightly regulates what ingredients are approved for animal feed. Hemp is currently not an approved ingredient for animal feed according to the FDA-CVM and the AAFCO (Association of American Feed Control Officials; www.AAFCO.org). Additionally, according to the FDA, in order for a material to be considered a supplement (for humans) versus a pharmaceutical, it needs to have been in use as a supplement prior to October 1994 when DSHEA was passed, or the company must file an NDI (New Dietary Ingredient) application. Currently, the FDA claims that there was no recognized use of hemp as a nutraceutical before GW Pharmaceuticals filed their IND for Epidiolex, their recently FDA-approved, CBD-containing drug to treat resistant pediatric epilepsy due to Dravet's syndrome. The limits surrounding this issue are currently being evaluated and will likely be argued in court.

The Drug Enforcement Agency has persisted in its controlled substance classification of the non-THC resins found in the cannabis plant, whether it's from the state-legal medical cannabis with high THC (aka: marijuana) or the federally legal low THC (aka: hemp). This is in spite of the fact that non-THC phytocannabinoids meet none of the requirements for a controlled substance that is a Schedule I. This scheduling category states that materials from this category have no medical applications and a great potential for abuse and/or toxicity. This Schedule I classification is in spite of the fact that the Federal Government holds a patent for the medicinal applications of CBD for neuroprotection (Hampson et al. 2003; US Patent #6630507). This classification of the non-THC resins in the hemp as a Schedule I plant needs to be changed to a nonscheduled classification in order for the nascent and burgeoning hemp industry to fully develop economically. As of Summer 2018, there is a bill introduced into Congress to remove the controlled substance status for hemp and all of its derivatives as a part of the 2018 Farm Bill.

The FDA-CVM, in a public statement in April 2018 about the medical use of cannabis in animals, points to the fact that currently there are no FDA-approved drugs for animals that contain cannabis, and there is no scientific evidence, as of Spring 2018, that supports the use of cannabis and/or CBD in animals. However, with a number of university veterinary studies now showing both safety and efficacy, that may change. The FDA has now approved Epidiolex™ as of June 2018 but has yet to be rescheduled by the DEA. The use of the term "CBD" or "cannabidiol" on a label or in the marketing of a hemp product for people or pets now has become a medical claim since CBD is in an approved drug, and this may leave the product open to enforcement by the FDA. Companies need to avoid using these two words and must choose other language when describing the contents of a product and its intended activity to the end user. Currently there is no established limit for naturally occurring CBD in hemp products, although it has been considered by regulatory agencies to keep the CBD content at or below that which is naturally occurring in the hemp plant, which in some cultivars may average 18% in the flowers. This potency limit has not yet been established, though.

The 2018 US Farm Bill and the Controlled Substance Act of 1970

Sect. 7606 of the 2013 US Farm Bill allowed for research into hemp cultivation and market research into the commercialization of hemp on a state-by-state basis, for each state that has passed legislation regarding hemp cultivation and commercialization in that state. Currently there are 34 states that have legislation on the books allowing for hemp cultivation, with Kentucky and Colorado the largest producers.

The 2018 Farm Bill contains the McConnell amendment which removes the controlled substance status of legally grown hemp, again, on a state-by-state basis. Each state can decide how they choose to regulate hemp within their state according to this amendment. Once the Farm Bill is passed with this amendment, it will remove any legal impediment to the commercialization of hemp and hemp derivatives in the United States.

This amendment is necessary because the Drug Enforcement Administration (DEA) has scheduled all cannabis (both hemp and marijuana) as a Schedule I controlled substance, which means it has no medical applications and is potentially toxic and/or addictive. Controlled substances cannot be transported across state lines, so many companies (especially the larger ones) that would normally be marketing a popular supplement like CBD will not get involved with commercializing hemp until this last barrier to trade is removed.

2.2 Hemp in Animal Feed

Hemp is becoming an agricultural commodity again in the United States, as the stigmas and restrictions on research and commercialization are gradually being removed as a result of the US Farm Bill of 2013, Section 7606. This landmark *omnibus* spending bill established the legal status of growing hemp in the United States, and as a result, an interest in the use of hemp for animal feed has developed.

The Colorado legislature passed a bill forming a stakeholders committee under the guidance of the Colorado Department of Agriculture to examine the use of hemp and hemp derivatives for animal feed for both companion animals and food animals. The final report of that stakeholders commission was published on December 29, 2017 (Glenn 2017).

To Summarize the Findings of This Stakeholders' Committee Report

The FDA and AAFCO both stated they would be receptive to a Feed Additive Petition (FAP) submitted to the FDA for the use of the noncontrolled substance part of the plant, the grain or sterilized seed, including the oil and its protein cake. This FDA approval is sought for dogs, cats, horses, and food animals. In animals destined to enter the human food chain, there will need to be studies demonstrating conclusively the safety to our food supply to feed a food that contains cannabinoids, even trace amounts of the non-psychoactive phytocannabinoids.

The Hemp Industries Association of Colorado has formed a steering committee to create a Feed Additive Petition for Hemp Seed to submit to the FDA-CVM for approval of hemp seed as an animal feed ingredient. Currently, hemp is an unapproved nutritional ingredient according to the FDA, and as such when contained in animal feed is considered to be adulterated, and may be subject to regulatory action when marketed as a food. Following a literature review, 6-month safety feeding studies will need to be performed before the FDA would agree to approve hemp as a feed ingredient. This process usually takes 2–3 years and a considerable amount of resources.

Currently, any animal food products that contain hemp that are labeled as nutritional products with a guaranteed analysis and hemp labeled as a nutrient will be considered adulterated until hemp is an approved feed ingredient. For now, hemp will have to be included in a product as a nutraceutical and have the label language reflect the support that hemp affords to the healthy structure and function of the body and be marketed as a dosage-form animal health product. This is provided the product meets the minimum limits for THC and does not contain phytocannabinoid concentrations that are greater than what would be normally found in the whole hemp plant on average.

The Nutritional Value of *Cannabis sativa* L.

Cannabis seed, also known as "grain," contains both valuable fatty acids and high-quality protein. The seed is particularly nutritious and is often consumed whole or used in food preparations. A protein cake made from the seed has been used for animal feed in Europe. Whole hemp seed contains approximately 20–25% protein, 20–30% carbohydrates, and 10–15% insoluble fiber (Callaway 2004; Deferne and Pate 1996). In addition, it contains a mixture of the saturated fatty acids palmitic and stearic acid as well as oleic acid. Hemp seed oil is an extremely rich source of unsaturated fatty acids, especially the essential fatty acids linoleic acid (LA) and alpha-linolenic acid (ALA) (Callaway 2004; Leizer et al. 2000).

Essential fatty acids (EFAs) cannot be produced naturally by an animal's body and must be sourced from the diet. LA and ALA are omega-6 and omega-3 fatty acids, respectively, and, in the dog, are considered to be essential, since the dog cannot synthesize them. In cats these two fatty acids are also essential; however, due to their liver function, cats cannot desaturate and elongate linoleic acid to form arachidonic acid (Hand et al. 2010).

Hemp seed oil also tends to contain high amounts of gamma-linolenic acid (GLA) and stearidonic acid (SDA), which are metabolites of LA and ALA (Callaway 2004). Since these metabolites are produced by the breakdown of dietary LA and ALA, they are not considered EFAs. However, supplementation in the diet can be extremely beneficial. Many chronic diseases of modern society, including cancer, diabetes, heart disease, arthritis, atopy, Alzheimer's disease, and others, have an inflammatory component (Kapoor and Huang 2006). Diets enriched in GLA have been shown to reduce inflammation (Tate et al. 1989), and therefore the nutritional value of GLA from hempseed oil is clear.

Cannabis seed oil has the proper ratio (4:1) of omega-6 to omega-3 fatty acids for optimal health. The pro-inflammatory eicosanoid cascade is promoted by a high omega-6/omega-3 fatty acid ratio. This results in increased *prostaglandin* 2a ($PG_2\alpha$), which is a pro-inflammatory eicosanoid. Diets rich in omega-3 s and poor in omega-6 s have a less pro-inflammatory nutrient profile, which can be anti-inflammatory with sufficiently high levels of long-chain polyunsaturated omega-3 fatty acids (LCPUFA) and/or the anti-inflammatory omega-6 LCPUFA, gamma-linolenic acid (GLA). The Western diet, high in grain-fed meat and grains which are all high in omega-6 fatty acids and low in omega-3 fatty acids, results in a 20:1 ratio of omega-6/omega-3. It is this high omega-6/omega-3 ratio that shunts the eicosanoid cascade to the pro-inflammatory side and which dietary omega-6 fatty acids and GLA will serve to reduce over inflammatory trends in the body (Bauer 2011).

Three clinical examples where the lower omega-6/omega-3 ratio tends to a less inflammatory environment in the body

are the following: (1) a ratio of 4:1 omega-6/omega-3 was associated with a 70% decrease in total mortality from cardiovascular disease in human patients; (2) in colorectal cancer a decrease in rectal cell proliferation was observed with a lower ratio of 2.5:1; and (3) a ratio of 5:1 was found beneficial in asthma patients (Simopoulos 2002).

3 Modern History of Cannabinoid Pharmacology

The therapeutic properties of cannabis have been appreciated over several millennia and its pharmacological properties studied since the mid-1900s. This effort was enhanced in the 1960s with the isolation, characterization, and subsequent synthesis of its major psychoactive ingredient (−)-Δ^9-THC by Mechoulam and Gaoni, and significant attention was given to developing synthetic compounds with more potent and targeted therapeutic effects (Gaoni and Mechoulam 1964). Concurrent approaches by individual research laboratories and the pharmaceutical industry produced a series of structurally related new compounds, which were collectively called cannabinoids. One of these drug development projects by Eli Lilly led to the first synthetic cannabinoid, nabilone (Cesamet), which was used to treat nausea, pain, and reduced appetite associated with cancer chemotherapy (Makriyannis 2014; Pertwee 2008). The major breakthrough in understanding the mechanism of action of cannabis, and more specifically Δ^9-THC, came with the discovery of the first biological targets for this compound. Following a very successful research meeting in 1987 by the National Institute on Drug Abuse in Bethesda, Maryland, collaborative work among the participating laboratories led to the discovery of a new G-protein-coupled receptor (GPCR), which was named CB_1, to be followed 2 years later by a second GPCR named CB_2 (Makriyannis 2014). The CB_2 cannabinoid receptor is mostly found in immunity-related cells, and it is largely involved in regulating the immune system and inflammatory conditions. Although under normal "homeostatic" conditions the CB_2 receptors have a very low presence in neurons, in "non-homeostatic" situations such as inflammation, neurodegenerative diseases such as Alzheimer, Parkinson, ALS, as well as in cancers such as gliomas, its presence in the brain is dramatically increased in astrocytes as well as microglial and cerebromicrovascular endothelial cells. Recent published work has provided evidence that this receptor may also have a role in modulating addictive disorders (Xi et al. 2011).

Both the CB_1 and CB_2 receptors play important roles in many processes including neuronal plasticity, pain, anxiety, neuroinflammation, immune function, metabolic regulation, reward, craving, and bone growth (Mackie 2006).

4 Endocannabinoid (eCB) Chemistry

The next discovery on the ECS was a group of compounds found in mammalian tissues, which were named endocannabinoids (eCBs). The most representative of which were arachidonoyl ethanolamide or anandamide (AEA, circa 1992), a long-chain fatty acid amide, and 2-arachidonoyl glycerol (2-AG circa 1995), the respective ester (Devane et al. 1992; Mechoulam et al. 1995; Pertwee 2000). These new substances are capable of activating both CB_1 and CB_2 receptors and, when tested in animals, produced biological effects paralleling those of Δ^9-THC (Fig. 2).

eCBs are produced on demand by a series of enzymes that are present within the cell membrane and are activated by elevated levels of calcium ions. eCB levels, also referred to as the "endocannabinoid tone," are tissue dependent and are regulated by another set of enzymes, the most prominent of which are fatty acid amide hydrolase (FAAH) and monoacylglycerol lipase (MAGL), whose role is to deactivate AEA and 2-AG and their congeners, respectively. An additional feature in the regulation of eCB tone is a transport mechanism that is involved in transporting released eCBs into the cell (Fig. 3) (Vemuri and Makriyannis 2015).

Anandamide is synthesized from its membrane precursor *N*-arachidonyl phosphatidylethanolamine (NAPE) through cleavage by a phospholipase D (NAPE-PLD). In contrast, anandamide is degraded by the enzyme fatty acid amide hydrolase (FAAH) into arachidonic acid (AA) and ethanolamine. 2-AG is produced through the activities of either diacylglycerol lipase (DAGL) or phospholipase C (PLC) using an AA precursor. 2-AG is then subsequently degraded by monoacylglycerol lipase (MAGL) into glycerol and AA (Hartsel et al. 2016)

eCBs are released from the postsynaptic neuron and act on cannabinoid receptors on the presynaptic neuron. The eCBs inhibit the influx of calcium intracellularly resulting in inhibition of neurotransmitter release. The actions of eCBs are relatively short lived as they undergo rapid reuptake by the cell and are then degraded. The production of eCBs can be

stimulated in a variety of ways such as neuronal injury or excessive neuronal firing (Basavarajappa 2007).

ECS signaling comes in two forms—tonic and phasic. Tonic signaling establishes eCB tone or a basal level of signaling, while phasic signaling involves temporal perturbations in eCB levels. Researchers have demonstrated that omega-3 fatty acids are essential for the proper regulation of the ECS tone, as these polyunsaturated fatty acids feed directly into the eCB signaling pathways (Lafourcade et al. 2011).

These new discoveries opened the door for characterizing the two cannabinoid receptors, the proteins that modulate their function and the eCB family of compounds that encompass the ECS system. The ECS plays a major role in the regulation of many aspects of human physiology. Today we know that the CB_1 cannabinoid receptor is the most abundant

GPCR in the brain but is also present in many other organs such as the heart, blood vessels, liver, lungs, and the digestive system, as well as fat and sperm cells (Mackie 2008).

4.1 The ECS Explained

The CB_1 receptor belongs to the Class A rhodopsin-like family of GPCRs. It is primarily found in the central nervous system being enriched in the cortex, hippocampus, outflow of the basal ganglia, and cerebellum. There can be both intra- and interspecies differences in the anatomical location of cannabinoid receptors in the ECS. It's important to note that CB_1 in humans is not prevalent in the brain stem or medulla oblongata, the organs responsible for controlling vital autonomic functions such as breathing and heartbeat. This is a strong contributing factor to the safety profile of cannabinoids in humans and the main reason that it is nearly impossible to overdose on THC. However, for dogs this is not true. This receptor is also found to a lesser extent in the periphery of cardiovascular, immune, gastrointestinal, and reproductive tissues. CB_2 receptors are located primarily in immune cells, among them leukocytes and those of the spleen and tonsils (Pertwee 2001). The CB_1 and CB_2 receptors share a significant degree of homology despite being located primarily in the CNS and immune system, respectively. One of the functions of cannabinoid receptors in the immune system is modulation of cytokine release. Activation of B- and T-cell CB_2 receptors by cannabinoids leads to inhibition of adenylyl cyclase in these cells and to a reduced response to immune challenge (Condie et al. 1996). Both CB_1 and CB_2 are coupled to Gi/o proteins and cause a decrease in adenylyl cyclase activity and the cAMP pathway. They also stimulate mitogen-activated protein kinase (MAPK) cascades, modulate ion channels, and modify intracellular calcium levels and hence neurotransmitter release (Howlett and Fleming 1984; Howlett 2002; Marcu and Schechter 2016; Pertwee 2005). Inwardly rectifying potassium channels can also serve as a signaling mechanism for the CB_2 receptor (Griffin et al. 1999; Ho et al. 1999).

Cannabinoid action is not limited to signaling outside of the cell. Fatty acid-binding proteins (FABP) have been demonstrated to be essential for the transport of cannabinoids into the cell where they can interact with cannabinoid receptors on the mitochondrial membrane or they recruit different transcription factors and are translocated into the nucleus where they modify gene expression (Elmes et al. 2015). Additionally there are other proteins that modify cannabinoid signaling such as CRIP1a which inhibits constitutive eCB signaling (Smith et al. 2015).

The cannabinoid receptor CB_1 has also been found intracellularly where it localizes to the mitochondrial membrane and regulates neuronal energy metabolism (Bénard et al. 2012). Mitochondrial CB_1 modifies cellular respiration through its inhibitory actions on soluble adenylyl cyclase and reduced complex I activity in the electron transport chain. Additionally, these mitochondrial receptors may also play a role in the pro-apoptotic mechanisms of cannabinoids in cancer cells.

4.2 Non-cannabinoid Receptor Interactions and Dimerization

Cannabinoids do not solely target CB_1 and CB_2 and can act through other receptor systems. Knockout mice for both of these cannabinoid receptors have been created; however, these mice still exhibit behavioral, biochemical, and electrophysiological responses when cannabinoids are applied, suggesting the presence of other cannabinoid receptor subtypes. For example, recently cannabidiol (CBD) has been shown to act as an inverse agonist at GPR3 and GPR6 (Laun and Song 2017). There are currently a few other GPCRs that are under investigation as potential cannabinoid receptors. One such receptor is GPR18 which has been shown to be activated by the eCB ligand *N*-arachidonoylglycine (NAGly). This receptor is thought to play a key role in microglial activation and hence response to neuronal injury (McHugh et al. 2010).

GPR55 is another putative cannabinoid receptor activated by lysophosphatidylinositol (LPI) and antagonized by CBD that has been shown to play a role in the regulation of bone physiology by regulating osteoclast number and function (Whyte et al. 2009). Similarly to GPR18 it also appears to play a role in the microglial function specifically mediating some of their neuroprotective activities (Kallendrusch et al. 2013). GPR119 is thought to be another component of the ECS. Specifically, this receptor regulates various physiological processes that improve glucose homeostasis, including glucose-dependent insulin secretion from pancreatic β-cells, gastrointestinal incretin hormone secretion, appetite control, epithelial electrolyte homeostasis, gastric emptying, and β-cell proliferation and cytoprotection. These properties make this receptor an attractive candidate as a drug target for metabolic conditions such as diabetes (Mo et al. 2014).

Other potential biological targets interacting with cannabinoids include PPARγ where CBD has been shown to attenuate a-beta inflammation and enhance hippocampal neurogenesis through actions at this site (Esposito et al. 2006). The pain receptor TRPV1 famous for its interactions with the capsaicin found in chili peppers also interacts with cannabinoids to reduce nociception. This target also appears to be implicated in cannabinoid hyperemesis syndrome (CHS) which has recently gained media attention. Treatment of CHS patients with topical capsaicin, a known TRPV1 agonist as well as alternating hot and cold showers, tends to resolve symptoms (Moon et al. 2018).

Opiate-Cannabinoid Receptor Dimerization

CB_1 has been shown to dimerize with both mu and delta opioid receptors (Fig. 4). The mu opioid receptor heterodimer has interesting properties, and when each individual component is activated, eCB signaling is enhanced. However, when both are activated simultaneously, this results in a decrease in signaling. In the case of delta opioid heterodimers, these receptors tend to antagonize each other if one is missing. For example, if the delta opioid receptor is missing from this complex CB_1, signaling increases and vice versa (Fujita et al. 2014).

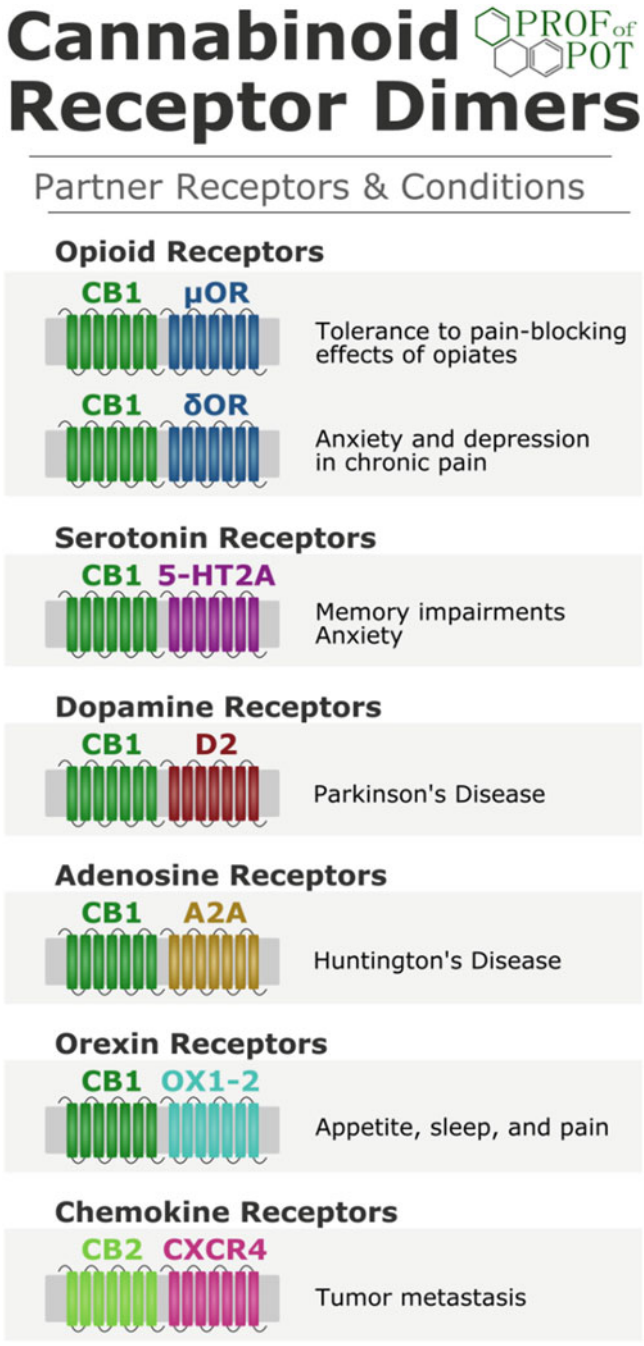

Fig. 4 Cannabinoid receptors have been shown to form dimers with other types of opioid, serotonin, dopamine, adenosine, orexin, and chemokine receptors. With permission from Professor of Pot

Serotonergic System and Cannabinoid Receptor Dimerization

CBD has been shown to produce agonist activity at the serotonin receptor 5-HT1A which may in part account for its anxiolytic properties. The cannabinoid receptor CB_1 has been shown to form heteromeric complexes with the serotonin receptor (5-HT2A). The activity of this receptor complex has been implicated in the memory augmenting properties of cannabinoids (Viñals et al. 2015). Interestingly the prevalence of this specific class of heteromeric complex increases in heavy users as they age and are implicated in certain conditions such as schizophrenia (Galindo et al. 2018). Additionally, cannabinoid agonists also inhibit signaling at the 5-HT3 receptor where they produce antiemetic effects (Fan 1995).

Other Receptor Systems

For an excellent review on this topic, see Prof of Pot's article on "Cannabinoid Receptor Dimerization" from which this figure was taken. See http://profofpot.com/cannabinoid-receptor-dimerization/

4.3 ECS in Health and Disease

Most of what we know about the medical and health benefits of cannabis relates to humans and not animals. Later in the chapter, we will focus on what we do know about cannabis as it relates to animals, but many of the biological interactions occur across the animal species. Below, we highlight many areas that cannabis can be helpful and acts as a starting point to evaluate cannabis as a therapeutic agent in veterinary species.

4.3.1 Sleep

Early studies from the 1970s indicate that THC causes a drastic increase in the production of melatonin, up to 4000% in some instances (Lissoni et al. 1986). It should be no surprise then that it has a profound effect on sleep (Babson et al. 2017). Additionally, cannabinoids affect the different stages of sleep and in particular act as a suppressor of REM sleep (Roehrs and Roth 2017).

4.3.2 Anxiety and Stress

Deficiencies in eCB signaling have been implicated in the etiology of a variety of conditions including PTSD, migraine, and fibromyalgia. In particular circulating levels of eCBs are markedly decreased in all of these disorders. This decline in circulating eCBs also tends to be correlated with anxiety-like

behaviors. A wide variety of studies have demonstrated that chronic environmental stress reliably leads to a down-regulation of CB_1 receptors and reduced levels of AEA increasing levels of 2-AG (Morena et al. 2016).

When tested in animal models, CBD was shown to have anxiolytic properties (Zuardi and Karniol 1983), as confirmed in a number of studies in humans. In an early study using healthy human volunteers subjected to a stressful public speaking test (SPST), a 300 mg dose reduced the volunteers' subjective anxiety to a level comparable to the standard anxiolytic diazepam (Zuardi et al. 1993). Neuroimaging confirmed these effects in follow-up studies (Bergamaschi et al. 2011; Crippa et al. 2009). CBD has also been shown to ameliorate some of the undesirable effects of THC and may be responsible for the improved properties of smoked cannabis compared to THC administration.

4.3.3 Obesity and Metabolic Diseases

Hypothalamic pro-opiomelanocortin neurons are responsible for feelings of satiety. CB_1 receptor activation on these neurons induces activity that causes the effects of these neurons to be silenced. This reduction in satiety can be attributed to the inhibitory effects of cannabinoids on the release of α-melanocyte-stimulating hormone (α-MSH) which normally produces appetite-suppressing effects. Recent studies have also demonstrated an inverse correlation between levels of orexin-A and α-MSH, which led to the discovery that orexin-A induces hyperphagia by increasing levels of the eCB 2-AG. Blockade of the OX-A receptor type 1 mitigated the impairment of α-MSH signaling which may serve as a target for controlling hunger responses (Morello et al. 2016). Because both GABAergic and glutamatergic presynaptic terminals on POMC neurons express CB_1, it is reasonable to assume that the bimodal effect of cannabinoids on feeding is due to the differential sensitivity of GABAergic versus glutamatergic axons to CB_1 activation (Koch et al. 2015).

Cannabis users who are prone to the munchies are generally thought to eat in greater quantities than their cannabis-naive counterparts. On average, users of cannabis display a slimmer waistline and lower BMI than nonusers. While seemingly paradoxical, Le Foll et al. (2013) have found that the prevalence of obesity is lower in regular cannabis users compared to nonusers, even after adjusting for important variables such as age, sex, and tobacco smoking status. A study in 3 T3-L1 adipocytes gives some insight into one possible mechanism by which cannabis users keep their weight in check and shows that treatment of these cells with CBD causes changes in the expression of certain signaling cues that lead to the browning of these cells (Parray and Yun 2016). In addition, cannabis users also display lower levels of fasting insulin and display better insulin sensitivity than their nonusing counterparts (Muniyappa et al. 2013).

Certain cannabinoids have demonstrated effects that may be useful for obesity treatment and prevention. The use of the cannabinoid THCV has correlated with weight loss, as well as decreased body fat and serum leptin concentrations in obese mice (Riedel et al. 2009; Wargent et al. 2013). Additional support for this idea comes from a recent paper by Silvestri et al., in which THCV and CBD were both shown to reduce accumulated lipid levels in adipocytes and in a model of hepatosteatosis (Silvestri et al. 2015).

4.3.4 Cancer

The ECS plays a key role in modulating cell differentiation, cell proliferation, and cell death. Additionally, cannabinoids such as THC stimulate appetite and reduce the emetic responses seen in chemotherapy. These qualities make the ECS an attractive target for use in cancer therapy. Cannabinoids can also be beneficial in certain cancers through their modulation of gene expression. For example, in lung cancers the application of CBD results in an upregulation of the expression of the intracellular adhesion molecules (ICAM) which in turn prevents the metastasis of cancerous cells beyond the tumor site (Haustein et al. 2014). In gliomas, the administration of CBD results in a dose-dependent reduction in the expression of pro-angiogenic factors (Vaccani et al. 2005). THC, when administered in conjunction with CBD, provides synergistic effects in the inhibition of human glioblastoma cell proliferation and survival. Another example of such changes in gene expression occurs in breast cancer cells where McAllister et al. demonstrated that the application of this cannabinoid downregulates the expression of ID-1, which is a large contributor to breast cancer metastasis (McAllister et al. 2007).

4.3.5 Inflammatory Conditions

Inflammation is a highly prevalent condition that contributes to the development and progression of many diseases and health conditions. The ECS has been shown both in vivo and in vitro to be involved in regulating the immune system through its immunomodulatory properties. Cannabinoids have been tested in several experimental models of autoimmune disorders such as multiple sclerosis, rheumatoid arthritis, colitis, and hepatitis.

As the cannabinoid receptor CB_2 is primarily found on the surface of immune cells, it should come as no surprise that these receptors modify the inflammatory response. These receptors have been shown to protect the host from the pathogenesis of these conditions through induction of multiple anti-inflammatory pathways such as suppression of T-cell-mediated immune responses by primarily inducing apoptosis and suppressing inflammatory cytokines and chemokines. However, some studies have shown both pro-inflammatory and anti-inflammatory effects, suggesting different thresholds for different cell populations.

Compounds found in cannabis that reduce inflammation are abundant and diverse. The most abundant phytocannabinoids in cannabis, THC and CBD, both have strong anti-inflammatory properties, while CBC, CBG, and THCV have also demonstrated anti-inflammatory properties. Cannabinoids act as anti-inflammatory agents by inducing apoptosis, inhibiting of cell proliferation, suppressing cytokine production, and inducing T regulatory cells. Apoptotic mechanisms induced by cannabinoids in immune cells include activation of CD95 to induce Bcl-2 and caspase cascades in immune cells. Cannabinoids have also been demonstrated to promote the production of anti-inflammatory interleukins such as IL-10 while inhibiting the production of pro-inflammatory cytokines such as TNF-α in a CB_1-dependent fashion (Klein et al. 2000).

Veterinarians and physicians alike might find it intriguing that nonsteroidal anti-inflammatory drugs (NSAIDs) produce their anti-inflammatory response through interactions with the ECS. Specifically, in the case of acetaminophen, its metabolism by the liver leads to the production of *N*-arachidonoylphenolamine (AM-404) which acts as both a cannabinoid receptor agonist and eCB reuptake inhibitor (Ottani et al. 2006). These interactions also block the conversion of arachidonic acid into inflammation- and pain-promoting prostaglandins (Saliba et al. 2017).

Additionally, certain terpenes also display anti-inflammatory activity. Among the terpenes, α-pinene, β-myrcene, and β-caryophyllene appear to act through prostaglandin receptors (PGE_1 and/or PGE_2) to have an anti-inflammatory effect. Additionally, beta caryophyllene is the only terpene currently known to bind to cannabinoid receptors attenuating inflammation in a CB_2 receptor-dependent fashion (Klauke et al. 2014). Hydrogenated terpenes and cannabinoids often display different characteristics as well and can exist in cannabinoid extracts at low levels as a result of the variety of distillation and refinement techniques being employed (USP #20160324909) (Scialdone 2017)

4.3.6 Pulmonary Effects

Studies performed in the 1970s at the University of California,—Los Angeles, by Donald Tashkin have shown that both inhaled and orally ingested THC produce bronchodilation for up to 2 hours after administration (Tashkin et al. 1974). Further investigations by the Respiratory Pharmacology Laboratory in Paris have shown that CB_1 receptor activation inhibits cholinergic contraction in a concentration-dependent fashion, offering a possible mechanism for the inhibiting of bronchospasms. Additional studies performed at the University of Sao Paulo using CBD have also shown some potential for improving the symptoms of COPD. They found decreased pulmonary inflammation and improvements in lung function in murine models of inflammatory lung disease using the inflammatory agent lipopolysaccharide (Ribeiro et al. 2015). Other findings using murine models have shown that intraperitoneal administration of THC results in a reduction of allergen-induced mucus production (Reddy et al. 2012).

4.3.7 Cardiovascular Effects

Cannabinoids can both increase and decrease blood pressure and heart rate, depending upon the specific context in which they are being used. These effects are only recently becoming better understood as more studies are being conducted regarding these effects (Dewey 1986; Wagner et al. 1998; Niederhoffer and Szabo 1999, 2000).

CBD specifically has been found to have direct effects on arteries, influencing vaso-relaxation, which is clinically observed as a mild hypotensive effect when CBD is administered. CBD has a protective effect against the vascular damage caused by hyperglycemia, as with type 2 diabetes, diabetic angiopathies, and systemic inflammatory processes. It is the antioxidant and anti-inflammatory effects of CBD that mediate these benefits (Stanley et al. 2013).

CBD has been found to have anti-arrhythmic effects in an in vivo rat model of coronary artery occlusion which may not be mediated through the CB_1 receptors found on myocardial cell membranes, but may have other non-receptor-mediated pathways that allow its control over cardiac rhythm (Hepburn et al. 2011).

It was determined in spontaneously hypertensive rats (SHR) that CB_1 antagonists increased blood pressure and left ventricular contractile performance. Additionally, by preventing the degradation of the endocannabinoid anandamide by fatty acid amide hydrolase (FAAH), as is found with CBD, reductions in blood pressure, cardiac contractility, and vascular resistance were found in normotensive rats. These effects were inhibited by CB_1 antagonists. It was found that CB_1 antagonists lower blood pressure much more in the SHR than in normotensive Wistar-Kyoto rats. Additionally, CB_1 receptors are upregulated in the heart and aortic endothelium in SHR versus the normotensive rat cohort (Bátkai et al. 2004).

4.3.8 Antioxidants and Neuroprotection

The NIH holds a patent on cannabinoids as antioxidants and neuroprotectants (Hampson et al. 2003; USP: 6630507). THC, CBD, and CBG have been shown to have antioxidant properties (Hampson et al. 1998; Borrelli et al. 2013). Through their actions as antioxidants, cannabinoids can neutralize reactive oxygen species. THC and CBD were both found to reduce ROS in vitro, with similar potency to known antioxidants such as ascorbate and butylated hydroxytoluene. Additionally, by inhibiting voltage-gated calcium channels, cannabinoids can inhibit the release of glutamate, hence curbing excitotoxicity due to excessive neuronal firing. During periods of ischemia and other traumatic brain events, the

neurotransmitter glutamate is released. Glutamate itself is toxic in excess and can lead to neuronal cell death in a process known as excitotoxic stress. Compounds with antioxidant properties are often neuroprotective, which is believed to be through the reduction of toxic ROS produced during ischemic metabolism. The neuroprotective effect of these compounds was found to be independent of their CB receptor binding activity. CBD in particular has been shown to protect against cerebral ischemic injury (Hayakawa et al. 2008) and also attenuates Alzheimer's-related neuroinflammation in animal models (Esposito et al. 2007).

Plant antioxidants such as ascorbic acid and tocopherols, polyphenolic compounds, terpenes, and numerous mono- and sesquiterpenes are important for human health. Cannabis terpenes with demonstrated antioxidant properties include β-caryophyllene (Calleja et al. 2013), limonene, and β-myrcene (Ciftci et al. 2011). In a mouse study of cerebral ischemia (Ciftci et al. 2011), β-myrcene protected against oxidative stress and histological damage induced by ischemia-reperfusion and is thus an effective neuroprotectant. Further, the compound is suggested as a good candidate for treatment of ischemic stroke.

The ECS is implicated in the etiology of a variety of neurodegenerative conditions, and cannabinoids have been shown to have neuroprotective qualities and the ability to attenuate neuroinflammation and promote neurogenesis (Jiang et al. 2005; Saito et al. 2012; Van der Stelt et al. 2001). In the case of Alzheimer's disease (AD), cannabinoids have shown promise for their ability to clear the toxic beta amyloid (Aβ) plaques that accumulate in the brain in patients with the disease. Considering patients treated with cannabinoids demonstrate improvement in symptoms, it should come as no surprise that a precursor to this debilitating disease is a loss of the body's natural production of eCBs. CBD has also been shown to reduce the expression of genes implicated in the phosphorylation of the tau protein, the hyperphosphorylation of which leads to the formation of neurofibrillary tangles that further contributes to the progression of the disease (Esposito et al. 2006). Furthermore, cannabinoids have been demonstrated to enhance the clearance of Aβ from the brain as well as prevent the inflammatory cascade that is produced by the accumulation of these misfolded proteins intracellularly (Eubanks et al. 2006).

4.3.9 Cannabis, Memory, and the ECS

Michael Pollan in his book, *The Botany of Desire: A Plant's-Eye View of the World*, addresses the short-term memory issues associated with the use of THC and especially the value of cannabis in treating post-traumatic stress disorder (PTSD) (Pollan 2001). Not all memories need to be retained. Some can be traumatic and toxic when recalled, as with PTSD. Pollan poses a question to the reader: "Do you really want to remember all the faces you saw on the subway this morning?"

The ECS acts as a filter for memory, promoting the retention of useful memories and removal of unnecessary ones. This ability to forget is critical for survival and goes awry in certain conditions such as PTSD. The ability of THC to enhance this process of forgetting is in part due to alterations in long-term depression (LTD) in the CA1-CA3 circuit of the hippocampus which is specifically dependent on astroglial CB_1 rather than neuronal cells—suggesting the cleanup of the synapse is impaired (Han et al. 2012). Newer research demonstrates that memory deficits from cannabis are also associated with increased COX-2 activity in the hippocampus (Chen et al. 2013).

It has also been suggested that chronic cannabis use is associated with structural changes in the hippocampus, such as reduced gray matter and alterations in shape. One particular study showed that long-term cannabis users had a 12% reduction in hippocampal volume on average. However, these findings may be flawed since there was a very small sample size used ($n = 15$) (Demirakca et al. 2011; Solowij et al. 2013; Yücel et al. 2008). If these changes are valid, they could have an influence on memory formation in cannabis users. However newer research refutes these findings, showing that daily cannabis use does not cause alterations in adolescents or adults. This study also used a much greater sample size than previous studies, comparing the brain morphology of 29 adult users and nonusers, as well as 50 adolescent users and nonusers using high-resolution MRI scans (Weiland et al. 2015). Other follow-up studies shed some light on the reasons behind these discrepancies by demonstrating that these changes in hippocampal volume and morphology are ablated when co-administered with CBD, displaying a protective effect of this cannabinoid against THC-induced changes (Yücel et al. 2016). Beale et al. examined this effect further and found that its restorative effects were limited to only certain hippocampal regions, specifically the left subicular complex (parasubiculum, presubiculum, and subiculum) (Beale et al. 2018).

4.3.10 Clinical Endocannabinoid Deficiency (CECD)

Deficiencies in eCB signaling have been implicated in the etiology of a variety of conditions including PTSD, migraine, and fibromyalgia (Russo 2016a, b). There are known mutations in ECS genes that contribute to such deficiencies. For example, patients with mutations in CNR1 and DAGLA exhibit CECD phenotypes (Smith et al. 2017). Another example of this is seen in IBS patients where the variant rs806378 *CT/TT* in the CNR1 gene showed a statistically

significant association with rates of colonic transit (Camilleri et al. 2013). Specifically, in the context of PTSD, fear extinction is impaired in patients who were homozygous for the CNR1 variant rs2180619 (Heitland et al. 2012).

In particular circulating levels of eCBs are markedly decreased in all of these disorders. This decline in circulating eCBs also tends to be correlated with anxiety like behaviors. A wide variety of studies have demonstrated that chronic environmental stress reliably leads to a downregulation of CB_1 receptors and reduced levels of 2-AG and AEA (Hill et al. 2009). Equally as predictable is a transient increase in 2-AG in the amygdala following chronic stress showing increases after 30 minutes that return to baseline after 60 min (Patel et al. 2009).

4.3.11 Limitations of the ECS as a Therapeutic Target

The involvement of the ECS in such a wide variety of physiological processes makes it enticing from a practitioner's perspective to understand how to manipulate this system. While the ECS can be viewed as a panacea for the treatment of various conditions, it is not without limitations. In particular, cannabinoid receptor agonists such as THC carry psychoactive effects which can be undesirable in certain populations. Additionally, persistent activation of the cannabinoid receptors results in receptor desensitization which ultimately leads to tolerance and the need for higher dosages, which also increases the likelihood of adverse responses. Unintended consequences of ECS stimulation include memory deficits and the development of withdrawal symptoms. One drawback of prolonged ECS stimulation that has recently gained attention is the development of cannabinoid hyperemesis syndrome (Chang and Windish 2009). This disorder only develops in certain subsets of the population and results in cyclical vomiting that can only be absolved by the administration of alternating hot and cold showers or a TRPV1 agonist such as capsaicin. One such focus area of research was that of appetite and metabolism and attempts to harness this avenue took form as a drug called SR141716A (Rimonabant), a CB_1 receptor inverse agonist. The use of rimonabant had negative outcomes, causing some to have negative thoughts and ideations of suicide, with some patients actually carrying it out. It was later discovered that such issues were attributed with effects on the central nervous system; therefore researchers are now working on developing CB_1 inverse agonists that are restricted to the periphery. There is also the possibility of synthesis issues producing off-target by-products which is still currently under investigation by the FDA.

4.4 Veterinary ECS: Our Current State of Knowledge

The CB_1 receptor is highly conserved across all mammalian species, but there are significant primary sequence differences that have been discovered between the human and rat cannabinoid CB_2 receptors and the newly cloned canine cannabinoid receptor, CB_2. It was found that the binding affinities for canine CB_2 receptor were 30 times less than those measured for human and rat CB_2 receptors. The functional properties of the cannabinoid CB_2 receptor were found to be highly dependent upon the receptor expression level and the nature of the signaling pathway selected (Ndong et al. 2011).

4.4.1 Anatomical Localization of Cannabinoid Receptors in the Dog

Cannabinoid Receptor 1

A recent study used immunohistochemistry to anatomically localize the CB_1 receptor in the normal canine nervous system. Nervous systems were examined from a healthy 4-week-old puppy, three 6-month-old dogs, and one 10-year-old dog. Strong "dot-like immunoreactivity" was found in the neutrophils of the cerebral cortex, *cornu ammonis* (CA), and dentate gyrus of the hippocampus, midbrain, cerebellum, medulla oblongata, and gray matter of the spinal cord. Dense CB_1 expression was found in fibers of the globus pallidus and substantia nigra surrounding immunonegative neurons. Astrocytes were consistently positive in all examined regions. In the PNS, CB_1 immunohistochemistry stained neurons and satellite cells of the dorsal root ganglia and myelinating Schwann cells in the PNS.

The younger dog examined had a lower general CB_1 expression in the brain, showing that the density of receptor expression was less than observed in human fetal and neonatal brain tissue. Lower CB_1 expression has been found in aged rats in specific regions, most prominent being the cerebellum, cerebral cortex, and basal ganglia and less prominent in the hippocampus. This reduction in CB_1 density with age in these rats was consistent with the findings in the older dog examined in this study (Freundt-Revilla et al. 2017). Previous studies have identified CB_1 receptors in salivary glands (Dall'Aglio et al. 2010), hair follicles (Mercati et al. 2012), skin, and hippocampus in dogs (Campora et al. 2012).

Immunohistochemistry was used to study the localization of CB_1 receptors on developing canine embryo (30 days old) with a commercially available antibody. CB_1 receptor immunoreactivity was found primarily in epithelial tissues and included most structures of the central and peripheral nervous system, inner ear, olfactory epithelium and related structures, eye, and thyroid gland (Pirone et al. 2015).

Canine CB_1 Receptor Localization
- Cytoplasm of basal and suprabasal layer cells.
- Hair follicle inner epithelial root sheaths and arrector pili muscles.
- Undifferentiated sebocytes at the periphery of sebaceous glands.
- Secretory and ductal cells of sweat glands.
- Mast cells and fibroblasts.
- Upregulated in atopic dermatitis.

Cannabinoid Receptor 2

As compared to human skin samples, clinically normal dogs have a homogeneous distribution of CB_1 and CB_2 receptors in all epidermal layers. In human, CB_1 is mainly detected in epidermal spinosum and granulosum layers, and CB_2 is detected mainly in basal keratocytes. Both CB_1 and CB_2 receptors have been found in the skin of healthy dogs and dogs with atopic dermatitis. The epidermis of dogs is thinner than that of humans (2–3 nucleated layers in the dog versus 6–7 in the human), which might account for this difference. In dogs with atopic dermatitis, hyperplastic epidermal changes were found, with strong CB_1 and CB_2 immunoreactivity in suprabasal keratinocytes and weak CB_1 and strong CB_2 immunoreactivity in basal keratinocytes indicating upregulation of these receptors during inflammation. CB_1 and CB_2 agonists decrease mast cell degranulation (Campora et al. 2012). To summarize, cannabinoid receptor localization on the skin of the dog was found in cytoplasm of epidermal and follicular keratinocytes, sweat and sebaceous gland epithelial cells, and the mesenchymal dermal cells

Canine CB_2 Receptor Localization
- Epidermis.
- Cytoplasm of cells in the basal and suprabasal layers.
- Hair follicles in the basal and suprabasal cells of the outer and inner epithelial root sheaths.
- Mild immunoreactivity in cells of arrector pili muscles and secretory and ductal cells of sweat glands.
- Sebaceous glands in the cytoplasm and peripheral reserve cells.
- Mast cells, fibroblasts, and endothelial cells.
- Lymph nodes.
- Strong B-cell zone immunoreactivity mainly in germinal centers of secondary follicles.
- Upregulated in atopic dermatitis.

4.4.2 Invertebrate ECS

The two cannabinoid receptors, CB_1 and CB_2, have been found in mammals, birds, reptiles, and fish. In a study of seven representative species of invertebrates, McPartland used tritiated ligand binding assays to characterize the cannabinoid receptors in *Ciona intestinalis* (Deuterostomia), *Lumbricus terrestris* (Lophotrochozoa), *Peripatoides novaezealandiae* (Onychophora), *Jasus edwardi* (Crustacea), *Panagrellus redivivus* (Nematoda) [the beer mat nematode], *Actinothoe albocincta* [white striped anemone] (Cnidaria), and *Tethya aurantium* (Porifera) [Orange Puffball sponge] (McPartland et al. 2006).

Cannabinoid binding was detected in all species studied except for the sea anemone (*A. albocincta*) and sponge (*T. aurantium*). The receptors were consistent with CB_1 receptors but not CB_2 receptors. Three of the organisms tested, earthworm (*L. terrestris*), velvet worm (*P. novaezealandiae*), and mat nematode (*P. redivivus*), were compared to a standard CB_1 ortholog in rat cerebellar tissue. A high affinity binding interaction was observed at various concentrations characteristic of CB_1 receptors.

The authors of this study hypothesize that cannabinoid receptors evolved in the last common ancestor of bilaterians, with secondary loss in insects and other clades. After conducting a systematic literature review, the authors found that cannabinoid receptors have been identified in sea urchins, leeches, earthworms, hydra, lobster (*H. americanus and J. edwardi*), and the beer mat nematode (*P. redivivus*), but not the nematode (*C. elegans*). No binding was observed in sponges (Porifera).

In a separate study, McPartland found that insects (*Apis mellifera* [western honey bee], *Drosophila melanogaster* [common fruit fly], *Gerris marginatus* [water strider], *Spodoptera frugiperda* [fall armyworm moth larva], and *Zophobas atratus* [darkling beetle]) are devoid of cannabinoid receptors. This loss of CB receptors is unique to comparative neurobiology, in that no other known mammalian neuroreceptor has been found to be missing in insects (Ecdysozoa). The authors suggest that the lack of cannabinoid receptors in insects is due to their lack of ligands, in that insects produce little or no arachidonic acid, the precursor to the biosynthesis of endocannabinoids (McPartland et al. 2001).

5 *Cannabis sativa* Chemistry

The fascinating effects that cannabis plant constituents have on the human experience have led to the discovery of 113 phytocannabinoids, each with a unique pharmacological profile (*C. sativa*. Pertwee *Handbook of Cannabis* 2014; Radwan et al. 2008). There is an emerging interest in another pharmacologically active group of 140 terpenes that have been identified in cannabis.

Terpenes have been shown to synergistically modulate the therapeutic effects of cannabinoids and also define the aromatic scent profile of the differing cultivars (Brenneisen and ElSohly 1988). The strain-specific effects are attributed to the unique chemotaxonomy of cannabinoids and terpenes (Russo 2011). Over 750 naturally produced compounds have been

found in cannabis (Upton et al. 2014), which may be divided into many different chemical classes. Covering each component of *C. sativa* is beyond the scope of this chapter and not relevant to the therapeutic activity of cannabis. An excellent review of *C. sativa* chemistry can be found in the body of work compiled in Table 1 (Brenneisen and ElSohly 1988; Callaway 2004; ElSohly and Slade 2005; Turner et al. 1980; Upton et al. 2014).

5.1 Phytocannabinoids

Plant-derived cannabinoids, or phytocannabinoids, refer to chemicals derived from botanical sources that interact with the ECS. The term is often synonymous with pharmacologically active compounds isolated from *Cannabis sativa*. Phytocannabinoids differ from eCBs with regard to their long-lived pharmacokinetic profile when compared to the relatively fast acting, short, and intermittent lifetime of the eCBs.

Of the 113 cannabinoids identified in *C. sativa*, the majority can be catalogued as analogs of Δ^9-tetrahydrocannabinol (Δ^9-THC), CBD, cannabichromene (CBC), cannabigerol (CBG), cannabinol (CBN), cannabicyclol (CBL), cannabielsoin (CBE), and cannabitriol (CBT). There are common points of variability on the phytocannabinoid scaffold that are highlighted in Fig. 5. The points of structural variability existing across the phytocannabinoid classes follow some general trends and quickly add up to over 100 potential cannabinoids when repeated across the common analogs shown in Fig. 5. The length of the alkyl side chain is a common site of variability and can range from one to five carbons in length (e.g., R^1, CBD, Fig. 5). The most recognizable and abundant cannabinoids contain *n*-pentyl side chains ($n = 5$), but *n*-butyl, *n*-propyl, ethyl, and methyl side chains have also been identified at lower concentrations (ElSohly and Slade 2005; Turner et al. 1980). Cannabivarins contain a 3-carbon side chain and are also commonly observed. The presence or absence of a carboxylic acid functional group is another point of common structural variability. Though THC and CBD are the most well-known cannabinoids, it is important to note that they are not synthesized in the cannabis flower directly. Rather, they are synthesized in their acidic forms in the plant, which are tetrahydrocannabinolic acid (THCA, R = COOH, R^1 = *n*-pentyl, R^2 = H) and cannabidiolic acid (CBDA, R = COOH, R^1 = *n*-pentyl). These compounds can be converted into THC and CBD by heating. The application of increased heat speeds up the reaction in which a CO_2 molecule is released from THCA to form THC in a process termed decarboxylation. Though some people refer to this reaction as "activating" the cannabinoids, it is a bit of a misnomer, as the acidic versions of these compounds also have been shown to induce medical benefits themselves, most notably anti-inflammation properties (Veress et al. 1990). Microbial hydroxylated forms also exist at low levels and remain relatively unstudied (Rashidi et al. 2009). The choice to decarboxylate can have important effects on the therapeutic application.

Table 1 Chemical components identified in *Cannabis sativa*

Chemical class	Identified compounds
Terpenes	140
Cannabinoids	113
Hydrocarbons	50
Sugars and related compounds	34
Nitrogenous compounds	27
Non-cannabinoid phenols	25
Fatty acids	23
Flavonoids	23
Simple acids	20
Simple ketones	13
Simple ester and lactones	13
Simple aldehydes	12
Proteins, enzymes, and glycoproteins	11
Steroids	11
Elements	9
Simple alcohols	7
Vitamins	3
Pigments	2

Tetrahydrocannabinol, or Δ^9-THC, is the main cannabinoid responsible for the characteristic psychoactive effects of cannabis with which most people are familiar. The binding activity of THC to the CB_1 receptor can cause downstream physiological changes such as mental euphoria, increased appetite, and slower cognitive functioning. A synthetic isolated version of THC called Marinol was approved by the FDA in the late 1990s for its antiemetic effects and prescribed to cancer patients undergoing chemotherapy.

Cannabidiol, or CBD, has received a surge of interest in the last decade by many interested parties, ranging from academic researchers to pharmaceutical drug developers to even nutritional supplement manufacturers. Part of this is due to the well-studied medical benefits. At the time of writing of this chapter, a CBD-based pharmaceutical drug (Epidiolex) has just been approved as a drug by the FDA on June 25, 2018.

Starting in the 1970s, investigators identified CBD's anticonvulsant properties in rats (Consroe and Wolkin 1977) and conducted an initial testing in humans in small groups (Carlini and Cunha 1981). This was followed by a larger human study using 900–1200 mg/kg daily which showed that CBD was effective in treating seizure states (Trumbly 1990). Overall, CBD exhibits the most reliable anticonvulsant effects of cannabis constituents. In very recent reports describing its use in children experiencing epileptiform

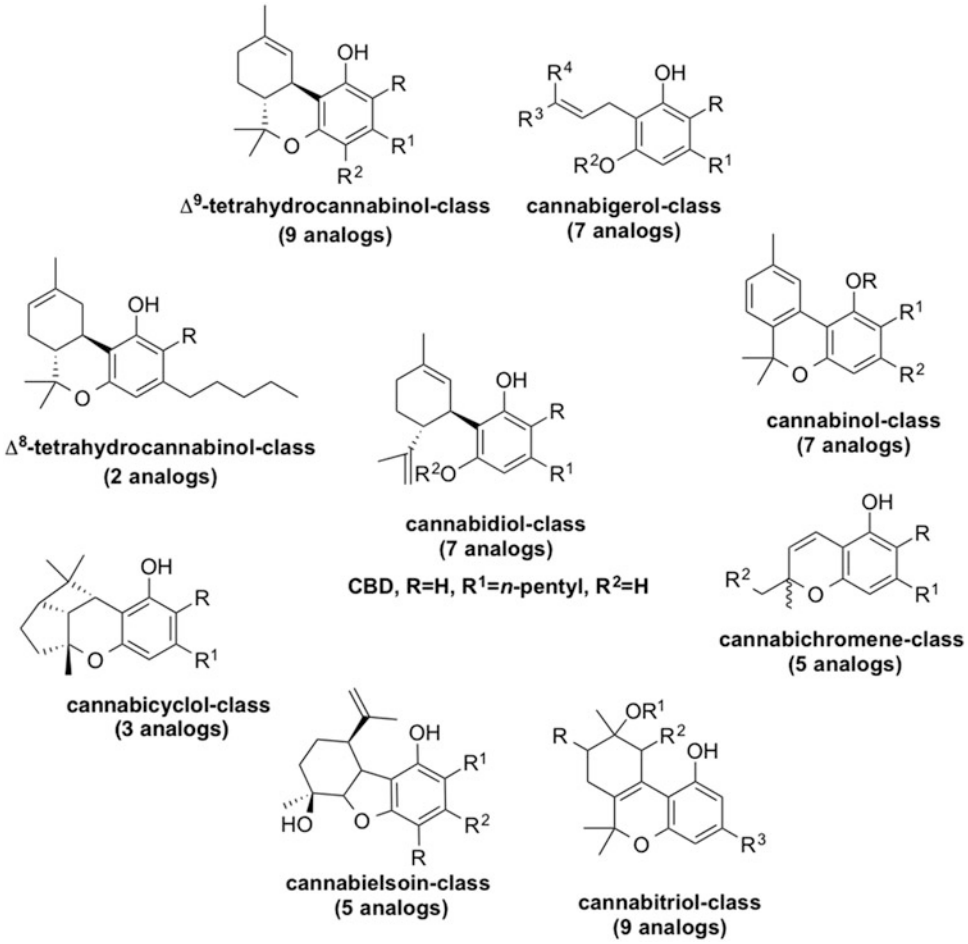

Fig. 5 Common cannabinoid analogs found in *Cannabis sativa*. This figure illustrates the common points of variability within each class and how many analogs have been discovered

conditions, CBD was shown to greatly ameliorate these effects. Also, initial results from a broad clinical evaluation of CBD in a seizure-associated condition in children are very promising. In epileptic patients there is a dysregulation of neuronal firing resulting in seizures and excitotoxicity. Increased levels of AEA have been found in the cerebrospinal fluid of dogs suffering from idiopathic epilepsy as compared to healthy dogs (Gesell et al. 2013).

Ligresti et al. (2006) examined the antitumor effects of a variety of cannabinoids, including both neutral and acidic forms. While CBD was determined to be the most potent antitumor cannabinoid tested, CBD-A was the least. The activity of CBD was due to its capability of inducing apoptosis via direct or indirect activation of CB_2 and potential vanilloid type 1 receptors (Ligresti et al. 2006) (Fig. 6).

A key structural distinction between THC and CBD is the freely rotatable bridge between the aromatic and nonaromatic cyclic systems that only exists in CBD. THC and CBD both have the same empirical formula as well as molecular weight. However, THC is conformationally constrained in a way that doesn't allow this region of the molecule to "flop" around. They are different in three-dimensional space, but CBD also has an additional free hydroxyl group that results in distinct

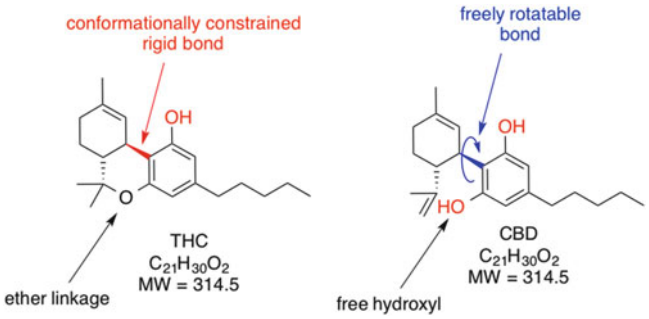

Fig. 6 Illustrates that CBD and THC have the same empirical formula and molecular weight. However, THC is conformationally constrained through an ether linkage and interacts with the receptors in a slightly different way compared to CBD

interactions with CB receptors and other biologically active targets.

(−) Δ^9-Tetrahydrocannabivarin (THCV) is the propyl analog of THC in which the 5-carbon side chain is shortened by two methylene units. Its pharmacological properties have been studied since the early 1970s when it was recognized that it behaves as a significantly weaker agonist (approximate fivefold) compared to THC.

Thus, as with THC, THCV produces analgesic but also cataleptic effects in animals (Hill et al. 2012; Pertwee 2008). These effects can be antagonized by synthetic CB_1 antagonists such as SR1716A or AM251. This property of being a weaker agonist than THC is consistent with extensive medicinal chemistry work showing the decreased potency of the cannabivarin family relative to the longer side chain analogs. Maximum potency is observed with side chains of 7–8 carbons (Makriyannis 2014).

Although THCV can behave as a CB_1 agonist in vitro, it can also act as a CB_1 antagonist capable of blocking the effects of more potent synthetic CB_1 agonists as well as THC and the eCBs AEA and 2-AG. For this reason, Δ^9-THCV can act as an in vivo CB_1 antagonist. At the CB_2 receptor, Δ^9-THCV behaves as a partial agonist and is capable of activating this receptor, although only to a limited extent. CB_2 receptor activation has been shown to be associated with attenuation of inflammation. The antiepileptic effects of this compound are being tested in humans currently.

Cannabigerol (CBG), in its acid form (CBGA), is the principal precursor and convergent intermediate of all phytocannabinoids. CBG is non-psychoactive and is a relatively weak partial agonist for both CB_1 and CB_2. Because of its low cannabinoid receptor potency, it can functionally antagonize the CB_1 effects of THC. It has been shown to relieve intraocular pressure, potentially useful in the treatment of glaucoma. Additionally, its antioxidant and anti-inflammatory properties make it a potential candidate for inflammatory bowel disease. Recent evidence identifies CBG as a potential candidate for the treatment of colon cancer (Ligresti et al. 2006).

There is some information on *tetrahydrocannabinolic acid (Δ^9-THCA)* and *cannabidiolic acid (CBDA)*, the two naturally non-psychotropic precursors of Δ^9-THC and CBD, respectively, that shows that their therapeutic value is derived from mechanisms other than classical CB_1/CB_2 receptor binding (Ahmed et al. 2008). THCA in vitro is capable of modulating the functions of two TRP channel receptors acting as a potent TRPA1 agonist and TRPM8 antagonist, inhibiting both cyclooxygenase enzymes, COX-1 and COX-2. When tested in rat models of nausea, THCA appears to be a better alternative for treating nausea and vomiting associated with cancer chemotherapy (Rock et al. 2013, 2014). THCA has also been shown to reduce levels of TNF-α in vitro, suggesting a mechanism for immune modulation (Ligresti et al. 2006). This reduction in TNF-α has been demonstrated in culture supernatants from U937 macrophages and peripheral blood macrophages after stimulation with LPS in a dose-dependent manner (Verhoeckx et al. 2006). Additionally, THCA has also been demonstrated to have potent activity as a PPARγ agonist (Nadal et al. 2017). However, these findings may only have implications for the periphery as there is some evidence to suggest that THCA's access to the central nervous system is restricted due to interaction with the BBB (Moreno-Sanz 2016). CBDA was shown to be a selective inhibitor of COX-2 (Takeda et al. 2008), implying anti-inflammatory activity. It also has been demonstrated to be a potent agonist at 5-HT1A (Bolognini et al. 2013). Unlike its congener, CBDA effectively reduced anticipatory nausea and may be useful against acute nausea induced by chemotherapy (Rock and Parker 2013).

Cannabinol (CBN) is a degradation product of Δ^9-THC caused by oxidation; therefore, it isn't surprising that it was the first phytocannabinoid to be isolated in pure form. CBN can activate both CB_1 and CB_2 receptors with a potency approximately ten-fold lower than Δ^9-THC. It can thus be viewed as a weak Δ^9-THC relative (Izzo et al. 2009). Less is known about the pharmacology of the diverse array of low abundance phytocannabinoids found in cannabis. Research on rare phytocannabinoids is rapidly expanding and an active area of investigation (Hartsel et al. 2016).

5.2 Chemotaxonomy of *C. sativa*

Chemical phenotypes (chemotypes) can be useful to classify *C. sativa* as drug- or fiber-type varieties. The United Nations Office on Drugs and Crime categorizes *C. sativa* into three chemotypes based on the proportion of THC and CBN relative to CBD [Eq. (1)] (Drugs 2009). Chemotype I (drug-type) cultivars are characterized by X values greater than one, while values less than one are representative of chemotype III cultivars (fiber-type). CBD-rich cultivars containing low levels of THC are regarded as fiber-type, or chemotype III cultivars. The evidence suggests that drug-type or chemotype I *C. sativa* cultivars with high levels of Δ^9-THC originated from below the 30°N latitude (Hillig and Mahlberg 2004). Equivalent levels of Δ^9-THC and CBD are known as chemotype III and are typically found above the 30 °N latitude. Hillig and Mahlberg (2004) used a statistical approach to define chemotaxonomic trends in *C. sativa* and found that most cultivars fell outside of the arbitrary values set by the United Nations Office on Drugs and Crime. They demonstrated that most cultivars clustered into either chemotype I ($X > 10$), chemotype II ($0.2 < X < 10$), or chemotype III ($X < 0.2$). The relative cannabinoid levels in *C. sativa* remain constant from the seedling stage throughout the plant life cycle (Broséus et al. 2010), making it possible to determine the chemotype at early development stages prior to flowering (Barni-Comparini et al. 1984; Vogelmann et al.

Equation 1 Chemotaxonomy is calculated by dividing the sum of THC and CBN concentration by the CBD concentration

$$X = \frac{[\mathrm{THC}] + [\mathrm{CBN}]}{[\mathrm{CBD}]}$$

1988). To date, 52 hemp cultivars that fall below the 0.3% legal limit for hemp have been approved for commercial use by the European Union (Directive 2013). These registered varieties originate from high latitude European nations, which are not acclimated for equatorial regions of the world. Little is known about the viability of the European cultivars in the United States, and this is currently being examined by agronomists. Several high CBD strains have come online in the United States in recent years that are being legally cultivated under the Farm Bill. Some of these strains have CBD contents above 15% and render traditional European cultivars obsolete for oil and resin production.

Over recent decades the cannabis gene pool has undergone selective pressure to maximize THC production at the expense of CBD and other minor or non-psychoactive cannabinoids. The observation that different high THC cannabis cultivars produce a variety of effects prompted researchers to look further into the other chemical constituents that may be impacting the therapeutic effects. It turns out that there is a wide spectrum of effects encountered when different terpene profiles are administered with THC. This has been a major focus of research as of late, and there are numerous publications that demonstrate the variability and unique signatures of terpene profiles in differing cultivars (Fischedick et al. 2010; Henry 2017; Lewis et al. 2018).

5.3 Cannabimimetics: Cannabinoids from non-*C. sativa* Species

Aside from cannabis, there are a variety of other plants that produce compounds that interact with the body's ECS. These compounds are classified as cannabimimetics or cannabinoid-mimicking compounds. Some of the plants that produce cannabimimetics are widely used in herbal medicine, and some are even part of our regular diet.

There is a class of lipid compounds that is widespread in the plant kingdom called *N*-acylethanolamines (NAE). Rather than directly binding to the body's cannabinoid receptors, these compounds inhibit the actions of the eCB-degrading enzymes such as the fatty acid amide hydrolase (FAAH) (Gertsch 2017). There is also a triterpenoid compound called pristimerin found in a family of shrubs called Celastraceae that reversibly inhibits another eCB-degrading enzyme, monoacylglycerol lipase (MAGL) (King et al. 2009). These compounds are significant because this type of activity indicates that their presence can modify eCB tone. Newer research on compounds with similar structural components suggests that *N*-alkylamides and their derivatives could also interact with the putative third cannabinoid receptor GPR55 (Dalle Carbonare et al. 2008).

Studies on *black truffles* have shown that eCBs are not just unique to mammals. The enzymes required for producing anandamide as well as the compound itself are found in certain species of truffles (Pacioni et al. 2015).

Researchers out of Zurich have been investigating a class of compounds in *Echinacea* called *N*-alkylamides, which possess immunomodulatory properties (Gertsch et al. 2008b; Raduner et al. 2006). In particular, *Echinacea* roots produce endocannabinoid-like molecules that have been shown to bind to cannabinoid receptors in rodents (Woelkart and Bauer 2007). Specifically, *N*-isobutylamide has been shown to bind to both cannabinoid receptors but shows preference for CB_2. Its actions there have been shown to cause a decrease in the expression of the pro-inflammatory mediator TNF-α (Gertsch et al. 2004).

South African *Helichrysum umbraculigerum* has been shown to contain CBGA, CBG, and other prenylated dibenzyls similar to cannabinoids in *C. sativa*. Cannabinoid-like molecules derived from *Helichrysum* and other Asteracea genera generally have a phenethyl group at the *n*-pentyl position and have been used in traditional medicine to treat a host of inflammation and infections (Pollastro et al. 2017).

Piper methysticum also known as *kava kava* contains yangonin, a kavalactone that displays significant binding affinity for CB_1 (Russo 2016a, b).

Liverwort (*Radula marginata*) has also been shown to produce a compound called perrottetinenic acid, which closely resembles Δ^9-THC (Toyota et al. 2002).

The Chinese *Rhododendron has* also been shown to produce compounds that are structurally similar to the cannabinoids CBC, CBL, and cannabicitran, although their pharmacological activities at cannabinoid receptors have yet to be explored (Iwata and Kitanaka 2011).

5.4 Cannabis Terpenes

Terpenes are the aromatic compounds in cannabis that contribute to its unique scents and aromas. Over 100 different mono-, di-, and sesquiterpene compounds are produced within the resinous trichomes of cannabis flowers. Terpenes are produced alongside cannabinoids, which share common biosynthetic pathways and intermediates (Fig. 7).

Terpenes are thought to modulate the therapeutic effects of the cannabinoids and are termed the ensemble effect, a reference in literature to a large body of evidence suggesting that whole plant cannabis is more effective than isolated cannabinoid compounds by themselves. The complex aromatic profile of terpenes is often a distinguishing factor between cannabis strains and contribute the pluripotent physiological effects. Despite the fact that the terpene profile can

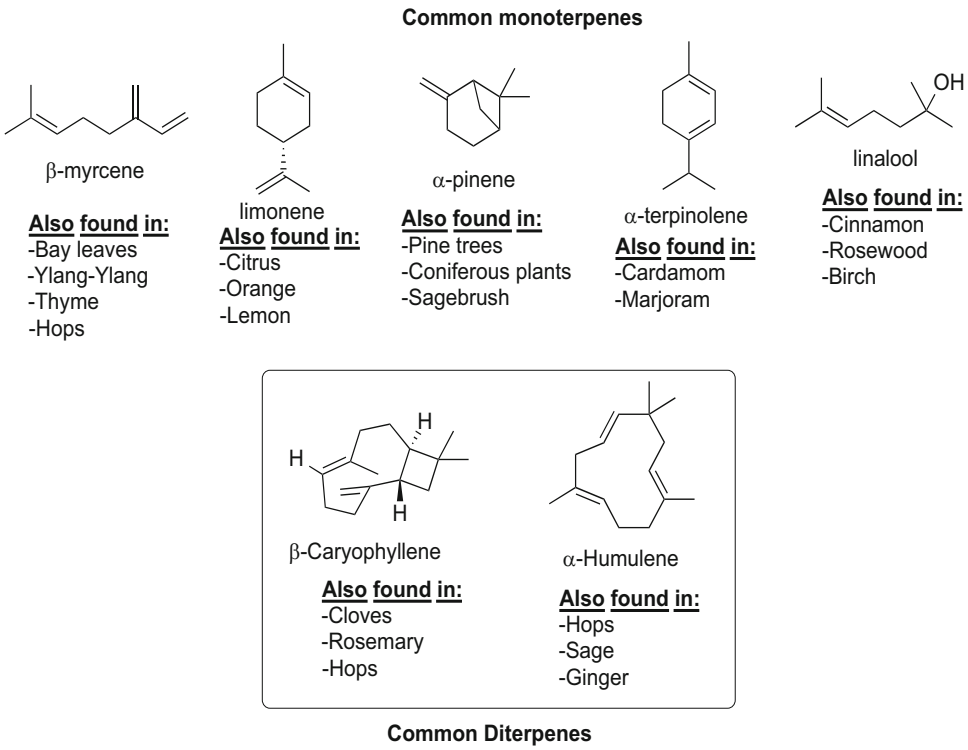

Fig. 7 Showcases five common monoterpenes and two diterpenes found in *Cannabis sativa*

make a cannabis strain unique, terpenes themselves are commonly found in other plants. In fact, many of these terpenes have been used in aromatherapy for millennia. In this section, we will cover five of the most common monoterpenes and two common diterpenes.

β-Caryophyllene is the primary sesquiterpene in black pepper that contributes to its spicy flavor. It is also a major constituent of cloves, hops, rosemary, and, of course, cannabis. Certain strains of cannabis such as Girl Scout Cookies can have levels of β-caryophyllene as high as 5% by mass. It is unique in that it has been shown to directly interact and bind with the CB_2 receptor, making it one of the most ubiquitous non-cannabis cannabinoids found in nature. CB_2, particularly in peripheral tissues in the body, is a therapeutic target for treatment of inflammation, pain, atherosclerosis, and osteoporosis (Gertsch et al. 2008a, b). β-Caryophyllene itself has shown promising results in animal models for colitis, osteoarthritis, diabetes, anxiety, depression, liver fibrosis, and cerebral ischemia. In support of the entourage effect hypothesis, co-administration of β-caryophyllene with the chemotherapy drug Paclitaxel on in vitro cancer cells stimulated increased cancer cell death and decreased tumor growth. β-Caryophyllene has received GRAS status by the FDA, meaning it is generally recognized as safe for oral consumption in humans.

Myrcene is known as the active sedating principle of hops, lemon grass, basil, and mangoes. *Myrcia sphaerocarpa*, from which myrcene is derived, is a medicinal shrub from Brazil traditionally used to treat diabetes, diarrhea, dysentery, and hypertension (Ulbricht 2011). Myrcene's earthy, fruity, and clove-like aroma is pungent in higher concentrations and commonly used in culinary and perfume preparations. Myrcene has been shown to enhance transdermal absorption (Schmitt et al. 2009). It also has a significant analgesic effect, which is blocked by the action of naloxone, an opioid antagonist, suggesting a mechanism of action through the opioid receptor (Rao et al. 1990). Myrcene lacks affinity for opioid receptors pointing to alpha 2-adrenoceptor-stimulated release of endogenous opiates. No tolerance was observed after repeated dosing in rats, which is in contrast to morphine (Lorenzetti et al. 1991). Myrcene was a sedative comparable to phenobarbital at very high doses in rats (Do Vale et al. 2002), an effect increased by simultaneous administration of citral, a mixture of other terpenes. Myrcene was also shown to improve glucose tolerance in alloxan diabetic rats comparable to metformin (Al-Omari 2007), without an effect on glucose levels in normal rats. Further, myrcene showed powerful anti-inflammatory and anti-catabolic effects in a human chondrocyte model of osteoarthritis (Rufino et al. 2015). Myrcene is the subject of a broad array of current research given that inflammation is the underlying cause of numerous diseases.

Limonene is one of the most abundant terpenes in cannabis and has been reported at concentrations up to 16% of the essential oil fraction. Limonene is a monoterpene commonly found in citrus rind and used in perfumes, household cleaners, food, and medicines. Limonene has numerous potential medicinal benefits demonstrated in human and

animal studies. Limonene's antioxidant and anticancer properties make it an excellent dietary source for cancer prevention (Aggarwal and Shishodia 2006). Multiple modes of anticancer activity and chemoprevention were observed for limonene (Crowell and Gould 1994). Perillyl alcohol is a metabolic product or limonene, which is also a subject of numerous cancer-related studies (Prates Ong et al. 2012). Anti-inflammatory effects in models of osteoarthritis (Rufino et al. 2015) and asthma have also been observed (Hirota et al. 2012). Anxiolytic effects in a mouse maze model were not antagonized by flumazenil and comparable to diazepam, implying a non-benzodiazepine biological target (Lima et al. 2013). Earlier results which also demonstrated antidepressant activity via the 5-HT_{1A} receptor pathway (Komiya et al. 2006) are in contrast to anxiolytic effects in the mouse maze model.

Humulene is the characteristic terpene of hops, *Humulus lupulus*, that is also abundant in cannabis. It is also found in sage and ginseng among other plant species. Humulene, also known as α-caryophyllene, is a ring-opened isomer of β-caryophyllene, which lacks in the CB_2 activity of the latter. β-Caryophyllene and humulene have been shown to interact in a synergistic manner in one study (Legault and Pichette 2007). Humulene also possesses powerful anti-inflammatory activity, equal to dexamethasone in an animal model (Fernandes et al. 2007). Both topical and systemic anti-inflammatory properties (Chaves et al. 2008) as well as topical, oral, and aerosol delivery methods as an analgesic have also been observed for humulene (Rogerio et al. 2009). It also has the potential to aid in wound healing (Satsu et al. 2004) from the increase secretion of IL-8, a chemokine with various functions, including promoting angiogenesis.

α-Pinene is a terpene commonly found in pine needles, and its pharmacological properties have been well studied. In particular, α-pinene acts as an acetylcholinesterase (AChE) inhibitor which may aid in memory function (Miyazawa and Yamafuji 2005). It also exhibits anti-inflammatory properties through numerous pathways decreasing levels of interleukin-6 (IL-6) and tumor necrosis factor alpha (TNF-α). It also reduces prostaglandin synthesis through its potent inhibition of prostaglandin E_1 (PGE_1) and like many terpenes also exhibits antimicrobial effects (Nissen et al. 2010; Russo 2011).

Terpinolene carries a woody and floral odor and is commonly found in "sativa" varieties of cannabis. Studies in mice carried out using *Microtoena patchoulii* which has terpinolene as a primary active constituent show that it exhibits sedating properties (Ito and Ito 2011). It also exhibits anticancer properties in the brain cells of rats (Aydin et al. 2013).

Linalool is a terpene commonly found in lavender that produces antianxiety and antidepressant effects. Studies performed in mice suggest that these properties are primarily due to its action on monoaminergic pathways in particular the serotonin receptor 5-HT1A (Chioca et al. 2013; Guzmán-Gutiérrez et al. 2015).

5.5 The Entourage/Ensemble Effect in Cannabis: Why It Matters

The idea of an entourage or ensemble effect in eCB signaling was first proposed by Ben-Shabat in 1998. Since then there have been numerous studies that support this theory. Ben-Shabat's initial work demonstrated this phenomenon with typically inactive fatty acids in the presence of eCBs. A few years later in 2001, McPartland and Russo published a paper titled "Cannabis and Cannabis Extracts: Greater Than the Sum of Their Parts" which extended this entourage concept presenting early evidence that terpenes enhanced the effects of the cannabinoids (McPartland et al. 2001). This work was further refined later by Russo in August of 2011 when he published "Taming THC: Potential cannabis synergy and phytocannabinoid terpene entourage effects" in the *British Journal of Pharmacology* (Russo 2011). This paper proposed that the terpenes in cannabis were capable of modulating the effects of cannabinoids and offered many possible mechanisms by which terpenes could induce this action.

Terpenoids are potent modulators of consciousness and have been used for thousands of years in aromatherapy for a number of conditions. Recent work using essential oils derived from cannabis void of any cannabinoids illustrates such effects where results revealed decreased diastolic blood pressure, increased heart rate, and significant increased skin temperature. There were also changes in the amplitude of alpha, delta, and theta brain waves (Gulluni et al. 2018).

More recent work confirms the concept of an ensemble effect. One such study demonstrates that CBD administered in a whole plant extract rather than an isolated form allows for the bell-shaped dose-response curve to be overcome and results in greatly enhanced therapeutic efficacy in the context of TNF-α production (Gallily et al. 2015).

A number of studies have found that although there is definite clinical potency to the isolated phytocannabinoids such as THC or CBD, when they are provided in a whole plant extract containing terpenes, flavonoids, and other cannabinoids, they have a greater effect. Romano et al. (2014) found that a standardized cannabis extract with a high content of CBD was able to inhibit colon carcinogenesis both in vitro and in vivo. It was found that the whole plant extract reduced cell proliferation in cancerous but not in healthy cells. Pure CBD reduced cell proliferation in a CB_1-sensitive antagonist manner only. In vivo, plant-based CBD reduced the carcinogen azoxymethane (AOM)-induced preneoplastic lesions and polyps as well as tumor growth in

the xenograft model of colon cancer. The authors concluded that plant-based CBD in the whole plant context attenuates colon carcinogenesis and inhibits colorectal cancer cell proliferation via CB_1 and CB_2 receptor activation (Romano et al. 2014).

6 Animal Studies and Veterinary Clinical Trials

For legal reasons, although cannabis for medical uses has been applied in an uncontrolled (and possibly illegal) fashion to pets and farm animals for many years, going back as far as the mid-1800s, there has been no basic, fundamental research into the safety, efficacy, or pharmacokinetics of phytocannabinoids, and specifically CBD, in our domestic or wild species of animals. With the federal legalization of hemp in the 2014 Farm Bill, as mentioned previously, there has been a loosening of the restrictions on research in states that have legal hemp cultivation and commercialization.

As a result of this legal loosening of cannabis research, several veterinary academic institutions have completed or nearly completed studies into the safety of high-dose, long-term use (6 weeks) of CBD in the dog, the relative pharmacokinetics of three different avenues of administration (transmucosal, oral, and transdermal), and the efficacy of CBD use for osteoarthritic pain and refractory epilepsy at a specific dosage. The efficacy studies are prospective, double-blind, placebo-controlled, randomized clinical trials. Additionally, several pet owner surveys/studies have been completed. One has been published in a peer-reviewed journal, and the second has been reviewed and is scheduled for publication later in 2018 by the same peer-reviewed journal. These surveys are from Colorado State University's College of Veterinary Medicine. A summary of the study results from the CSU comparative pharmacokinetics study is reported here. The safety and efficacy studies for epilepsy and osteoarthritis will be published later in 2018. The preliminary data from the two studies are reported here based on presentation of this data from conference proceedings.

Cornell University's College of Veterinary Medicine has just released a pharmacokinetics, safety, and efficacy study of CBD used in dogs with osteoarthritis. This document was presented at the American College of Veterinary Sports Medicine and Rehabilitation track at the World Rehabilitation Summit (IAVRPT) in Knoxville, TN, July 31, 2018. This study's results are reported in this chapter as well. Both the Cornell and CSU studies used "macro-dosages," which are substantially higher (4–5 times) than have been reported as effective by veterinarians and pet owners based on anecdotal and observational data.

6.1 Pet Owner Experiences with Hemp Products

Kogan et al. (2015, 2018) from Colorado State University conducted a survey of pet owners who had visited an e-commerce site to purchase animal hemp products. The survey was intended to inform future research of the best veterinary applications for low THC cannabis, otherwise known as "industrial hemp." This study was designed to determine what hemp products pet owners are purchasing, reasons for their purchases, and the perceived value of these products on their pet's health. An anonymous survey was given to pet owners who bought products from a single online hemp company. A total of 632 responses were recorded, and 58.8% of these indicated they currently use a hemp product for their dog. Most dog owners (77.6%) indicated they use the product for an illness or condition diagnosed by a veterinarian, with the most common conditions including seizures, cancer, anxiety, and arthritis.

Of the total responses, fewer participants indicated they currently use the hemp products for their cat (11.93%), with 81.8% indicating they use the product for an illness or condition diagnosed by a veterinarian. The most common conditions being addressed by the hemp products included cancer, anxiety, and arthritis. This study provides a guide to researchers seeking to perform clinical studies on hemp in terms of its best areas of efficacy and potential adverse outcomes with its use. The authors suggest, for this first evidence-based publication in the veterinary realm of the clinical effects of cannabinoids, to consider controlled clinical trials in areas that include pain management, behavioral interventions for sleep disorders and anxiety for dogs, inflammation reduction, and improvement in sleep patterns for cats (Kogan et al. 2015).

6.2 Demographics and Dog Owner Perceptions of Cannabis

In a follow-up questionnaire-based study to the 2015 publication cited above, Kogan et al. created a second online survey to assess US perception regarding hemp and marijuana products for their dogs. The survey originated from Colorado State University in collaboration with investigators at North Carolina State University. Survey participants were recruited via social media in late 2017. The data was collected anonymously. Dog owners residing in the United States were the only inclusion factors used in this study. Survey participants were asked for their demographics; the state they lived in was compared to states that currently have medical marijuana laws permitting legal use of marijuana for

medical and/or recreational purposes. Further questioning determined if they had given their pets a marijuana product or not and the reasons for use or nonuse of it. Finally, survey participants were asked for what reasons they had given the marijuana products to their pets.

A total of 1196 responses were collected, and after eliminating non-dog owners or non-US residents, there were 1068 responses. Eighty-four percent were female, the remainder, male. Eighty percent of respondents had used cannabis for their dogs. Those that did not use cannabis cited no medical reasons to do so or weren't aware that it could help. Pain relief, reduction of anxiety, and reduction of inflammation were the most common reasons for the use of cannabis in dogs in this study. Other reasons (total 36%) less commonly selected were for epilepsy (11.5%), cancer (9.4%), arthritis (1.9%), and allergies (1.3%)

The type of cannabis product most commonly used in the study were capsules or pills marketed for animals (57%), as compared to capsules or pills marketed for humans (3.9%). For edibles this same trend was seen, with more animal-labeled products being used in dogs than edibles labeled for people. No mention was made in this study of the most commonly used format which is the liquid oil infusion, also known as the "tincture." Side effects associated with the use of cannabis in dogs were reported only by a minority of dog owners (<5%), with the most common adverse effects being sedation, xerostomia, and associated polydipsia.

6.3 Safety of High-Dose Long-Term Exposure to CBD in Dogs

A study evaluating the safety of cannabidiol in the dog was published in the Fall of 2018. It was conducted at Colorado State University's College of Veterinary Medicine, Department of Neurology. The principal investigator, Dr. Stephanie McGrath, who is a veterinary neurologist and Assistant Professor at CSU's Veterinary Teaching Hospital, conducted a 6-week high-dose evaluation of the tolerability of two high doses of CBD in healthy beagle dogs. A sample population of 30 healthy beagle dogs were randomly assigned to receive 1 of 3 formulations: microencapsulated oil beads, CBD-infused oil, or CBD-infused transdermal cream for 6 weeks. Two dosage tiers were evaluated in this study, 10 mg/kg/day and 20 mg/kg/day. These dosages far exceed the dosages used in the two efficacy studies that followed this by a factor of 2× and 4× greater. The two efficacy studies evaluated the use of CBD for refractory epilepsy and osteoarthritis in the dog.

Complete blood counts, chemistry panels, urinalysis, and pre- and postprandial bile acids were performed at 0, 2, 4, and 6 weeks. Elevations in alkaline phosphatase double the high end of the reference range (140 IU/L) were observed in some dogs (11/30:36%) after being on the CBD for 4 weeks, although it did elevate in some dogs at 2 weeks, especially at the higher dosing tier. Long-term liver toxicity was not evaluated in this study, although bile acids and liver enzymes remained normal for all dogs throughout the study. None of the dogs receiving the transdermal formulation developed elevated alkaline phosphatase values. All dogs experienced mild diarrhea, although there was no correlation with formulation or dose. Six out of the 30 dogs developed vomiting, but there was no significant difference between the occurrence of vomiting and CBD dose or formulation.

Erythematous pinnae were the next most commonly reported clinical sign in this study. These otic changes were seen in 36% of dogs with the otic changes becoming more severe after 2 weeks in the 10 mg/kg/day dosage group for all three formulations. The transdermal cream had more incidences of otic changes than either the transmucosal or oral routes of administration, which is understandable since the transdermal crème was applied to the inside of the pinna. Less common findings included ocular discharge in 10/30 dogs (33%) and nasal discharge in 10/30 dogs (33%). Five dogs (17%) had salivary staining on their feet and occasionally on their ventral abdomen. Two dogs had spontaneous prolapsed glands of the nictitans. One dog had a transient elevated body temperature (104.2 °F). It was also observed that some dogs would salivate following administration of the CBD-infused oil formulations at both doses. The study concludes that CBD seems to be well tolerated in the dog at these high dosages but emphasizes that a larger and longer in duration safety study is needed to evaluate the very long-term effect of CBD on the liver and its association with diarrhea (McGrath et al. 2018).

6.4 Pharmacokinetics, Safety, and Clinical Efficacy of CBD Treatment in Osteoarthritic Dogs

The objectives of a recent Cornell study were to determine the oral pharmacokinetics and safety, as well as analgesic efficacy, of using CBD in dogs with osteoarthritis (OA). Single-dose pharmacokinetics were performed using two different doses of 2 mg/kg and 8 mg/kg of CBD in a carrier oil. From this data, a prospective, randomized, placebo-controlled, double-blind crossover study was conducted using 16 client-owned dogs with radiographically confirmed evidence of osteoarthritis who were enrolled and who completed this study. Dogs were randomized to receive either 2 mg/kg q 12 h orally of CBD oil or a placebo consisting of olive oil with a benign herbal extract at a similar volume q 12 h for 4 weeks. Subjects were given a 2-week washout period, and then the treatments were crossed over, and each subject received the other treatment twice daily for 4 weeks.

Veterinary assessment of lameness, movement, and response to manipulation, owner questionnaires (Canine Brief Pain Inventory (CBPI), Hudson activity scale), objective kinetic analysis on a pressure-sensitive walkway, hematology, and chemistry analysis were obtained at weeks 0, 2, and 4 for both oils. Statistical analysis was performed on the results, with a $p < 0.05$ considered to be significant.

Pharmacokinetics showed a half-life of elimination of 4–5 h at both doses and no observable side effects. Median maximum concentration of CBD oil was 102 ng/ml (61–132 ng/ml), and this peak was reached at 90 min following administration of the single dose of 2 mg/kg. The investigators on this study decided that since the pharmacokinetics of the 2 mg and 8 mg doses were so similar, they would use the lower of the two doses for the efficacy wing of this study.

Assessment of pain and mobility showed a significant decrease in pain and increase in activity ($p < 0.001$) at weeks 2 and 4 during CBD treatment as compared to baseline at each bi-weekly evaluation. It was found that the CBD oil resulted in reduced pain scores when compared to baseline on both bi-weekly examinations ($p = 0.03$). No side effects were reported by owners, but serum chemistry demonstrated an increase in serum alkaline phosphatase (9/16 dogs, 56%) while receiving the CBD oil, which reached significance at week 4 ($p < 0.005$).

The authors of this study conclude that the dogs with OA who received 2 mg/kg q 12 h were found to be more comfortable and active with very few undesirable side effects compared to placebo. The authors note that the CBD oil used in this study was a "strain-specific" extract and other products that do not have this same strain specificity may not have the same efficacy as measured for this proprietary product (Gamble et al. 2018).

6.5 Evaluation of Trends in Marijuana Toxicosis in Dogs Living in a State with Legalized Medical Marijuana: 125 Dogs (2005–2010)

This study correlated the number of medical marijuana licenses issued in the state of Colorado between 2005 and 2010 and the number of admissions to the ER for marijuana toxicosis. This is a retrospective case series from January 1, 2005, to October 1, 2010. A total of 125 client-owned dogs presented for known or suspected marijuana toxicosis with or without a urine drug screening test (UDST).

A significant correlation was found between the number of medical marijuana licenses and marijuana toxicosis cases seen in two veterinary hospitals in Colorado. Ingestion of baked goods made with high potency THC butter extractions resulted in two recorded deaths. The authors note that due to the difference in urine metabolites in the dog as compared to the human, the UDST test may not be valid in dogs. It is also important to note here that there have been no recorded deaths in the many hundreds of years of human use of marijuana. These two canine deaths were due to the toxicity of chocolate in dogs combined with the cardiovascular effects of THC on the myocardium. In each case, brownies or chocolate chip cookies were made with very large amounts of THC butter, and the two dogs, each rather small, ate very large quantities of the chocolate with cannabis. The authors were not able to attribute both deaths to the THC alone and felt there was a major influence of the chocolate contributing to their deaths (Meola et al. 2012).

6.6 Comparative Pharmacokinetic Study of Three Routes of Administration of CBD in the Beagle Dog

This study was designed to determine the pharmacokinetics of CBD in healthy dogs. A sample population of 30 healthy research dogs were assigned to receive 1 of 3 different formulations at a dose of 75 or 150 mg q12 h for 6 weeks. The dosage formats were (1) liquid oil infusion administered to the oral mucosa; (2) oral capsules with microencapsulated oil beads; and (3) transdermal application. Serial CBD plasma concentrations were measured over the first 12 hours and repeated at 2, 4, and 6 weeks. Greater plasma concentrations were measured with the oral CBD oil-infused formulation. The plasma half-life of CBD administered via this route after 75 mg and 150 mg doses, respectively, was 199.7 +/− 55.0 and 127.5 +/− 32.2 min. This study found that blood levels are dose proportional, as expected, and the oral liquid CBD absorbed transmucosally was the superior formulation of the three formulations tested, with orally administered microencapsulated beads the second-best formulation in terms of pharmacokinetic profile (Bartner et al. 2018).

6.7 Clinical Efficacy of CBD for Treating Osteoarthritis and Refractory Epilepsy in the Dog: A Pilot Study

The osteoarthritis (OA) wing of this efficacy study consisted of 24 client-owned dogs with clinical evidence of OA radiographically and who had an identifiable lameness. A double-blinded, randomized, placebo-controlled, study design was utilized, with each study group receiving medication for 6 weeks and a placebo for 6 weeks. The treatment group received 2.5 mg of CBD oil q 12 h. Gait analysis and an

activity monitor were used to gain objective data, and a behavioral questionnaire was given to the dog owners which provided subjective information. The study results for OA were not yet available at the time of this publication (McGrath 2018).

The epilepsy segment of the study consisted of 16 client-owned dogs who were diagnosed with idiopathic refractory epilepsy, having 2 or more breakthrough seizures per month while receiving conventional anticonvulsant therapies. Inclusion criteria included a normal neurologic exam and a normal epilepsy workup with an MRI and CSF analysis. Nine dogs were randomly assigned to the treatment group and seven to the control (placebo) group. The treatment group received 2.5 mg/kg CBD oil q 12 hours by mouth. The control group received placebo oil for 12 weeks. Study subjects were required to stay on their standard anticonvulsant drugs (AED). Routine blood work and CBD levels were determined every 4 weeks. AED levels were measured at the conclusion of the trial.

Sixty-seven percent (6/9) of the dogs in the treatment group experienced a greater than 40% reduction in average monthly seizures during the study, whereas only 29% (2/7) of the dogs in the control group had a greater than 40% reduction in average monthly seizures.

Elevations in alkaline phosphatase (ALP) were recorded for the treatment group and one dog in the control group. The single control dog had previously measured elevations in ALP, so this elevation was not considered to be relevant to the study. Six dogs (67%) in the treatment group had elevations in ALP measured at the end of the study. The mean ALP value was 619 IU/L (range 15–140 IU/L).

AED concentrations in the treatment group for phenobarbital decreased in 2/7 dogs (29%) and increased in 5/7 dogs (71%). In the control group, phenobarbital levels decreased in 3/5 dogs (60%) and increased in 2/5 dogs (40%); there was no significant change in either group. This is an interesting finding to note, because there has been a concern that CBD, which is metabolized through the P450 group of cytochromes, might interfere with the drug disposition of pharmaceuticals that also are metabolized through that pathway. From the results of this pilot study, that effect is not apparent, at least with respect to phenobarbital levels.

Potassium bromide (KBR) levels in the treatment group decreased in 2/3 dogs (67%) and increased in 1/3 dogs (33%). In the control group, KBR levels decreased in one out of two dogs (50%) and increased in one out of two dogs (50%). There was no significant change in either group, although the total number of study subjects was low in this pilot study. This research and the osteoarthritis section of this study have not yet been published, pending the results of the plasma analysis of cannabinoid levels that were measured at 0, 4, 8, and 12 weeks and the completion of the efficacy study of the effects of CBD on osteoarthritis.

The American Kennel Club Canine Health Foundation has granted nearly $400,000 in funding to this research group at CSU for a larger, expanded study with 60 dogs, as a result of the positive results of this pilot work, with respect to the use of CBD oil to address refractory epilepsy. This study will also be looking at uncontrolled epileptics having two or more seizures per month while receiving standard therapy. In this expanded study, which will use a crossover design, each subject will receive 12 weeks of treatment or placebo with a 4-week washout period between treatments. This study began in January 2018 and is currently enrolling patients (McGrath 2018).

7 Guidance on Veterinary Cannabis Products in the US Market

Cannabis preparations have historically been used for home remedies, as medicine, as a functional food, and as a source of nutrition, primarily for humans. However, there have been reports of cannabis products being used in animals dating back to the 1800s, when cannabis had become a popular herbal remedy at a time prior to the development of the pharmaceutical industry. Patent medicines containing cannabis, usually in an alcohol tincture, were sold to horse owners for colic and other equine ailments, and topical liniments were used externally for joint and lameness problems.

As cannabis became vilified and stigmatized in the 1930s, and as pharmaceutical medicines became more available as substitutes for cannabis products, the use of cannabis in the horse became less common to nonexistent. For our companion animal species, dogs, cats, and horses, the use of cannabis products did not gain popularity until the state-by-state legalization of cannabis for medicinal purposes began in the mid-1990s. Pet owners, learning of the many benefits that cannabis has created for people, naturally began to explore its use in their pets for the medical problems that were not easily solved by conventional veterinary medicine. These are problems such as epilepsy that are resistant to pharmaceutical remediation; pain that is poorly responsive to opiates, steroids, and nonsteroidal anti-inflammatory drugs; cancer treatment side effects such as nausea and vomiting; and to treat cancer. Some veterinary patients respond well to NSAIDs for osteoarthritis, but the drugs themselves can cause toxicity in sensitive patients. The use of cannabis as an alternative means of remediating the pain of arthritis can substitute for these drugs or allow for lower and safer dosages of the pharmaceuticals. Several veterinary randomized placebo-controlled clinical trials that have been conducted have demonstrated objectively the benefit of cannabis for osteoarthritic pain in the dog (McGrath 2018; Gamble et al. 2018).

7.1 Cannabis Product Formats and Delivery Methods

There are several formats of cannabis products for companion animals, currently in the marketplace, and several up-and-coming formats currently undergoing research and development efforts by forward-thinking companies. The route of administration is a primary contributing factor in the effectiveness of any medicine, natural or otherwise. Choosing the appropriate delivery method for the patient can greatly affect medical outcomes. The associated bioavailability of the drug should be balanced with the practical needs of the patient.

Dogs have proven to be highly sensitive to the adverse neurological effects of the psychoactive decarboxylated THC. They can benefit from the use of the non-decarboxylated non-psychoactive THCA, without any fear of a visit to the veterinary ER. THCA, although not psychoactive, is still a Schedule I controlled substance according to the Drug Enforcement Agency. Although the THCA does not bind to CB_1 receptors in the brain, which is why it is psychoactive, it is regulated through many other entourage non-cannabinoid receptor-mediated pathways.

Juicing of cannabis leaves is gaining popularity as a method of preparation and consumption. The cold extraction of raw cannabis preserves the heat-sensitive acidic cannabinoids THCA and CBDA that readily undergo degradation through the decarboxylation pathway. Decarboxylation typically occurs at temperatures above 100 °C that are common for combustion (smoking), vaporization, or hot extraction. THCA has a significantly lower affinity for the endogenous cannabinoid receptor CB_1 and does not have the same psychoactive effects as preparations containing "activated" of "decarboxylated" THC. Consumption of unheated cannabis preparations allows for the administration of significantly higher doses of acidic cannabinoids, without the psychoactive effects of THC. Juicing of raw cannabis would have the advantage of retaining volatile terpenes, which also have important medicinal properties. Original terpene profiles are generally altered in extraction methods involving heat.

7.1.1 Oral Route of Administration

Ingested route is very common and still quite effective, in spite of its poor bioavailability. Pharmacokinetic (pK) studies documenting the bioavailability of oral cannabis extracts, specifically the major cannabinoids THC and CBD in both humans and dogs, demonstrate that only 5–10% of the lipophilic drug reaches its intended active site. In spite of this relatively poor bioavailability, good clinical responses have been documented in both species. pK studies documenting the bioavailability of cannabinoids in the equine species remain to be performed, as well as in other veterinary species. The majority of products currently available for animal species are targeted toward ingestible formulated products. Some examples of these formulations are highlighted below.

Capsules—The first animal companion cannabis product to be launched in the United States, shortly after the federal legalization of low THC cannabis ("hemp"), contained powdered hemp seed meal infused with the lipophilic extracts of the cannabis plant and was manufactured into capsules. Capsules contain a fixed volume of active materials and are limited in efficacy to specific weight ranges of patients. This limitation necessitates manufacturing and packaging multiple capsule sizes to accommodate the many different sizes of veterinary species, Chihuahua to Great Dane to draft horse. Capsules are convenient to keep and administer and are a dosage-form that is familiar to most consumers. They can be hidden in a small amount of food to facilitate absorption on an empty stomach, but they are also subjected to rapid first pass liver metabolism and, based on the published pK study from Colorado State University, are less bioavailable than a lipophilic liquid absorbed through the oral mucosa (Bartner et al. 2018).

Tinctures—The second cannabis product format introduced to the US animal health market was a product that has become commonly known in the cannabis industry as a "tincture." These are oil infusions of lipophilic extracts of the cannabis plant and can contain either high THC cannabis ("marijuana") or low THC cannabis ("hemp"). Carrier oils can be any oil, but most commonly grape seed oil, hemp seed oil, and medium-chain triglycerides are used in these formulations. It's worth mentioning that the word "tincture" was derived from botanical medicine and in that context denotes an ethanolic extract of a botanical material.

Tinctures can contain just cannabis or can be compounded with additional terpenes and other botanicals and nutraceuticals or even pharmaceuticals for a more targeted effect. Tincture labels should include the potency of the formulation in total milligrams of CBD and THC and other measurable levels of cannabinoids, as well as listing the other amounts of the active ingredients in the bottle, and any preservatives that have been added to improve shelf life. Tinctures have the advantage of being scalable in terms of being able to dose different sizes of animals, since all that is needed for a larger or smaller patient would be more or less volume, respectively. Tinctures can also be added or mixed with a small amount of tasty food to facilitate administration but are most efficiently absorbed transmucosally from the oral cavity.

A pharmacokinetic study comparing the bioavailability of transmucosal, oral, and transdermal routes of administration for CBD was recently completed (Bartner et al. 2018). It was

found that transmucosal administration of a lipophilic liquid produced the highest C_{max} values in this study. Thus, the oil-based proprietary tincture in this study, applied transmucosally to the oral mucous membranes, gums, inner lips, tongue, and buccal pouch, would be the most bioavailable means of administration compared to the other two materials evaluated in this study.

Extended stability studies of cannabis products are needed to determine the shelf life of the formulation, which generally ranges from 12 to 24 months. This "outdating" should be expressed on the label as a manufacturing date or a "best by" date so as to inform the consumer of how recently the product has been manufactured. This dating of the formulation guides the consumer in selecting a product where its potency should meet label claims based on its aging over time and the subsequent gradual deterioration of the delicate active materials contained therein. For a patient who doesn't need much extract on a daily basis, a bottle containing a large amount of material could conceivably expire before it is finished.

Dosage-form animal health products are commonly used to administer pharmaceuticals and nutraceuticals. Treats that contain nutraceuticals or pharmaceuticals, aka "dosage-form treats," have become very popular among pet-owning consumers. Dosage-form treats need to have the intent, and be labeled, as nutraceuticals, not as nutritional compounds. Neither cannabis nor hemp are approved feed ingredients by the FDA-CVM and AAFCO. This means that the guaranteed analysis (GA) and a nutritional statement on the label and/or product package with total calories and calories from fat is not appropriate for a dosage-form treat and could cause a "stop sale" letter to be issued by the FDA-CVM for selling an adulterated nutritional product.

The label of dosage-form treats, based on NASC and FDA-CVM guidelines, needs to contain a listing in the order of decreasing weights of the materials that are the "active ingredients" and the "inactive ingredients." This second category would include the nutritional components of the treat on the label.

Hard biscuits and soft-chews currently are the most popular dosage-form treats available in the marketplace. Like capsules, these products can contain only a fixed amount of the active ingredients, thus limiting the weight ranges addressed by a single dosage-form treat size. The advantages of dosage-form treats are the relative ease of their administration. The potential disadvantages could be patient hypersensitivity to the ingredients in the treat, the need for multiple treats at a time to treat a larger weight patient, the reduced shelf life, and the potential that the manufacturing process that involves baking or heating and extruding the material could cause heat adulteration of the product. Postproduction product analyses are critical to ensure that product potency has not been compromised by the manufacturing process.

Pellets and powders are scalable for dosing a wide variety of target species weights. There are a few powders made from low THC cannabis ("hemp") available. These powders can be manufactured from the powdered plant material or from the pharmaceutical modification of the lipophilic extract of the plant material into a powder format or may use an inert powder that is infused with the lipophilic extract of the cannabis plant. For most of the applications for animals, the low THC variety of cannabis is the preferred raw material for manufacturing this powder due to the potential for problems with high THC cannabis both in regard to the patient response and as regards the stricter regulatory environment for high THC cannabis.

Powders can be contained in wide-mouthed bottles with a measuring scoop in them that can be used to estimate effective dosages. Standard kitchen measuring spoons can also be used to scoop out the appropriate dosage for the size and condition of the patient. Powders can be packaged into stand-up pouches, as well as sticks, sachets, and, of course, capsules. Individual serving sizes make sticks, sachets, and capsules more convenient for dosing but remove the scalability benefit of powder over dosage-form treats.

Pellets are pressed from dried cannabis plant material, most commonly using the low THC cannabis variety ("hemp"). These pellets can be given to horses, goats, sheep, and other farm animals, as well as poultry, swine, zoo animals, caged birds, and pocket pets. A big concern with giving horses cannabis, even low THC cannabis, is that there would be enough THC even in low THC cannabis that the horse would test positive for THC on drug testing and be disqualified from whatever event it was being tested for.

Water-soluble cannabinoids apply existing technology using lipid emulsifiers and reducing the size of the oil droplets to as small a size as possible, usually in the range of nanometers. Water solubility increases the plasma concentrations and helps the lipophilic drug reach the active site. Further, a rapid onset is observed with water-soluble formulations that do not have the same long-lasting effects. Although published pK studies comparing the bioavailability of lipophilic versus hydrophilic preparations of cannabinoids administered through the same route do not exist, there are credible pK studies using other lipophilic materials, such as Coenzyme Q10, which document the improved bioavailability to be as much as 5–8 times better than the lipophilic material with this approach. The impact of increased bioavailability on clinical outcomes remains to be measured as these water-soluble cannabinoids become more available; however, less cannabinoids are required in water-soluble formulations to achieve similar active site concentrations compared to oil-based solutions.

Transmucosal routes of administration can be very effective in most contexts, as it is fairly easy to apply the liquid cannabinoids to the oral mucous membranes. Bartner

measured the comparative bioavailability of transmucosal with oral and transdermal routes in 30 beagle dogs. The transdermal method of administration was 12–32% as bioavailable as the transmucosal approach between 75 mg and 150 mg/day, based on the C_{max} values. The oral approach was 55–68% as bioavailable as the transmucosal approach. It was concluded from this study that the most bioavailable administration avenue among these three dosage formats was the transmucosal approach (Bartner et al. 2018).

7.1.2 Topical Administration

Topical applications of cannabinoids have low systemic bioavailability but will penetrate locally to benefit the regional anatomy. For most veterinary species that have hair or feathers covering their bodies, "salves" and "balms" that are oil-based run the risk of matting the hair and interfering with the application to the epidermis where it will be absorbed locally. Products that are in solvents like alcohol or use emulsifiers to create a water-soluble cream or lotion have a better chance of penetrating the hair or feathers and ultimately penetrate the skin. These are termed "liniments" if they contain alcohol and "creams" or "lotions" if they are emulsified and water soluble.

Transdermal applications involve the use of a bipolar material such as a phospholipid to carry the cannabinoids into the local circulation and from that enter the systemic circulation. Transdermals can be creams or can be in "patches" that use a membrane to separate the transdermal solution from the skin. For veterinary species, transdermal liquids and patches will need to have a spot of hair clipped prior to application. Some anatomical sites that are hairless, such as the inside of the pinna and the ventral inguinal regions, do not need clipping and facilitate administration. It is recommended prior to reapplication of the transdermal cream to cleanse the site of application to improve absorption. Administration to the inside of the ear flap prevents the veterinary patient from licking the transdermal cream from an accessible area such as the inguinal region. Transdermal medication absorption is dependent upon the amount of local vascularity to carry the medication from the skin into the systemic circulation.

7.1.3 Inhalation

Inhalation is an impractical delivery method for veterinary species, except maybe primates or laboratory animals connected to breathing masks. As water-soluble versions of cannabinoids are developed, the possibility exists that a nebulization method could be employed to allow for absorption through the large surface area of the lungs. Inhalation methods are rapid onset and bypass first pass metabolism in the liver.

7.2 Zero-THC Hemp Extracts

Although low THC cannabis, which is called "hemp," already has less than 0.3% THC on a dry matter basis at the time of harvest, there are a number of situations where significantly reducing the amount of THC to undetectable levels has distinct advantages for veterinary species. Dogs are more sensitive to the adverse neurological effects of THC when they are naïve to exposure and have not developed tolerance. Some dogs are more sensitive than others, and anecdotal reports from veterinary clients (personal communication) indicate that there is a small percentage of dogs who react adversely to the small amount of THC present in hemp cultivars. For these dogs a zero-THC product would be advantageous.

Horses can have unpredictable responses to THC, potentially increasing the risk to the horse, the horse owner, and the veterinarian. Additionally, both horses and dogs in competitive events are commonly drug tested in order to qualify to compete. The use of a zero-THC product would make it less likely the animal would fail the drug test due to detectable levels of THC. Drug testing laboratories commonly test both urine and blood for many substances, including THC and CBD. Most venues will disqualify if any THC is detected (zero tolerance), but many do not disqualify for the detection of CBD. It is up to the individual event to decide what the disqualifying parameters are. The World Anti-Doping Agency (www.WADA-ama.org) has allowed the use of CBD in athletes since January 2018. It still disqualifies for THC, synthetic cannabinoids, and cannabimimetic agents. For this reason, Olympic athletes that are using a zero-THC source of CBD will not be disqualified, per the example of gold medal winner, Michael Phelps.

The veterinarian co-author of this chapter has distributed over 40,000 bottles of zero-THC tincture to veterinarians over the past 2 years. Reports from hundreds of these veterinarians have documented the clinical strength of the zero-THC formulation to reduce pain, improve mobility, bring some tumors into remission, and successfully address uncomplicated epilepsy, type 2 diabetes, and anxiety-related behavior problems such as noise phobias.

Prior to the discovery and use of all of the many non-THC cannabinoids in hemp, it was thought that THC was absolutely necessary for any clinical benefits. It is now known from these many cases that have successfully been treated with zero-THC extracts that the entourage effect does not need THC to be activated. In patients with reduced endocannabinoid tone, it may be necessary to use a small amount of THC to replace the endogenous ligand for better clinical response. Cases of severe pain and aggressive cancers may also benefit from THC, but for most other clinical cases, THC is not necessary.

7.3 Dosing Considerations and Strategies for Veterinary Species

The determination of evidence-based dosages through dosage-tiered Phase I studies in any veterinary species has yet to be conducted. Several of the randomized clinical trials recently published from veterinary academic institutions have used dosages extrapolated from published studies in human and laboratory animals, verified by single-dose pharmacokinetics to ensure detectable blood levels over a therapeutic period of time. These veterinary studies in dogs used a single dosage, which is quite high, but these high dosages did have statistically significant results with clinical improvement in response to clinical patients with OA and refractory epilepsy. However, there have not been any incremental dose-to-response studies performed to see if a lower dose might also benefit veterinary patients and be more cost-effective for the pet-owning public.

Dosages in the human patient have been derived both from published objective studies and from the clinical impressions of hundreds of physicians who have been trained in medical cannabis in the 29 states with medical cannabis legislation since 1996 when cannabis was first legalized for medical purposes in the United States (MacCallum and Russo 2018). Due to the legal considerations affecting veterinarians' clinical use of cannabis, there has not been this kind of hands-on practical empirical dosage-setting by veterinary clinicians. Instead, dosages have been empirically and anecdotally determined largely by pet owners and by a few veterinarians willing to risk their veterinary licenses to employ cannabinoids with their patients.

The data from veterinarians who have been recommending phytocannabinoids for their patients shows that veterinary species have a "biphasic response" to cannabis dosages in the same way that humans do. "Biphasic" means that a low dose (or "microdose") will generate one set of effects and address one set of clinical issues and a high dose (or "macrodose") will produce a second set of effects and address a second set of clinical issues.

Microdoses are considered to be less than 0.5 mg/kg BID of cannabinoids. Macrodoses would be greater than 2.0 mg/kg BID. Individual responses to dosage levels may vary. Based on anecdotal reports by veterinarians and pet owners who are using microdoses, the effective dosages used in dogs and cats have been reported to be as much as 40 times less than the macrodoses used in the CSU safety study or 5 times less than those used in the CSU efficacy study. There will be a small portion of animals that will develop the reported side effects of diarrhea, sedation, or elevated serum alkaline phosphatase, even with these lower doses.

McGrath evaluated the safety of administering high doses of CBD over a 6-week period. The results found that at the macrodose level (10–20 mg/kg/day), there were a greater frequency of adverse reactions to hemp extracts. Diarrhea, sedation, and serum alkaline phosphatase elevations were recorded in the subjects receiving 10 and 20 mg/kg/day (McGrath et al. 2018).

Tischler in his presentation at the Second Annual Conference at the Institute of Cannabis Research at Colorado State University in Pueblo discussed the value of microdoses in the human patient over the use of macrodoses. Microdosing serves to reduce or eliminate the psychotropic effect of THC through sub-psychotropic dosing and through the development of tolerance over a period of 2 weeks. Veterinary patients, for whom the use of THC is necessary and therapeutic (severe pain, appetite stimulation not effective with CBD, certain types of neoplasia), using the microdose strategy initially will facilitate the development of tolerance to the adverse effects of THC. Once this is achieved, THC dosages can be escalated to achieve the desired clinical benefit(s) (Tischler 2018).

In an unpublished study, the veterinarian co-author of this text gave 30 horses, in 3 different stables, dosages of 25–50 mg of CBD in a zero-THC hemp extract once or twice daily to address complaints of anxiety, gait abnormalities, mild to severe laminitis, and metabolic syndrome. Study subjects averaged around 1000 pounds. It was found that for anxiety and mild cases of lameness or gait abnormalities, administration of 25 mg once or twice daily was adequate to elicit a response with regard to anxiety from loading up into a trailer, or at events, or for mild gait abnormalities. In one stable the horses were only able to be given their dose once daily, yet that single dose still produced good clinical results.

For more severe conditions such as moderate laminitis, other sources of lameness, or metabolic syndrome, it was found that 50 mg once or twice daily was sufficient for clinical response. When horse owners were asked to discontinue giving the hemp extracts so as to determine withdrawal times for CBD, for situations in which the horses may be drug tested for an event, many refused to stop administration of the hemp, as they were very pleased with their horses' response to the hemp extracts. Horses have evolved to be very efficient in absorbing fats from their diet, as their natural diet of forage is very low in fats and oils. pK studies in the equine are very much needed to better understand dosing intervals and levels.

For most other animals, we use the dosage range established empirically through thousands of veterinary uses, starting with a low dosage and slowly increasing the dose over time. It is recommended to give a dose for 10–14 days to allow for the upregulation of CB receptors, and if after 2 weeks patient clinical response is inadequate, then increasing the dosage twofold greater than the starting dose may produce a better response in a given patient. Following through with dosage escalation, slowly over time, will yield the best clinical results. "Start low, go slow, stay low" is the mantra for dosing a patient whether human or veterinary,

and this protocol, combined with the safety and efficacy studies of McGrath, allows the practitioner to be able to provide a dosage as high as 20 mg/kg/day safely (MacCallum and Russo 2018; McGrath et al. 2018).

7.3.1 Ratio Dosing

Ratio dosing is the use of cannabis formulations that contain both THC and CBD in specific proportions to each other. The goal of this approach is twofold:

1. It allows for the development of tolerance to THC through the initial use of a high CBD to low THC ratio (THC:CBD/1:25) to avoid psychoactivity while tolerance to the adverse effects of THC is being established.
2. Once tolerance has been established, the dosage of the THC fraction in this combination formula can then be escalated safely. Escalation of the THC dose will also escalate the CBD dose administered, which may be the desired approach for a given patient's clinical needs.

If it is determined that a patient needs a higher amount of THC to provide better medical benefits but may not need as much CBD as escalating the THC dose in a low ratio formula would provide, then moving to a ratio formulation with an equal amount of THC:CBD may be more efficacious. Equivalent ratio formulations of THC:CBD (1:1) are being used empirically and effectively for moderate to severe pain and in oncology patients for whom the low THC ratio product does not provide sufficient antineoplastic activity or remediation of oncologic side effects from therapeutics or the disease itself.

In rare situations in veterinary species, it may be necessary to provide a high THC formulation for improved pain management or to better address the needs of the oncology patient. THC:CBD/4:1 is typically the ratio that is being used clinically. The need and use of this in veterinary patients has a higher potential for adverse effects than the lower THC ratio formulations. In all cases of using THC in veterinary species, it is important to develop tolerance first by using the low THC or THC-free products mentioned previously for the first 2 weeks of therapy to avoid adverse reactions or trips to the veterinary ER.

7.3.2 Adverse Events (AEs) and Dosage

McGrath reported that the CBD safety study determined that a dosage of 10 or 20 mg/kg/day of a full-spectrum CBD divided BID produced a greater incidence of adverse events than reported at lower dosages. Diarrhea and sedation were the two dominant AEs. Elevation of serum alkaline phosphatase levels was also observed to be significant events at these higher dosages. Other liver function tests, such as bile acids and ALT, were within normal limits (McGrath et al. 2018).

Sellers et al. (2013) found that the use of a 1:1 ratio of THC:CBD in their sublingual spray, Sativex™, was associated with significantly less AEs than the 100% pure synthetic THC capsule, Marinol™. This illustrates the harm reduction that comes with adding CBD to a formulation containing THC or a synthetic THC (Sellers et al. 2013).

Russo reported that the incidence of AE associated with the drug Sativex™, approved throughout the world for muscle spasticity with MS, was significantly less when the drug was gradually titrated to the patient's response. This study found that most AEs will be early and transient using a modification of the dosing strategy by starting at a lower dose increasing it slowly to achieve to clinical effect (Russo et al. 2011). In a later paper, MacCallum and Russo state, "Cannabis medicine doses must be individually determined, as (the effective dosage for a specific patient) . . .. depends on the endocannabinoid tone of that patient" (MacCallum and Russo 2018).

7.3.3 Drug Interactions with Cannabis

It is reported that in human medical marijuana patients, physicians have only rarely observed clinically significant drug interactions. MacCallum and Russo (2018) state, "there is no drug that cannot be used with cannabis, if necessary" (MacCallum and Russo 2018). Depending on the strength of the affinity of the metabolite for the metabolizing cytochrome, serum levels of cannabinoids or pharmaceuticals may increase with inhibitors or decrease with enzyme inducers. It is known that THC and CBD in human are oxidized by the p450 cytochromes (CYP2C9, 2C19, and 3A4). It is assumed that this is similar to the metabolic pathways in the dog and other veterinary species, but studies still need to be conducted in each species to detail possible interspecies variation.

In human patients the main AEs have been associated with the concomitant use of other CNS depressants with cannabis. High-dose CBD has been found in human to interfere with the metabolism of clobazam, thus potentially requiring a dose reduction of that drug when used with CBD (Devinsky et al. 2017). Drug interaction studies for each individual drug and cannabinoid are lacking, but the studies that currently exist have found no increased toxicity or loss of effect with concomitant medications. It is good medical practice, however, to continue to test for these interactions as individual responses may not be the same or predictable from population responses.

McGrath in her refractory epilepsy study measured both post-pill phenobarbital levels and potassium bromide (KBR) levels in her study subjects at the end of the 6-week study period. She found no statistical difference between the treatment and placebo groups for either anticonvulsant. This may indicate that, in spite of the theoretical potential for herb-drug interaction between CBD and P450-metabolized drugs, at

least in dogs on anticonvulsants, the interference may not be clinically relevant. Regardless, it is good medical practice to retest important serum drug levels 2 weeks following initiation of CBD therapy, especially if using macrodose protocols. McGrath mentioned the small study group size in this pilot work as possibly not giving an accurate indication of whether there really is herb-drug interaction or not, and she mentioned that she will analyze these levels not just at the end of her AKC-funded clinical trial but at regular intervals during the trial (McGrath 2018).

8 Current Good Manufacturing Practices (cGMP)

The National Animal Supplement Council (NASC.cc) in partnership with the FDA-CVM has established cGMP guidelines for animal nutraceuticals. These have recently been updated to include the recently enacted FDA Food Safety Modernization Act (FSMA). The NASC will provide third-party inspections of manufacturing facilities of its members to ensure that they meet cGMP standards. NASC member companies that pass their audits successfully can display the NASC seal on the product labels which can guide the consumer to locate products that meet the highest standards of quality and transparency.

Product labels need to contain information about the batch or lot number of the manufacturing process, outdating, company contact information, precautions and contraindications, and the intended use of the product, which, as a nutraceutical, cannot have any medical claims made in the label copy or marketing material or even in the name of the product. For instance, a product that contains the letters CBD, or the word "cannabidiol" in its name or on the label, runs the risk of enforcement by the FDA. This is because the FDA has recently approved CBD as a drug to treat resistant pediatric epilepsy. Medical claims are a common reason for FDA-CVM stop sale letters.

8.1 Third-Party Lab Testing

Quality control testing is a critical aspect of any manufacturing process. Without QC testing, manufacturers would not be able to manufacture products with standardized concentrations.

In addition, contamination can be introduced, and the only way to assure that the product remains unadulterated is through validated testing methods. Other important things to consider include organic cultivation methods, Good Agricultural Practices (GAP), and cGMP protocols.

The analytical laboratory performing the analysis must be validated for accuracy and precision in its measurements in order for the standardization of product potency to be effective. Companies that use in-house laboratories must have those results validated through the use of validated third-party analytical laboratories. It is also up to the labs to apply statistically valid sampling methods to obtain a representative sample of a batch in order to generate meaningful data.

There are a few major concerns that third-party testing can alleviate:

Cannabinoid and Terpene Potency Testing—This is absolutely essential in order to achieve effective and consistent dosing of a patient. An accurate analysis for each manufactured batch is needed to meet strict food and drug guidelines. The contents need to be listed on the product label and in marketing materials to allow the clinician to more accurately establish an effective dosing strategy for the patient. Further, it allows the pet-owning consumer to better select the appropriate potency of product for their size of animal and the potential duration of therapy needed for that product. Manufacturers can make label claims regarding the cannabinoid and terpene content of their products in order to mislead consumers and inflate perceived value of their products. This can pose a serious health risk if a patient is not getting the required dosage necessary to alleviate their conditions. Certificates of analysis on cannabis-derived products convey the potency and potential dosages of products.

Pesticide Contamination—The application of pesticides has long been a standard practice in cultivation of cannabis plants, despite market demand for organic products. The pesticides that are commonly sold in hydroponic stores can present a specific health risk to both animals and humans. For example, a commonly sold fungicide called Eagle 20 has a principal active ingredient called myclobutanil, a compound that when exposed to heat can generate hydrogen cyanide as a reactive by-product. Another fungicide and plant growth regulator called paclobutrazol has been shown to cause downstream kidney and liver damage in animal case studies, and the state of California has designated it as a Category I pesticide, meaning absolutely no detectable amount is allowed in a cannabis product. Be sure to ask for a robust multiresidue pesticide analysis from a third-party laboratory for any organic cannabis products.

Microbiological Contamination—Food testing has long set the standard for ensuring microorganisms are not present in products meant for consumption, but certain cannabis operations have yet to fully mitigate this risk. While it is fairly rare to find organisms like *E.coli* or *Salmonella* in cannabis, it is very common to find *Aspergillus*, a certain type of mold that is very prevalent in outdoor cannabis. *Aspergillus* poses a very specific health risk, especially for patients with a compromised immune system. This is due to a type of neurotoxic by-product produced in the spores collectively referred to as mycotoxins. If the veterinary patient has

any type of immune disorder, it is imperative that any products purchased come with a certificate of analysis certifying the absence of microorganisms.

Heavy Metal Contamination—Cannabis is known to be a bioaccumulator, meaning it will absorb contaminants from the soil. While this can be useful in some applications such as remediating poor soils, it can cause a huge risk if the hemp or cannabis plant was grown in contaminated soils. Arsenic, cadmium, lead, and mercury are the principal dangers, and heavy metal testing should be conducted on any plant-based products to ensure a clean product. Be especially wary if the plants were grown in a country with poor environmental regulations.

9 Concluding Remarks and Future Directions

Veterinary medicine has not seen the same advances compared to human medicine for objective, non-biased scientific evidence for the use of medical cannabis in veterinary species. This is due, in part, to the fact that the legalization statutes, state by state, do not provide for similar legal privileges for veterinarians and their patients as physicians have for recommending cannabis for their human patients.

Nonetheless, there are now several university-based, prospective, double-blinded, placebo-controlled, randomized clinical studies examining CBD from hemp extracts to measure its safety and pharmacokinetics. Included with these studies, once safety has been confirmed, is measuring the efficacy of hemp oil extracts over diagnosed veterinary conditions such as osteoarthritis and epilepsy. Some of these studies have already been published, some have been presented at professional conferences, and some are in press. These landmark studies have all been reported and summarized in this chapter.

Due to the nearly universal distribution of the endocannabinoid system in all chordates, and in many invertebrates, the same or similar benefits of cannabinoids found in humans also can be applied to most veterinary species. This chapter highlights what we know about cannabinoids and their interactions with the endocannabinoid system in animals. A thorough review of the scientific literature has been compiled here for veterinarians and veterinary scientists to better understand this fascinating and emerging therapy and, by understanding it, to be better able to deploy cannabinoid therapies for their patients and formulate more effective cannabinoid medications.

Acknowledgments The authors of this chapter would like to thank the many individuals and institutions who have had the courage and insight to work tirelessly in this field of cannabinoid therapeutics to contribute substantial understanding to the world scientific literature of the many benefits and few risks associated with the use of cannabis and its derivatives, in both human and veterinary species. In particular, the authors of this chapter want to express their gratitude to the veterinary clinical research teams from Colorado State (under the guidance of Stephanie McGrath) and Cornell Universities (under the guidance of Joe Wakslag) for having completed in the canine patient the first-ever safety studies, comparative pharmacokinetic studies, and efficacy studies to determine the ability of cannabinoids to reduce osteoarthritic discomfort and to help patients with refractory epilepsy. The authors would also like to extend their gratitude to Dr. Ethan Russo, Dr. Jahan Marcu, and Kevin McKernan for their thoughtful insights and review of the chapter. We look forward to the continued development of evidence supporting the clinical use of cannabis and its derivatives for many valuable applications in veterinary species. It is our fervent hope that the information presented in this chapter will help future research efforts bring more detailed data regarding the range of applications for cannabinoids in veterinary species.

Essential Oils

Ajay Srivastava, Rajiv Lall, Anita Sinha, and Ramesh C. Gupta

Abstract

The essential oils (EOs) have been used in humans and animals for several millennia, as they represent an important part of folk medicine for their medicinal properties. EOs are a very heterogeneous group of complex mixtures of secondary plant metabolites. The nature of an EO varies from plant to plant, species to species, and within botanical families. By now, more than 3000 varieties of volatile aromatic compounds have been identified. Hundreds of chemical compounds have been identified in the essential oils (EOs) of some plants, with properties such as antioxidative, anti-inflammatory, antibacterial, antiviral, antifungal, antiseptic, antimycotic, antitumor, antispasmodic, immunostimulating, etc. In addition to aromatherapy, they are either ingested or topically applied for conditions such as pain, arthritis, bruises, scratches, scars, flea control, and many others. This chapter describes EOs of plant and non-plant origins, their active constituents, and clinical applications in animal health and disease.

Nutraceuticals · Veterinary nutraceuticals · Essential oils · Animal diseases

1 Introduction

Essential oils (EOs) are naturally occurring volatile aromatic compounds that are found in the bark, stems, flowers, seeds, and other parts of many plants. EOs are a very heterogeneous group of complex mixtures of secondary plant metabolites. The composition of EOs can vary depending on a number of factors, such as geographic location, cultivation, time of day, weather, season, and method and duration of distillation. In fact, every step during the production process is a critical determinant of the quality of the EO product.

EOs have been used for at least several millennia for natural healings in humans and animals. EOs also offer calming and invigorating fragrances via aromatherapy. The physical and chemical properties of EOs allow them to quickly move through the air and directly interact with the olfactory sensors in the nose, which is why EOs are commonly used for aromatherapy for dogs. There is growing interest in aromatic and medicinal plants because of their antioxidative and anti-inflammatory properties in both scientific research and industry (Singh et al. 2005; Isbilir and Sagiroglu 2011). EOs can be used for a wide range of emotional wellness of dogs and cats. Depending on a need, they can be used as a single EO or in combination with other EOs. In case of dogs, EOs are commonly used for arthritis, bruises, scars, strains, skin issues (such as eczema, bacterial or fungal infections), flea control, and many other conditions. Additionally, EOs can be used as biopreservatives, reducing or eliminating pathogenic bacteria and increasing the overall quality of animal and vegetable food products (Solórzano-Santos and Miranda-Novales 2012). In dairy cows, EOs such as garlic oil, eugenol, cinnamaldehyde, and capsicum (singly or in combination) have been found to modulate rumen fermentation and responses of immune and lactation (Cardozo et al. 2004; Tekippe et al. 2013; Oh et al. 2015; Oguey and Wall 2016; Stelwagen et al. 2016). This chapter offers a brief account of some commonly used EOs, while other are listed in Table 1.

Table 1 Essential oils (EOs), chemical constituents, and their clinical applications

Essential oil/source	Chemical constituents	Clinical applications	References
Ajenjo oil (*Artemisia echegarayi* Hieron.)	Thujone, camphor	Antibacterial, free radical scavenging	Laciar et al. (2009)
Alpinia galanga Willd. (L.) oil	1,8-Cineole, α-terpineol, α-pinene, β-pinene, terpinene-4-ol, chavicol, (*E*)-β-farnesene, β-sesquiphellandrene, β-bisabolene, eugenol acetate	Antiseptic, expectorant, anesthetic	Raina et al. (2014)
Alpinia officinarum Hance. oil	1,8-Cineole, α-terpineol, α-pinene, β-pinene, terpinene-4-ol, camphor, α-fenchyl acetate	Antiseptic, expectorant, anesthetic	Raina et al. (2014)
Alpinia polyantha D. Fang oil	Camphor, α-pinene, β-pinene, β-agarofuran, globulol, β-cubebene, fenchyl acetate, β-maaliene, aristolone, δ-cadinene, β-caryophyllene, α-muurolene		Huong et al. (2015)
Anthemis aciphylla Boiss.	α-pinene, terpinen-4-ol, isofaurinone	Antimicrobial	Baser et al. (2006)
Arborvitae oil (*Platycladus orientalis* L.)	α-Pinene, α-cedrol, δ-3-carene, limonene, β-caryophyllene, myrcene	Anti-inflammatory, antibacterial, antifungal, antihypertensive, hemostatic, anticancer, anti-gout, insecticidal	Hashemi and Safavi (2012), Puškárová et al. (2017)
Basil oil (*Ocimum basilicum* L.)	Monoterpenes, sesquiterpene hydrocarbons, oxygenated sesquiterpenes	Antioxidative, anti-inflammatory, antiviral, antibacterial, diuretic, antispasmodic, appetizer, nervous system stimulatory, anti-warts, anti-fatigue, muscle relaxant, food preservative	Lemberkovics et al. (1998), Suppakul et al. (2003), Kuorwel et al. (2011), Chenni et al. (2016), Sakkas and Papadopoulou (2017)
Cardamom oil (*Elettaria cardamomum*)	Pinene, methyl eugenol, sabinene, geraniol, myrcene, phellandrene, 1,8-cineole, citronellol, linalool, limonene, *p*-cymene, terpinolene, *trans*-nerolidol	Restores hair loss, skin treatment, antioxidative, anti-inflammatory, analgesic, muscle relaxant, antispasmodic, diuretic	Al-Zuhair et al. (1996)
Chamomile oil/Blue oil (*Matricaria chamomilla* L.)	Terpenoids, Flavonoids, α-bisabolol, sesquiterpene derivatives, chamazulene	Anti-inflammatory, antiseptic, carminative, sedative, spasmolytic	Salmon (1992), McKay and Blumberg (2000), Srivastava et al. (2010), Singh et al. (2011)
Cinnamon/Cassia oil (*Cinnamomum cassia*)	(−)-Cinnamaldehyde, *o*-methoxy-cinnamaldehyde, cinnamyl acetate, cinnamic acid	Antibacterial	Burt (2004), Oussalah et al. (2006)
Citrus maxima Burm., *Citrus sinensis* L.	DL-Limonene	Antioxidative, antifungal	Singh et al. (2010)
Clove oil (*Syzygium aromaticum*)	Eugenol, eugenin, eugenitin, acetyl eugenol, bicornin, β-caryophyllene, vanillin, crategolic acid, campesterol, sesquiterpenes, α-humulene	Antioxidative, anti-inflammatory, antibacterial, antifungal, anti-gingivitis	Pinto and Santos (2017), Nagababu and Lakshmaiah (1992), Viuda-Martos et al. (2007a, b), Rodrigues et al. (2009), Białoń et al. (2017), Puškárová et al. (2017)
Coriander oil (*Coriandrum sativum*)	Tannins, terpenoids, alkaloids, phenolics, flavonoids, sterols, glycosides	Antioxidative, anti-inflammatory, analgesic, antibacterial, antifungal, anthelmintic, anxiolytic, antidepressant, sedative, hypnotic, anticonvulsant, anti-Alzheimer's, neuroprotective, hypolipidemic, antidiabetic, anticancer, hepatoprotective	Cantore et al. (2004), Al-Snafi (2016)
Cudrania tricuspidata oil	Cudraxanthone L, cudratricusxanthone A, cudratricusxanthone E, macluraxanthone B	Antibacterial, hepatoprotective	Tian et al. (2005), Bajpai et al. (2013)

(continued)

Table 1 (continued)

Essential oil/source	Chemical constituents	Clinical applications	References
Cumin oil (*Cuminum cyminum* L.)	β-Pinene, γ-pinene, *p*-cymene, γ-terpinene, cuminic aldehyde, cuminal	Antimicrobial, antifungal	Viuda-Martos et al. (2007b), Wanner et al. (2010)
Dill seed oil (*Anethum graveolens* L.)	α-Phellandrene, β-phellandrene, dill ether, *p*-cymene, limonene, anethofuran, carvone, carveol, isoeugenol, dill apiole	Antioxidative, antibacterial, antifungal, sensory importance	Porter et al. (1983), Brunke et al. (1991), Vera and Chane-Ming (1998), Hosseinzadeh et al. (2002), Singh et al. (2005), Isbilir and Sagiroglu (2011), Rana and Blazquez (2015)
Eucalyptus oil (*Eucalyptus citriodora*, *E. tereticornis*, *E. globulus*)	Borneol, 1,8-Cineole, globulol, *p*-cymene, limonene, α-pinene, cryptone, α-terpineol	Antibacterial, anti-gingivitis, anti-gum bleeding, anti-plaque, anti-inflammatory, central and peripheral analgesic	Silva et al. (2003), Sebei et al. (2015), Singh et al. (2016)
Fennel oil (*Foeniculum vulgare*)	*Trans*-anethole, (*E*)-anethole	Antioxidative, anti-inflammatory, analgesic, antimicrobial, laxative, carminative, facial cleanser	Yamini et al. (2002), Choi and Hwang (2004), Cetin et al. (2010), Picon et al. (2010), Mohamad et al. (2011), Qiu et al. (2012)
Frankincense/ Olibanum/Levona oil (*Boswellia Sacra*)	Monoterpenes, sesquiterpenes, monoterpenols, sesquiterpenols, phellandrene, ketones, limonene, α-thujone, α-pinene, β-pinene	Perfume, cosmetic, aromatherapy, antidiabetic, cytochrome P450 inhibitor	Frank and Unger (2006), Woolley et al. (2012)
Garlic oil (*Allium sativum* L.)	Diallyl trisulfide, diallyl disulfide, methyl allyl trisulfide, thiosulfinates, allicin	Antibacterial, antifungal, antiviral, antiparasitic	Rao et al. (1999), Kyung (2012), Djiri et al. (2014)
Geranium oil (*Pelargonium graveolens* L.)	Geraniol, citronellol, linalool, α-pinene, myrcene, linalool, γ-terpinene, neral	Antioxidative, aromatherapy, muscle relaxant, skin care, anti-dysentery, anti-hemorrhoids, anti-inflammatory, antidiabetic, anti-diarrhea, anti-gastric ulcers, anticancer	Sharopov et al. (2014)
Ginger oil (*Zingiber officinale* Roscoe)	Zingiberene, e-citral, z-citral, camphene, ocimene, ar-curcumene, β-bisabolene, β-sesquiphellandrene	Antioxidative, free radical scavenging, hydrogen peroxide scavenging, antibacterial, antifungal	Stoyanova et al. (2006), Bellik et al. (2013), Raina et al. (2013)
Helichrysum oil (*Helichrysum italicum*)	α-cedrene, α-curcumene, geranyl acetate, limonene, nerol, neryl acetate, α-pinene	Antioxidative, anti-inflammatory, antibacterial, antiviral, antifungal	Sala et al. (2002), Nostro et al. (2003), Djihane et al. (2017)
Hemp oil/CBD oil (*Cannabis sativa* L.)	Cannabidiol (CBD), THC, β-caryophyllene, limonene, β-myrcene	Relief of pain, anti-arthritis, anti-atopic dermatitis, antidiabetic, anti-epileptic seizures, neuroprotection, antioxidative, anti-inflammatory	–
Juniper oil (*Juniperus communis* L., *J. oxycedrus*)	α-Pinene, sabinene, β-myrcene, *p*-cymene, geranial, α-caryophyllene, β-caryophyllene, germacrene D, δ-cadinene, *trans*-calamenene, D-limonene, terpinene-4-ol, terpinolene, 3-carene, β-phellandrene, β-thujone, α-humulene	Antibacterial, antifungal	Filipwicz et al. (2003), Białoń et al. (2017), Glisic et al. (2007)
Lantana xenica Mold. oil	(*E*)-caryophyllene, γ-cadinene, α-pinene, ocimene, germacrene D	Antimicrobial	Juliani Jr et al. (2002)
Lantana achyranthifolia Desf. oil	Carvacrol, 1,8-cineole, isocaryophyllene, α-bisabolol, β-bisabolene	Antibacterial	Hernández et al. (2005)
Lavender oil (*Lavandula latifolia*, *L. angustifolia*)	1,3,7-Octatriene, 3,7-dimethyl, α-pinene, limonene, 1,8-cineole, *cis*-ocimene, *trans*-ocimene, camphor, linalool, caryophyllene, terpinen-4-ol, lavandulyl acetate, eucalyptol, camphor	Antiseptic, analgesic, anticonvulsant, antidepressant, antirheumatic, antioxidative, anti-inflammatory, antiviral, antibacterial, carminative, cholagogue, deodorant, diuretic, emmenagogue, hypotensive, sedative, sudorific	Shellie et al. (2002), Hui et al. (2010), Robu et al. (2011), Adaszynska-Skwirzynska and Szczerbinska (2017)

Lemon citrus oil (*Citrus limon*)	Limonene, β-pinene, α-pinene, sabinene, myrcene, limonene, 1,8-cineole, linalool, α-terpineol, nerol, neradiol, geranial, farnesol	Antioxidative, antimicrobial, antifungal	Hsouna et al. (2017)
Lemon grass oil (*Cymbopogon citratus*)	Myrcene, citronellal, geranyl acetate, neral, nerol, geraniol, limonene, citral	Anti-stress, anti-mental fatigue, glandular secretion stimulatory, antimicrobial, insect-repellent	Abdulazeez (2016),Lawal (2017)
Marjoram oil	α-Pinene, β-pinene, limonene	Antibacterial, antiviral, antifungal, antidiabetic, antidepression, pain killer	Białoń et al. (2017)
Metasequoia glyptostroboides Mikiex oil	α-Pinene, β-caryophyllene, α-thujone, bornylene, totarol, δ-3-carene, 2-β-pinene, α-humulene	Antifungal	Bajpai et al. (2007), Bajpai and Kang (2010)
Myracrodruon urundeuva oil	α-Pinene, β-pinene, *trans*-caryophyllene, limonene	Antibacterial, cytotoxic	Rebouças de Araujo et al. (2017)
Myrrh oil (*Commiphora myrrha*)	Furanoeudesma-1, 3-diene, curzarene, sterols, steroids	Antibacterial, antiviral, antifungal, astringent, analgesic, antispasmodic, amoebocidal, anti-inflammatory, hypoglycemic	Dolara et al. (2000), Zhu et al. (2003), Tipton et al. (2006)
Myrtle oil (*Myrtus communis* var. *italica* L.)	α-pinene, 1,8-cineole, flavonoids, hydrolysable tannins (gallotannins), catechin	Antioxidative	Aidi et al. (2010)
Nigella sativa oil	Thymoquinone	Antioxidative, anti-inflammatory, anticancer, anti-proliferative	Burits and Bucar (2000), Gupta et al. (2016)
Nutmeg seed oil (*Myristica fragrans* Houtt.)	Sabinene, α-pinene, α-thujone, α-myrcene, α-terpinene, α-terpineol, 4-terpineol, myristicin, safrol, citronellol	Locomotor inhibitory, anxiogenic, anti-chronic inflammatory pain	Muchtaridi et al. (2010), Zhang et al. (2016)
Olive oil (extra virgin)	Phenolic compounds	Antioxidative, anti-inflammatory, antimicrobial	Cicerale et al. (2012)
Omani luban oil (*Boswellia sacra* Flueck)	Limonene, myrcene, α-pinene	Antibacterial	Al-Saidi et al. (2012)
Oregano oil (*Origanum vulgare* L.)	α-Thujone, α-pinene, sabinene, β-pinene, β-myrcene, α-phellandrene, α-terpinene, *p*-cymene, limonene, 1,8-cineole, linalool, γ-terpinene, thymol, carvacrol, caryophyllene, etc.	Antioxidative, antibacterial, antiviral, antifungal, cytotoxic, food preservative	Lambert et al. (2001), Figiel et al. (2010), Bolechowski et al. (2011), Kuorwel et al. (2011), Sakkas and Papadopoulou (2017), De Falco et al. (2013), Siroli et al. (2014), Stanojević et al. (2016), Białoń et al. (2017), Puškárová et al. (2017)
Palmarosa oil (*Cymbopogon martinii* var. *motia* Burk.)	(*E*)-β-ocimene, linalool, geraniol, geranyl acetate, (*E,Z*)-farnesol, β-caryophyllene	Antioxidative, anti-inflammatory, antibacterial, antiviral, antifungal, fever, arthritis	Puškárová et al. (2017)
Palo Santo oil (*Bursera graveolens*)	α-Terpinene	Antioxidative, antimicrobial	Mendez et al. (2017)
Peppermint oil (*Mentha piperita* L.)	Menthol, menthone, menthyl acetate, 1,8-cineole, limonene, β-pinene, flavonoids, β-caryophyllene	Antioxidative, anti-inflammatory, analgesic, cytoprotective, antiulcer, chemopreventive, anti-gingivitis	Blumenthal et al. (1998), Kumar et al. (2009), Taheri et al. (2011)
Perilla oil (*Perilla frutescens* L.)	(−)-perillaldehyde, (−)-perillylalcohol, (+)-limonene, α-pinene, luteolin, perillic acid, carvane, *trans*-shisool, perillaketone	Olfactory stimulation, prefrontal cortex inhibitory, cytostatic, antiallergic, antidepressant, antibacterial, antifungal, anti-inflammatory	Solórzano-Santos and Miranda-Novales (2012), Igarashi and Miyazaki (2013), Igarashi et al. (2014)
Piper cernuum oil	α-Pinene, β-pinene, bicyclogermacrene, β-caryophyllene, spathulenol, germacrene D	Antimicrobial	Constantin et al. (2001)

(continued)

Table 1 (continued)

Essential oil/source	Chemical constituents	Clinical applications	References
Piper regnellii oil	Linalool, myrcene, bicyclogermacrene, β-caryophyllene	Antimicrobial	Constantin et al. (2001)
Plectranthus spp. (*P. cylindraceus*, *P. asirensis*, *P. barbatus*) oil	Maaliol, β-caryophyllene, α-pinene, borneol, spathulenol	Antioxidative, Antimicrobial, anticancer, larvicidal	Govindarajan et al. (2016), Mothana et al. (2018)
Protium oil *heptaphyllum* Aubl.	α-Pinene, *p*-mentha-1,4(8)-diene, α-phellandrene, α- and β-amyrin	Gastroprotective, anxiolytic, antidepressant, antioxidative	Aragão et al. (2006), Araujo et al. (2011)
Rose oil (*Rosa damascene* Mill.)	Citronellol, geraniol, nonadecane, nerol, heneicosane, linalool	Flavor, fragrance	Almasirad et al. (2011), Verma et al. (2011)
Rosemary oil (*Rosmarinus officinalis*)	1,8-Cineol, camphor, α-pinene, β-pinene	Antioxidative, anti-gastric ulcers, antimicrobial	Bozin et al. (2007), Viuda-Martos et al. (2007b), Zaouali et al. (2010), Takayama et al. (2016)
Sage oil (*Salvia officinalis*, *Salvia hispanica*)	Aesculetin, camphor, 1,8-cineole, camphene, α-humulene, α-thujene, α-thujone, β-thujone, α-terpineol, α-terpenes, α-pinene, linalool, limonene, salviol, thujanol, terpinolene	Antibacterial, antifungal, antioxidative, antiseptic, antispasmodic, cholagogue, choleretic, febrifuge, emmenagogue, anti-dermatitis, anti-dementic	Perry et al. (2003), Delamare et al. (2007), Viuda-Martos et al. (2007b), Pierozan et al. (2009), Porte et al. (2013)
Sandalwood oil (*Santalum spicatum*, *S. acuminatum*, *S. album*, *S. latifolium*)	Santalols, α-bergamotol, nuciferol, γ-elemene, *cis*-lanceol, α-cedrol	Anti-inflammatory, aromatherapy	Howes et al. (2004), Kusuma and Mahfud (2016)
Savory oil (*Satureja montana* L.)	α-Thujone, α-pinene, myrcene, *p*-cymene, sabinene, α-terpinene, camphor, borneol, carvacrol, thymol, caryophyllene oxide	Antibacterial	Milos et al. (2001), Oussalah et al. (2006)
Senecio atacamensis Phil. oil	α-terpinene, α-phellandrene, *p*-cymene	Antimicrobial	Benites et al. (2011)
Sideritis hirsuta L. oil	α-Phellandrene, β-phellandrene, α-pinene, (*Z*)-β-guaiene, Sabinene, 1,8-cineole	Anti-inflammatory, antirheumatic, antibacterial, antimicrobial	Palá-Paul et al. (2006)
Sidris italica Miller. oil	Sesquiterpenes, phenyl propane derivative	Antibacterial, antioxidative	Lemberkovics et al. (1998), Basile et al. (2006)
Spanish oregano oil (*Corydothymus capitatus*)	–	Antibacterial	Oussalah et al. (2006)
Spearmint oil (*Mentha spicata* L.)	Carvone, 1,8-cineole, β-pinene, β-caryophyllene, *trans*-dihydrocarvone	Antioxidative, antimicrobial	Hussain et al. (2011), Şarer et al. (2011)
Spruce oil (*Picea abies* L.)	α-Pinene, camphene, limonene, myrcene, bomyl acetate,δ-cadinene, muurolene, cadinol, muurolol, manool	Antimicrobial	Radulescu et al. (2011)
Summer savory oil (*Satureja hortensis* L.)	γ-Terpinene, carvacrol, α-thujone	Antioxidative, antibacterial, antifungal, antispasmodic	Sahin et al. (2003), Khalid (2016)
Tea tree oil (*Melaleuca alternifolia*)	Terpinen-4-ol, γ-terpinene, 1,8-cineol, α-cymene, δ-cadinene, globulol, linalool, limonene	Antimicrobial	Carson et al. (2006)
Thyme oil (*Thymus vulgaris*, *T. zygis*, *T. hyemalis*)	Thymol, carvacrol, terpinene-4-ol, α-pinene, γ-terpinene, *cis*-sabinene hydrate, caryophyllene, *p*-cymene, myrcene, borneol, linalool	Antibacterial, antiseptic bandages, mouth rinses, antifungal agent in toenails, anxiolytic, antioxidative, anti-inflammatory, carminative, antispasmodic, food preservative	Pierce (1999), Ramsewak et al. (2003), Burt (2004), Tawfik et al. (2006), Viuda-Martos et al. (2007a, b), Rota et al. (2006), Sakkas and Papadopoulou (2017), Kuorwel et al. (2011), Fachini-Queiroz et al. (2012), Cerda et al. (2013), Borugă et al. (2014), Komaki et al. (2016), Al-Asmari et al. (2017), Puškárová et al. (2017)

Table 1 (continued)

Essential oil/source	Chemical constituents	Clinical applications	References
Thymus longicaulis subsp. *Chaubardii* oil	Limonene, thymol, geraniol, geranyl acetate, linalool, α-terpinyl acetate	Antimicrobial	Tzakou et al. (1998)
Valerian oil (*Valeriana officinalis* L.)	Valerenic acid, β-sitosterol, ursolic acid, caryophyllene, valerane	Anti-insomnia, anxiolytic, anti-epilepsy, antirheumatic, aphrodisiac, antispasmodic, anthelmintic, diuretic, diaphoretic, emmenagogue	Jiang et al. (2007), Nandhini et al. (2018)
Vetiver oil (*Vetiveria zizanioides*)	Khusimol, germacrene D, α- and β-vetivone, cedrane, bisabolane, eudesmane, eremophilane, zizaane, valerenol, β-caryophyllene	Antibacterial, antifungal, antioxidative, anti-inflammatory, insecticidal, herbicidal, calming dogs afraid of loud noises	Khesorn et al. (2010), Chahal et al. (2015)
Ylang Ylang oil (*Cananga odorata*)	Monoterpenes, Sesquiterpenes, phenylpropanoids	Stomach ailments, asthma, gout, rheumatism, antibacterial, antifungal, amoebocidal, cytotoxic, antibiofilm, anti-inflammatory, anti-vector, antidiabetic, antifertility, insect-repellent	Tan et al. (2015)

2 Essential Oils

2.1 Thyme Oil

There are more than 150 species of Thymus that are found in North America, Asia, and Africa. *Thymus vulgaris* is an aromatic perennial evergreen herbal plant with great medicinal value. Thyme oil contains vital ingredients for human and animal health. Oil of thyme contains 12–61% thymol. The structural formulas of thymol and carvacrol are shown in Fig. 1.

Thyme oil may also contain carvacrol (0.4–20.6%), 1,8-cineol (0.2–14.2%), *p*-cymene (9.1–22.2%), linalool (2.2–4.8%), borneol (0.6–7.5%), α-pinene (0.9–6.6%), and camphor (0.6–7.3%). Thymol and carvacrol are the main phenolic components that are primarily responsible for thyme's antioxidative activity (Yanishlieva et al. 1999; Rota et al. 2006; Komaki et al. 2016; Al-Asmari et al. 2017).

Thymol possesses an antiseptic property, and therefore it is used in bandages and several commercially available mouthwashes, including Listerine (Pierce 1999). Ramsewak et al. (2003) reported that thyme oil can be used as an antifungal agent for infected toenails. Its use has also been indicated for coughs and bronchitis. Recently, Komaki et al. (2016) demonstrated that the extract of *Thymus vulgaris* exerts an anxiolytic effect in rats.

In recent years, thyme oil as a nutraceutical has become more popular than ever before due to its antioxidant and anti-inflammatory properties (Amiri 2012; Cerda et al. 2013). Additionally, thyme is known to exert antispasmodic, antivirotic, antifungal, carminative, sedative, diaphoretic, antihypertensive, anticancer, and anti-acne effects (Viuda-Martos et al. 2007a, b; Fachini-Queiroz et al. 2012; Ahmad et al. 2014).

2.2 Rosemary Oil

Rosemary essential oil (EO) is obtained from the leaves and flowers of the *Rosmarinus officinalis* plant, which is native to the Mediterranean region. The ancient Greeks, Romans, Egyptians, and Hebrews considered rosemary oil a sacred substance as it improved memory, soothed digestive problems, boosted the immune system, and relieved aches and pains. Phytochemical analysis of rosemary oil revealed

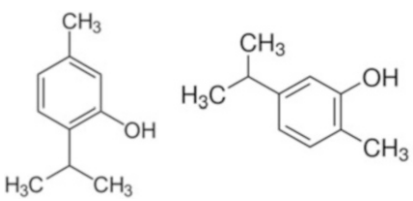

Fig. 1 Structural formula of thymol (left) and carvacrol (right)

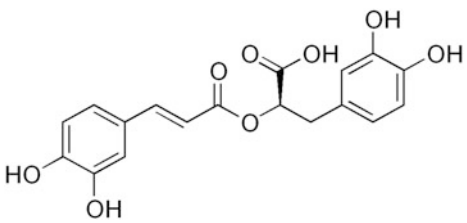

Fig. 2 Structural formula of rosmarinic acid

the presence of rosmarinic acid (Fig. 2), 1,8-cineol, camphor, carnosol, carnosic acid, ursolic acid, and caffeic acid (Zaouali et al. 2010; Takayama et al. 2016). Using GC/MS, Takayama et al. (2016) identified three major monoterpenes: cineol (28.5%), camphor (27.7%), and α-pinene (21.3%) in *R. officinalis* essential oil.

For thousands of years, rosemary EO has been used in many health conditions, including alopecia, cognition dysfunction, and as an antinociception, liver cleansing, cortisol lowering, and anticancer agent. In GI abnormalities, the gastric epithelium is often attacked by physical, chemical, or microbiological agents acting in the gastric lumen. Rosemary EO protected the gastric mucosa via its antioxidative property (Rozza and Pellizzon 2013; Dawidowicz and Olszowy 2014) by modulating the activities of enzymes (superoxide dismutase and glutathione peroxidase) and increasing or maintaining the levels of glutathione (Takayama et al. 2016). In several other experimental models of GI inflammatory conditions, rosemary EO has been found effective (Dias et al. 2000; Minaiyan et al. 2011).

Zaouali et al. (2010) reported antioxidative and antimicrobial activities of *R. officinalis* L. varieties (var. *typicus* and var. *troglodytorum*). The bactericidal and antioxidative activities were higher with EO from var. *troglodytorum* than those from var. *typicus*.

2.3 Oregano Oil

Oregano (*Origanum vulgare*) is native to the Mediterranean countries, such as Italy and Spain, and is used as a spicy herb. The EO of oregano contains more than 25 compounds, including α-thujone, α-pinene, sabinene, β-pinene, β-myrcene, α-phellandrene, α-terpinene, *p*-cymene, limonene, 1,8-cineol, γ-terpinene, linalool, thymol, carvacrol, caryophyllene, etc. (Figiel et al. 2010; Bolechowski et al. 2011). Oregano EO is known to exert strong antioxidant, antimicrobial, cytotoxic, and antifungal activities (Viuda-Martos et al. 2007a, b; Wojdylo et al. 2008; Siroli et al. 2014). By having these properties, the EO of oregano can be used in many ailments of humans and animals, as well as a food preservative.

2.4 Basil Oil

The EOs of basil (*Ocimum basilicum* L.) have been used extensively for a long time in food products, dental and oral products, and perfumery. Chenni et al. (2016) identified 65 chemical compounds in EOs extracted from Egyptian basil leaves. The main components were linalool (43.5–48.4%), methyl chavicol (13.3–14.3%), and 1,8-cineol (6.8–7.3%). These authors suggested that the solvent-free microwave extraction (SFME) method may be a better alternative to the conventional hydro-distillation (HD) method for the extraction of EO from basil leaves. This is because the SFME method may provide a richer source of natural antioxidants as well as strong antimicrobial agents for food preservation. Basil EOs and their major chemical constituents have been reported to exhibit antimicrobial activity against a wide range of Gram-negative and Gram-positive bacteria, fungi, and yeast (Suppakul et al. 2003).

2.5 Chamomile Oil

Chamomile is one of the medicinal herbs native to Southern and Eastern Europe. Currently, it is grown in many European countries, Brazil, India, and many other parts of the world. On the international market, there is a growing demand for chamomile oil. German chamomile (*Matricaria chamomilla*), commonly referred to as "Blue oil," and Roman chamomile (*Chamaemelum nobile*) are more popular than other chamomiles. Phytochemical analysis of chamomile has revealed more than 120 secondary metabolites, 28 terpenoids, and 36 flavonoids (McKay and Blumberg 2000; Singh et al. 2011). The principle components of the essential oil extracted from the German chamomile flowers are the terpenoids α-bisabolol and its oxide azulenes, including chamazulene and acetylene derivatives. Both chamazulene and bisabolol are very unstable and are best preserved in an alcoholic tincture. The essential oil of Roman chamomile contains less chamazulene and is mainly constituted of esters of angelic acid and tiglic acid. It also contains farnesene and α-pinene. In chamomile, α-bisabolol, bisabolol oxides A and B, chamazulene or azulene, farnesene, spiroether sesquiterpene lactones, glycosides, hydroxycoumarines, flavonoids (apigenin, luteolin, patuletin, and quercetin), coumarins (herniarin and umbelliferone), terpenoids, and mucilage are considered to be the major bioactive ingredients (Singh et al. 2011). Depending upon the chemical constituents and qualitative and quantitative composition, there are four basic types of chamomile essential oils (EOs):

Type A: Dominant component is bisabolol oxide A
Type B: Dominant component is bisabolol oxide B
Type C: Dominant component is (−)-α-bisabolol
Type D: (−)-α-bisabolol and bisabolol oxide A and B present in 1:1 ratio

The biological and pharmacological properties of chamomile oil include antioxidative, anti-inflammatory, antiseptic, carminative, sedative, and spasmolytic activities, and as a result its preparations have been used for many human ailments such as hay fever, skin conditions (eczema, chicken pox, and psoriasis), muscle spasms, neuralgia, sciatica,

rheumatic pain, menstrual disorders, insomnia, ulcers, wounds, GI disorders, and hemorrhoids (Salmon 1992; Srivastava et al. 2010; Singh et al. 2011). In veterinary medicine, the use of chamomile is yet to be explored.

Srivastava et al. (2010) reported an anti-inflammatory effect due to chamomile constituents, such as bisabolol, chamazulene, apigenin, and luteolin, although the exact mechanism is yet to be elucidated. In experimental studies, coumarins, bisabolol, and flavonoids have been shown to exert smooth muscle relaxant and antispasmodic effects (Gardiner 2007; Srivastava et al. 2010). In humans, Merfort et al. (1994) demonstrated that chamomile flavonoids and essential oils penetrate below the skin surface into the deeper skin layers, thereby exerting an anti-inflammatory activity. Chamomile oil produced an anti-inflammatory effect by inhibiting LPS-induced prostaglandin E_2 release and accumulation of cyclooxygenase-2 (COX-2) enzyme activity without affecting the constitutive from COX-1 (Srivastava et al. 2009).

Topical applications of chamomile have been shown to be moderately effective in the treatment of atopic eczema and other skin diseases (Nissen et al. 1988; Graf 2000). Results revealed that it was about 60% as effective as 0.25% hydrocortisone cream (Albring et al. 1983). In a partially double-blind randomized study, Roman chamomile-based cream Kamillosan® showed a slight superiority over 0.5% hydrocortisone (Patzelt-Wenczler and Ponce-Pöschl 2000). More investigations need to be done in this area of research.

Chamomile has been used in many GI conditions, including GI spasms, GI irritation, stomach upset, flatulence, and ulcers (Kroll and Cordes 2006), and GI inflammatory conditions such as esophageal reflux, diverticular disease, etc. Chamomile has specifically been found useful in dispelling gas, soothing the stomach, and relaxing the muscles that move food through the intestines (reviewed in Srivastava et al. 2010). Reports suggested that chamomile ointment may improve hemorrhoids by reducing the inflammation (Misra and Parshad 2000). Studies also proved that chamomile inhibits *Helicobacter pylori*, the bacteria that can contribute to stomach ulcers. Chamomile reduces smooth muscle spasms associated with various GI inflammatory disorders.

Chamomile has been indicated in the treatment of generalized anxiety disorder. One of chamomile's bioactive compounds apigenin has been shown to reduce latency in the onset of picrotoxin-induced convulsions and reduction in locomotor activity but did not demonstrate any anxiolytic, myorelaxant, or anticonvulsant activities (Avallone et al. 2000).

Chamomile has been found very effective in managing hyperglycemia and diabetes. It ameliorates hyperglycemia and diabetic complications, independent of insulin secretion, by suppressing blood sugar levels, increasing liver glycogen storage, inhibiting sorbitol in the erythrocytes, and protecting pancreatic beta cells from oxidative stress (Cemek et al. 2008; Srivastava et al. 2010).

Chamomile has been reported to be statistically efficacious in producing wound drying, speedy epithelialization, and wound healing (Glowania et al. 1987; Nayak et al. 2007). In aromatherapy, chamomile massage has also been shown to exert positive effects on anxiety (Hadfield 2001). Additionally, chamomile can be used in many other conditions such as cardiovascular, mucositis, osteoporosis, sleep disorder, sore throat, vaginitis, immunodeficiency, and cancer (Srivastava et al. 2010; Singh et al. 2011).

Although chamomile is listed on the FDA's GRAS (generally recognized as safe) list, it may produce allergic reaction probably due to its contamination with "dog chamomile," a highly allergenic plant of similar appearance (Srivastava et al. 2010).

2.6 Cinnamon Oil

Cinnamon essential oil (EO) is obtained from the outer bark or leaves of *Cinnamomum zeylanicum* and *Cinnamomum vervun* (both names refer to the same tree). The main chemical constituents of cinnamon bark and leaf EOs, in varying amounts, are cinnamaldehyde, cinnamyl acetate, eugenol, and eugenol acetate. The EO of the bark of *C. altissimum* Kosterm consists of linalool (36.0%), methyl eugenol (12.8%), limonene (8.3%), α-terpineol (7.8%), terpinen-4-ol (6.4%), γ-terpinene (3.5%), α-terpinene (2.3%), and 1,8-cineol (2.3%) (Abdelwahab et al. 2017).

Cinnamaldehyde exhibits antibacterial and antifungal activities, in addition to imparting an aroma scent. Cinnamyl acetate is usually used to repel and prevent insect infestation, in addition to its common use as a fixative in manufactured perfumes. Eugenol exerts anti-inflammatory, antiseptic, and analgesic properties, soothes ulcers and gastric pain, reduces chances of developing sores, eliminates bacteria, and prevents the growth of many fungi. Eugenol acetate is a well-known antioxidant.

Cinnamon EO is known to diminish the feelings of depression, faintness, and exhaustion. It stimulates the libido and is often regarded as a natural aphrodisiac. It also stimulates the GI and immune systems and relieves muscle and joint pain associated with rheumatism. Cinnamon EO has calming and tonic effects on the mind and can improve cognitive function and memory. In essence, cinnamon EO has many medicinal properties such as antioxidative, anti-inflammatory, antibacterial, antifungal, antiviral, astringent, antispasmodic, immunostimulating, carminative, emmenagogue, antirheumatic, etc.

2.7 Clove Oil

Clove essential oil or oil of clove is obtained from the buds and stems of clove trees (*Syzygium aromaticum*) which grow in tropical regions. Xu et al. (2016) identified 22 chemical compounds in the EO of clove with 76.23% eugenol. Clove EO has been found very effective against many strains of bacteria, including *E. coli*, *Salmonella*, *Helicobacter pylori*, *Staphylococcus aureus*, *Streptococcus pneumonia*, and many others. Its other properties include antioxidative, anti-inflammatory, antibacterial, antiviral, antifungal, antitumoral, anticoagulant, and anticancer (cytotoxicity and apoptosis toward cancerous cells).

2.8 Dill Seed Oil

Anethum graveolens L., commonly known as dill, is native to the Mediterranean countries and Southeastern Europe. In an earlier study, Porter et al. (1983) found four major constituents (phellandrene, limonene, anethofuran, and carvone) in dill oil. Limonene and phellandrene were maximally present in stems and leaves. Anethofuran was a major component of the oil from umbels at flowering but declined during seed maturation. Within the umbels, the carvone was present in the seeds only and not the pedicels (Porter et al. 1983). Using GC/MS, at least 36 chemicals (including α-phellandrene 56.5%, dill ether 20.8%, limonene 10.9%, *p*-cymene 3.8%) have been identified in the EO of *A. graveolens*, totaling 92% (Vera and Chane-Ming 1998; Singh et al. 2005; Rana and Blazquez 2015). Carvone is commonly regarded as the component having the strongest influence on the character of dill oils.

Phytoconstituents of dill oil and its extract have free radical scavenging, hydrogen peroxide scavenging, antioxidative, antibacterial, and antifungal properties (Singh et al. 2005; Isbilir and Sagiroglu 2011). Dill is used as a diuretic and also to solve certain gastrointestinal (GI) problems, such as flatulence, intestinal spasms, and various digestive problems (Hosseinzadeh et al. 2002).

2.9 *Eucalyptus* Oil

Eucalyptus EO is obtained from *Eucalyptus citriodora*, *E. camaldulensis*, *E. urophylla*, *E. lehmani*, *E. leucoxylon*, *E. cinerea*, and many other species. The value of *Eucalyptus* oil for medicinal purposes can vary depending on several factors, such as species of *Eucalyptus* and its chemical constituents (Sebei et al. 2015). The EOs from *Eucalyptus* leaves have been found to contain chemicals from three classes: (1) oxygenated monoterpenes (1,8-cineole, *trans*-pinocarveol, and α-terpineol), (2) oxygenated sesquiterpenes (borneol, spathulenol, viridiflorol, and globulol), and (3) monoterpene hydrocarbons (α-pinene, *p*-cymene, and limonene). The major constituents in *E. camaldulensis* leaf EO are α-pinene (22.52%), *p*-cymene (21.69%), α-phellandrene (20.08%), 1,8-cineole (9.48%), c-terpinene (9.36%), and limonene (4.56%) (Cheng et al. 2008). In a recent study, Sebei et al. (2015) reported that the EOs of *Eucalyptus* leaves contain two major phytoconstituents, 1,8-cineole (49.07–83.59%) and α-pinene (1.27–26.35%).

Eucalyptus EO has been reported to exert antiradical and antioxidative (Ben Hassine et al. 2012), anti-inflammatory (Silva et al. 2003), antipyretic (Silva et al. 2003), antibacterial (Cimanga et al. 2006; Sebei et al. 2015), and antifungal (Su et al. 2006) properties. In humans, *Eucalyptus* oil is widely used for many health conditions, including asthma, bronchitis, plaques and gingivitis, head lice, and toenail fungi.

2.10 Citrus Lemon Oil

Citrus, including lemon (*Citrus limon*), plants constitute one of the main valuable sources of EOs used in foods and for medicinal purposes (Hsouna et al. 2017). Phytochemical analysis of citrus EO revealed the presence of many chemicals with an abundance of limonene (39.74%) and β-pinene (25.44%). In a number of studies, citrus EO has been investigated for antimicrobial activities against a wide range of food-associated microorganisms (bacteria, molds, and yeasts) (Hsouna et al. 2017). Hsouna et al. (2017) suggested that citrus EO has great potential as a natural antioxidant and antimicrobial agent and can be applied in food systems and the nutraceutical industry.

2.11 Lavender Oil

Lavender EO is obtained from the flowers of certain species of lavender (*Lavandula latifolia*, *L. angustifolia*, *L. intermedia*). The phytoconstituents present in lavender oil may be more than 100 and vary from species to species. The EO primarily consists of linalool and linalyl acetate, with moderate amounts of lavandulyl acetate, terpinene-4-ol, and lavandulol. Camphor and 1,8-cineole are present in small amounts. Smigielski et al. (2009) reported 78 chemical constituents in the EO of dried flowers of *Lavandula angustifolia* (cultivated in Poland), including linalool (30.6%), linalyl acetate (14.2%), geraniol (5.3%), β-caryophyllene (4.7%), and lavandulyl acetate (4.4%). In a similar study, Robu et al. (2011) found linalool (20.60–35.99%), linalyl acetate (12.58–19.65%), lavandulyl acetate (3.74–10.48%), t-p3-ocimene (1.26–9.23%), α-terpineol (3.67–6.73%), nerol (0.81–3.32%), neryl acetate (0.95–3.64%), and β-caryophyllene (0.93–2.43%). Recently, Adaszynska-Skwirzynska and Szczerbinska (2017)

investigated the antimicrobial activity of lavender EO and its influence on the production performance of broiler chickens. These investigators found 26 chemical compounds in lavender EO with 87.79% oxygenated monoterpenes, 8.17% monoterpene hydrocarbons, and 2.93% sesquiterpene hydrocarbons. Linalool acetate (46.25%) and linalool (35.17%) were the main compounds. Results revealed that the lavender EO exhibited antimicrobial activity and significantly enhanced chicken production performance. In another study, Hui et al. (2010) reported antioxidative activity and inhibitory activity of lavender EO against rhinitis-related bacteria (*Staphylococcus aureus*, *Micrococcus ascoformans*, *Proteus vulgaris*, and *Escherichia coli*). Other uses of lavender EO include antiseptic, analgesic, anticonvulsant, antidepressant, antirheumatic, antioxidative, anti-inflammatory, antiviral, antibacterial, carminative, cholagogue, deodorant, diuretic, emmenagogue, hypotensive, sedative, and sudorific.

2.12 Sage Oil

Sage EO is obtained from *Salvia officinalis*, a perennial shrub native to the Mediterranean region. Porte et al. (2013) identified 47 chemicals in the EO of sage, including α-thujone (40.9%), camphor (26.12%), α-pinene (5.85%), and β-thujone (5.62%). By having antimicrobial and antioxidative properties, sage EO is commonly used on meat, sausage, poultry stuffing, fish, soups, canned foods, and other food stuffs (reviewed in Porte et al. 2013).

2.13 Peppermint Oil

Peppermint (*Mentha piperita* L.) is a hybrid of water mint and spearmint and is native to Europe. The EO is extracted from the leaves and flowers of the plant. Its oil consists of menthol, menthone, menthyl acetate, 1,8-cineole, limonene, β-pinene, β-caryophyllene, and flavonoids. Peppermint EO is used for more than 35 purposes, including neurological pain, digestive issues, oral health, infectious diseases, immune deficiency, muscle and arthritic pain, skin care, burn, allergies, and lice and flea control.

2.14 Hemp/CBD/Cannabis Oil

Cannabis/hemp/cannabidiol (CBD) oil has been used in medicine for millennia. The phytochemistry of hemp oil is complex as it contains CBD, THC, β-caryophyllene, limonene, β-myrcene, humulene, α-pinene, linalool, terpinolene, etc. Due to behavioral side effects from the abuse of cannabis products, the use of medical marijuana continues to be an emotionally and politically charged issue. CBD oil has shown remarkable health benefits in many conditions including pain, seizures, osteoarthritis, atopic dermatitis, obesity, diabetes, COPD, hypertension, cancer, etc. Readers are referred to a chapter on cannabis in this book for detailed phytochemistry, pharmacology, uses, and health risks.

2.15 Palmarosa Oil

Palmarosa EO is extracted from the *Cymbopogon martinii* var. motia plant. The plant is indigenous to India. Rao et al. (1999) identified 17 phytoconstituents accounting for 95.6–97.1% of the oil. Major phytoconstituents were (*E*)-β-ocimene (1.2–4.3%), linalool (0.8–2.0%), geraniol (70.1–85.3%), geranyl acetate (4.3–14.8%), and (*E,Z*)-farnesol (1.6–3.4%). Whole herb oil was found to be richer in linalool, β-caryophyllene, and *(E,Z)*-farnesol. While leaf lamina and leaf sheath oils were found to be rich in geraniol, inflorescence oil was rich in (*E*)-β-ocimene and geranyl acetate. In addition its rose-like aroma, palmarosa EO has antioxidative (Puškárová et al. 2017), anti-inflammatory, bactericidal, antiviral, and antifungal activities and is commonly used for fever, infectious diseases, wounds, arthritis and rheumatism, digestive disorders, and damaged and dry skin as well as stress and nerve-related pain.

2.16 Cardamom Oil

Cardamom EO is obtained from *Elettaria cardamomum*. The oil consists of many phytochemicals, including pinene, methyl eugenol, sabinene, geraniol, myrcene, phellandrene, 1,8-cineole, citronellol, linalool, limonene, *p*-cymene, terpinolene, and *trans*-nerolidol. In addition to aromatherapy, cardamom EO exhibits antioxidative, anti-inflammatory, analgesic, and antispasmodic properties. The oil is commonly used for skin treatment, coughs, nausea, and heartburn (Al-Zuhair et al. 1996). It is also used as a muscle relaxant, diuretic, and an antibacterial agent.

2.17 Coriander Oil

Coriander EO is extracted from *Coriandrum sativum*. Phytochemical analysis revealed the presence of many bioactive chemicals, including alkaloids, terpenoids, tannins, phenolics, flavonoids, sterols, and glycosides (Al-Snafi 2016). Al-Snafi (2016) and Cantore et al. (2004) reported that coriander EO has many biological and pharmacological properties and is thereby used as an antioxidative, anti-inflammatory, analgesic, antibacterial, antifungal, anthelmintic, anxiolytic, antidepressant, sedative, hypnotic, anticonvulsant, anti-Alzheimer's, neuroprotective, hypolipidemic, antidiabetic, anticancer, and hepatoprotective agent.

2.18 Geranium Oil

Geranium EO is extracted from *Pelargonium graveolens* L. The oil contains many phytochemical compounds, including geraniol, citronellol, linalool, α-pinene, myrcene, γ-terpinene, and neral. Pharmacologically, geranium oil is very important because it has antioxidative and anti-inflammatory activities. Geranium EO has been indicated in aromatherapy, muscle relaxation, skin care, dysentery, hemorrhoids, inflammatory conditions, diabetes, diarrhea, gastric ulcers, and cancer.

2.19 Lemon Grass Oil

Lemon grass EO is obtained from *Cymbopogon citratus*, which is native to warm and tropical regions, such as India, Southeast Asia, and Oceania. Phytochemicals present in lemon grass EO are heterogeneous in nature including limonene, citronellal, myrcene, geranyl acetate, neral, nerol, geraniol, and citral. Additionally, the oil is rich in vitamins (vitamin A, B1, B2, B3, B5, B6, C, and folate) and essential minerals (calcium, copper, iron, manganese, magnesium, phosphorus, and zinc). The oil exerts antioxidative and anti-inflammatory activities. Lemon grass EO has a wide application in aromatherapy, health, and diseases. It reduces fever, stress, mental fatigue, and pain associated with nerves, muscles, and the GI tract (gas irritation and gastric ulcers). The oil also has glandular secretion stimulatory, diuretic, immune stimulatory, antibacterial, antifungal, skin healing (antiseptic and astringent), and insect-repellent properties (Abdulazeez 2016; Lawal 2017).

2.20 *Sideritis hirsuta* Oil

The EO of *Sideritis hirsuta* L. is commonly used in the Mediterranean region. Palá-Paul et al. (2006) identified more than 70 chemicals in the EO, predominantly β-phellandrene (23.8%), α-phellandrene (9.2%), α-pinene (8.2%), and (*Z*)-β-guaiene (8.1%). The oil exerts anti-inflammatory, antirheumatic, antimicrobial, and antibacterial properties. The EO of *Sideritis hirsuta* L. appears to have great potential as a nutraceutical in veterinary medicine.

2.21 Tea Tree Oil

The EO of tea tree is extracted from fresh leaves and wood of the tree *Melaleuca alternifolia*. Chemical constituents present in the oil include terpinen-4-ol, γ-terpinene, 1,8-cineol, limonene, linalool, α-cymene, δ-cadinene, and globulol. The applications of tea tree oil are diverse encompassing from cleaning to skin care to massage to prevention and treatment of diseases. In the 1920s, Arthur Penfold, a chemist in Australia, stated that tea tree oil has 11–13 times more antimicrobial activity than phenol. Due to high terpinene-4-ol content, the oil exerts antibacterial and antifungal activities. Its use in oral health and periodontal diseases is well established (discussed in detail in Chap. on nutraceuticals in periodontal health and diseases in dogs and cats). Other uses of tea tree oil include in the treatment of acne, cuts, scrapes, wounds, scars, eczema, psoriasis, itch, warts, toenail fungus, athlete's foot, ringworm, and cancer. Additionally, it can be used as a powerful insecticide.

2.22 Myrrh Oil

Myrrh EO is obtained from the tree trunk bark and branches of *Commiphora myrrha*, which is native to Middle Eastern countries. Its use has been described throughout history (Roman literature, Bible, Koran) for various purposes, including rituals, ceremonies, mummification, and in health and diseases (Ayurvedic, Unani, and Chinese medicine). Myrrh oil contains many chemicals including sesquiterpenes (furanoeudesma-1,3-diene and curzarene), sterols, and steroids (Zhu et al. 2003). Its use has been well documented for oral hygiene and periodontal diseases. Phytoconstituents in myrrh oil exert antibacterial, antiviral, antifungal, amoebocidal, astringent, antispasmodic, hypoglycemic, and anti-inflammatory properties (Dolara et al. 2000; Tipton et al. 2006).

2.23 Ozonated Olive Oil

Studies have shown that when ozone gas is passed through olive oil, the ozone reacts with polyunsaturated fatty acids (PUFA). This ozonated olive oil thus contains a highly reactive and oxidizing agent ozonide which displays a strong antimicrobial effect. Vets Plus Inc. (Menomonie, WI, USA) has developed a patent pending ozonated olive oil formulation Ozoderm, which is a proprietary blend of omega fatty acids and curcumin in ozonated olive oil. In clinical studies (unpublished), Ozoderm has been found to be very effective against a variety of skin conditions.

2.24 Emu Oil

Emu oil is obtained in Australia from the fat of an emu. The oil is very rich in antioxidants and polyunsaturated fatty acids (including omega-3 fatty acids). By having antioxidative and anti-inflammatory properties, emu oil is commonly used to treat skin conditions (such as acne, eczema, psoriasis, rashes, and rosacea), for hair health, and

healing wounds. Emu oil is believed to improve back pain, chronic pain, headache, diabetes, gum disease, osteoarthritis, and rheumatoid arthritis.

3 Essential Oils as Modifiers of Rumen Fermentation, Immune System, and Lactation

Busquet et al. (2006) reported that increased rumen fermentation is indicated by an increase in propionate and a decrease in methane, acetate, and ammonia nitrogen, without reducing total volatile fatty acids (VFAs). VFAs are natural hydrogen sinks that help maintain the equilibrium of hydrogen and keep the fermentation process active. Retention of energy from glucose is the highest in propionate (109%), intermediate in butyrate (78%), and the lowest in acetate (62.5%). Recently, some EOs have been reported as modifiers of rumen fermentation (Lillehoj et al. 2018). In in vitro studies, garlic oil is reported to reduce the proportions of acetate and branched-chain VFAs and increase the proportions of propionate and butyrate (Busquet et al. 2005, 2006). Its fermentation profile is consistent with changes observed when methane inhibitors are supplied to ruminants (Lillehoj et al. 2018). The anti-methanogenic effect of garlic and its active components is due to direct inhibition of Archaea microorganisms in the rumen through the inhibition of hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase, a specific pathway essential for the membrane stability of Archaea. Garlic oil has a strong inhibitory action on VFA production with variable effect, and the margin of safety in the doses between adequate and toxic levels is narrow.

In other studies, cinnamaldehyde and eugenol are reported to reduce the molar proportion of acetate and increase the molar proportions of propionate and butyrate (Cardozo et al. 2004; Busquet et al. 2005). Cinnamaldehyde caused (1) inhibition of methanogenesis, (2) reduction of ammonia nitrogen, and (3) increase in free amino acids, suggesting that deamination of amino acids was inhibited in the rumen. In an in vitro rumen simulation system, cinnamaldehyde has been reported to reduce *Prevotella* spp. (bacteria involved in deamination) (Ferme et al. 2004). Busquet et al. (2005) demonstrated that eugenol inhibits the breakdown of large peptides to small peptides and amino acids. Recently, Lillehoj et al. (2018) suggested that the combination of cinnamaldehyde and eugenol may work in synergy to inhibit peptidolysis and deamination and then improve the overall supply of amino acids and small peptides to rumen flora and the host.

Tekippe et al. (2013) reported that feeding cinnamaldehyde alone or in combination with eugenol results in increase in milk production (1.7–2.7%). In some other studies, a combination of cinnamaldehyde, eugenol, and capsicum, when fed to dairy cattle, increased energy-corrected milk production from 3.2% to 5.2% (Bravo et al. 2009; Wall et al. 2014; Oguey and Wall 2016). Feeding rumen-protected capsicum has been shown to improve milk production by modulating immune function (Oh et al. 2015; Stelwagen et al. 2016).

4 Safety of Essential Oils

Do not add concentrated EOs to dog or cat food and drinking water. Also, avoid using EOs with puppies under 10 weeks of age. Use hydrosols, instead. As needed, dilute EOs and then apply topically or administer via food or water.

5 Concluding Remarks and Future Directions

Essential oils (EO) are extracted from plant and non-plant origins. They may contain up to 100 plus chemicals, which can be of heterogeneous classes. A good number of these chemicals possess antioxidative, anti-inflammatory, immunostimulatory, and antimicrobial properties. Some of the oils also have analgesic, antispasmodic, antiparasitic, antifungal, skin healing, and many other medicinal properties. In dairy cows, some EOs (such as eugenol, cinnamaldehyde, and capsicum) can stimulate immune system and improve milk production. These oils are of immense value to promote human and animal health and prevent and treat diseases. In the future, new oils and novel uses of existing oils will be discovered for the prevention and treatment of animal diseases.

Acknowledgment The authors would like to thank Ms. Robin B. Doss for her technical assistance in preparation of this chapter.

Omega Fatty Acids

Szabina A. Stice

Abstract

Nutraceuticals are bioactive compounds that may be used to prevent and treat diseases and to promote health. They include vitamins, minerals, and other bioactive chemical compounds, such as omega fatty acids. This chapter discusses the potential benefits of omega fatty acids to animals, including their use in treating osteoarthritis, atopy, inflammatory bowel disease and other inflammatory conditions, renal and cardiovascular diseases, lipid and metabolic disorders, and cancer. Additionally, the effects of omega fatty acids on neurological development, behavior, and cognitive function are summarized along with recommended dosing levels and potential adverse effects such as immune function impairment, platelet dysfunction, and altered glucose and lipid metabolism.

Keywords

Omega fatty acids · Omega-3 fatty acids · Omega-6 fatty acids · Polyunsaturated fatty acids

1 Introduction

Nutraceuticals may have profoundly beneficial effects on the well-being and health of animals and humans, including both the prevention and treatment of disease. They may also help reduce or eliminate the need for conventional medications and may confer some beneficial effects that are not available from pharmaceuticals. Nutraceuticals include vitamins, minerals, and other bioactive chemical compounds, or mixtures of compounds, such as fish oil. Fish and marine-life oils, important sources of omega-3 fatty acids, along with purified polyunsaturated fatty acids, are examples of widely available nutraceuticals.

Omega-3 fatty acids have beneficial effects in animals with osteoarthritis, atopy, inflammatory bowel disease, or other inflammatory conditions. They are important for neurologic and retinal development and can improve skin and coat. A low-fat diet combined with omega-3 fatty acid supplementation can be effective in managing canine hypercholesterolemia and hypertriglyceridemia. In dogs, supplementation with fish oil seems to help preserve renal function, as well as to prevent arrhythmias, treat ventricular premature contractions, minimize the loss of heart muscle in congestive heart failure, and exhibit beneficial effects in early chronic valvular diseases. Omega-3 fatty acids have been investigated in both humans and animals for cancer prevention, support, or therapy, both as lone agents or, more often, combined with chemotherapeutic agents, to potentially enhance their effects. Fish oil treatment reduces cachexia (wasting syndrome) and improves food intake in dogs with anorexia (Fig. 1).

While the use of polyunsaturated fatty acids for the management and treatment of numerous conditions in animals is mostly considered safe, it is not completely without some adverse effects. For example, while supplementation with omega-3 fatty acids appears to be renoprotective, long-term supplementation with omega-6 fatty acids has enhanced renal injury in dogs. In addition, concurrent administration of the NSAID carprofen or the antiplatelet medication clopidogrel and omega-3 fatty acids may negatively impact hemostasis.

2 Omega Fatty Acids

A fatty acid is a carboxylic acid with a long aliphatic chain that is either saturated or unsaturated. In the case of unsaturated fatty acids, the position of the double bond in the aliphatic chain can be indicated in two ways. When employing the ω-n notation, the position of the double bond is counted from the methyl ($–CH_3$) end of the fatty acid. For

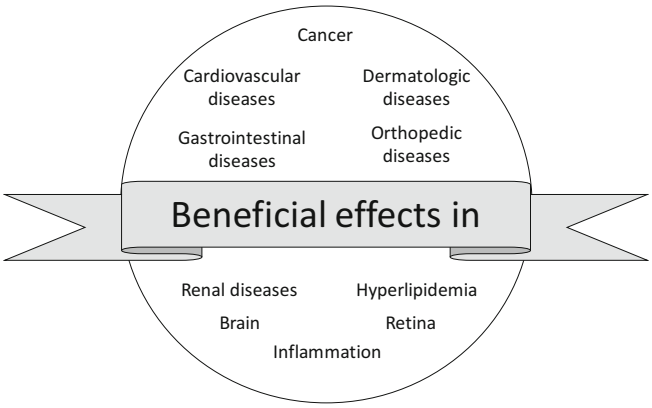

Fig. 1 Potential beneficial effects of omega fatty acids in animals

instance, in the case of an 18-carbon fatty acid, a double bond between C-15 and C-16 counted from the carboxylic acid (–COOH) end may be reported as ω-3 (or omega-3). The naming of the unsaturated fatty acids (i.e., if they are ω-3 fatty acids, ω-6 fatty acids, or ω-9 fatty acids) is based on the location of the first double bond determined by the ω-n notation. In this chapter, the term "omega-3 fatty acids" refers to compounds that are polyunsaturated fatty acids containing a double bond at the ω-3 position. The International Union of Pure and Applied Chemistry (IUPAC) naming of unsaturated fatty acids starts from the –COOH end (Fig. 2).

Fatty acids are important structural components of cells, precursors for other chemicals that are needed for many physiological processes, and provide fuel for animals. For example, eicosapentaenoic acid (EPA) is a precursor of many important chemicals in the body, such as prostaglandin-3, thromboxane-3, and leukotriene-5 eicosanoids; hence, it contributes to platelet aggregation and the regulation of immune responses, along with other functions. Docosahexaenoic acid (DHA) is an important component of the retina, skin, and brain and may lower markers of inflammation. Arachidonic acid (AA) is present in the phospholipids of cell membranes and is abundant in the liver, brain, and muscles. Additionally, AA is involved in cellular signaling and is a key inflammatory intermediate.

Essential fatty acids (EFAs) are fatty acids that humans and other animals cannot synthesize. Therefore, they must obtain EFAs from the diet for optimal health. Diets deficient in EFAs may cause essential fatty acid deficiency (EFAD), characterized by scaly dermatitis, alopecia, thrombocytopenia, hyperlipidemia, altered platelet aggregation, and poor wound healing (Morley 2016; Mogensen 2017). Treatment of fatty acid deficiency requires the dietary administration of, or supplementation with, EFAs. Important fatty acids include, but are not limited to, the ω-3 fatty acids α-linolenic acid (ALA), EPA, and DHA and the ω-6 fatty acids linoleic acid (LA), γ-linolenic acid (GLA), and AA. In humans, LA and ALA are EFAs, while DHA, EPA, GLA, and AA may be synthesized from EFAs or obtained from the diet. Some mammals either have a limited capacity, or completely lack the ability, to convert LA to AA, and for these animals, AA is an essential fatty acid. Due to the inefficient rate of conversion of ALA to EPA, diets containing ALA as the only source of omega-3 fatty acids may not be as effective as those containing EPA and DHA. Natural sources of fatty acids include seeds (ALA, LA, GLA); nuts (ALA, LA, GLA); vegetable oils (ALA, LA, GLA); oily fish, fish oil, or marine-life oil (EPA, DHA); algae (EPA, DHA); meat (AA); and eggs (AA).

3 Omega Fatty Acids as Nutraceuticals in Veterinary Medicine

3.1 Development of the Brain and Retina

DHA is an important component of the brain and the retina and can be synthesized from ALA or obtained from the diet. Kittens and puppies need high concentrations of DHA during gestation and as neonates to support the healthy development of their brain and retinas (Bauer 2006, 2007). Insufficient amounts of maternal DHA during gestation and lactation may lead to suboptimal neurological and retinal development in offspring; therefore, adequate maternal intake of ALA and DHA must be ensured. After weaning, dietary supplementation of DHA from fish oil is recommended to improve overall retinal and nervous system development in puppies and kittens. This is preferred to feeding them foods containing ALA, as neonatal dogs appear to preferentially synthesize DHA from ALA only for a short time while they are suckling, and because the conversion of precursors may be insufficient to meet kittens' DHA needs.

3.2 Anti-inflammatory Effects

3.2.1 Modification of Inflammatory and Immune Responses

Omega-3 fatty acids were shown to modify inflammatory and immune responses. A fish oil-supplemented diet consisting of 1.75 g EPA/kg and 2.2 g DHA/kg diet (ω-6:ω-3 ratio of 3.4:1) appears to suppress, not promote, lymphocyte proliferation in healthy dogs (LeBlanc et al. 2007). The exact same diet was associated with significant reductions in serum prostaglandin E_2 (PGE_2, a potent inflammatory mediator) and concentrations and activities of interleukin-1 and interleukin-6 (IL-1 and IL-6, regulators of immune and inflammatory responses) in dogs (LeBlanc et al. 2008).

The effect of dietary omega-3 fatty acids on inflammation and immune response was also evaluated in cats (Park et al. 2011). For 12 weeks, cats were fed either control, fish oil (high in EPA and DHA)-supplemented, or flaxseed oil (high in ALA)-supplemented diets with ω-6:ω-3 ratios of 20:1, 5:1, and 5:1, respectively. Skin inflammatory response to histamine

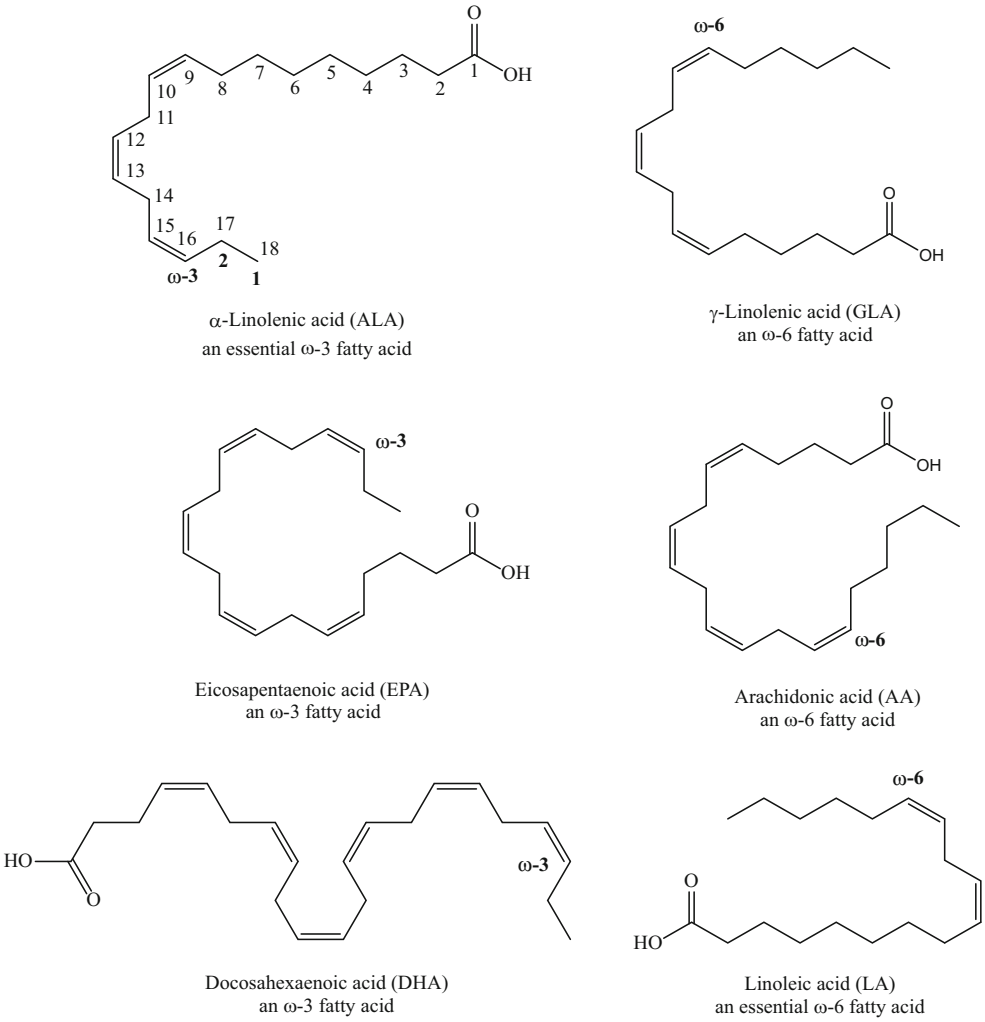

Fig. 2 Numbering of carbon atoms in fatty acids and naming of omega fatty acids

significantly decreased in the fish and flaxseed oil groups. In these groups, lowered B, total T and T_h subpopulations, and leukocyte proliferative response to pokeweed mitogen were noted. Cats fed fish oil had significantly higher leukotriene LTB_5, but cats fed flaxseed oil did not. These results indicate that even though both fish and flaxseed oils can reduce feline skin inflammatory responses, flaxseed oil is less immunosuppressive than fish oil.

The effects of omega-3 fatty acid supplementation on selected immune responses were also evaluated in normal horses by a delayed-type hypersensitivity skin test to keyhole limpet hemocyanin (KLH) and by measuring antibody titers to KLH along with other measurements (Hall et al. 2004). Supplementation with fish oil inhibited the lipopolysaccharide (endotoxin)-induced increase in PGE_2 production of bronchoalveolar lavage fluid (BALF) cells. The authors concluded that fish oil could have a beneficial role in the treatment of equine recurrent airway obstruction or other equine inflammatory diseases, as fish oil did not increase PGE_2 production. Indeed, in horses with recurrent airway obstruction or inflammatory airway disease, omega-3 fatty acid supplementation was later shown to improve clinical signs, lung function, and BALF (decreased neutrophils) when compared to placebo (Nogradi et al. 2015).

The anti-inflammatory and immunosuppressive effects of omega-3 fatty acids are potentially beneficial to animals with chronic inflammatory diseases. Some of these inflammatory diseases and the reported beneficial effects of treatments with omega fatty acids are discussed below.

3.2.2 Therapeutic Use in Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is common in cats (Trepanier 2009) and has also been reported in dogs. IBD is usually treated by modifying the diet first, and if that fails, by administering immunosuppressive therapies. Unfortunately, these treatments do not always help or do not help enough; hence, adjunctive treatments are often sought. One of these potential adjunctive therapies is omega-3 fatty acid supplementation, because omega-3 fatty acids have anti-

inflammatory properties. They have been shown to be beneficial in the treatment of IBD in humans.

In rats, cod liver oil showed positive effects in treating inflammatory colitis; i.e., cod liver oil supplementation significantly diminished the severity of the inflammatory lesions of the bowel and their progression to chronicity (Guarner et al. 1992). In a mouse model of colitis, dietary administration of omega-3 fatty acids reduced clinical colitis and colonic immunopathology by multiple mechanisms (Whiting et al. 2005). A second study in mice showed that dietary omega-3 fatty acids reduced the severity and manifestation of colitis, in addition to suppressing the production of tumor necrosis factor-α that appears to play a pivotal role in the pathogenesis of chronic IBD (Chapkin et al. 2007).

In dogs with food-responsive diarrhea (FRD) or IBD, omega-3 fatty acids significantly decreased the canine IBD activity index (CIBDAI) in both the FRD and IBD groups, demonstrating that omega-3 fatty acids may be beneficial for the treatment of canine chronic enteropathies (Ontsouka et al. 2012). While marked suppression of intestinal inflammatory activity was reported in dogs with FRD, dogs with IBD required a combination of dietary omega-3 fatty acids and immunosuppressive drugs to reduce their CIBDAI values to levels similar to those of dogs in the FRD group receiving omega-3 fatty acids. Unfortunately, efficacy studies in cats are lacking; thus, dosing in cats is empirical and extrapolated from dosages used to treat IBD in humans. Careful titration of the dose is recommended.

3.2.3 Treatment of Pruritus and Atopic Dermatitis

Pruritus, or itch, is a skin sensation that provokes the desire to scratch. Atopic dermatitis (AD), a type of skin inflammation, is characterized by chronic itch, along with red, swollen, and cracked skin or skin lesions. Allergen-specific immunotherapy, corticosteroids, antihistamines, and cyclosporine have been used to control or reduce itching. These treatments may have undesired side effects, take a long time to produce improvement (immunotherapy), or are not effective in all patients. Some cases require a combination of medications to adequately control symptoms. Hence, there is a need for a safer alternative or one that may reduce the number and/or the dosage of medications given to an animal. The effects of fish oil supplementation were examined in multiple studies to determine if omega fatty acid supplementation may be a safer alternative for the treatment of pruritus and atopic dermatitis or to help reduce the doses of medications used.

In a single-blinded, self-controlled study, atopic dogs were fed a diet with an ω-6 to ω-3 fatty acid ratio of 5.5 to 1 (Scott et al. 1997). The itching was satisfactorily controlled within 1–3 weeks in almost half of the animals. After the fatty acid supplementation was stopped, the itching returned soon after but was controlled again when the diet was reinstated. In a second single-blinded, randomized trial, the effects of a similar dietary ω-6 to ω-3 fatty acid ratio (i.e., 5:1) on canine perennial atopic dermatitis were evaluated (Bensignor et al. 2008). The test diet contained 1.6% ω-6 and 0.32% ω-3 EFAs. While both the canine atopic dermatitis extent and severity index scores and the pruritus scores significantly declined on the test diet, proving its efficacy, the score reductions were less than 50%, and most cases required adjunctive therapy to fully resolve symptoms.

In a double-blinded, placebo-controlled, randomized trial, dogs with nonseasonal atopic dermatitis were supplemented with either flax oil (containing ALA and LA), a commercial fatty acid supplement (containing EPA and DHA), or mineral oil as placebo for 10 weeks (Mueller et al. 2004). Average global (supplementation plus dietary) intakes of omega-3 fatty acids were 84, 327, and 141 mg/kg body weight (bw) in the placebo, flax oil, and commercial capsule groups, respectively. Average global intakes of omega-6 fatty acids were 509, 468, and 426 mg/kg bw in the placebo, flax oil, and commercial capsule groups, respectively. In each treatment group, approximately half of the dogs improved by more than 50% and 10–20% achieved complete remission. In a double-blind, crossover study, dogs with idiopathic pruritus, confirmed atopy, and/or flea allergy were randomly placed on either 1 omega-3 fatty acid capsule containing 180 mg EPA and 120mg DHA or a control capsule containing 570 mg LA and 50 mg GLA per 4.55 kg (10 lbs) of body weight for 6 weeks (Logas and Kunkle 1994). This was followed by a 3-week period of no supplementation. After the washout period, the dogs were crossed over to the other supplement for an additional 6 weeks. Dogs on 180 mg EPA and 120 mg DHA supplementation from marine oil displayed significant improvements in pruritus, alopecia, and coat character over time, providing evidence that high-dose marine oil is an effective anti-inflammatory treatment of canine allergic skin disease and may provide a safe alternative to glucocorticoids for short-term symptom relief.

The steroid-sparing effect of omega fatty acid supplementation was demonstrated in studies by Bond and Lloyd (1994) and Saevik et al. (2004). Bond and Lloyd (1994) studied perennially affected atopic dogs, whom they gave a concentrated fatty acid supplement containing GLA and EPA for 12 weeks to examine if it would reduce their prednisolone (steroid) requirements. Seventy-three percent of the dogs required reduced doses of prednisolone for satisfactory control of their atopy. The steroid-sparing effect of essential fatty acid supplementation in canine atopic dermatitis was also indicated in the 12-week randomized, double-blind, placebo-controlled clinical trial by Saevik et al. (2004). In this study, dogs received either a combination of borage seed oil and fish oil, or a placebo, in addition to prednisolone tablets. Investigators noted a 64-daytime lag before finding a statistically significant difference between the placebo and control groups; nonetheless the results indicated that the treatment had a steroid-sparing effect. Unfortunately, based

on the results of this study, they could not suggest an optimal dose for a steroid-sparing effect of fatty acid supplementation for the treatment of canine atopic dermatitis.

A review of the literature by Saevik et al. (2004) concluded that different studies showed different lengths of time needed for the fatty acid treatment to show benefits. For example, in the study by Scott et al. (1997), results were seen just after 1–3 weeks, while in the studies by Bond and Lloyd (1994) and Saevik et al. (2004), the period was much longer; hence, the length of time required to achieve maximum benefit is still being debated.

The timing of the start of fatty acid supplementation may also be important in achieving optimal benefits in treating pruritus and atopic dermatitis. In a study by Abba et al. (2005), the effects of omega fatty acid supplementation were evaluated in nonseasonal atopic dogs during a 2-month trial. While animals were divided into two groups, dogs with early stages of atopy and dogs with chronic atopy (immunotherapy nonresponsive), all dogs received 17 mg EPA/kg, 5 mg DHA/kg, and 35 mg GLA/kg supplementation that provided an ω-6 to ω-3 fatty acid ratio of 5.5 to 1 globally. Based on the results, early stages of atopy seem to be more responsive to fatty acid supplementation than chronic atopy; hence, the study authors recommended that omega fatty acid administration be started early in treatment.

In addition to the enteral administration of polyunsaturated fatty acids, a topical preparation of polyunsaturated fatty acids and essential oils was shown to be beneficial in reducing the clinical signs of canine atopic dermatitis. In a randomized, double-blinded, placebo-controlled clinical trial, dogs were treated once a week for 8 weeks with placebo or a spot-on formulation containing 6 mg ALA/mL, 30 mg LA/mL, neem oil, rosemary extract, lavender oil, clove oil, tea tree oil, oregano extract, peppermint extract, cedar bark extract, and vitamin E (Blaskovic et al. 2014). Weekly, dogs weighing less than 10 kg, 10–20 kg, or 20–40 kg were administered 0.6, 1.2, or 2.4 mL, respectively. While significant improvement of symptoms was reported in the treatment group compared to the placebo group, most dogs did not attain complete remission. According to Blaskovic et al. (2014), the efficacy of this topical treatment with polyunsaturated fatty acids and essential oils appears to be comparable to oral treatment with polyunsaturated fatty acids, but neither oral nor dermal treatment with polyunsaturated fatty acids is as efficacious as treatment with glucocorticoids or cyclosporine. Nonetheless, omega fatty acids are safe alternatives to other anti-inflammatory therapies and may have steroid-sparing effects when used as adjunctive therapy.

3.3 Treatment of Osteoarthritis

Osteoarthritis (OA) results from the degeneration of joint cartilage. It causes joint pain, swelling, stiffness, and restricted movement of the joint. It is a prevalent cause of lameness in equine species and is also common in dogs and older cats (Vandeweerd et al. 2012; Corbee et al. 2013). In cats, dogs, and horses, nonsteroidal anti-inflammatory drugs (NSAIDs) are the basic treatment for OA. Corticosteroids, polysulfated glycosaminoglycans, or hyaluronic acid (a nonsulfated glycosaminoglycan) injections are also employed in horses and dogs (Vandeweerd et al. 2012). Various nutraceuticals for the management of OA are also available.

Based on a review of scientific literature, Vandeweerd et al. (2012) concluded that omega-3 fatty acids significantly alleviate the clinical signs of OA in dogs, unlike other nutraceuticals, whose evidence of efficacy is poor. Dogs fed diets containing a total of 0.8% (baseline therapeutic food), 2.0%, and 2.9% EPA and DHA on a dry matter (DM) basis were evaluated for the symptomatic relief of OA (Fritsch et al. 2010a). Animals on the diet containing 2.9% EPA and DHA, but not those on the 2.0% diet, displayed significant improvement in clinical signs of lameness and weight bearing, overall arthritic condition, and progression of OA, compared to those on the baseline diet (0.8%) at day 90 of the study. In a second dietary study, dogs were fed diets containing either approximately 0.11% omega-3 fatty acids and 2.78% omega-6 fatty acids (very high ω-6:ω-3, control diet) or 3.47% omega-3 fatty acids and 2.46% omega-6 fatty acids (low ω-6:ω-3, test food) (Roush et al. 2010a). Owners of dogs that were provided the test food reported some improvements in their dogs' clinical signs of OA, such as the ability to walk after 12 and 24 weeks on the test food. To evaluate the effects of food supplemented with omega-3 fatty acids on weight bearing in dogs with OA, investigators randomly assigned dogs to consume either typical commercial food (controls) or test food containing 3.5% omega-3 fatty acids (Roush et al. 2010b). Supplementation with omega-3 fatty acids resulted in significant improvement in weight bearing and lameness. When the effects of diets containing either 1.47% omega-3 and 1.86% omega-6 fatty acids (ω-6:ω-3 ratio of 1.3) or 0.18% omega-3 and 2.43% omega-6 fatty acids (ω-6:ω-3 ratio of 13.6) were compared in dogs with OA over a 13-week period, dogs on the high omega-3 fatty acid diet displayed improved locomotor ability and performance of daily living activities (Moreau et al. 2013). Moreover, the results of a randomized controlled study suggested that dietary supplementation at the 3.5% level with omega-3 fatty acids in dogs with chronic OA receiving carprofen (a NSAID) to manage pain may allow for the reduction of carprofen dosage (Fritsch et al. 2010b). In summary, multiple studies have shown that omega-3 fatty acids can significantly alleviate the clinical signs of OA in dogs.

The efficacy of omega-3 fatty acids in the management of OA was also evaluated in cats and horses. In a randomized, controlled, blinded clinical study, cats with degenerative joint

disease fed a diet high in EPA and DHA and supplemented with green-lipped mussel extract and glucosamine/chondroitin sulfate significantly improved in objective measures of mobility over a 9-week period (Lascelles et al. 2010). The test diet contained 2.97 g of total omega-3 fatty acids/1000 Kcal and 8.03 g of total omega-6 fatty acids/1000 Kcal. The effects of omega-3 fatty acid supplementation on owners' perception of behavior and locomotion in cats with OA were investigated in a randomized, double-blinded, placebo-controlled study (Corbee et al. 2013). Fish oil containing 15 mg eicosatetraenoic acid (ETA)/mL, 500 mg EPA/mL, and 100 mg DHA/mL (test supplement) or corn oil containing 0 mg EPA and DHA/mL (control supplement) were provided to cats at a dosage of 1 mL/5 kg bw/day over a 10-week period. Cats on the test supplement had higher activity levels, more walking up and down stairs, less gait stiffness, more interaction with their owners, and higher jumps compared with cats on the control supplement.

Arthritic horses that consumed approximately 89.2 g of omega-6 fatty acids and 17.8 g omega-3 fatty acids (ω-6:ω-3 ratio of 5:1) for 90 days experienced a greater decrease in synovial fluid white blood cell concentration and plasma prostaglandin E_2, as well as a trend toward lower normalized plasma fibrinogen concentrations compared to arthritic horses in the control group consuming approximately 114 g of omega-6 fatty acids and 10.2 g omega-3 fatty acids (ω-6:ω-3 ratio of 11:1) (Manhart et al. 2009). While more studies are needed, the above results indicate that omega-3 fatty acids may be beneficial in the treatment of feline and equine OA as well.

3.4 Renoprotective Effects

To examine the utility of EPA as a renoprotective agent, the effects of fish oil supplementation were investigated in an ischemic model of acute renal failure in dogs (Neumayer et al. 1992). Randomly selected dogs received either vehicle capsules (controls) or 55 mg EPA and 40 mg DHA/kg/day (fish oil group) throughout the study. After 3 weeks on the diet, each dog's right kidney was removed. Three weeks after the right-sided nephrectomy, the renal artery of the left kidney was occluded for 2 h to initiate ischemia. Unlike in control animals, no significant effect on renal function or urine volume was reported in dogs pretreated with fish oil. In uninephric dogs, pretreatment with fish oil seemed to protect the animals from ischemic renal failure.

Marked reduction of renal mass in dogs leads to progressive loss of renal function, and as such, this model has been used to study progressive renal injury (Brown et al. 1998, 2000). The long-term responses of dogs with reduced renal mass to dietary manipulation of polyunsaturated fatty acids were studied to investigate the chronic course of induced renal disease (Brown et al. 1998). Partially nephrectomized dogs were randomly assigned to three supplement groups 2 months post-nephrectomy: omega-3 fatty acids (fish oil), omega-6 fatty acids (safflower oil), and saturated fatty acids (beef tallow). Over a 20-month period, significantly reduced survival in the safflower oil-supplemented group was observed compared to the fish oil group. The fish oil group also had significantly lower proteinuria, which may indicate damage to kidneys, than in the safflower oil and beef tallow groups and higher mean urinary clearance of exogenously administered creatinine, a measure for approximating glomerular filtration rate and used to assess the excretory function of the kidneys. Histologic severity of glomerular injury was significantly higher, and renal interstitial cellular infiltrate was more severe in the safflower oil and beef tallow groups compared to the fish oil group. The incidence of glomerulosclerosis, the hardening of the glomeruli responsible for filtration, was significantly lower in the fish oil group compared to the safflower oil and beef tallow groups. Renal tubulointerstitial fibrosis, a progressive detrimental connective tissue deposition on the kidney parenchyma, was significantly more severe in the safflower oil group than in the fish oil group. In summary, while supplementation with omega-3 fatty acids was suggested to be renoprotective, long-term supplementation with omega-6 fatty acids enhanced renal injury in dogs.

Unlike the studies by Neumayer et al. (1992) and Brown et al. (1998), the study by Brown et al. (2000) studied the same model of kidney disease and diets but before the onset of decreased kidney function (Brown et al. 2000). That is, they investigated the effects of omega-3 and omega-6 fatty acid supplementation in dogs with early chronic renal insufficiency. The partially nephrectomized dogs were randomly assigned to three supplement groups 8 weeks post-nephrectomy: omega-3 fatty acids (fish oil), omega-6 fatty acids (safflower oil), and saturated fatty acids (beef tallow) (Brown et al. 2000). In addition, the animals were supplemented with 5 IU of vitamin E/kg/day. The supplemented diets were administered for 10–13 weeks, during which time the kidney injury was minimal and not different among groups. Omega-6 fatty acid supplementation resulted in worsening of glomerular hypertension and hypertrophy. Significant lowering of serum cholesterol concentration and concurrent maintenance or reduction of the ratio of HDL cholesterol to total cholesterol was observed with omega-3 fatty acid supplementation.

In conclusion, there is plenty of evidence supporting the use of omega-3 fatty acids in slowing the progression of chronic kidney disease in dogs. Omega-3 fatty acid supplementation is recommended in dogs and cats with chronic kidney disease in addition to renin-angiotensin antagonism, calcium channel antagonism, and antihypertensive and antiproteinuric therapy (Brown 2008). Dietary

supplementation with specific antioxidants, such as vitamin E, is also important in helping to slow the progression of chronic kidney disease. Unfortunately, the optimum amount of omega-3 fatty acid and the ratio of ω-3 to ω-6 fatty acid for supplementation have not been established conclusively. Nonetheless, the dietary inclusion of 0.4–2.5% DM omega-3 fatty acids has been recommended for dogs with chronic kidney disease (Forrester et al. 2010). In a review of the therapeutic use of fish oils in companion animals, Bauer (2011) recommends that a diet with 0.4% DM [equivalent to a dose of approximately 130–140 mg EPA and DHA/(kg bw)$^{0.75}$ or ~790 mg EPA and DHA for a 10-kg dog] may be helpful, and the highest dose recommended by Forrester et al. (2010) should be used with caution until more data is obtained.

3.5 Beneficial Effects in Hyperlipidemia

Lipid disorders are common in dogs (Johnson 2005). Hyperlipidemia refers to abnormally elevated levels of any or all lipids or lipoproteins in blood. They can be classified by the types of lipids that are elevated and as familial (primary) or acquired (secondary). Several of these conditions have been recognized in specific dog breeds. For example, hypercholesterolemia (high cholesterol) has been associated with briards, an ancient breed of large herding dog originally from France. Primary idiopathic hypertriglyceridemia, the most common type of primary hyperlipidemia in dogs living in the USA, is recognized in miniature Schnauzers (Xenoulis and Steiner 2010).

Canine secondary lipid disorders (SLDs) can be caused by high-fat diets, diabetes, hyperadrenocorticism, hypothyroidism, acute pancreatitis, protein-losing nephropathy, and cholestasis. They are far more common than primary lipid disorders. High plasma cholesterol levels predispose dogs to narrowing of the arteries due to plaque buildup. In addition to atherosclerosis, complications of hyperlipidemia in dogs can include pancreatitis, seizures, and liver and ocular diseases. Treating SLDs involves correcting or managing their causes.

A double-blind, randomized, placebo-controlled study investigating the effect of a fish oil-supplemented diet and doxorubicin on hemograms and biochemical profiles of dogs with lymphoma and hemangiosarcoma reported that dogs receiving an omega-3-supplemented diet had significantly lower serum cholesterol levels than dogs fed the control diet (Walton et al. 2000). In the studies by Brown et al. (2000) and Neumayer et al. (1992), mentioned in the section titled "Renoprotective Effects," supplementation with omega-3 fatty acids lessened hypercholesterolemia in canine renal insufficiency and significantly lowered cholesterol and triglyceride values in canine ischemic renal failure, respectively.

Hypertriglyceridemia was also reported to be effectively controlled with reduced intake of dietary fat and supplementation with one omega-3 fatty acid-rich fish oil capsule/4.55 kg bw/day (1 g/4.55 kg bw/day) (Bauer 1995). This dose equates to approximately 120 mg of EPA and DHA/kg bw$^{0.75}$ (Bauer 2011). In one study, fish oil supplementation (1.75 g/kg of dietary EPA and 2.2 g/kg of dietary DHA with an ω-6:ω-3 fatty acid ratio of 3.4:1) safely decreased triglycerides in dogs, further evidencing fish oil supplementation's possible benefit in the treatment of canine hyperlipidemia (LeBlanc et al. 2005). In addition to lipid-decreasing drugs such as gemfibrozil, supplementation with omega-3 fatty acids, fish oil, or marine-life oil, in conjunction with a low-fat diet, is a viable lipid-reducing strategy in dogs.

3.6 Beneficial Effects in Cardiovascular Diseases

Omega-3 fatty acids have been shown to be beneficial in human cardiovascular diseases. Atherosclerosis is commonly reported in captive birds (Petzinger et al. 2010). Based on the review of the scientific literature, Petzinger et al. (2010) concluded that omega-3 fatty acid supplementation of captive birds may reduce the prevalence of atherosclerosis and help maintain their health. In addition, studies evidencing the beneficial effects of omega-3 fatty acids in canine cardiovascular diseases have been reviewed by Freeman (2010) and Bauer (2011). The findings of these reviews support the antiarrhythmic properties of omega-3 fatty acids and their potential usefulness in treating ventricular premature contractions in dogs. Fish oil supplementation providing 780 mg EPA and 497 mg DHA/animal/day significantly reduced the number of ventricular premature contractions in boxer dogs with arrhythmogenic right ventricular cardiomyopathy (Smith et al. 2007). In a dog model of cardiac sudden death, intravenous administration of either 860 mg EPA, DHA, or ALA each was protective against fatal ventricular arrhythmias, indicating that purified omega-3 fatty acids can prevent ischemia-induced ventricular fibrillation (Billman et al. 1999). Omega-3 fatty acids were also found to benefit dogs with early chronic valvular diseases and to significantly reduce the size of myocardial infarct in dogs with occlusion-perfusion myocardial ischemia. In dogs with stable chronic heart failure secondary to idiopathic dilated cardiomyopathy, fish oil treatment (providing approximately 27 mg EPA/kg bw/day and 18 mg DHA/kg bw/day) reduced cachexia (wasting syndrome) and improved food intake in dogs with anorexia (Freeman et al. 2006). Recommended doses of omega-3 fatty acids for dogs with anorexia and cachexia are 40 mg EPA/kg and 25 mg DHA/kg (Freeman and Rush 2006).

That said, the optimal doses of omega fatty acids for different cardiac diseases, for different stages of the same

disease, or for different species, are not yet clearly known; hence, further research is needed. Until more information is available, Freeman (2010) recommends 40 mg EPA/kg and 25 mg DHA/kg with a ratio of EPA:DHA of approximately 1.5:5 for both cats and dogs with cardiac disease. These amounts can be added directly to the diet or administered orally using fish oil capsules. The use of flax and flaxseed oil is not recommended, as the omega-3 fatty acid in these products is ALA and the conversion of ALA to EPA and DHA is inefficient in dogs and nearly nonexistent in cats.

3.7 Therapeutic Role Against Cancer

In vitro cell culture studies, in vivo studies in rodents with various cancers, clinical trials in humans with cancer, and clinical trials in dogs with cancer have indicated that omega-3 fatty acids may prevent the development of carcinogen-induced tumors, alter tumor growth and metastasis, and sensitize tumor cells to anticancer drugs (Hardman et al. 1997; Ogilvie et al. 2000; Roudebush et al. 2004; Gleissman et al. 2010; Nabavi et al. 2015). In a double-blind randomized study, 12 dogs with malignancies of the nasal cavity received either a diet supplemented with menhaden fish oil and arginine (used to improve wound healing and immune responses, experimental diet) or an otherwise identical diet supplemented with corn oil instead of fish oil (control diet) (Anderson et al. 1997). The animals received 4 weeks of radiation therapy. Diets were administered 1 week before radiation therapy, during therapy, and for at least 6 weeks after therapy. Omega-3 fatty acids normalized elevated blood lactic acid levels and decreased inflammatory mediators. Furthermore, histopathological examination of the skin and mucosa revealed that dogs on the experimental diet had less thinning and ulceration.

In a double-blind, randomized, placebo-controlled study, dogs with lymphoma received either a diet supplemented with fish oil and arginine or a control diet supplemented with soybean oil (Ogilvie et al. 2000). These diets were provided before and after the dogs attained remission, along with up to five doses of doxorubicin (a chemotherapeutic agent used to treat lymphoma and other cancers). Dogs fed fish oil had significantly higher mean serum levels of DHA and EPA compared to controls, which in turn helped normalize elevated blood lactic acid in a dose-dependent manner. For dogs with stage III lymphoma who were fed fish oil, higher serum levels of DHA were significantly associated with longer disease-free interval and survival time. As the diet was supplemented with both arginine and omega-3 fatty acids, distinguishing the effects of each was not possible.

Major pathways responsible for the beneficial effects of omega-3 fatty acids in cancer therapy are (a) alteration of membrane-associated signal transduction, (b) increase of lipid peroxidation that results in irreversible cell damage enhancing sensitivity to anticancer drugs and inducing apoptosis, and (c) modulating gene expression in numerous signaling pathways (Nabavi et al. 2015). For a more thorough review on the antineoplastic effects of omega-3 fatty acids and their potential modes of action in animals and humans, see Nabavi et al. (2015), Gleissman et al. (2010), Calviello et al. (2009), and Roudebush et al. (2004). The findings of these reviews indicate that omega-3 fatty acids clearly have a therapeutic role against certain types of cancers and can improve the tolerability and efficacy of chemotherapy and radiation therapy. Cats with cancer, however, should be given lower levels of omega-3 fatty acids or fish oil than are recommended for dogs, as some cat studies indicated a potential for bleeding problems (Roudebush et al. 2004).

3.8 Treatment of Aggression and Depression

Clinical studies in humans suggest that that supplementation with omega-3 fatty acids may reduce aggressive, impulsive, and depressive behaviors (Hibbeln et al. 2006). Male rat pups subjected to an omega-3 fatty acid-deficient diet for 15 weeks exhibited significantly increased depression and aggression compared to pups on an adequate omega-3 fatty acid diet (DeMar et al. 2006). While supplementation with omega-3 fatty acids seems to reduce aggressive behavior and depression, the offspring of mice exposed to high levels of omega-6 fatty acids during gestation through the maternal diet (2.3 g LA/day) were more aggressive than the offspring of mice on the control diet (0.8 g LA/day), indicating that in utero exposure to a high omega-6 fatty acid diet increases aggression (Raygada et al. 1998).

Aggression is a common problem in dogs. Because omega-3 fatty acid supplementation had led to reduced aggression in humans and rodents, Re et al. (2008) studied the relationship between omega-3 fatty acid plasma level and aggressive behavior in dogs. Aggressive dogs were found to have lower DHA plasma levels and higher ω-6 to ω-3 ratio compared to normal dogs, suggesting that low omega-3 fatty acid levels may adversely affect behavior. Whether omega-3 supplementation is useful in reducing aggressive behavior in dogs needs further investigation.

3.9 Potential Use for the Prevention of Preterm Labor

In humans, marine omega-3 fatty acids reduce the rate of preterm birth and increase birthweight when administered in pregnancy (Salvig and Lamont 2011). In rats, average gestational age at birth was positively related to a high maternal dietary intake of omega-3 fatty acids (Olsen et al. 1990). In

sheep, when preterm labor was induced by betamethasone, intravenous administration of omega-3 fatty acids delayed the onset of labor and the time of delivery (Baguma-Nibasheka et al. 1999). In two of the six animals in the treatment group, labor was completely stopped. These observations indicate that omega-3 fatty acids may be beneficial for the prevention of preterm labor in animals, but further investigations are needed before they become widely used for this purpose.

4 Potential Adverse Effects of Omega Fatty Acids in Dogs and Cats

Based on the review of the scientific literature, Nabavi et al. (2015) concluded that high doses of omega-3 fatty acids may be associated with immune function impairment, platelet dysfunction, and altered glucose and lipid metabolism. According to Freeman's (2010) review, most studies have not identified the reported hemostatic alterations due to anti-aggregatory effects on platelets, vitamin E deficiency and lipid peroxidation, and mild diarrhea to be of clinical relevance. Slow transition of the animal to the high omega fatty acid-supplemented diet, decreasing the dosage of omega fatty acids, and other dietary modifications may help with the management of diarrhea. To avoid or decrease lipid peroxidation and to prevent vitamin E deficiency, either the omega fatty acid-enriched diets can be supplemented with vitamin E, or vitamin E can be added to omega fatty acid supplements (Lenox and Bauer 2013). In addition to the abovementioned potential direct adverse effects from omega fatty acids, there is a potential for omega fatty acid-drug interactions. Concurrent administration of the NSAID carprofen or the antiplatelet medication clopidogrel and omega-3 fatty acids may negatively impact hemostasis (Lenox and Bauer 2013). Consequently, it is important to consider the individual animal before starting omega-3 fatty acid treatment. For instance, animals with low platelet counts may not be candidates for omega-3 fatty acid supplementation. All animals supplemented with high doses of omega-3 fatty acids should be monitored regularly for possible adverse effects.

5 Concluding Remarks and Future Directions

Nutraceuticals, when correctly used as supplements, offer health benefits and play a role in the safe management of numerous human and veterinary diseases. Evidence regarding the beneficial effects of omega fatty acids in both human and veterinary diseases has been accumulating. Nonetheless, more research is needed to firmly establish the amount of and the type of omega fatty acids, as well as the ω-6:ω-3 fatty acid ratio required for the treatment of various diseases in different species. Once these studies become available, refinements in the current recommendations or the establishment of recommended doses for clinical veterinary applications can be implemented.

Polyphenols and Flavonoids

Satish Kumar Garg, Amit Shukla, and Soumen Choudhury

Abstract

Majority of the plants used in traditional system of medicine are rich in polyphenols and flavonoids which not only regulate the growth of plants but also are rich source of phytochemicals employed in human and animal health. Polyphenols and flavonoids have been advocated as nutraceuticals in human medicine to treat certain modern lifestyle diseases including cancer. These phytochemicals seem to possess great potential for their use in animal health and production system and to replace certain synthetic chemicals which are deleterious on account of their residual effects on human and animal health. Some of the common polyphenols and flavonoids possessing desirable pharmacological activities and the potential for use in livestock and poultry sectors are kaempferol, quercetin, genistein, rutin, catechin, etc. Similarly, some of the plants rich in polyphenols and flavonoids can be used as green fodder and as feed supplements to formulate certain functional foods for augmenting productivity of animals and poultry.

Keywords

Polyphenols · Flavonoids · Anthocyanin · Flavanones · Isoflavones · Flavonols · Nutraceuticals · Human health · Animal production

1 Introduction

Use of plants and vegetables in treatment of human and animal diseases has been advocated since time immemorial. The famous quote of Hippocrates "Let food be thy medicine and medicine be thy food" expressed almost 2000 years ago also adds credence to the fact that before the advent of allopathic drugs, plants were the major sources of drugs in traditional systems of medicine and used by traditional healers in human and veterinary medicine worldwide including India. Ancient literature of therapeutics in Ayurveda also described the role of plants in treatment of diseases. Advancements in science and understanding of the pharmacological activities, mechanism(s) of action at cellular and molecular levels, toxicity potential and possible therapeutic uses of the active principles of plants and their secondary metabolites opened the vistas for discovery and synthesis of various semi-synthetic and synthetic drugs having their origin from plants, e.g. aspirin, quinine, atropine, cardiac glycosides, reserpine, morphine, senna, etc. Therefore, several modern-day drugs have their roots in the ancient medicinal literature.

Understanding of the human health and diseases is becoming more and more complex with advancements in science, especially at molecular level, due to complex interactions between different factors including environmental pollutants, food habits and lifestyle. During the last two decades, incidence of several diseases like hypertension, diabetes, obesity, renal failure and even various types of cancers has increased several folds, and these are becoming more and more challenging both in developed and developing countries. Lifestyle and food habits have been identified to be the precipitating factors for those diseases which were not very rampant few decades ago. Nutraceutical sector has seen unprecedented growth during the last decade, and now these are considered as complementary and supplementary to modern human medicine as these are expected to play an important role in holistic health management in humans. Nonetheless, their importance in veterinary medicine in health management and augmenting animal productivity cannot be undermined.

The term "nutraceutical" was coined from "nutrition" and "pharmaceutical" combo by Stephen DeFelice, founder and Chairman of the Foundation for Innovation in Medicine (FIM), Cranford, New Jersey in 1989 (Maddi et al. 2007).

S. K. Garg (✉) · A. Shukla · S. Choudhury
Department of Pharmacology and Toxicology, College of Veterinary Science and Animal Husbandry, U.P. Pandit Deen Dayal Upadhyaya Veterinary University (DUVASU), Mathura, Uttar Pradesh, India

R. C. Gupta et al. (eds.), *Nutraceuticals in Veterinary Medicine*, https://doi.org/10.1007/978-3-030-04624-8_13

According to De Felice, nutraceutical can be defined as "a food (or a part of food) that provides medical or health benefits, including prevention and/or treatment of a disease". On the other hand, Health Canada has defined nutraceutical as "a product prepared from foods, but sold in the form of pills, or powder (potions) or in other medicinal forms, not usually associated with foods" (Wildman 2001; Bull 2000). According to the report of Business Communications Company Research (2007), world nutraceutical market has grown to $74.7 billion from $46.7 billion in 2002. The USA, UK and Japan are amongst the leading market countries of nutraceuticals. Nutraceuticals provide functional and dietary supplements and impart medicinal effects in individuals. Therefore, functional and dietary food has been stemmed as a key to human health in modern-day lifestyle.

2 Phytochemicals (PCs)

Plants being very rich in several active principles and constituting the active "pharmacophore moieties" possess diverse pharmacological activities and therapeutic potential. Alkaloids, glycosides, tannins, saponins, gum and resins, etc. are the common active principles present in plants (Figs. 1 and 2). There has been tremendous increase in studies pertaining to the discovery of secondary metabolites in plants and their pharmacological activities. Chemical moieties present in plants have been optimistically considered for their adaptogenic properties not only for plant itself but also to improve human and animal health (Valdes et al. 2015).

Basic and applied research in chemistry and biological life science has revealed the role of different primary metabolites in basic physiological functions in plants such as respiration, growth and development, storage and reproduction (Montero 2016). Discovery of plant metabolite-based drugs started with isolation of morphine from opium by Friedrich Wilhelm Sertürner in 1800s. Kossel (1891) was credited for defining the secondary metabolites of plants in comparison to the primary ones for the very first time, and Czapek (1925) was the second person who described the new role of phytochemicals and coined the term "end products" for these compounds.

Fig. 1 Images of flora containing polyphenols and flavonoids. (**a**) Black currant fruit. (**b**) Pecans. (**c**) Clove flower. (**d**) Cocoa. (**e**) Tea leaves. (**f**) Grapes. (Source: Google web page)

Fig. 2 Images of polyphenol- and flavonoid-rich flora for animal use. (**a**) Sea buckthorn. (**b**) *Azadirachta* leaves. (**c**) *Moringa oleifera* leaves (Source: Google web page)

Phytochemicals are pervasive category of diverse and biologically active secondary metabolites of plants, having diverse pharmacological activities, and form an essential part of the feed and fodder for animals and diet of human beings. Phytochemicals have the advantages of accessibility, specificity of responses and comparatively lower toxicity. But the major disadvantages are low bioavailability and rapid elimination due to rapid biotransformation and excretion. Food and feed of humans and animals, respectively, contain complex mixtures of PCs along with numerous antinutritional factors which can affect the concentrations of these PCs in body.

2.1 Polyphenols

Polyphenols are secondary plant metabolites which are present in vegetables, fruits, coffee beans, tea leaves, chocolates, cereals, legumes, beverages etc. More than 8000 polyphenols have been identified in different plants, and these mainly act as antioxidants. Phenolic compounds are also important constituents and affect the quality of fruits which include taste, colour and nutritional properties. On an average, about 300 mg polyphenol is present in 100 mg of fresh fruits such as grapes, apple, pear, cherries etc., and the relief from stress after consumption of coffee and tea is attributed to polyphenols. Several

meta-analysis data and epidemiological findings have revealed the prophylactic and therapeutic roles of polyphenols and flavonoids against chronic diseases such as cardiovascular, cerebrovascular and neurodegenerative diseases, tumour, diabetes mellitus, etc. in human medicine.

2.1.1 Classification of Polyphenols

On the basis of chemical configuration, polyphenols have been classified into several types, namely, phenolic acids (hydroxybenzoic acids and hydroxycinnamic acids), flavonoids (flavonols, flavones, flavanols, flavanones, anthocyanidins, chalcones, catechins, isoflavones and proanthocyanidins), stilbenes (resveratrol) and lignans (matairesinol) (Manach et al. 2004, 2005; Bohn 2014).

Phenolic acids: These are predominantly present in blueberries, coffee, tea, cinnamon, plum, apple and cherries and subdivided into two subgroups termed as hydroxybenzoic acids and hydroxycinnamic acids.

Flavonoids: These are commonly found in fruits, vegetables, legumes, red wine and green tea.

Stilbenes: These are derived from red wine and peanuts, and resveratrol is the most popular entity of this group.

Lignans: These are commonly found in seeds like that of flax, linseed, legumes, cereals, grains and fruits, algae and certain vegetables.

2.1.2 Phenolic Acids

Hydroxybenzoic acid and hydroxycinnamic acid are the two distinguished classes of phenolic acids. Hydroxybenzoic acids are composed of hydrolysable tannins such as gallotannins and ellagitannins and are generally present in red fruits such as raspberries, blackberries and strawberries (Clifford and Scalbert 2000). The percentage of hydroxybenzoic acid content in edible plants is generally very low. There are certain exceptions to it e.g. black radish and onion contain concentration in tens of milligrams per kilogram weight (Shahidi and Naczk 1995). Gallic acid is commonly found in tea leaves, and its concentration is around 4.5 g/kg fresh weight (Tomas-Barberan and Clifford 2000). Plants containing hydroxybenzoic acid are less commonly used in human food; therefore, nutraceutical aspect of these compounds has not been explored well.

Hydroxycinnamic acids are more common form of phenolic acids as compared to hydroxybenzoic acids and are chiefly consisted of chemicals like p-coumaric, ferulic, sinapic, caffeic acids etc. These acids in plant are commonly distributed in bound forms which are the glycosylated products or esters of shikimic acid, quinic acid and tartaric acid. Processing of the food material either by freezing or by fermentation only yields the free form of hydroxycinnamic acid. Chlorogenic acid (CGA) is an important and valuable polyphenol and an inexpensive source of dietary phenol (Clifford 1999; Garg 2016) and is composed of caffeic, ferulic, coumaric, quinic and 3,4 dimethoxycinnamic acid (Belay and Gholap 2009; Tajik et al. 2017) and found in very high concentrations in green coffee beans (Garg 2016). Outer parts of ripe fruits are rich in hydroxycinnamic acids. About 0.5–2 g hydroxycinnamic acids/kg fresh weight is present in the fruits of blueberries, kiwis, plums, cherries, apples etc. Cereal grains are rich in ferulic acid, and wheat grains contain around 0.8–2 g/kg of ferulic acid on dry weight basis which constitutes up to 90% of the total polyphenols (Lempereur et al. 1997; Hatcher and Kruger 1997).

2.1.3 Flavonoids

Flavonoids chemically constitute the class of low-molecular-weight phenolic compounds that are widely distributed amongst the kingdom *Plantae*. Many of them serve as flower pigment commonly encountered in angiosperms. Flavonoids are an important class of secondary metabolite phytochemicals having the polyphenolic structure; are widely present in fruits, vegetables, tea, cocoa and wine; and therefore are termed as "dietary flavonoids" as these constitute an important component of the normal human diet.

Flavonoids are further classified into different subgroups depending on the basis of stereochemistry and chemical structure as the site of attachment of B ring on C ring and degree of oxidation of the C ring and unsaturation (Fig. 1).

Flavonoids where B ring is linked in position 3 of the C ring are called isoflavones. But if B ring is linked in position 4 of the C ring, these are classified as neoflavonoids (Fig. 3). Those in which the B ring is linked in position 2 of the C ring can be further divided into several subgroups on the basis of oxidation and unsaturation of C ring. These subgroups are flavones, flavonols, flavanones, flavanonols, catechins, anthocyanins and chalcones. Examples of the different subtypes have been illustrated in Fig. 4.

Flavonols

Flavonols are the most ubiquitous flavonoids present in dietary foods, and kaempferol and quercetin are the chief representative molecules (Manach et al. 2005). Flavonols are generally present in relatively low concentrations of 15–30 mg/kg fresh weight, but onion (1.2 g/kg fresh weight), leeks, broccoli and blueberries are the richest sources of flavonols (Manach et al. 2004). Flavonols are generally present in glycosylated form with glucose or rhamnose as major sugar.

Flavanols

Flavanols are generally present in two forms, i.e. polymer form known as proanthocyanidins and monomer form known as catechins. Apricot is the richest source of catechins and

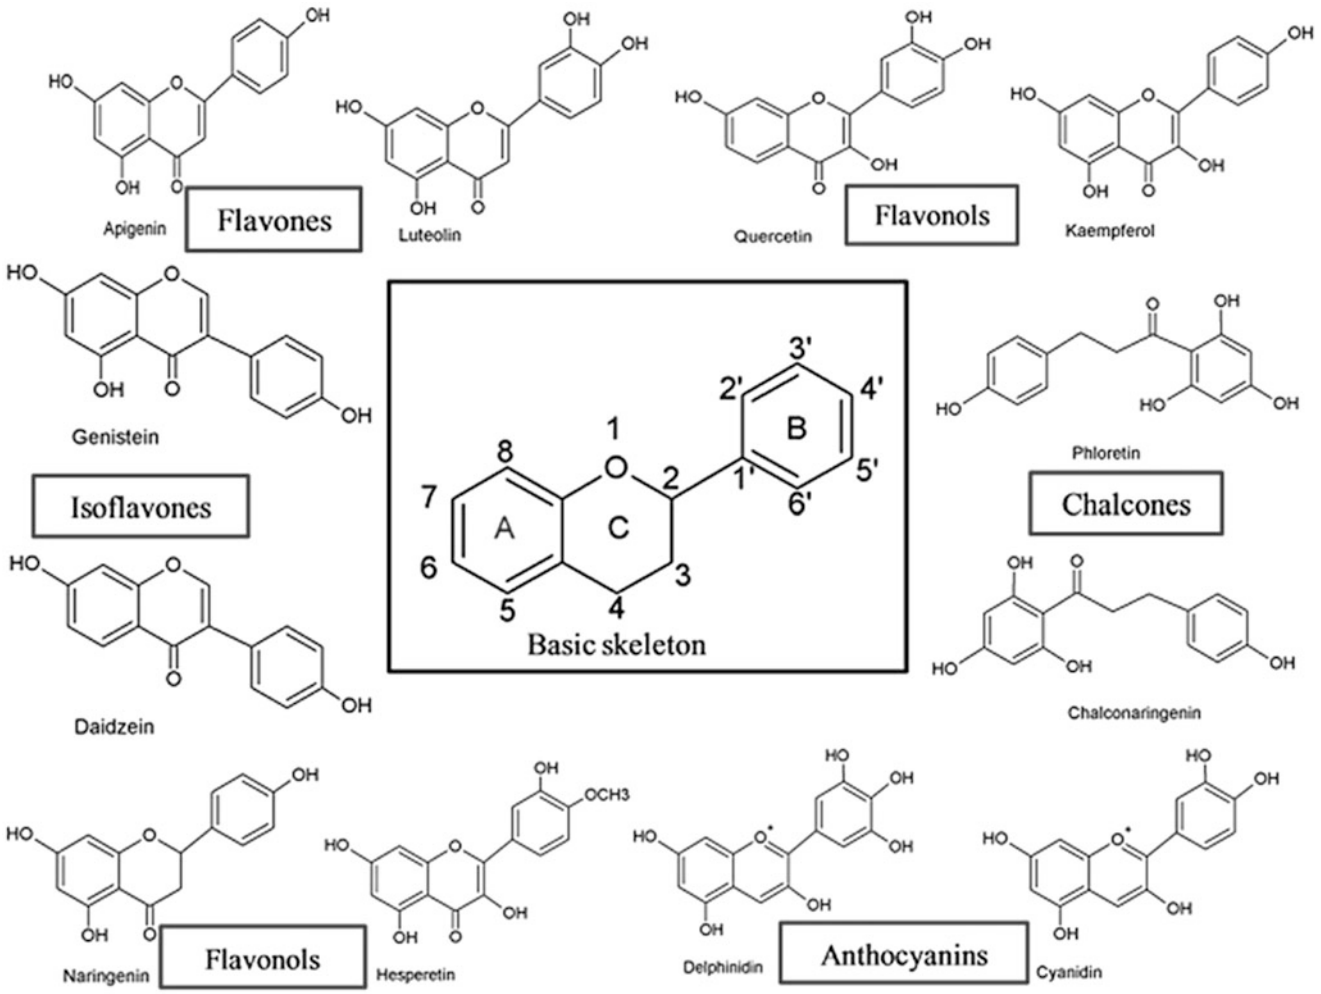

Fig. 3 Basic chemical structures of flavonoids and their classes (Source: Panche et al. 2016)

contains around 250 mg/kg of catechins on fresh weight (Manach et al. 2005). Green tea, red wine and chocolate are also having catechin in great amounts.

Flavones

These are less commonly found in fruits and plants as compared to flavonols and are chiefly consisted of glycosides of luteolin and apigenin. According to Manach et al. (2005), parsley and celery are the only edible sources of flavones. Cereals such as millet and wheat contain C-glycosides of flavones (Erlund et al. 2002; Graefe et al. 2001).

Anthocyanins

These are the colouring pigments present in plants. Cyanidin, malvidin, pelargonidin, delphinidin and peonidin are the most studied anthocyanins. These are commonly present in the outer cellular layers of fruits such as black currants, red grapes, raspberries, strawberries, blueberries, etc. These compounds are generally stable in nature; therefore health benefits along with the stability propel them to be used in nutraceutical industry.

Isoflavones

Soybean-derived products are the richest source of isoflavones. Isoflavones are found in abundance in legumes. Soybeans contain between 580 and 3800 mg isoflavones per kg on fresh weight basis, and soymilk contains between 30 and 175 mg per litre (Hollman and Katan 1997; Moon et al. 2000). Some isoflavones are also present in microorganisms (Matthies et al. 2008).

Chalcones

Chalcones are characterised by the absence of "C ring" in the basic flavonoid skeleton structure, and thus these are termed as "open-chain flavonoids". Examples of chalcones are arbutin, phloridzin, chalconaringenin and phloretin. Chalcones are present in significant amounts in strawberries, pears, tomatoes, bearberries, wheat products, etc.

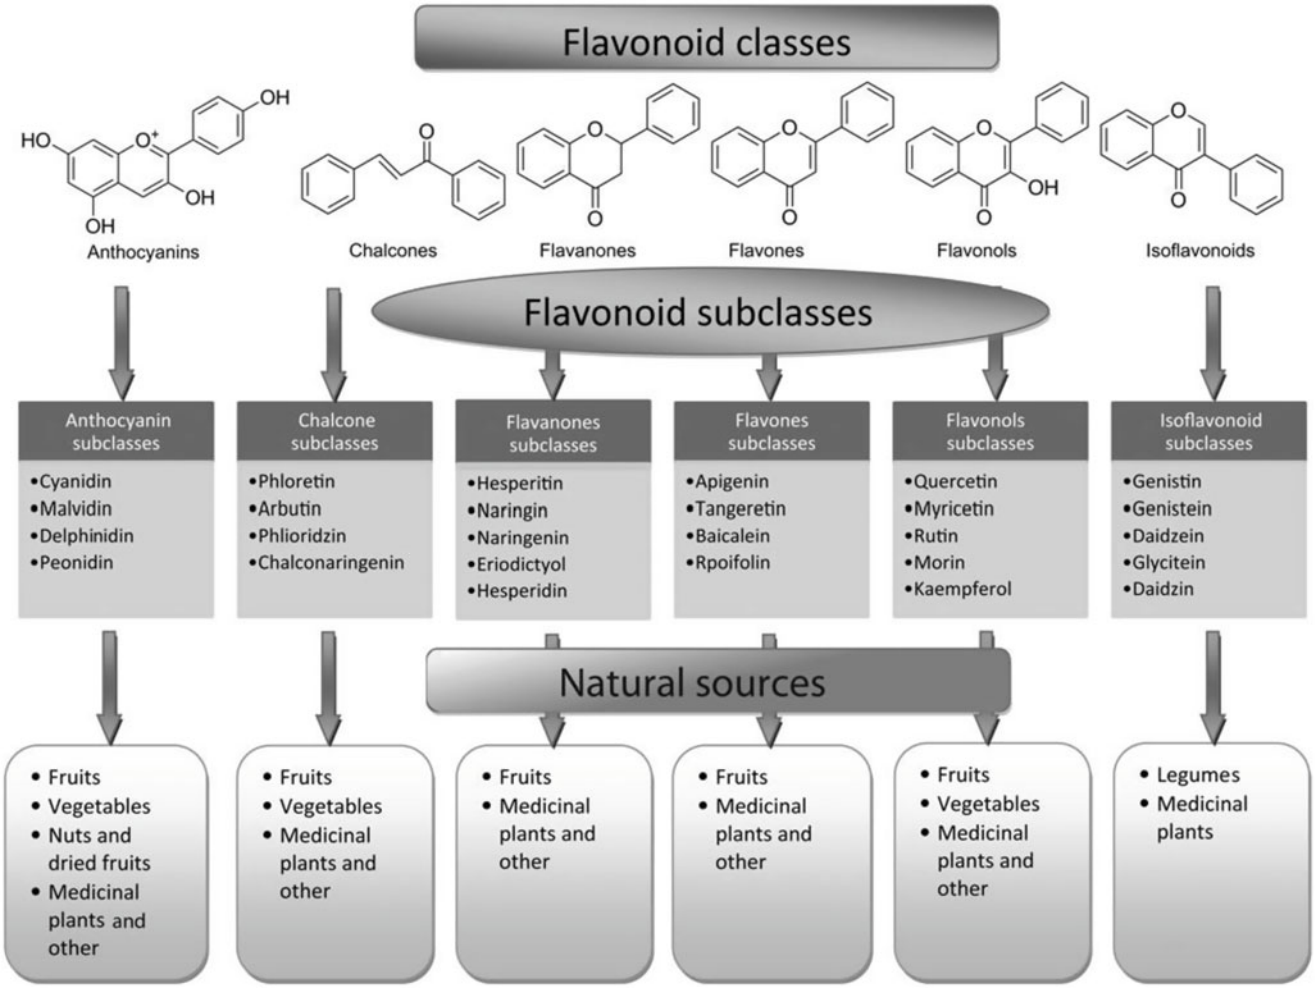

Fig. 4 Classes, subclasses and natural sources of flavonoids (Source: Panche et al. 2016)

2.1.4 Lignans

Lignans are composed of two phenylpropane units. Linseed is the richest dietary source of lignans and contains secoisolariciresinol and matairesinol. Concentration of lignans in linseed is 1000 times more than in other cereals, fruit, grains and certain vegetables (Adlercreutz and Mazur 1997). Lignans are biotransformed by gut microbiota into enterolactone and enterodiol moieties. These two moieties are primarily excreted out in urine, bile and seminal fluids of humans and animals (Wang 2002). These moieties serve as phytoestrogens and thus produce antioestrogenic effects.

2.1.5 Stilbenes

Stilbenes are best exemplified with resveratrol, an antioxidative and antineoplastic agent, found in low quantities in red wine (Bhat and Pezzuto 2002). These are generally found in very low concentrations; hence antineoplastic effect cannot be associated with dietary intake of these molecules.

Phenolic and flavonoid contents in some of the common plants

Source	Total phenolic content {mg gallic acid equivalent/gram on dry weight basis}	Flavonoid content {mg rutin/catechin equivalent/gram on dry weight basis}
Liquorice root	23.65	18.51
Clove	194.47	46.30
Nutmeg	37.26	51.97
Black pepper	17.16	23.57
Mulberry leaf	25.22	21.66
Ginger	21.24	26.21
Peppermint	13.17	27.05
Bamboo leaves	2.75	1.51
Lotus leaf	8.66	12.55
Emblica	26.59	1.35
Ficus	12.36	0.86

(continued)

Source	Total phenolic content {mg gallic acid equivalent/gram on dry weight basis}	Flavonoid content {mg rutin/catechin equivalent/gram on dry weight basis}
Azadirachta indica	12.0	3.14
Terminalia arjuna	12.8	3.49
Acacia nilotica	16.5	4.93

2.1.6 Structural Activity Relationship (SAR) of Polyphenols and Flavonoids

Stereochemistry of flavonoids has been closely associated with pharmacological activities/properties. On the basis of known target chemistry, the newer molecules could also be generated following the new dimensions in molecular biology as well as bioinformatics. Thorough understanding of the SAR of flavonoids can help in evolving several newer semi-synthetic and synthetic compounds having promising pharmacological activities and better therapeutic and clinical applications in human and veterinary medicine.

The antioxidant activity of flavonoids is profoundly influenced not only by the position and number of hydroxyl groups on the A and B rings but also by the degree of conjugation between the B and C rings (Sichel et al. 1991; Chen et al. 1996). Antioxidative potential of polyphenols and flavonoids follows the Bors' criteria (Bors et al. 1990) as discussed below:

a. The *o*-dihydroxy (3′,4′-diOH, i.e. catechol) structure in the B ring confers high stability to phenoxyl radicals of the flavonoids via hydrogen bonding or by expanded electron delocalization.
b. The C2–C3 double bond with the 4-oxo group determines the coplanarity of the hetero ring and imparts radical stabilization via electron delocalization over all three ring (A, B and C) systems.
c. 3-OH and 5-OH groups are required for the maximal radical scavenging capacity and the strongest radical absorption.
d. In the absence of *o*-dihydroxy structure in the B ring, hydroxyl substituents in a catechol structure on the A ring are able to compensate and become a larger determinant of the flavonoid antiradical activity (Amic et al. 2007).
e. Hydroxyl group substitution at C-5 in the A ring and C-4′ in the B ring and the methoxyl group substitution at C-3 and C-8 in A ring are quiet essential for DNA gyrase inhibitory action and for inhibition of *Escherichia coli* multiplication (Wu et al. 2013).

3 Classification of Nutraceuticals

Nutraceuticals have been classified as "established and potential nutraceuticals" (Pandey et al. 2010). Polyphenols and flavonoids are considered under "potential nutraceuticals" category in view of their promising pharmacological activities and potential for use in human health and for improving animal health and productivity. Therefore, there is vast scope for exploiting the polyphenols and flavonoids "as nutraceuticals under 'one health mission' too".

4 Significance of Polyphenols in Flora and Fauna and Human Health

Polyphenols have protective role in floral world and also protect humans and plant species from ill and hazardous effects of ultraviolet radiations and microbiological infestations. Due to their antioxidative attributes, these are recognized to have cytoprotective role as these prevent cellular injury.

The popular saying "You are what you eat" predicts the positive correlation between the healthy diet and sound body and mind. Ameliorative potential of different phytochemicals against number of human ailments, such as obesity, cardiovascular disorders, hypertension, hepatomegaly, carcinomas, infectious diseases etc. (Ganesan and Xu 2017) has been well documented, and their protective efficacy has been attributed to modulation/regulation or inhibition of cellular signalling pathways, reduced platelet aggregation, modulation of cholesterol synthesis, decrease in total peripheral resistance and mural tension on blood vessels or antioxidant effects (Vita 2005). Presence of different PCs including polyphenols in plants and their promising therapeutic potential has been the basis of "reverse pharmacology" research which has resulted in discovery of several newer drug molecules during drug development programmes.

4.1 Extraction of Polyphenols and Flavonoids

Although common extraction methods can be employed for extraction of polyphenols and flavonoids, some of the main methods for better extraction of polyphenols and flavonoids are solvent extraction, pressurized liquid extraction, ultrasonic-assisted extraction, microwave-assisted extraction and supercritical extraction. Conventional liquid–liquid and solid–liquid extraction procedures are also frequently used for extraction of polyphenols. In view of the stereochemistry of polyphenols, it is better to use specific extraction protocols for each polyphenol. Time taken for extraction, chemical

structure of the polyphenols and the organic solvents used play very crucial role in extraction procedures and ultimate recovery of the target phytoconstituents.

Phytoconstituents are attached to the cell-wall matrix through glycosidic/ester linkage; therefore, their water solubility is reduced. Studies on extraction procedures have shown that an antioxidant as a basic stabilizer is required in several extraction approaches. Advanced analytical techniques such as high-performance liquid chromatography and/or gas chromatography–MS spectrometry (GC-MS) can also be used for the high-quality extraction of lignans (Brglez 2016).

4.2 Pharmacokinetic Attributes of Polyphenols and Flavonoids

Pharmacokinetic studies of polyphenols and flavonoids have revealed that following ingestion of dietary flavonoids and polyphenols, which predominantly reside in plants as glycoside conjugates, absorption of some of the components, not all, into the circulatory system takes place from the small intestine (Donovan et al. 2006). There are two major pathways of absorption, namely, "lactase-phlorizin hydrolase (LPH)/diffusion" and "transport/cytosolic β-glucosidase (CBG)". Lactase-phlorizin hydrolase (LPH) is present in the brush border of small intestine epithelial cells and exhibits broad substrate specificity for flavonoids, and the released aglycone moieties get passively absorbed through epithelial cells due to its high lipophilicity (Day et al. 2000). CBG-catalyzed hydrolysis is an active process that involves active sodium-dependent glucose transporter (SGLT1) to transport the polar glucosides into epithelial cells (Gee et al. 2000), and this pathway provides an alternative mean of the hydrolytic cleavage of polyphenols and flavonoids within the epithelial cells.

Prior to passage of flavonoids and polyphenols into circulation, aglycones undergo conjugation process, i.e. there are sulphation, methylation and glucuronidation. Additionally, some of the metabolic products might efflux back into the lumen of small intestine, and this efflux might be attributed to the action of ABC [adenosine triphosphate (ATP)-binding cassette] transporters, including multidrug resistance protein (MRP) and P-glycoprotein (P-gp). Then these metabolites undergo phase II metabolism. In addition, there is enterohepatic recycling back to small intestine via biliary excretion (Donovan et al. 2006). Various studies have suggested that after ingestion of the dietary flavonoids, substantial quantities may pass from the small to large intestine (Jaganath et al. 2006; Marks et al. 2009).

Bioavailability is the proportion of the drug or nutrient entity which reaches to systemic circulation in chemically unchanged form. There is no correlation between the concentration of polyphenol and its bioavailability. Prior to absorption, these compounds have to undergo hydrolysis by intestinal enzymes or colonic bacterium. Polyphenols undergo extensive chemical alterations through conjugation reactions in liver and intestine. Methylation, sulphation and/or glucuronidation are the major contributors to conjugation pathways of polyphenols. Polyphenols reach to the tissues, particularly those in which they are metabolized, but these compounds do not possess any accumulation property. Major route of excretion is either via urine or through faeces.

Most of the polyphenols undergo bacterial enzymatic degradation with the help of beta-glucuronidase in distal part of intestine, and the resultant metabolites are reabsorbed into circulation. Thus, enterohepatic recycling may lead to longer half life of polyphenols in body. This microbial catabolism of polyphenols and flavonoids is best exemplified with proanthocyanidins (oligomers and polymers of flavan-3-ols). It results in sequential production of lactones and aromatic and phenolic acids with hydroxylated derivatives depending on the precursor structures as phenylvalerolactones, phenylpropionic acids, phenylacetic acids, phenylvaleric acid, hippuric and benzoic acids (Saura-Calixto et al. 2007).

Absorption percentage of catechins ranges from 47 to 58% and that of aglycones of quercetin is reported to be 4–13%. Glycosylated quercetin moiety showed better bioavailability through improved absorption as compared to the intact quercetin molecules (Hollman and Katan 1997).

Microbiological mode of biotransformation of ellagitannins or hydrolysable tannins, nonflavonoid polymeric molecules, has also been studied during the last almost 10 years (Larrosa et al. 2010). Strawberries, raspberries, walnuts, oak-aged wines, pomegranates, etc. release free ellagic acid after its hydrolysis in lumen of intestinal tract. *Clostridium* and *Eubacteria* are the main bacterial genera which are involved in metabolism of most of the polyphenols and phenolics such as isoflavones (daidzein), flavonols (quercetin and kaempferol), flavones (naringenin and ixoxanthumol) and flavan-3-ols (catechin and epicatechin) (Selma et al. 2009).

Plasma concentration of total polyphenolic metabolites ranged from 0 to 4 μmol/L with dietary intake of 50 mg aglycone equivalents, and the urinary excretion was found to be in the range of 0.3–43% of the ingested dose (Manach et al. 2005). Amongst the 97 well-known polyphenols studied, gallic acid and isoflavones are the most absorbed polyphenols, followed by catechins, flavanones and quercetin glucosides, while proanthocyanidins, the galloylated tea catechins and the anthocyanin were amongst the least absorbed polyphenols.

Despite poor bioavailability of polyphenols, dietary polyphenols (e.g. resveratrol genistein, curcumin and several others) continue to draw enormous attention of the scientific

community due to their promising pharmacological activities like antioxidative, anti-inflammatory, anti-ageing, antineoplastic and antihyperlipidaemic (Farzaei et al. 2016). Crofelemer, an oligomeric proanthocyanidin, has revolutionized the use of polyphenols as pharmaceuticals for managing the side effects of certain HIV drugs, e.g. FDA approval of crofelemer, Polyphenon E, a green tea polyphenol mixture, for the treatment of genital warts in 2006.

Direct and indirect interactions of polyphenols, flavonoids, proteins or polysaccharides or other phytochemicals with human food may alter the pharmacokinetic attributes of the nutraceutical entities and drugs on concurrent administration. Gut pH, intestinal fermentation, biliary excretion, etc. affect the overall gut health and thus may affect absorption of polyphenols (Bohn 2014; Faria et al. 2014; Marin et al. 2015).

The role of concurrently administered xenobiotics and metabolic enzyme inducers and inhibitors cannot be overlooked in terms of their effect in altering the absorption rate. Addition of milk to black tea has been reported to abolish the antioxidant potential (Serafini et al. 1996). But on the contrary, Hollman et al. (2001) showed that addition of milk to black or green tea had no effect on the bioavailability of certain polyphenols and flavonoids as quercetin, catechins or kaempferol in humans, while the alcohol in red wine could improve the intestinal absorption of polyphenols by increasing their dissolution and disintegration, thereby improving solubility. On the contrary, Donovan et al. (1999) have reported that plasma concentrations of catechin metabolites were similar with or without consumption of alcoholised red wine in humans. Existing reports do not suggest marked effect of various diet components on bioavailability of polyphenols in humans and animals.

4.3 Pharmacological Attributes of Polyphenols and Flavonoids

Supplementation of human diet with important bioactive molecules has been reported to enhance the bioavailability of various drugs and modify body functions. Dietary supplements rich in polyphenols and flavonoids have been reported to possess antioxidant, immune booster, antineoplastic and several other activities. Some of the desirable pharmacological properties and mode of action of the polyphenol and flavonoid moieties are described here.

4.3.1 Antioxidant Activity

Cellular damage to body system mainly occurs due to hydrogen abstraction-mediated generation of free radicals; the hyperactive chemical moieties produced include reactive oxygen species (ROS) and reactive nitrogen species (RNS). These ROS and RNS further produce cascade of reactions and damage cellular integrity. Polyphenols protect against oxidative insult-induced cellular damage and also prevent from the ill-effects of radiations or microbiological contamination. The importance of natural dietary antioxidants such as polyphenols and flavonoids as novel therapeutic entity has been suggested in the treatment of several human ailments like neurodegenerative disorders, diabetes, cardiovascular dysfunctions, inflammation and senescence.

Mechanism of Antioxidative Action Polyphenols and flavonoids produce antioxidant action by impeding the hydrogen abstraction and generation of ROS and RNS. Polyphenolic catechins and rutin scavenge the ROS generated due to free radical cascading effect after initiation and propagation of oxidative insult phenomenon (Yang et al. 2008). Metal-chelating property of catechins also stems their potential to combat oxidative insult (Hider et al. 2001; Kumamoto et al. 2001). In addition, polyphenols also produce their antioxidative action by preventing oxidation of LDL lipoprotein, preventing platelet aggregation and damage of red blood cells (Cheynier 2005).

4.3.2 Anti-inflammatory Activity

Cyclooxygenase (COX) is the endogenous enzyme which catalyses the conversion of arachidonic acid into prostaglandins and thromboxanes. COX2 is an inducible enzyme, which is mainly targeted by flavonoids and polyphenols. Depending on the site of origin and also multiple aetiologies, there are different types of inflammation. Rheumatoid arthritis and inflammatory bowel diseases are serious conditions in human medicine and require continuous and long-term use of anti-inflammatory drugs. Rutin, quercetin, resveratrol, catechin, genistein, etc. have been tested and found to be very effective against these conditions in human (Kauss et al. 2008).

Mechanism of Action Polyphenols have shown their efficacy against rheumatoid arthritis and other inflammatory conditions, and the mechanisms include inhibition of macrophage differentiation and osteoclastic function (Kauss et al. 2008), oestrogen modulation (Wang et al. 2008) and antiproliferative and generalised inhibition of migration of inflammatory cells. In allergic rhinitis, bronchitis and asthmatic patients too, the role of flavonoids has been established by Jung et al. (2007). It has been proposed that quercetin and its glycoside rutin helped in lowering the airway resistance and also reduced histamine, phospholipase A2 and endoperoxidase levels. The cellular infiltration was also observed to be inhibited at the site of inflammation.

4.3.3 Antimicrobial Activity

Polyphenols possess antimicrobial activity and also act as clarifying agents (Proestos et al. 2005). Chlorogenic acid

produces bactericidal effect by significantly disrupting the cell membrane, increasing the plasma membrane permeability and ultimately leakage of cytoplasmic macromolecules including nuclear material (Lou et al. 2011; Garg 2016). Antimicrobial activity of honey was found to be potentially augmented in the presence of phenolic acids (Aziz et al. 1998). Researchers have advocated the antibacterial, antifungal and antiviral activities of these polyphenols and flavonoids. Quercetin produces its antibacterial action through inhibition of DNA gyrase. Similarly, sophoraflavone G and (−)-epigallocatechin gallate inhibit cell membrane function and that licochalcones A and C are involved in inhibition of the energy metabolism (Cushnie and Lamb 2005).

5 Polyphenols and Flavonoids in Human Medicine

5.1 Treatment of Neurodegenerative Disorders

Neurodegenerative disorders such as Parkinson's disease are attributed to dysregulation of iron metabolism and oxidative insult conferring production of reactive oxygen species (ROS) from hydrogen peroxide. This in conjunction with inflammatory cytokines and other mediators propagates the cascading events which terminate into apoptosis (programmed cell death) or necrosis.

Mechanism of Neuroprotection Polyphenols and flavonoids produce protective effect against neurodegenerative disorders by altering iron metabolism. Mandel et al. (2004) advocated the iron-chelating property of epigallocatechin-3-gallate (EGCG) to be responsible for its therapeutic efficacy against neurodegenerative disorders. EGCG has been reported to have therapeutic role against Alzheimer's disease by protecting against beta-amyloid-induced neurotoxicity in cultured hippocampal neurons in central nervous system (Choi et al. 2001). The molecular mechanism describes that EGCG modulates the conversion of amyloid precursor protein (APP), through PKC activation, to non-amyloidogenic soluble APP (sAPP), thereby preventing the formation of neurotoxic beta-amyloid protein (Levites et al. 2003). Additionally, *beta*-secretase (BACE1) enzyme is responsible for processing sAPP to beta-amyloid and is also being inhibited by EGCG, thus producing additional inhibitory effect on neurodegenerative processes (Jeon et al. 2003).

5.2 Treatment of Neoplasms

Neoplasia or cancer is defined as uncontrolled cellular growth and metabolism. A therapeutic agent must possess the property of inhibiting the uncontrolled growth and cellular proliferation (Guo et al. 2009). Nutraceuticals have been shown to be effective in reducing the number of cases of neoplasia in vegan and fruit consumers.

Chemical metabolites of polyphenols generated after microbial degradation possess anticancer activity. Forester and Waterhouse (2008) observed that incubating the anthocyanin extract from Cabernet Sauvignon grapes with the large intestine of pigs for 6 h resulted in generation of three identifiable metabolites. Lala et al. (2006) suggested that these metabolic products had the protective potential against colon cancer. In vivo and in vitro studies have also revealed the protective role of ferulic acid against breast cancer (Kampa et al. 2004) and hepatocarcinoma (Lee et al. 2004).

Mechanism of Action Somatic mutation theory of cancer states that DNA alterations result in development of neoplasia (Vogelstein and Kinzler 2004). It has been suggested that low concentrations of kaempferol protect against DNA damage induced by different carcinogens, thus imparting it an anticancer activity (Cemeli et al. 2004). Polyphenols exert protective and therapeutic effects against carcinogenesis by several mechanisms which include removal of the carcinogenic agents (Owen et al. 2000), modulation of cell signalling, cell cycle progression (Corona et al. 2009) and prompting apoptosis (Mantena et al. 2006). Polyphenols also act as metal chelators and alter the enzymatic activities, e.g. resveratrol acts as a chemopreventive agent by inhibiting the ribonucleotide reductase and certain other cellular events involved in carcinogenesis such as initiation, promotion and progression.

Mitogen-activated protein kinase (MAPK) and PI3-kinase signalling pathways have also been targeted as the therapeutic interventional site by some of the flavonoids and polyphenols (Corona et al. 2009). Flavonoids having antioxidant potential also inhibit carcinogenesis (Stefani et al. 1999). Flavonoids such as apigenin, fisetin and luteolin also produce antineoplastic activity by inhibiting cellular proliferation (Fotsis et al. 1997). Possible mechanisms of action of anthocyanin against colon cancer include decrease in colonic cell proliferation, decreased carcinogen-induced aberrant crypt formation and oxidative insult due to antioxidant property (Lala et al. 2006).

5.3 Treatment of Cardiovascular Diseases

Cardiovascular disorders are one of the major causes of mortality in new world. Hypertension is the primary risk factor for stroke, heart disease and renal failure and is one of the most critical issues in human health (Domanski et al. 2002; Lloyd-Jones et al. 2002; Whelton et al. 2002). Endothelial dysfunction is considered an initial stage of

arteriosclerosis with the pivotal role of endothelin as vasoactive substance (Ross 1999). Individual diet schedule and lifestyle monitoring with nutraceutical supplementation can protect against cardiac diseases. Substantial evidence indicate that balanced diet is a boon in prevention of cardiovascular diseases, thus opening the scope of use of polyphenols and flavonoids in functional foods as well as nutraceuticals in human medicine.

Mechanism of Cardioprotective Action Polyphenols ingestion from various sources such as tea, red wine, red clover, etc. results in decrease in levels of total cholesterol, low-density lipoprotein (LDL) and apolipoprotein B and increase in level of good cholesterol, i.e. high-density lipoprotein (HDL) cholesterol and apolipoprotein A-I. Polyphenols thus produce antilipidemic effect and contribute towards cardioprotection.

Cardioprotective efficacy is also attributed to the antioxidant activity of flavonoids and polyphenols. Anthocyanins exert cholesterol-lowering properties, and its mechanism includes anthocyanin-induced activation of AMP-activated protein kinase (AMPK) that inhibits the activity of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-Co-A) reductase enzyme and thereby reduces cholesterol biosynthesis (Guo et al. 2012; Towler and Hardie 2007). Corder et al. (2001) reported that red wine inhibits the synthesis of endothelin-1, a vasoactive peptide, that has role in coronary atherosclerosis. Hence it proves the beneficial and protective efficacy of polyphenols and flavonoids in cardiovascular dysfunctioning.

6 Polyphenols and Flavonoids in Veterinary Medicine

Nutraceuticals have become very popular in human medicine, and their use in human health programmes is increasing at a very fast pace and the market share of nutraceuticals is expected to grow from 4 billion US dollars as of today to 10 billion US dollars by 2022. In view of the promising effects of nutraceuticals in human medicine, there is growing scope for use of nutraceuticals in veterinary medicine too to address the health and production issues related to livestock. Use of antibiotics as growth promoter has been banned in European and certain other countries including India; therefore, these drugs have to be replaced with certain substances which have the property to build biological molecules within the body and trigger growth promotion. Residues of drugs, feed supplements and feed additives in food of animal origin including poultry have further increased the scope for use of nutraceuticals in veterinary medicine as the veterinary nutraceuticals have been jotted down as nondrug substances which are produced either in purified form or extracted form and are administered orally in order to supply elements required for normal body functioning with the aim of improving the health of animals. Quercetin, rutin, resveratrol etc. are amongst the well-studied active moieties. Applications of veterinary nutraceuticals encompass their widespread use in avian, porcine, canine, feline and rodent's production system.

It is reported by Evan et al. (2007) that around 25% dogs over 7 years of age have suffered with cardiac diseases. About 10% of the dogs presented to veterinary clinics have been associated with one or other sort of cardiovascular diseases (Atkins et al. 2009).

Most of the commercially used nutraceuticals include polyphenols and/or flavonoids as one of their major active principles. Quercetin, rutin, stilbene, etc. are the most commonly used components of nutraceuticals, and there is wider scope for inclusion of several other polyphenols and flavonoids in this class.

6.1 Use in Poultry Sector

Quercetin possesses several promising pharmacological properties. Feeding diets supplemented with quercetin counteracted the oxidative stress and improved meat quality of broiler chickens (Rupasinghe et al. 2010). It has also been reported to produce anti-inflammatory effect in birds and animals (Huang et al. 2010). Immune system critically modulates the health and production in animals. Humoral and cellular immune responses regulate the immunological profile in animals. Polyphenols and flavonoids impart better immune health through various pathways such as augmentation of immunoglobulin production, multiplex role in lymphoid organs, enhancing natural killer cell activity, increasing organ weights of immune organs and maintaining balance between the pro- and anti-inflammatory cytokines (Iqbal et al. 2015).

Quercetin has been reported to improve the overall health of broilers and enhance feed conversion efficiency through immunomodulation (Korver 2012). Flavonoids have also been documented to have beneficial effects on various traits such as growth, body weight, feed conversion ratio (FCR), carcass traits, meat and egg quality, immune status and antioxidative profile in animals and birds (Goliomytis et al. 2014).

Flavonoids and polyphenols are also reported to have antidotal property. Quercetin binds to heavy metals like molybdenum, aluminium and nickel and chelates these metals; therefore, there is scope for exploiting this attribute of quercetin not only in treatment of affected animals but also to ameliorate the likely adverse effects of these metals and certain other heavy metals in animals as an antidotal therapy and also to ensure production of quality and residue-free poultry eggs and meat (Maleser and Kuntic 2007).

6.2 Use in Piggery Sector

Nutraceuticals improve the carcass quality and modulate immune system. Pigs are very prone to viral infections. Antimicrobial and immunomodulatory attributes of polyphenols and flavonoids provide extra cushion against these infections and thus reduce neonatal mortality and improve feed conversion ratio. Wein and Wolffram (2014) have advocated the efficacy of quercetin, a polyphenol, in hyperglycaemic pigs by lowering the postprandial glucose level and lipid concentration. Lipid-lowering attribute of the polyphenols, therefore, gives an insight about the scope of use of polyphenols as dietary supplement in pigs in the form of nutraceutical to produce good-quality pork which is low in cholesterol and lipids and can be safely used for human consumption. Soy-genistein at dietary concentrations of 200–400 ppm has been reported to modulate immune response in virally challenged pigs and improve body weight in pigs (Greiner et al. 2001).

Catechin(s), a polyphenol, has also been found to be good antibacterial and reported to promote growth in pigs. Epigallocatechin gallate (EGCG), most abundant catechin of green tea leaves, has proved to be safe and equipotent to other antimicrobials (Caturla et al. 2003). Furthermore, lack of cross-resistance with use of polyphenols and flavonoids seems an added advantage of this phytoconstituents.

Resveratrol also possesses lipid-lowering and antioxidative properties (Resuleo 2016). It reduces the oxidation of low-density lipoproteins and also serves as chelator of copper in blood of pigs (Fremont et al. 1999). Resveratrol has also been used in cosmetic industry as anti-ageing substance based on the studies conducted on porcine as poor absorption from stratum layer and localised beneficial effects (Zhang et al. 2007).

6.3 Use in Companion Animals

Flavonoids are employed as antioxidant and immunomodulator in canines. Flavonoids improve vascularity in canines and reduce the occurrence of purpura and haemorrhages following exposure to radiation (Field and Rekers 1949).

Tea flavonoids have been associated with reduction in atherogenesis process, inhibition of platelet aggregation and also prevention of coronary thrombosis in dogs (Tijburg et al. 1997). Flavonoids and phenolic acids are also reported to inhibit viral replication (Rees et al. 2008; Saha et al. 2009; Kim et al. 2010; Gravina et al. 2011). Antiviral activity of quercetin (30,4,3,5,7-pentahydroxil flavonol) has been documented against adenovirus 3 (AdV-3), herpes simplex virus (HSV) and influenza virus (Choi et al. 2009; Thapa et al. 2011), while morin (20,40,3,5,7-pentahydroxil flavonol) was found to be effective against equine herpesvirus 1 (EHV-1) (Gravina et al. 2011). Rutin (quercetin-3-orutinoside), a glycosidic flavonoid, has also been reported to show antiviral activity against HSV, dengue virus 2 (DENV-2) and human immunodeficiency virus (HIV) (Tao et al. 2007; Zandi et al. 2011), whereas hesperidin is effective against influenza virus (Saha et al. 2009). Antiviral activity of phenolic acids has also been reported against DENV, EHV-1 and HIV (Ichimura et al. 1999; Rees et al. 2008; Gravina et al. 2011).

Dogs are vulnerable to viral infections especially canine distemper (CD). Canine distemper results in disturbances in gastrointestinal (GI) tract, respiratory and nervous systems. Although vaccines are available, the mortality rates have not been curtailed, and even the nervous form of CD is almost incurable. Flavonoids and polyphenols have been reported to prevent virus replication (Kim et al. 2010; Gravina et al. 2011). Antiviral effect of flavonoids and phenolic acids has been shown through the inhibitory mechanisms, which include interaction with the viral envelope glycoproteins (Schnitzler et al. 2008) and/or viral polymerase inhibition and interference with synthesis of viral genome (Formica and Regelson 1995; Cushnie and Lamb 2005).

Biological actions of these active principles have been attributed to their chemical structure, and with the change in chemical structure of flavonoids, change in biological activity and mechanisms have been reported. For instance, isoquercetin, a glycosylated form of quercetin, has been reported to show higher inhibitory activity than quercetin against influenza virus in both in vitro and in vivo experimental models (Kim et al. 2010). Antiviral activity of various derivatives of quercetin with hydroxyl substitutions at C-3, C-30 and C-5 was studied by Thapa et al. (2011), and these synthetic analogues of quercetin were found to show higher therapeutic index than quercetin against influenza virus.

Demrow et al. (1995) suggested that red wine and grape juice reduce platelet activity and thrombosis in stenosed coronary arteries of canine. This effect is attributed to the presence of flavonoids and polyphenols in red wine and grape juices.

Risk of carcinogenesis, especially venereal tumours, is one of the most commonly encountered tumorous conditions in canines. Flavonoids have been reported to be associated with chemopreventive activity in cancer therapy in humans as well as animals. The chalcones, apigenin, luteolin etc. have found to be potent cytotoxic agents against canine cancer cell line DH82 (Silva et al. 2013), thus suggesting their possible use in targeted chemotherapy against malignant and benign tumours in canines and may be in humans too.

Pain management is very challenging and critical both in animals and humans and sometimes even warrants the use of very strong analgesics including narcotic analgesics. Indiscriminate use of analgesics, both narcotics and nonnarcotics, poses great threat to human and animal health due to their

side effects. Gastric impairment, constipation and hepatotoxicity, etc. are the major side effects of nonnarcotic analgesics. The use of flavonoids and polyphenols as nutraceuticals has been suggested to produce relief from degenerative neuropathic pain and osteoarthritis in dogs following supplementation of baicalin and catechin mixture as nutraceutical to dogs through dual inhibition of cyclooxygenase and 5-lipoxygenase by flavonoids (Burnett et al. 2009).

Ocular damage in humans and canines results into nyctalopia terminating into blindness. The flavonoids and polyphenols present in grapefruit have been reported to counteract the damage induced by oxidative insult to canine lens epithelial cells (Barden et al. 2008). Therefore, nutritional supplementation of grapefruit or the flavonoids and polyphenols isolated from this in the diet can be useful in maintaining the corneal visibility for a longer duration. Low et al. (2014) have also suggested efficacy of ferulic acid, an acid having polyphenolic antioxidant activity against halitosis in canines, thus preventing dental caries and indigestion problems in canines. Therefore, ferulic acid can be employed as a constituent in functional feeds/foods for canines.

6.4 Use in Equine Sector

Equines, which include horses, mules and donkeys, are used for race and recreational purposes and carrying load in day-to-day life as well as in difficult areas, not only by general people but also by defence forces. Generally, horses receive hay and green fodder along with some concentrate. Due to racing and weight load especially in difficult terrains, these animals are very prone to excessive wear and tear, inflammatory changes and ageing. Studies on the beneficial effects of polyphenols in equine diet have revealed that age-related inflammation, i.e. inflammageing, is reduced following dietary supplementation of curcumin in equine diet; thereby it reduces the chances of pounder and osteoarthritis in equines (Siard et al. 2016).

In reproduction science also, quercetin has been identified as a new and promising antioxidant to improve vitality of spermatozoa in stored semen as it reduces lipid peroxidation in sperm and maintains internal adenosine triphosphate (ATP) concentration and thereby improve the overall fertility rate by improving capacitation (McNiven and Richardson 2006). Therefore, there is vast scope for use of polyphenols and flavonoids as nutraceuticals in equines.

6.5 Use in Laboratory Animals

Flavonoids and polyphenols are established to possess promising potential against several diseases including degenerative joint diseases; and the use of green tea extract has shown improvement in arthritis due to inhibition of matrix-degrading enzymes/factors at the mRNA level via inhibition of NF-κB pathway (Haqqi et al. 1999). Flavonoids obtained from *Ficus* have been reported to be as effective as vitamin E as nutraceutical and also proven to be a hepatoprotectant against carbon tetrachloride-induced hepatic injury in rats (Augusti et al. 2005).

Anti-inflammatory activity of flavonoids using guinea pig model has been established, and flavonoids have cyclooxygenase (COX) inhibitory potential (Kim et al. 1998). Thus flavonoids have the potential to be used as nutraceuticals against anti-inflammatory conditions. Grape contains polyphenols such as anthocyanins, quercetin, myricetin, kaempferol, resveratrol, etc. These polyphenols as nutraceuticals in guinea pig diet have been proven to alter the hepatic cholesterol metabolism and affect "very low density lipoprotein (VLDL) secretion". This effect results in reduced accumulation of triglycerides and cholesterol in coronary arteries, thereby reducing the chances of coronary heart diseases (Zern et al. 2003). Therefore, these can be used as a constituent in animal feeds to produce healthy and disease-free laboratory animals for biomedical research.

7 Potential Use of Polyphenols and Flavonoid-Rich Plants in Animal Feeding

Moringa oleifera, sea buckthorn, *Curcuma longa*, *Trachyspermum ammi* and several other plants have been widely used either as green fodder or as feed supplements in animal and poultry sector. The pharmacological properties of these plants are attributed to their several active principles especially polyphenols and flavonoids.

Oil and fruit of sea buckthorn have cytoprotective effect against sodium nitroprusside-induced oxidative insult (Geetha et al. 2002). This plant is also known for its potential immunomodulatory action. It improves the cellular arm of immunity by increasing the multiplication of immune cells in respective immune organs such as spleen. Leaves and fruits of sea buckthorn contain flavonoids and exert cardioprotective effect by decreasing myocardial oxygen consumption along with antiplatelet aggregatory effect. Flavonoids in plants also improve cardiac contractions through calcium signal modulation by inhibiting calcium influx and thus prevent congestive heart failure.

Beneficial effects of feeding polyherbal feed supplement (Herbiotic FS) in broilers as reflected by economic returns from broilers have been reported, and the improved FCR was attributed to the three constituent plants-based materials, namely *Trachyspermum ammi*, *Rheuma emodi*, and *Curcuma longa*. These plants are known to be rich in phenolic compounds (Bhushan et al. 2008).

Trachyspermum ammi has been reported to possess antilipedimic, anti-inflammatory, antibacterial and antifungal activities, and these activities have been attributed to the phenolic compounds present in seeds of this plant (Pathak et al. 2010). Bamboo leaves also have lipid-lowering effect in rat model due to presence of flavones (Yang et al. 2015). Additionally, bamboo leaves also possess antimicrobial activity which is attributed to polyphenols and flavonoids (Singh et al. 2012). Aqueous extract of *Nyctanthes arbor-tristis* flowers possesses promising immunomodulatory action by augmenting antibody production and modifying cytokines production (Bharshiv et al. 2016). Similar immunomodulatory effect of *Moringa oleifera* leaf extract has also been reported (Jayanthi et al. 2015), thus suggesting the possible use of leaves and flowers of these plants as biomass in poultry and animal feeding.

Moringa oleifera and *Nyctanthes arbor-tristis* leaves and some other parts of these plants are also rich in flavonoids and polyphenols. Swain et al. (2017) have also shown that addition of *Moringa oleifera* leaf meal at 0.50 kg/100 kg diet as biomass replacer in laying hens improved egg production and feed conversion ratio (FCR) in layers. Divya et al. (2014) reported that powder of *Moringa oleifera* leaves possesses antilipidemic activity and also improves FCR in broilers when used as feed supplement. Alam et al. (2015) reported that feeding neem leaf powder to broilers showed significant improvement in meat yield and overall growth. Thus, it proves the potential of these plants as feed supplements and biomass replacer along with the beneficial effect on health of animals.

8 Toxicity of Polyphenols and Flavonoids

Possibly therapeutic use of polyphenols and flavonoids have been widely investigated, but their toxic effects on animal and human health have not been thoroughly investigated. Flavonoids and polyphenols have been advocated as source of alternative medicine without working out their adverse effects, if any. These substances have pro-oxidant activity that could trigger early lipid peroxidation leading to increase in free radicals and thus increased ROS generation. Green tea catechin and (−)-epigallocatechin-3-gallate (EGCG) are known to trigger production of H_2O_2 and induce oxidative damage to cytosolic DNA in the presence of transition metal ions such as copper. This increase in pro-oxidant activity of EGCG is significantly claiming its role in nitrosamine-induced colon cancer.

Tea is the most commonly used beverage around the globe. Polyphenols and flavonoids in tea prove it to be a nutraceutical drink; however, xanthine content in tea results in variety of toxic signs and symptoms. Commonly encountered toxic effects include irritation to nerves, tonic convulsions, arrhythmia, tachycardia and GI irritation. Additionally, certain varieties of tea also elicit severe allergic reactions such as asthma, nausea, emesis, hay fever, body ache and neck pain in sufferers (Subiza et al. 1989).

Green tea causes hepatotoxicity, mitochondrial toxicity, headache, nausea and oxidative insult in the intoxicated subjects on chronic exposure, whereas black tea causes precipitation of digestive juices and reduction in iron absorption. Excessive consumption of oolong tea can lead to elimination of calcium in urine leading to osteoporosis (Heaney 2002). Hence, it should be limited to only up to three tea cups a day. Further overdosing of oolong tea can lead to hypokalaemia, QT prolongation, atrioventricular block and ventricular tachycardia (Toshiya et al. 1999).

Quercetin is also known to be mutagenic in cultured cells. A procarcinogenic effect of quercetin in rat model of nitrosomethylurea-induced pancreatic cancer or azoxymethane-induced colon cancer has been reported (Barotto et al. 1998). Phase II metabolizing enzymes are the key factors for toxic effects of polyphenols.

Phytoestrogens stimulate the proliferation of oestrogen-responding cells and increase the risks of carcinogenesis (Breinholt et al. 2000). Genistein has been reported to stimulate the proliferation of breast cancer cells implanted in ovariectomized mice (Ju et al. 2001).

With the balance between pro- and antioxidant properties of flavonoids and polyphenols, maximum therapeutic advantage should be exploited from these entities; hence, these should be used with due precaution.

9 Concluding Remarks and Future Directions

Use of phytomedicines in human and animal health in folklore medicine dates back to thousands of years. With advancements in scientific knowledge and scientific-validation methods role of folk medicines and traditional herbal formulary is increasing with passage of time. Polyphenols are a group of vast therapeutic entities that have the potential for use as antioxidant, anti-inflammatory, cardio-protectant, anti-neoplastic, anti-allergic, antibacterial, antiviral, etc. Low bioavailability of flavonoids and polyphenols is a matter of concern. Scientists should evolve methods to improve the pharmacokinetic profile of polyphenols. Encapsulation and nanotechnology tools may prove to be useful in enhancing the bioavailability of these polyphenols and flavonoids.

Efforts should be made for evolving targeted drug delivery systems and to validate molecular insights for stereochemistry-based actions and validate the drug-receptor interaction. Polyphenols and flavonoids have the potential to serve as panacea for modern lifestyle diseases as dietary supplements in human diet apart from their use in the treatment of some of the occupational diseases. These

phytoconstituents should also be exploited for their use in livestock and poultry feeds apart from encouraging the inclusion of biomass of those plants in animal feeding which are rich in polyphenols and flavonoids.

Antioxidants in Prevention and Treatment of Diseases and Toxicity

Dejan Milatovic and Ramesh C. Gupta

Abstract

Oxidative stress reflects an imbalance between the production of reactive oxygen (ROS) and reactive nitrogen species (RNS) and the body's ability to detoxify their toxic effects through antioxidant defense system. Reactive radicals derived from molecular oxygen or nitrogen are generated internally in animal and human body systems or through external sources like environmental pollution, toxic metals, and pesticides. ROS and RNS attack a variety of essential biological molecules, including lipids, cellular proteins, and DNA, cause alterations in normal cell and organ physiology, and activate disease processes. Given the important role of oxidative stress in the cell and tissue injury, several antioxidants have been exploited for their beneficial effect in regulation of ROS/RNS production and neutralization as well as for preservation of equilibrium. This chapter analyzes oxidative stress and its biomarkers and discusses antioxidant systems essential for preventing and ameliorating detrimental effects of ROS and RNS.

Keywords

Oxidative stress · Reactive oxygen species · Biomarkers · Antioxidants

1 Introduction

Reactive oxygen species (ROS) and reactive nitrogen species (RNS) are highly reactive molecules with one or more unpaired electron(s) in their external shell. These oxidant species can be generated in a variety of endogenous processes (cellular respiration, phagocytic oxidative bursts, antibacterial defense, and others) or during exposures to various agents (pesticides, metals, xenobiotics, and ionizing radiation) (Chakravarti and Chakravarti 2007; Mangialasche et al. 2009; Il'yasova et al. 2012). The imbalance between the generation of ROS and RNS and the cell's ability to neutralize them by antioxidant defense is defined as oxidative stress. ROS and RNS produced under oxidative stress are known to damage cellular biomolecules, including lipids, sugars, proteins, and polynucleotides, and to initiate detrimental effects (Negre-Salvayre et al. 2010; Roberts et al. 2010; Marrocco et al. 2017).

Free radicals are mostly generated in the cell as superoxide by mitochondrial oxidative phosphorylation (Federico et al. 2012; Trewin et al. 2018; Sas et al. 2018). Superoxide can generate another ROS, hydroxyl radical (HO·), by the Fenton and the Haber–Weiss reactions or RNS by forming peroxynitrite ($ONOO^-$) in reaction with nitric oxide (NO·) (Dix and Aikens 1993; Guéraud et al. 2010; Vatassery 2004).

ROS and RNS are also generated by tightly regulated enzymes or enzyme systems located in cellular membranes or organelles. They are produced by enzymes associated with respiratory chain system, prostaglandin synthesis, phagocytosis, and cytochrome P450 systems (Halliwell and Gutteridge 2007; Bahorun et al. 2006; Kumar and Pandey 2015; Pacher et al. 2007; Pizzino et al. 2017). Enzyme nitric oxide synthase (NOS) catalyzes the production of NO from L-arginine with nicotinamide adenine dinucleotide phosphate (NADPH) and oxygen. There are three major isoforms of NOS: (a) neuronal NOS (nNOS), (b) endothelial NOS (eNOS), and (c) inducible NOS (iNOS) produced by microglia, astrocytes, and neurons. Nitric oxide synthases and nicotinamide adenine dinucleotide phosphate (NADP) oxidase isoforms that produce ROS/RNS are also involved in neuronal transmission, cellular signaling, reactions to stress and various agents, synaptic plasticity, and the induction of mitogenic and apoptotic responses (Beal 2000; Valko et al. 2007; Mangialasche et al. 2009). Therefore, ROS/RNS

generated by enzyme systems do not only act as toxic by-product but also have controlling function in the cell (Babior 1999; Valko et al. 2007). This chapter describes various biomarkers of oxidative stress, attenuation of oxidative injury, and antioxidant systems.

2 Biomarkers of Oxidative Stress

Products of ROS/RNS-induced modification of lipids, proteins, carbohydrates, and DNA can be used as markers of oxidative stress (Salisbury and Bronas 2015; Frijhoff et al. 2015; Liguori et al. 2018). ROS/RNS may induce protein oxidation, nitrosylation, and hydrolysis of the peptide bond in the presence of proline, affect DNA modifications including nucleotide oxidation, strand breakage, loss of bases, and adduct formation (Berlett and Stadtman 1997; Wiseman and Halliwell 1996; Dizdaroglu et al. 2002; Marrocco et al. 2017), or directly damage lipids containing carbon–carbon double bounds such as cholesterol, phospholipids, and polyunsaturated fatty acids (PUFAs) (Morrow et al. 1990; Montine et al. 2002). Over the years, lipid products of oxidative damage have generated intense interest as in vivo markers of oxidative damage (De Zwart et al. 1999; Milatovic et al. 2011). These compounds include the F_2-isoprostanes (F_2-IsoPs) and F_4-neuroprostanes (F_4-NeuroPs) (Morrow et al. 1990; Yin et al. 2007; Janicka et al. 2010; Milatovic et al. 2011).

F_2-IsoPs are prostaglandin-like compounds that are produced by a noncyclooxygenase free radical-catalyzed mechanism involving the peroxidation of the PUFA, arachidonic acid (AA, C20:4, ω-6). F_2-IsoPs are formed primarily in situ, esterified to phospholipids, and subsequently released by phospholipases (Famm and Morrow 2003; Gao et al. 2006). In contrast to F_2-IsoPs, prostaglandins (PGs) are generated only from free arachidonic acid (Morrow et al. 1990).

F_2-IsoPs analogs termed neuroprostanes (F_4-NeuroPs), due to the high levels of their precursor in the brain, are formed by peroxidation of docosahexaenoic acid (DHA, C22:6, ω-3) (Roberts et al. 1998). While DHA is highly concentrated in neuronal membranes, AA is evenly distributed in all cell types in all tissues (Salem et al. 1986). Therefore, F_2-IsoPs provides an index of global oxidative damage in the brain and determination of F_4-NeuroPs permits the specific quantification of oxidative damage to neuronal membranes. Both prostaglandin-like compounds can be quantified by mass spectrometry-based methods with the lower limit of detection of the F_2-IsoPs to be in the low picogram range (Montine et al. 2004; Milatovic et al. 2005a, b; Milatovic et al. 2011).

Malondialdehyde (MDA) product is also used to quantify oxidative stress. This product is generated by enzymatic and free-radical peroxidation of PUFAs which contain at least three double bonds. MDA can be generated by thromboxane synthase, but also derived from nonenzymatic peroxidative degradation of unsaturated lipids (Kadiiska et al. 2005). MDA-TBA adducts, produced in reaction of MDA with thiobarbituric acid (TBA), are used to spectrophotometrically measure the levels of oxidative stress and consequent lipid peroxidation (Spickett et al. 2010; Fang et al. 2017).

ROS and RON can react with the DNA molecule and induce nitration and deaminations of purines, purine or pyrimidine base or sugar lesions, DNA–DNA, or DNA–protein cross-links (Dizdaroglu et al. 2002). The most investigated DNA adduct, 8-hydroxy-2′-deoxyguanosine (8-OHdG), can be evaluated by multiple techniques including GC-MS, HPLC, LC-MS, immunoassay, and capillary electrophoresis (Lovell and Markesbery 2007; Fang et al. 2017).

ROS and RNS can also attack any amino acid and produce carbonyl derivatives (Stadtman and Levine 2003). Protein carbonyls can be detected with 2,4-dinitrophenylhydrazine (DNPH) and used as biomarkers of oxidative stress (Dalle-Donne et al. 2003). Products of proteins oxidative/nitrosative modification are relatively stable and sensitive assays are available for their detection (Chakravarti and Chakravarti 2007).

3 Oxidative Stress and Neurodegeneration

Oxidative stress plays an important role in neurodegenerative processes such as excitotoxicity and neurotoxicity associated with anticholinesterases or metals. Brain is very sensitive to oxidative stress because of its high metabolic activity, high density of oxidizable substrates, and relative deficiency in antioxidant systems (Garcia-Mesa et al. 2016; Simioni et al. 2018).

Previous studies have supported a role for oxidative stress and excessive generation of ROS and RNS in kainic acid (KA)- and anticholinesterase-induced neurotoxicities (Dettbarn et al. 2001; Yang and Dettbarn 1998; Gupta et al. 2001a, b, 2007; Milatovic et al. 2000a, b, 2001, 2005a; Zaja-Milatovic et al. 2008). Exposure to anticholinesterases, diisopropylphosphorofluoridate (DFP) and carbofuran (CF), significantly suppressed AChE activity in rat brain, induced severe seizure activity, and significantly increased biomarkers of global free radical damage (F_2-IsoPs) and oxidative damage to neuronal membranes (F_4-NeuroPs) (Gupta et al. 2007; Zaja-Milatovic et al. 2009). Following DFP exposure, F_2-IsoPs and F_4-NeuroPs levels are more than twofold and fivefold higher compared to controls, respectively (Zaja-Milatovic et al. 2009). Our studies in mice also showed that KA-induced excitotoxicity caused an increase in biomarkers of oxidative damage, F_2-IsoPs and F_4-NeuroPs (Zaja-Milatovic et al. 2008) (Table 1).

Table 1 Cerebral concentrations of F_2-IsoPs and F_4-NeuroPs and dendritic degeneration of hippocampal pyramidal neurons following KA-induced seizures in mice

	F_2-IsoPs (ng/g)	F_4-NeuroPs (ng/g)	Dendritic length (μm)	Spine density (number/100 μm dendrite)
Control	3.07 ± 0.05	13.89 ± 0.58	1032.10 ± 61.41	16.45 ± 0.55
KA 30 min	4.81 ± 0.19*	34.27 ± 2.71*	363.44 ± 20.78*	8.81 ± 0.55*
KA 60 min	3.40 ± 0.18	18.55 ± 1.26	425.71 ± 23.04*	7.44 ± 0.56*

Data from KA exposed mice were collected 30 min or 60 min post-injection
*One-way ANOVA showed $p < 0.0001$ for each end point. Bonferroni's multiple comparison test showed significant difference ($p < 0.001$) compared to vehicle-injected control

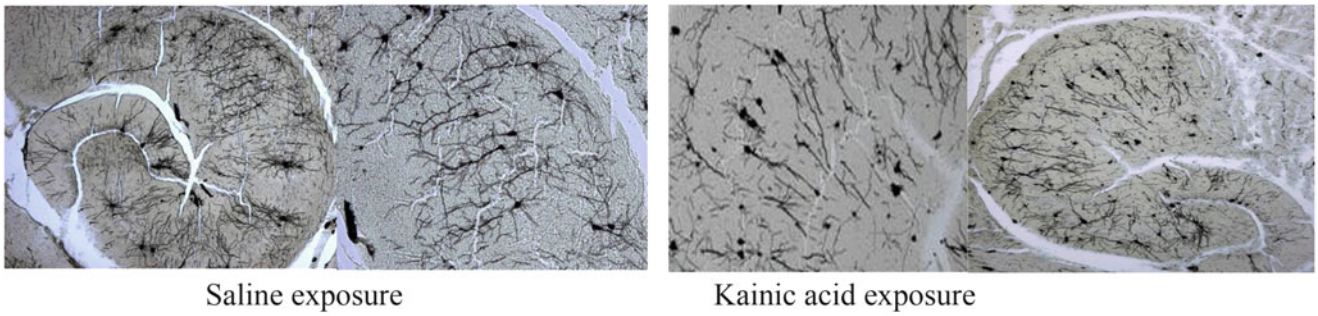

Fig. 1 Photomicrographs of mouse hippocampi with pyramidal neurons from the CA1 hippocampal area of brains 1 h after saline (control) and kainic acid (KA, 1 nmol/5 μl, ICV) injections. Treatment with KA-induced degeneration of the hippocampal dendritic system and decrease in the total length of the dendrite and spine density of hippocampal pyramidal neurons

Furthermore, we have investigated whether seizure-induced cerebral oxidative damage in adult rats and mice is paralleled by alterations in the integrity of the hippocampal CA1 dendritic system. Results from our studies evaluated by Golgi impregnation and Neurolucida-assisted morphometry showed that both KA- and anticholinesterase-induced excitotoxicity targeted the dendritic system with profound degeneration of spines and regression of dendrites in both animal models (Table 1 and Fig. 1) (Zaja-Milatovic et al. 2008, 2009). Together, our studies demonstrate that both models of excitotoxicity lead to profound cerebral oxidative damage and neurodegeneration in the CA1 hippocampal region of brain.

Exposure to some metals, including manganese (Mn), may also lead to oxidative damage and pathological conditions, including neurodegeneration. Early studies demonstrated that mitochondria actively sequester Mn, causing inhibition of oxidative phosphorylation (Cotzias and Greenough 1958; Gavin et al. 1990, 1992). Our studies with primary astrocytes have also shown that Mn exposure induces oxidative damage and a consequent increase in biomarkers of oxidative stress (Milatovic et al. 2007, 2009). Mn concentrations known to elicit neurotoxic effects (100 μM, 500 μM, or 1 mM) in astrocytes induced significant elevations in F_2-IsoPs levels at all investigated exposure times (Milatovic et al. 2007).

Mn-induced oxidative stress and neurotoxicity is also confirmed in our in vivo model. Our study showed that a one-time challenge of mice with Mn (100 mg/kg, s.c.) was sufficient to produce significant increases in cerebral F_2-IsoPs (Milatovic et al. 2009) 24 h following the injection. Our study also demonstrated that Mn exposure altered mice dendritic systems with profound dendrite regression of striatal medium spiny neurons (MSNs). Together, these studies demonstrated that oxidative stress is the underlying mechanism in Mn-induced vulnerability of striatal neurons.

4 Oxidative Stress and Antioxidants in Non-neurodegenerative Diseases

The role of oxidative stress in pathophysiology and antioxidants in the prevention and treatment of diseases associated with cardiac (Wolfram et al. 2005; Willcox et al. 2008; Šterba et al. 2013), respiratory (Janssen 2008; Behndig et al. 2009; Kontakiotis et al. 2011; Nyunoya et al. 2011), hepatic (Jaeschke et al. 2012; Bischoff et al. 2016; Gwaltney-Brant 2016), renal (Tucker et al. 2013; Modaresi et al. 2015), pancreatic (Brownlee 2001), skeletal joints (Gupta 2016) and skeletal muscles (Gupta et al. 2014), and others have been well documented.

5 Antioxidant systems

Antioxidant defense protects biological systems from harmful effects of ROS and RNS. Defense mechanisms are largely based on the presence of antioxidants (exogenous and

endogenous molecules) and the repair or removal of the injured molecules/systems. Antioxidant defense involves a variety of strategies, both enzymatic, such as reductase, superoxide dismutase, or catalase, and nonenzymatic, involving carotene, tocopherols, flavonoids, ascorbate, and glutathione (GSH) (Halliwell 2007).

Antioxidant enzymes, such as superoxide dismutase, glutathione peroxidase, catalase, and reductase, exert synergistic actions in scavenging free radicals. Superoxide dismutase is considered to be the first line of defense against free radical formation. It catalyzes dismutation of superoxide radical into oxygen and hydrogen peroxide. Glutathione peroxidase and reductase are glutathione-dependent enzymes located in the cytoplasm, mitochondria, and nucleus (Gamble et al. 1999). Glutathione peroxidase metabolizes hydrogen peroxide to water using reduced glutathione as a hydrogen donor and is recycled back to glutathione reductase by cofactor NADPH. It plays an important role in the defense mechanism in the erythrocytes against lipid peroxidation damage (Sen 2000; Shah et al. 2014). Superoxide radical may directly inactivate enzymes like glutathione peroxidase and catalase which are needed to eliminate hydrogen peroxide from intracellular medium (Johnson and Giulivi 2005). Another antioxidant enzyme, catalase, is located in peroxisomes (80%) and cytosol (20%) and decomposes hydrogen peroxide to water and oxygen without the production of free radicals (Jones et al. 1981). Catalase does not show significant activity under physiological conditions due to its lower affinity than glutathione peroxidase for hydrogen peroxide but becomes an important enzyme at disease state where concentration of H_2O_2 is elevated (Chance et al. 1979). The antioxidant defense system also involves glutathione-*S*-transferase (Birben et al. 2012).

Glutathione (GSH, L-γ-glutamyl-L-cysteinylglycine), an important element of nonenzymatic antioxidant system, is a tripeptide representing the most abundant nonprotein thiol present in the cell (Wu et al. 2004a; Lu 2009). GSH acts as an antioxidant defense system by its ability to scavenge ROS through the reversible oxidation of GSH. Oxidized form (GSSG) can be enzymatically reduced to GSH by the activity of glutathione reductase and the reducing power of NADPH. In healthy cells and tissues, more than 90% of the total glutathione pool is in the reduced form (GSH) and less than 10% exists in the oxidized form (Schafer and Buettner 2001).

Vitamin E has been identified as one of the most relevant nutritional antioxidants. Vitamin E refers to a group of fat-soluble compounds that include tocopherols and tocotrienols. α-Tocopherol is the most biologically active form, and it has been shown to protect the cells from lipid peroxidation (Azlina et al. 2018; Simioni et al. 2018), oxidative damage of DNA and cellular proteins, and membrane degeneration (Topinka et al. 1989). Vitamin E acts as a radical scavenger and chain breaking antioxidant, protecting cells from peroxidation of PUFA in membrane phospholipids (VanAcker et al. 1993). In addition, vitamin E maintains oxidative phosphorylation in mitochondria, regulates ROS production, and accelerates restitution of high-energy metabolites (Chow et al. 1999; Punz et al. 1998). Decreased levels of vitamin E in response to hyperoxia or treatment with convulsant reported in multiple studies (Mori et al. 2004; Onodera et al. 2003; Rauca et al. 2004) suggest that vitamin E in the brain is consumed to prevent oxidative damage. Vitamin E also exerted anticonvulsive effects by upregulating catalase activity in pilocarpine models of epilepsy (Xavier et al. 2007; Barros et al. 2007; Santos et al. 2008).

The efficacy of the antioxidant vitamin E to suppress an increase in NO and lipid peroxidation and prevent neurodegeneration of hippocampal neurons was also tested in the mice model of KA-induced excitotoxicity (Zaja-Milatovic et al. 2008). Our study showed that vitamin E suppressed KA-induced increases in citrulline and cerebral and neuronal markers of oxidative damage, F_2-IsoPs and F_4-NeuroPs, respectively (Fig. 2) (Zaja-Milatovic et al. 2008). Importantly, vitamin E completely suppressed reduction in both spine density and dendrite length of pyramidal neurons from the CA hippocampal area from KA-exposed mice (Fig. 3). Since vitamin E treatment did not alter severity

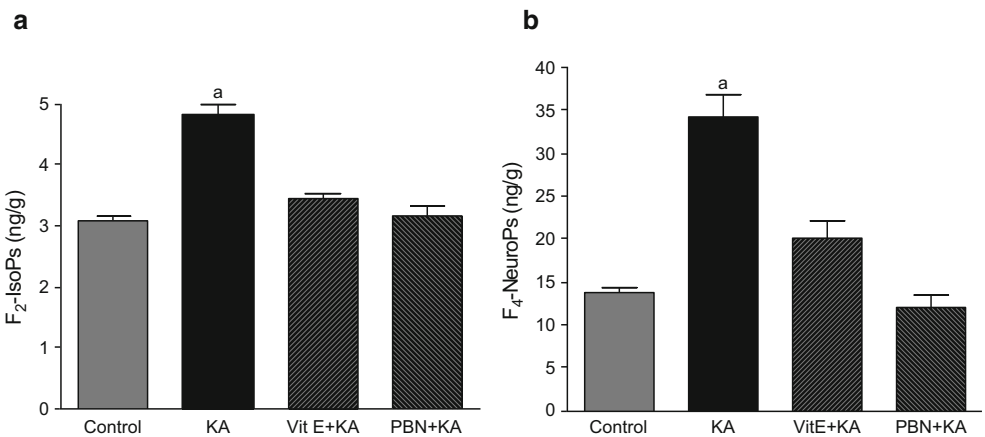

Fig. 2 Ipsilateral cerebral F_2-IsoPs (**a**) and F_4-NeuroPs (**b**) concentrations following i.c.v. KA with or without vitamin E (Vit E) or *N-tert*-butyl-α-phenylnitrone (PBN) pretreatment. Brains from mice exposed to KA were collected 30 min post-injections ($n \geq 5$ for each group). One-way ANOVA had $p < 0.0001$ with Bonferroni's multiple comparison tests significant for KA vs control, Vit E + KA or PBN + KA treatment

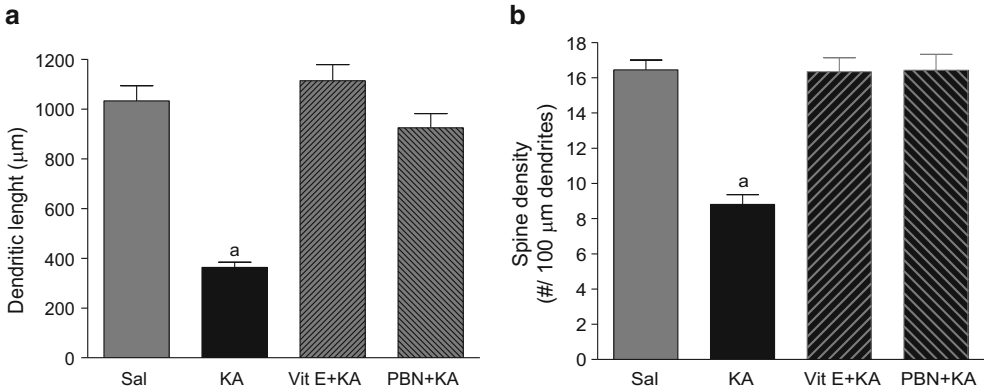

Fig. 3 Dendritic length (**a**) and spine density (**b**) of pyramidal neurons from the CA1 hippocampal area of mice following ICV KA with or without vitamin E or PBN pretreatment. Brains from mice exposed to KA were collected 30-min post-injection ($n \geq 5$ for each group). [a]One-way ANOVA had $p < 0.001$ with Bonferroni's multiple comparison tests significant for KA versus control, vitamin E + KA, or PBN + KA treatment

of kainite-induced seizure, its protective affect is most likely mediated by preventing lipid peroxidation and consequent neuronal damage, but not by its effect on seizures per se (Zaja-Milatovic et al. 2008).

Vitamin C, ascorbic acid, is a water-soluble natural antioxidant and a powerful inhibitor of lipid peroxidation. Vitamin C scavenges free radicals through the formation of ascorbyl radical and thereby prevents damage to macromolecules such as lipids or DNA. This molecule also inhibits propagation of free radicals and reduces α-tocopheroxyl radicals and inhibits propagation of free radicals (Huang et al. 2002). Results from animal models also demonstrated that vitamin C ameliorates edema and hypotension and improves arteriolar responsiveness and capillary blood flow (Tyml et al. 2005; Wu et al. 2004b; Wilson 2009). Vitamin C inhibits the expression of intracellular adhesion molecules and thereby inhibits the intake of immune cells into the microcirculation (Berger and Oudemans-van Straaten 2015). Importantly, vitamin C not only mitigates oxidative stress but also restores vascular responsiveness to vasoconstrictors (Tyml 2017), ameliorates microcirculatory blood flow, preserves endothelial barriers, prevents apoptosis, and augments bacterial defense (Oudemans-van Straaten et al. 2014; Yamamoto et al. 2010).

Vitamin A belongs to a group of unsaturated hydrocarbons and can be found in two main lipid-soluble forms, retinol or retinyl esters and carotene. It has functions in growth and development, good vision, and maintenance of the immune system. The most well-known β-carotene is a potent antioxidant able to quench singlet oxygen (Di Mascio et al. 1991) and reduce lipid peroxidation (Upritchard et al. 2003). Depletion of α-carotene, lycopene, β-cryptoxanthin, and lutein/zeaxanthin has been associated with a variety of diseases including cardiovascular disease (Gaziano et al. 1995) and atherosclerosis (Prince et al. 1988). Together, vitamin C, vitamin E, and carotenoids have shown to synergistically counteract lipid peroxidation (Niki et al. 1995).

Natural food-derived antioxidants have also received great attention in the last two decades. Natural flavonoids, present in fruit, vegetables, and herbs, have shown positive health effect in neurodegenerative disorders, owing to their free radical scavenging activities, preventing lipid peroxidation or chelating metal ions (Lee et al. 2010; Rahal et al. 2014). They are a class of polyphenolic compounds with a benzo-γ-pyrone structure largely represented in plants, responsible for several pharmacological activities (Mahomoodally et al. 2005; Pandey 2007). They account for >85% of the phenolic components in red wine and include different molecules, especially quercetin, and nonflavonoids include mainly resveratrol. Flavonoid affects ROS synthesis suppression, scavenging ROS, and improvement of antioxidant defenses (Halliwell and Gutteridge 1998).

Melatonin, a mammalian hormone synthesized from serotonin, has also shown antioxidant properties (Nishida 2005; Sharman and Bondy 2016). Melatonin exerts its antioxidant capacity by stimulating expression and activity of glutathione peroxidase and superoxide dismutase and inhibiting that of nitric oxide synthase (Pieri et al. 1995; Dato et al. 2013). Melatonin has anti-inflammatory and antiapoptotic effects, but it can also act as an antioxidant scavenger for radical oxygen and nitrogen species (Mahomoodally et al. 2005; Pandey 2007). Several animal studies demonstrated beneficial antioxidant properties of melatonin in septic shock conditions (Heim et al. 2002; Kumar et al. 2013; Kumar and Pandey 2013). Melatonin also suppressed mitochondrial dysfunction as its administration affected mitochondrial NOS activity and restored mitochondrial production of ATP (Escames et al. 2003; Lopez et al. 2006; Mantzarlis et al. 2017).

A synthetic spin trapping agent such as phenyl-*N*-*tert*-butylnitrone (PBN) is also capable of scavenging many types of free radicals. PBN reacts with ROS and forms stable adducts that can be quantified by electron paramagnetic resonance spectrometry. Various in vitro and in vivo studies demonstrated beneficial effects of PBN on the prevention of neuronal degeneration, inhibition of NOS induction (Miyajima and Kotake 1995), in different models of seizures (He et al. 1997; Thomas et al. 1997), protective effects in

models of brain ischemia/reperfusion (Carney and Floyd 1991; Gido et al. 1997; Fetcher et al. 1997), and excitotoxicity (Lancelot et al. 1997; Milatovic et al. 2002). Experimental studies also demonstrated that PBN prevented neurodegeneration in Parkinson's disease (Frederiksson et al. 1997; Sack et al. 1996), anticholinesterase neurotoxicity (Gupta et al. 2001a, b), and Alzheimer's disease (Sack et al. 1996). PBN demonstrated direct effect on striatal function, including inhibition of excitation–contraction coupling (Andersen et al. 1996), Ca^{2+} channel blockade in vascular muscle causing vasodilatation (Anderson et al. 1993), and induction of hypothermia (Pazos et al. 1999). Our studies have demonstrated that PBN treatment prevented KA-induced oxidative damage; suppressed increases in citrulline and cerebral and neuronal markers of oxidative damage, F_2-IsoPs and F_4-NeuroPs (Fig. 2); as well as prevented dendritic degeneration of pyramidal neurons from the CA hippocampal area from KA-exposed mice (Fig. 3) (Zaja-Milatovic et al. 2008). Since antioxidant treatment minimizes lipid peroxidation, then a parallel reduction in neuronal damage provides strong evidence that oxidative stress and lipid peroxidation in a causal way mediate seizure and the corresponding injury.

6 Concluding Remarks and Future Directions

Growing evidence supports the pivotal role played by oxidative stress in tissue injury development. Overproduction of reactive oxygen and nitrogen species, in combination with a lowered antioxidant defense eventually, leads to disturbed cell functions, loss of synapses, neuronal damage, and cell death that gives rise to the clinical symptoms associated with brain disease. Results from multiple studies supported an association between oxidative stress and neurotoxicity and indicated that excitotoxicity leads to profound cerebral oxidative damage and neurodegeneration in the hippocampal brain region. Importantly, our studies have demonstrated that antioxidant therapy, such as vitamin E and PBN, prevented excitotoxicity-induced oxidative damage and dendritic degeneration of pyramidal neurons from the CA hippocampal brain area. Since antioxidant treatment minimize lipid peroxidation, parallel reduction in neuronal damage provides strong evidence that oxidative stress and lipid peroxidation in a causal way mediate seizure and the corresponding injury. The role of oxidative stress and its amelioration by antioxidants in other vital organs have also been well documented. Future studies should be directed at deciphering the mechanisms of protection and guide the development of selective and efficacious antioxidant therapies that target pathways in neuronal and non-neuronal tissues. Antioxidant therapies, including natural antioxidants provided by nutrition, hold great promise.

Resveratrol: Biological Activities and Potential Use in Health and Disease

Gianfranco Risuleo and Camillo La Mesa

Abstract

Resveratrol (RV) is a polyphenol non-flavonoid compound present in strongly pigmented vegetables and fresh fruits as well as dried nuts such as peanuts. High concentrations of this natural compound were found, in the modern occidental world, in the peel of the berries of the red grape *Vitis vinifera*, but usage of this natural drug in popular medicine has been documented much earlier. Resveratrol exhibits diverse biological activities such as antitumor, antioxidant, antiviral, and phytoestrogenic. In particular, as the work reported from our laboratories, the compound shows an inhibitory effect on murine polyomavirus DNA replication, while at higher concentrations, RV shows a significant cytotoxic effect. This complex dose-dependent behavior is not intrinsic to the drug. Other natural substances behave in a similar way, curcumin and a semi-purified fraction of the whole neem oil being two different examples. Most likely, the administration of RV to cultured cells alters the permeability and fluidity of the cell membrane. Also, data presented in literature ascribe to RV an antiproliferative action, thus rendering this drug a good candidate for the control of neoplastic growth. The potential usage of RV both in human and veterinary medicine is also examined in this review.

1 Prologue

The expression "the research on natural compounds and nutraceuticals is in a continuous and ever growing expansion" may sound overused, if not abused and trivial. But, just to give the reader an example about the validity and timeliness of this saying, we will report on a result easily acquired from a simple and quick literature database search. When one of us (G. R.) was invited to write a chapter for a book on *Nutraceuticals: Efficacy, Safety and Toxicity*, back in 2016 (Risuleo 2016), the number of review articles published, from the 1960s of last century up to 2014, on the general subject "natural substances and their biological activities," was about 1650. Now the same search using simply **resveratrol**, as a keyword, yields an amazing 1560 entries (only in terms of review articles) from 2001 up to the present days. It is easy to assert, therefore, that the general interest on this topic has not at all dwindled but remains a central theme for the research in alternative commodities, foodstuffs, and, last but not least, drugs aimed at therapeutic usages.

In this condensed chapter, we shall focus on resveratrol as a potential medicinal remedy in the human and veterinary field. In any case, an overview on the biological properties of resveratrol is necessary. We deliberately kept the language very plain and comprehensible also to scientists not necessarily or directly engaged in biomolecular/physical research on natural compounds, as well as to the layman and people interested in alternative ways to look at nutrition and health care. As a matter of fact, we are convinced that a subject raising such a vivid attention should be easily accessed by everybody.

2 Introduction

2.1 Phytoalexins in a Nutshell

Phytoalexins are natural compounds endowed of antimicrobial and antioxidative action; they include molecules like terpenoids, glycosteroids, and alkaloids. They are synthesized

R. C. Gupta et al. (eds.), *Nutraceuticals in Veterinary Medicine*, https://doi.org/10.1007/978-3-030-04624-8_15

de novo by plants under stress conditions which may originate, for example, by a pathogenic attack and/or by physical adverse conditions, e.g., drought. Pathogen infection may cause a rapid accumulation of phytotoxic substances, at the site of infection: here, phytoalexins show their character as broad-spectrum inhibitors of the infectious progression. The family of phytoalexins has manifold chemical characteristic and includes terpenoids, glycosteroids, and alkaloids. In any case, the definition of phytoalexin is applied to all types of phytochemical molecules involved in the plant defense: in a very broad sense, their action could be compared to the animal immune system. As a matter of fact, the susceptibility of the plant tissue to infection increases when the biosynthesis phytoalexin is inhibited. With respect to this, authors showed that plant mutants incapable of producing these natural "defenders" are more vulnerable to pathogen colonization as compared to wild type; conversely, host-specific pathogens able to degrade phytoalexins cause a higher virulence toward the plant (Glazebrook and Ausbel 1994; Thomma et al. 1999).

As mentioned above, polyphenols, flavonoids, and chemically related substances play a key role in the defense against fungal and other pathogens. We shall mention here a few examples of these "plant-protective" molecules:

Danielone is a phytoalexin found in the fruit of the papaya plant (*Carica papaya*) showing a potent antifungal activity against *Colletotrichum gloeosporioides*, an infectious pathogenic fungus (Echeverri et al. 1997).

Sakuranetin is a flavanone found in rice and other exotic plant like *Polymnia fruticosa* where it inhibits the germination of the spores of *Magnaporthe grisea* (Molnár et al. 2010; Cho and Lee 2015). Finally, it has been suggested that in *Sorghum*, the interactions with the abovementioned *Colletotrichum* seem to be inhibited by the expression of the SbF3'H2 through the synthesis of the pathogen-specific phytoalexins 3-deoxyanthocyanidin (Shih et al. 2006) whose gene encodes a flavonoid 3′-hydroxylase.

Stilbenes are produced in *Eucalyptus sideroxylon* in case of pathogens attacks. Such compounds can be implied in the hypersensitive response of plants. Actually one of the reasons why some woods show a natural preservation against rot may reside in the presence of high levels of polyphenols as reported by a "classical" work by Hart and Hillis (1974).

Finally, going back to the main subject of our work, also resveratrol belongs to the chemical family of phytoalexins. In particular *trans*-resveratrol in *Vitis vinifera* grapes is produced by the plant to combat the infection and proliferation of fungal pathogens such as *Botrytis cinerea* (Favaron et al. 2009). Figure 1 shows the structures of some common phytoalexins with different chemical features.

From what we have briefly discussed above, it is clear that the importance of these molecules goes beyond the intrinsic scientific interest and derives also by their enormous commercial significance. In fact phytoalexins may be considered very important to counteract plant disease and more in general in pest control.

This brief overview on phytoalexins, however, is far from being exhaustive; the reader who wants to deepen this subject should refer to reviews dealing specifically with this matter. See for instance: (Harborne 1999; Ahuja et al. 2012; Großkinsky et al. 2012; Sanchez Maldonado et al. 2015; Meyer et al. 2016; Oliveira et al. 2016; Burow and Halkier 2017; Santos Silva et al. 2018).

2.2 Resveratrol: The Molecule and Its Synthesis

As mentioned above, resveratrol is a phytoalexin of natural origin produced by both bryophytes and higher plants in response to stimuli of different nature. Resveratrol is a stilbenoid with a low molecular weight (MW = 228,25 dal); it is characterized by two aromatic rings linked by an ethane or ethylene residue. The aromatic rings that compose it present three hydroxyl groups at positions 3′, 4′, and 5′. In the IUPAC nomenclature is classified as 5-[(*E*)-2-(4-idrossiphenil)-ethenil] benzene-1,3-diol, but it is also known as 3,4,5 tri-hydroy-stilbene or 3,4,5 stilbene-triol.

In plants, the synthesis of RV is mediated by the enzyme, resveratrol synthase (Schröder et al. 1988). The drug is normally found in two geometric isomer forms: *cis*-(*Z*) and *trans*-(*E*) resveratrol; both isomers can exist in a free or glucose-bound form. The *cis–trans* isomer transition occurs by photoisomerization, a process mediated by UV-light (Mattivi et al. 1995; Lamuela-Raventos et al. 1995) (Fig. 2).

Resveratrol is water soluble up to a concentration of 16.9 mg/L at 25 °C, but solubility is higher in ethanol. Its melting temperature is 253 °C. In addition, the *trans*-resveratrol powder is stable at 40 °C in the presence of air and in a relatively dry atmosphere (75% humidity). This isomer is also stabilized by the presence of transport proteins (Prokop et al. 2006, see also below). The commercially available preparation consists of a white powder with a yellowish-orange hue.

Resveratrol is synthesized in *Vitis vinifera* following the metabolic pathway of the phenyl-propanoids (Dixon and Paiva 1995) where the starting compound is phenylalanine. The enzyme phenylalanine ammonium lyase mediates the elimination of the NH2 group from the amino acid and catalyzes the formation of cinnamic acid: the series of metabolic steps leading to the synthesis of RV is shown in Fig. 3 (reproduced

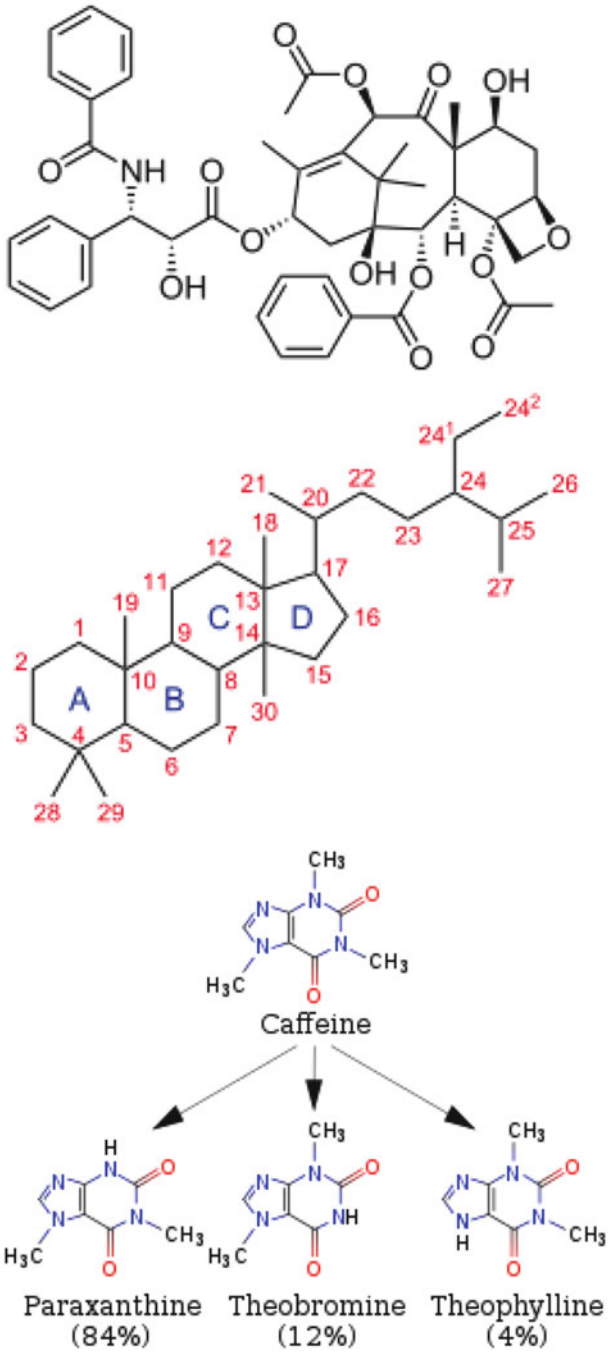

Fig. 1 Structure and function of some common natural substances. Top panel: The terpenoids, also known as isoprenoids, derive from terpenes which are hydrocarbons with additional functional groups, usually containing an oxygen atom. They form a large and diverse class of natural organic chemicals. About 60% of known natural products are terpenoids. The figure reports the chemical structure of the terpenoid taxol, a well-known anticancer drug obtained from the tree *Taxus baccata* and now produced also in laboratory in plant cell culture systems. Center panel: Steroids are biologically active organic compounds with four rings arranged in a specific molecular configuration. They are important components of cell membranes playing a role in membrane fluidity. They may also function as signaling molecules. A large number of steroids are found in plants, fungi, and animals. Bottom panel: Alkaloids can be purified from crude extracts by acid-base extraction by bacteria, fungi, plants, and animals. They show a very broad range of pharmacological activities. Unlike other natural compounds, alkaloids are characterized by a great structural and functional diversity; therefore their univocal classification is almost impossible. Obsolete methods have classified alkaloids by the common natural plant source. This was due mainly to lack of knowledge about their chemical structure. More recent classifications are based on similarity of the carbon skeleton or the biochemical precursor. However, due their diversity the classification of alkaloids is sometimes still uncertain. The picture shows the structure formula of caffeine and its metabolic modifications

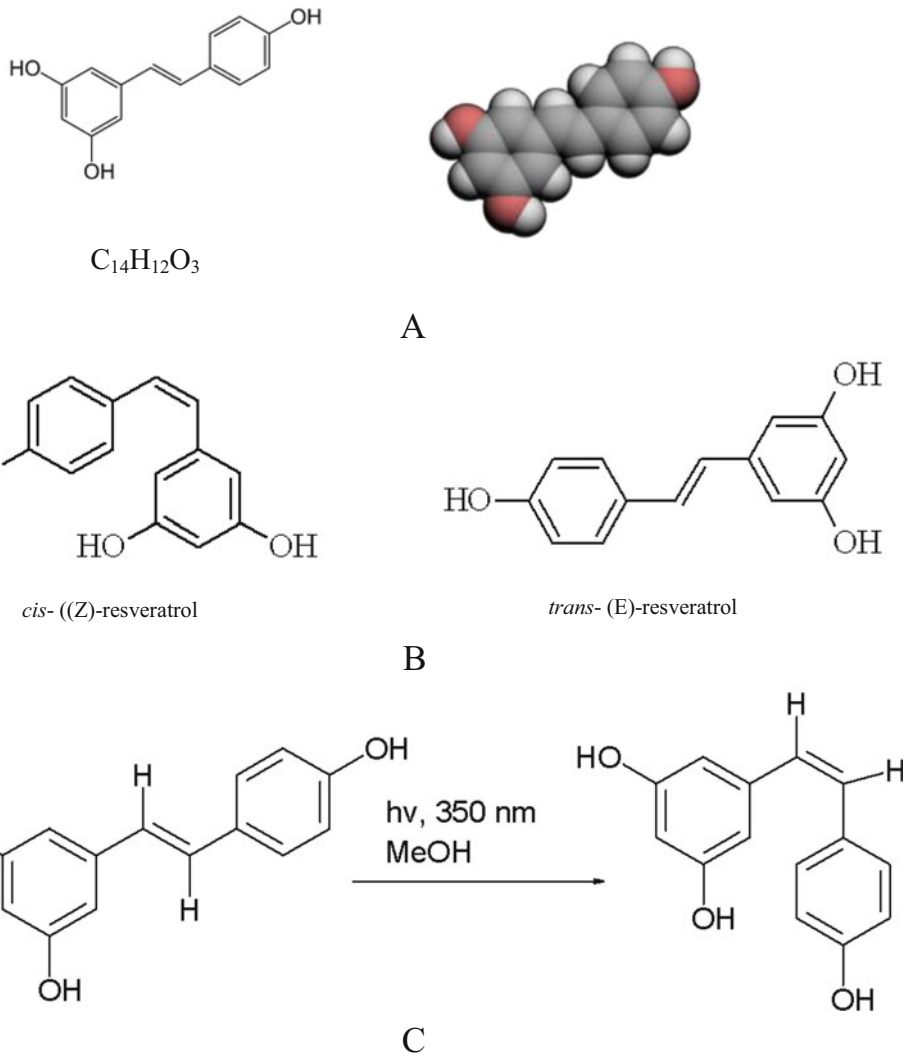

Fig. 2 (**a**) Empirical and structure formulas of *cis*-resveratrol (left and right, respectively). The number of C, H, and O atoms is also given. with modifications from: Soleas et al. 1997; Schröder 1999; Jeandet et al. 2002, Cichewicz and Kouzi 2002).

2.3 Occurrence in Nature

Resveratrol was originally found in the berries of the wine grape (*Vitis vinifera*), but it is also present in the roots, seeds, and stock of the plant. The highest concentration is found in the peel of the berries although the content may vary significantly depending upon the fruit source from which resveratrol is extracted and upon the way the fruit is processed. Red wine contains a relevant amount of RV, but it can be also obtained from diverse sources like pea- and pine nuts as well as mulberries: actually the compound can be isolated from all intensely pigmented fruits (Table 1 shows the amount of RV present in various foods and beverages). In any case, this natural product is known since centuries and was used in the Japanese and Chinese traditional medicine: actually, RV was obtained in its crude original form, from the desiccated roots of the Japanese knotweed (*Polygonum cuspidatum*) where is present at a 400-fold higher concentration as compared to grapes or red wine (Fig. 4).

3 Relevant Biological Actions

3.1 Antitumor Activity in Mammals

The main feature of a transformed tumor cell is represented by its unregulated proliferation that determines a significantly increase in duplicative speed as compared to normal tissue cells. There are a number of reasons accounting for this metabolic dysregulation, essentially loss of control of the cell cycle and/or evasion from the apoptotic death mechanisms which represent the principal mode to control differentiation and size of the cell population. With respect to this, cyclins constitute a

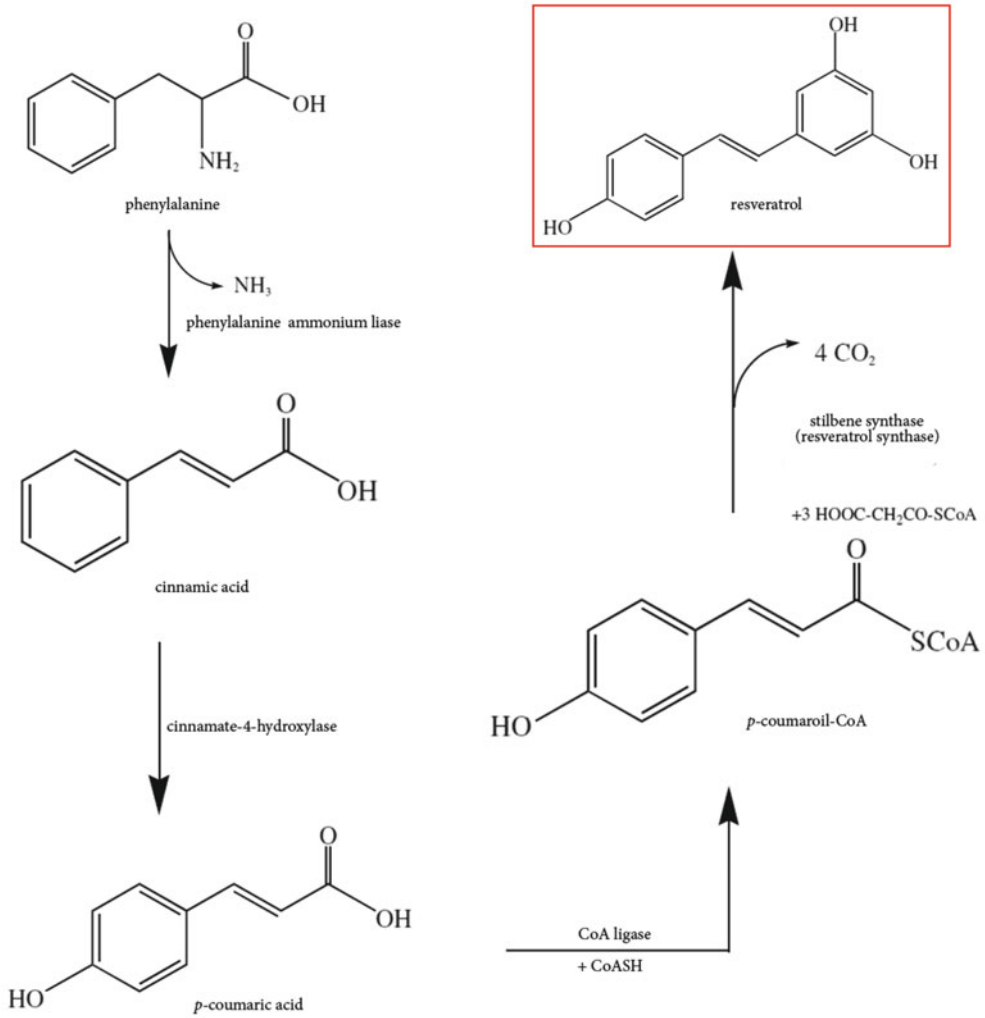

Fig. 3 Schematic illustration of the RV chemical biosynthesis of *Vitis vinifera*. See text for details

Table 1 Resveratrol content in various commercially available commodities

Food	Total resveratrol (mg/100 gm)	Beverages and seasonings	Resveratrol (mg/100 mL)	
			Mean	Range
Peanuts	0.08	Red wine	0.27	0–2.78
Peanut, roasted	0.06	Rosé wine	0.12	5.00×10^{-3} to 0.29
Peanut butter	0.04	White wine	0.04	0.00–0.17
Red grapes	0.24–1.25[a]	Sparkling wine	9.00×10^{-3}	8.00×10^{-3} to 1.00×10^{-2}

Cocoa–chocolate (dark)	0.04[a]	Vinegar	6.86×10^{-3}	0.02–7.75
Pistachio, dehulled	0.11			
Lingonberry, raw	3.00			
Red currant, raw	1.57			
Strawberry, raw	0.35			

Re-elaborated from stilbenes resveratrol in foods and beverages. Phenol-Explorer 2016. Link: http://phenol-explorer.eu/contents/polyphenol/592

[a]These values may vary according to the cultivar of red grapes, the hydration of the powder (cocoa), or its percentage (w/w) in the finished product (chocolate). The same applies to wines and seasonings. Furthermore, the RV content in wine is different from that of grapes since its extraction from the fruit depends on the wine making and fermentation techniques (e.g., the duration of the contact time with the peels of the grape berries). Also, resveratrol in its 3-glucosidic form is hydrolyzed, thus yielding both *trans*- and *cis*-resveratrol. Data for soy sauce and other oriental seasonings as well traditional foods like kosher pickles are not available. Traces of resveratrol and other lycopenes, on the other hand, are present in cosmetics, but the skin adsorption of these compounds deserves further assessment

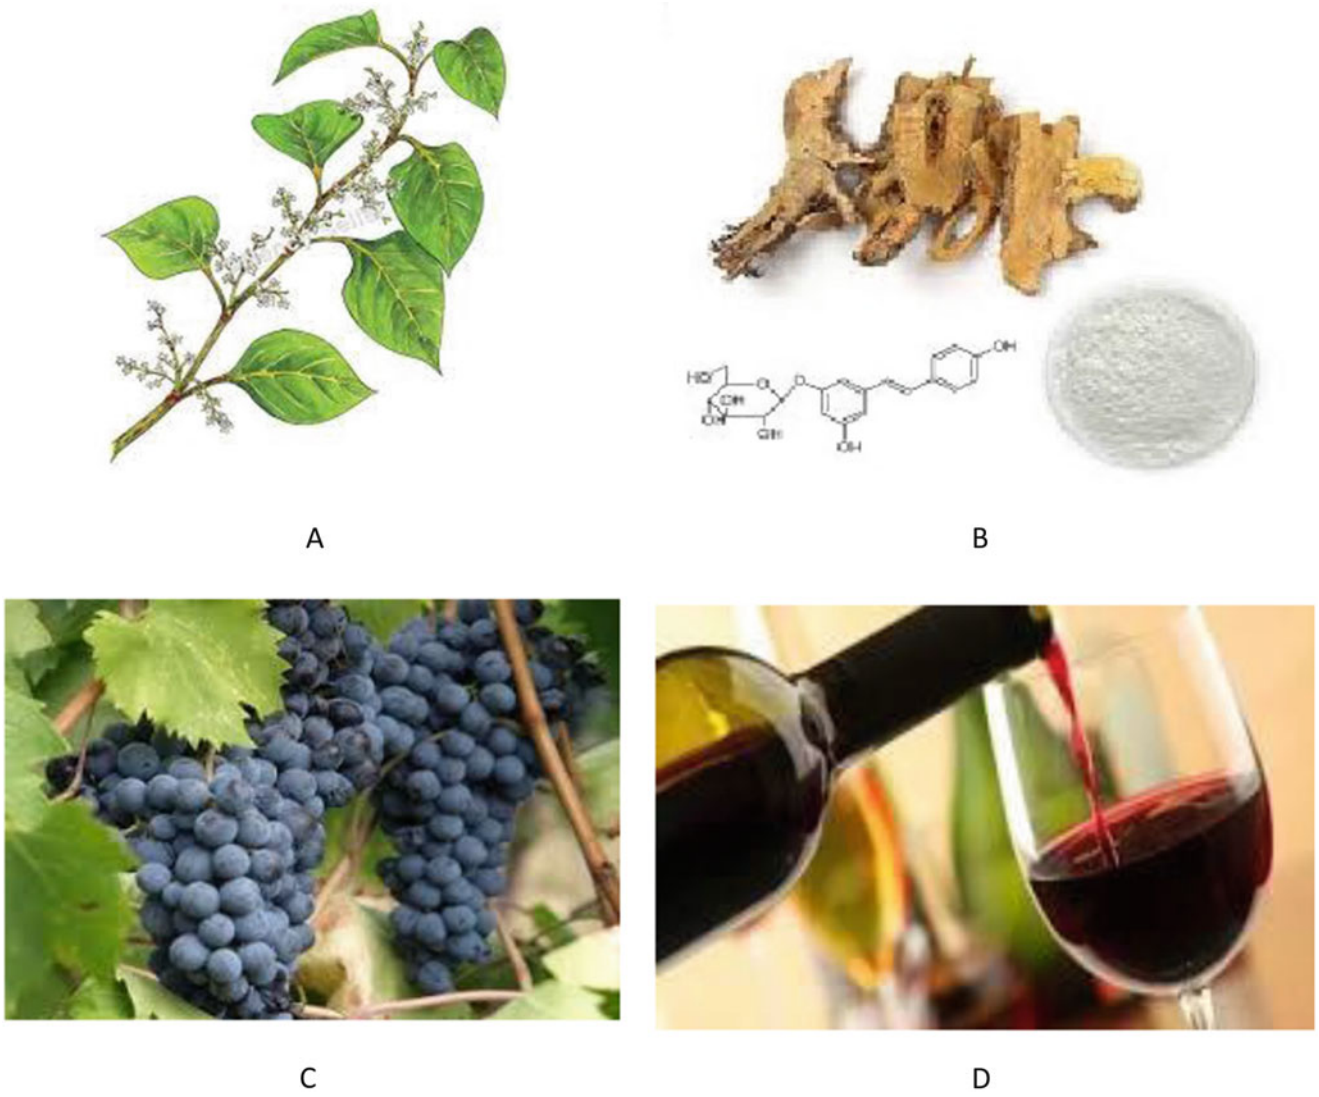

Fig. 4 Top panels. (**a**) Graphic representation of the plant *Polygonum cuspidatum* also known as *Fallopia japonica*. (**b**) Desiccated roots of the plant; *trans*-resveratrol chemical formula; final commercially available powder. (**c**) Bunches of wine blue grapes. (**d**) The final product, red wine. Due to its high content of resveratrol, the moderate assumption of red wine is considered beneficial (the French paradox). However, it should be borne in mind that the "liberal" usage of alcoholic beverages is highly detrimental for the psychophysical human conditions

family of protein factors able to regulate the correct execution and completion of the cell cycle: if the block in G1 phase takes place, the apoptotic pathway is activated. This phenomenon was observed, for instance, in the human epidermal carcinoma (Ahmad et al. 2001), and somewhat more recent data demonstrated the hindrance of progression toward the S phase (Liao et al. 2010). With respect to this, RV has been shown to modulate the cdk-cyclin-dependent mechanisms. This drug has been also involved in the development of the human colon-rectal since it induces clustering of the Fas ligand and its redistribution in sphingolipid matrix of the transformed cells which, in turn, is associated with the formation of DISC (death-inducing signaling complex; Delmas et al. 2011). Studies in a mouse model of epidermal tumor in mammary glands demonstrate that RV counteracts tumorigenesis. Resveratrol also increases the antitumor activity of the mTOR inhibitors, and finally, it represses the activation pathway of tumor-stimulating factors in mammary tumor cell lines (He et al. 2011). The gene product nf-kb is involved in the regulation of a vast number of protein factors modulating very complex biological phenomena such as inflammation, cell proliferation, and carcinogenesis: it has been suggested that RV inhibits the action of this factor (Singh et al. 2011). An interesting consideration, not directly associated to the antitumor property of RV, is that this compound is also a regulator of the human SIRT-1 gene which encodes a protein involved in aging and is considered as a potential factor of longevity (Signorelli and Ghidoni 2005; Singh et al. 2011). However, as of 2018, the evidence that resveratrol has life-prolonging properties in humans remains a matter of debate. Furthermore, the limited

bioavailability of resveratrol may further impede its potential effects (Pallauf et al. 2016; Wahl et al. 2018. See also the section on RV pharmacology in this chapter).

3.2 Antioxidant Properties

The main causative agent of atherosclerosis, and chronic artery inflammation, depends both on the individual lifestyle and environmental conditions. Therefore, tobacco smoking, pollution, hypercholesterolemia, hypertension, and other conditions (e.g., diabetes and obesity) are at the basis of cardiac/coronary problems. One of the final stages in the complex genesis of atherosclerosis is the damage of the vasal endothelium, the deposit of the low-density lipid fraction (LDL) and, finally, the aggregation of platelets. Resveratrol may play a protective role due to its very high antioxidant character (Matos et al. 2012): for instance, treatment of bovine aorta cells with RV delays the formation of the atheroma. Parallel treatment with mitosis-stimulating factors such as PDGF may act synergistically with RV (Araim et al. 2002).

Lipids containing unsaturated fatty acids, or their esters, are oxidized by the molecular oxygen present in cells; lipid peroxidation is a direct consequence of the formation of free reactive oxygen species (ROS). Resveratrol can inhibit the oxidation of the low-density lipid (LDL) fraction circulating in the blood. This oxidation is a primary event in the development of atherosclerosis: the strong antioxidant character of RV attenuates the formation of ROS and, consequently, the cytotoxicity induced by LDL peroxidation as well as the accumulation of intracellular calcium which is also an effect induced by the drug. The final result is the inhibition of caspase-3, an enzyme playing a crucial role in the execution of apoptosis (Shalini et al. 2015). It should be considered that high levels of ROS stimulate platelet aggregation: also in this case, the antioxidant action of the drug and its ability to reduce platelet adhesion to the type I collagen enable *trans*-resveratrol to limit this phenomenon. This ends in an impairment of blood coagulation and establishment of the atherosclerotic process (Zbikowska et al. 1999).

3.3 Cell Death

The strong antioxidant activity of RV with consequent protection from cell damage, as repeatedly stated above, is common knowledge; however the drug may also paradoxically induce apoptosis and autophagy (Kou and Chen 2017). These effects, monitored in a time- and concentration-dependent mode, were demonstrated in different models of cell cultures (Berardi et al. 2009; Whitlock and Baek 2012; Aluyen et al. 2012; Hasima and Ozpolat 2014). Cytofluorimetric analysis also showed activation of the apoptotic marker factors and the occurrence of typical apoptotic morpho-functional alterations (Zhang et al. 2011). In any case the preferential target of RV seems to be represented by the transformed cells (Berardi et al. 2009; Zhang et al. 2012; Risuleo 2016). As far as the cell cycle is concerned, RV can induce an arrest in S phase in murine pre-adipocytes and a significant increase of the intracellular concentration of lactic dehydrogenase (LDH): a hallmark of apoptosis. However the paradoxical effects of the drug which can protect the cell or vice versa induce its death, and its synergistic effects with diverse antioxidant, are a clear sign of the complex interactions of the drug with the target cells. A number of studies demonstrated that this behavior is shared by other natural products (see for instance: De la Lastra and Villegas 2007; Ricci et al. 2009; Chen et al. 2011; Ullah et al. 2015; Wang et al. 2012).

3.4 Antiviral Activity

The first evidence of the antiviral action of RV dates back to 1999 when the inhibition of the replication of herpes simplex virus (HSV) was published (Docherty et al. 1999). Also, its improving effects in a mouse model system of vaginal infection were also shown (Docherty et al. 2005). Subsequently the same authors demonstrated the RV-dependent inhibition of varicella-zoster DNA replication in a human fibroblast cell line. This action is exerted in the early phases of the infection mainly at the level viral mRNA transcription (Docherty et al. 2006). Later studies, however, ascribed this indirect antiviral action to the inhibition by RV of the formation of the NF-kb dimeric complex, an essential prerequisite for DNA synthesis (Gregory et al. 2004); an analogous phenomenon occurs in the case of influenza A virus where the proteins necessary for the assembly and maturation of the viral capsid, after cytoplasmic synthesis, are not efficiently transported to the nucleus (Palamara et al. 2005). Relatively recent work suggested a possible role of RV in the control of the complications after the infection by the H1N1 virus. As reviewed by Uchide and Toyoda, this negative control would be due to the RV-mediated neutralization of the superoxide anion produced by macrophages which would limit the consequences of the viral infection. Resveratrol has also been suggested to influence negatively the vitality of lymphoma cells infected with the Epstein-Barr virus (De Leo et al. 2012) which is involved in different human pathologies (Tooze 1981).

It has been suggested that RV may also have a role in the control of the HIV infection in humans since it potentiates the action of antiviral agents used in anti-HIV therapy; however due to the extremely complicated pathological picture of AIDS, in the opinion of the authors of this chapter, this observation deserves further and deeper evaluation. Finally, in our laboratory, we explored the action of RV on the murine

polyomavirus (Py) replication. Also in this case, RV has shown strong antiviral properties since it reduces the viral DNA synthesis both in murine fibroblasts and in human promyelocytic leukemia cells. The inhibition occurs at low non-cytotoxic doses of the drug which does not seem to impede viral adsorption and entry into the cell. These data combined with other observations from our laboratory on another natural substance strongly suggest that the cell membrane is the main target of RV (Ricci et al. 2009; Aiello et al. 2011). In particular, the role of the membrane permeability with respect to the RV bioactivity will be discussed in further detail in the following section.

3.5 Resveratrol and the Cell Membrane

What discussed previously opens new questions about the mode of action of RV in particular: How does the drug find its target(s)? Is the multifaceted "therapeutic" efficacy also mediated by binding molecular carriers which improve the penetration across the cell membrane and stabilize its intracellular "survival?" Finally, is it possible to construct "cargo" vehicles able to deliver to right cell district thus improving its efficacy? This aspect, in particular, will be the subject of another chapter.

In any case, albumin could act as a good transporter since this protein is able to bind amphiphilic molecules, and in addition to RV, it interacts with other natural substances such as genistein and curcumin (Bourassa 2010). Studies indicate that RV is able to bind one of the major human plasma proteins (HAS). However, the amount of bound drug is inversely proportional to its plasma concentration which makes this result of very difficult interpretation (Jiang 2008). The entry of RV has been suggested to occur through a clathrin-independent process of endocytosis; but lipid rafts seem to play a role since agents that damage their functionality also inhibit penetration of the drug within the cell (Colin et al. 2011). We investigated the mechanism of RV entry into the cell by electrorotation: a biophysical approach which was amply discussed and reviewed (Bonincontro and Risuleo 2015). By this experimental strategy, we were able to evaluate the cell membrane function and intrinsic role in mediating the action of RV. Result from our laboratory demonstrates that the drug is promptly uptaken by the cell population which is not blocked in G1 at a relevant extent (Berardi et al. 2009; Bonincontro et al. 2018).

For a more detailed review on the various and diversified biological properties of resveratrol, the reader should address a previously published work (Risuleo 2016). Table 2 reports a synopsis of the different bioactivities of the drug and the related reference data.

4 Pharmacological Aspects: Pharmacodynamics and Pharmacokinetics

Resveratrol has been identified as a pan-assay interference compound, which produces positive results in many different laboratory assays. The pan-assay-defined compounds may produce false positives, especially in high-throughput screenings, since they tend to react in a nonspecific manner with numerous biological targets within the cell, rather than affecting a specific one (Baell and Walters 2014). Therefore some caution is necessary when analyzing the ample spectrum of actions inhibited by RV. One of the ways to rationalize the multi-target effect of this natural product takes into account its ability to interact with the cell membrane which could cause a cascade of effects in other districts of the cell not directly involved with the membranes (Ingólfsson et al. 2014; Bonincontro and Risuleo 2015, Vang 2015; see also references on this matter reported above in the section: "Resveratrol and the cell membrane"). As a matter of fact, many and very diverse specific biological targets of resveratrol, e.g., hormone receptors, apoptotic factors, and cell cycle regulators, have been identified (Vang 2015). The cell membrane allows the cytoplasm matrix to communicate with the outer world and acts as a highly selective filter. Biological membranes participate to a number of transport mechanisms such as passive osmosis and diffusion. Therefore, their

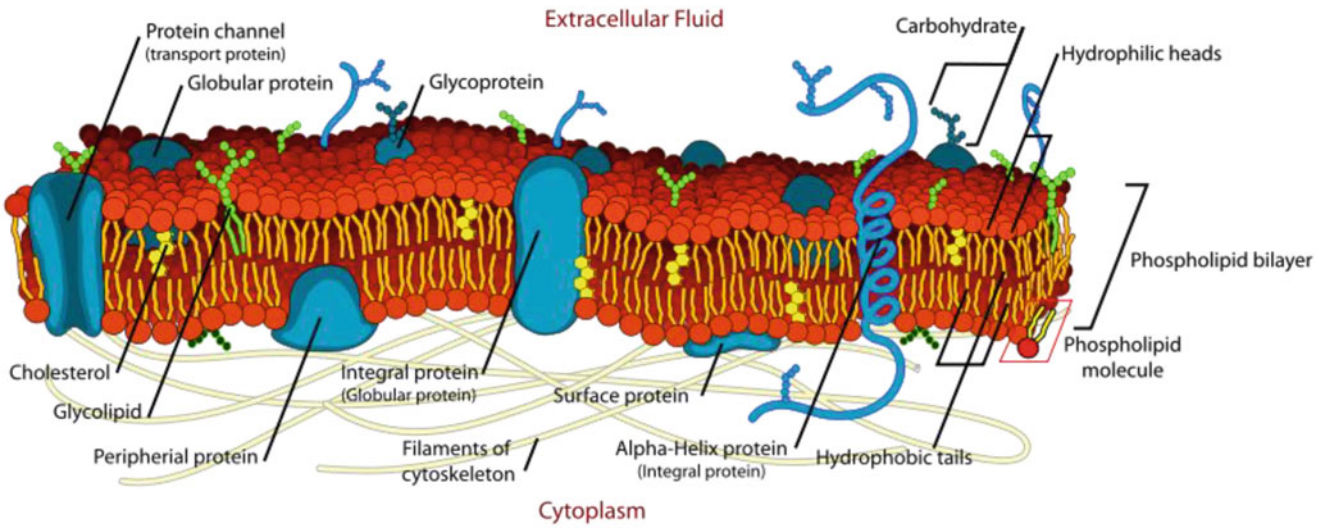

Fig. 5 The cartoon depicts the structure of a typical cell membrane. Its involvement in numerous cell functions and activities is clearly illustrated. The image is freely available on the net and not covered by copyright. We report here the www-link: https://en.wikipedia.org/wiki/Cell_membrane#mediaviewer/File:Cell_membrane_detailed_diagramen.svg. The work of the author of this picture, Lady of Hats, is acknowledged

integrity plays a fundamental role in a number of cell functions such as metabolism, maintenance of the basal homeostasis, and, although in an indirect manner, cell differentiation and development. Recently, it has become clear the role of the cell membrane in "filtering" the paracrine apoptogenic and/or intrinsic death signals; therefore, any agent affecting the efficient function of the cell membrane could play a binary role: helping cell survival and correct proliferation or vice versa triggering mechanisms leading to damage; for a relatively recent review, see Mattetti and Risuleo (2014) and references therein. The complexity and function multiplicity of the cell membrane are depicted in Fig. 5.

Other studies conducted in vitro indicate that resveratrol activates sirtuins. These proteins influence a wide variety of cellular processes such as aging, transcription, apoptosis, inflammation, and stress resistance, as well as energy efficiency and alertness during energy situations such as low-calorie diets. Finally, resveratrol seems to stimulate the production of superoxide dismutase (SOD-2) and GPER activity. This latter is a G protein that in humans interacts with the estrogen receptor-1 GPER and is activated by the female sex hormone. Resveratrol was shown to act in vitro, as an agonist of peroxisome proliferator-activated receptor gamma, a nuclear receptor under pharmacological research as a potential agent for the treatment of type 2 diabetes (Yang et al. 2015).

One way of administering resveratrol in humans is buccal delivery without swallowing, that is, by direct absorption through tissues inside the mouth. One milligram of resveratrol in solution (50% alcohol/water) retained in the mouth for 1 min can be monitored 2 min later in the plasma at concentration of 37 ng/mL (free resveratrol). This same concentration of non-modified native RV is reached after administration of 250 mg of the drug in a pill form (Asensi et al. 2002). However, the relatively low solubility of RV in water limits the amount that can be absorbed through the buccal mucosa. Therefore the viability of the buccal delivery method is questionable due to the relatively low aqueous solubility of the molecule. Therefore further assessment of the efficacy of RV buccal delivery for RV is required (Madhav et al. 2009; Ansari et al. 2011).

According to pharmacological evaluations, about 70% of resveratrol is absorbed after oral administration; however its oral bioavailability is approximately 0.5% due to extensive chemical modifications, such as glucuronidation and sulfation, undergone by the drug: these occur at liver level (Walle 2011). Finally, the production of the RV proprietary formulation SRT-501 was discontinued by GlaxoSmithKline since "the company decided to terminate the Phase 2 trial of SRT501 in multiple myeloma and halt development of the drug as a potential myeloma treatment. The SRT501 formulation of resveratrol may only offer minimal efficacy, while increasing the chances of kidney failure."

See The Myeloma Beacon Staff. Nov 30, 2010 (https://myelomabeacon.org/news/2010/11/30/glaxosmithkline-halts-all-further-development-of-resveratrol-drug-srt501/).

Resveratrol was detected in cerebrospinal fluid in a human study involving oral administration of 500 mg over 13 weeks, (Turner et al. 2015) which suggests that the drug is able to cross the blood-cerebrospinal fluid barrier. Resveratrol is also extensively metabolized in the liver and lungs which are the major sites of its metabolic transformations (Sharan and Nagar 2013).

5 Adverse Effects

A limited number of human studies have shown that resveratrol is generally well-tolerated. Clinical trials showed that one person taking a 1000 mg daily dose developed an itchy rash that was resolved after discontinuation; in the same study, also the blood pressure seemed to be affected. In four of the published trials, people had increased frequency of bowel movements and loose stools in first month of the treatment. In a yearlong Phase 2 trial in people with Alzheimer's, the most frequent adverse effects were diarrhea, weight loss, and nausea (Hausenblas et al. 2014; Fogacci et al. 2018). All in all, these effects do seem to be very important if one considers the potential advantages deriving from the treatment with RV.

6 Concluding Remarks and Future Directions

Control of cell death and senescence seems to be the most relevant effects of the administration of resveratrol. This action is essentially exerted through the interaction of RV with the cell membrane. However, like other natural products, RV may give rise to paradoxical effects; therefore its use as a multi-target therapeutic means should be considered with some *caveats*. For instance, resveratrol is apparently able to cross the membrane without causing serious consequences for the cell viability and survival, but its limited water solubility and bioavailability may reduce the use of this natural substance for therapeutic purposes. This should urge the search for new ways to deliver the drug to the cell population or to the cell district where it may play its role to contrast and/or eliminate pathological phenomena. In any case, the usage of this, as well as other medicaments of natural origin, should be done only after an accurate evaluation of their biocompatibility even though resveratrol does not seem to show significant adverse effects. With respect to the pharmacological use of RV, nanotechnologies may be of great support for an efficient and biocompatible application for the resolution of health problems. As a matter of fact, delivery mediated by nanoparticles such as liposomes, vesicles, or nanotubes may represent the new way for a safe and efficient way to dispatch molecules endowed of therapeutic capacities.

Egg Shell Membranes for Veterinary Uses

Dan DuBourdieu

Abstract

Eggshell membrane (ESM) is a relatively new ingredient on the list of ingredients that have been used to mitigate the effects of joint inflammation in animals. Eggshells contain a thin membrane that coats the inner surface of the shell that is comprised of a wide number of proteins, amino acids, collagen-like proteins, enzymes, and glycosaminoglycans. When ESM is consumed by an animal, the compounds found in ESM will play a role in maintaining joint health. However, ESM also has antimicrobial effects. The antimicrobial effects of ESM can be utilized in animal feeds as an alternative to antibiotics for growth promotion in production animals. Thus, ESM represents a new ingredient for veterinarian use for not only fighting inflammation in joints but also as an alternative to antibiotics for growth promotion activities.

Keywords

Veterinary nutraceuticals · Eggshell membrane

1 Introduction

Animals face many of the same basic issues that humans face when it comes to health. How to treat these health issues is the constant challenge to researchers and manufactures alike. Among the health issues are various joint problems that occur as the animal ages. There are now numerous nutraceutical products on the market that have emerged from the human side to help treat or prevent joint issue in animals. Another such item is ESM. Eggs have been used by humans since time began, but yet, still new ways are being found to exploit the egg. Among the new uses of eggs is the ESM found on the inside of the egg. Besides uses for fighting joint inflammation, a new veterinary use includes as an alternative to antibiotics and for growth promotion in production animals.

2 Eggs and Eggshell Waste

The common bird egg content of yolk and white has been used by humans as a source of food for a very long time. But the shell is typically discarded, and this means a lot of eggshell waste. The US food industry generates more than 24 billion eggshells every year. This generates more than 150,000 tons of shell waste a year (Hecht 1999). However, many landfills are unwilling to take the waste because the shells and the attached membrane attract vermin. Therefore getting rid of the eggshells has presented an issue for disposal. About 25% of waste eggshells are used as fertilizer. This is because eggshells contain calcium that raises, or neutralizes, the pH level of overly acidic soil. But the calcium of the shell can also be used in calcium supplements, food thickeners, and other uses (Yoo et al. 2009). As such, another 25% is used in animal feed ingredients, but still 25% is discarded in municipal dumps, and the rest is used in other ways (Daengprok et al. 2002). But this situation makes for new opportunity to take a waste product and turn it into something useful.

3 Structure of Eggshells and Membranes

From a biological standpoint, the eggshell structure is important for some obvious reasons (Hunton 2005). The shell forms an embryonic chamber for the developing chick, providing mechanical protection and a controlled gas exchange medium. Eggshell consists almost entirely (95–97%) of calcium carbonate ($CaCO_3$) with some magnesium carbonate ($MgCO_3$) present as a columnar structure that creates as many as 17,000 narrow transverse pores between palisade columns of $CaCO_3$. These pores allow air and water

vapor to pass in and out of the egg (Rovenský et al. 2003). Secondly the shell is a container for the market egg, providing protection of the contents and a unique package for a valuable food. But of current interest are the eggshell membranes that coat the inside of the shell (Fig. 1).

4 Eggshell Membranes

There are actually several membranes found in eggs (Fig. 2). The inner shell membrane adheres to the egg whites, while the outer shell membrane adheres on the shell. The inner shell membrane and the outer shell membrane adhere to each other except at the air space. The yolk also is surrounded by a membrane. These membranes are formed before the shell during development since calcium is required to form on the outer membrane.

Fig. 1 Picture of eggshell and eggshell membrane

5 Separation Methods of ESM

Separating ESM from shells by manual hand techniques obviously can be pretty laborious and time-consuming. From a commercial standpoint to generate enough ESM to be useful, there are various ways in which the membrane of an eggshell is separated from the shell. These include chemical, mechanical, steam, and vacuum processes (Vlad 2009; Yoo et al. 2009; MacNeil 2001; Adams 2006; New 2013). The goal of these methods is to use as little degradative force as possible to the membrane. The methods that are of a mechanical nature may be best for maintaining the biological activity of the membrane. Typically, the shell is crushed in some suitable manner such as using a roller apparatus, and then the crushed shells with membranes still attached to shell fragments are placed in a tank of water or other solvent. Stirring by various methods occur to actually separate the membranes from the shells. The shells sink to the bottom of the tank, and membranes float up to achieve separation and subsequent removal. There are many variations of the techniques to separate the membranes from the shells. But once the isolated membrane is dried to produce a powder, it can then be utilized in veterinary products.

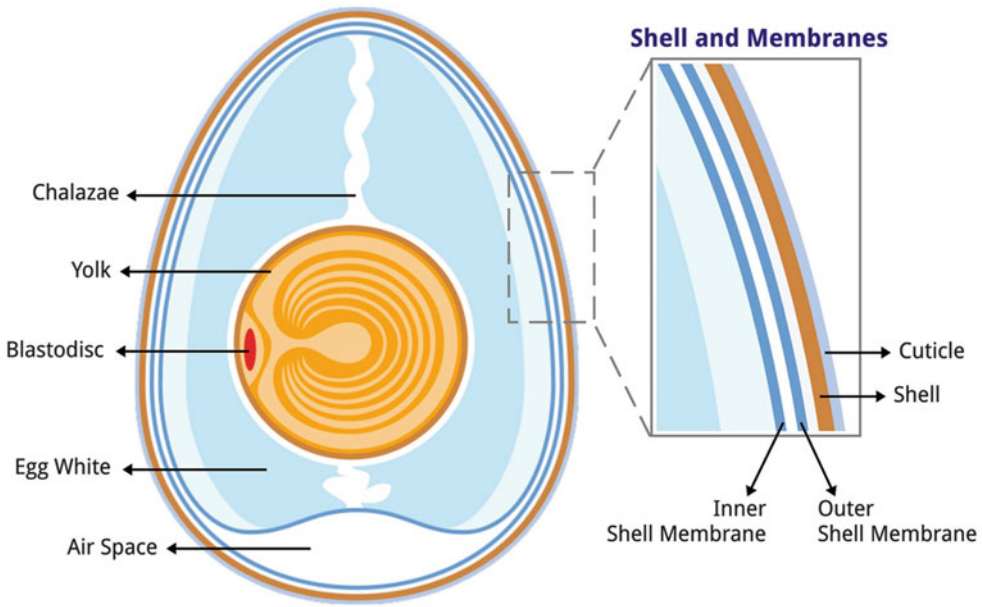

Fig. 2 Structure of eggshell and membranes

6 Components of ESM

The inner and outer shell membranes are the first layers of extracellular matrix covering the egg (yolk and whites) (Creger et al. 1976). The separate layers of the eggshell have been analyzed and found to contain several types of collagen (types X, I, V). The outer membrane is predominantly made of type I collagen, whereas the inner membrane consists mainly of type V collagen (Wong et al. 1984). In addition, type X collagen has been reported to occur in both of these membrane structures (Arias et al. 1991). ESM amino acid profiles have also shown high concentrations of arginine, glutamic acid, histidine, cystine, and proline (Britton and Hale 1977). Additionally, a number of collagen-like proteins (including hydroxyproline, hydroxylysine, desmosine, and isodesmosine) are primary structural components of the membranes (Baker and Balch 1962; Candlish and Scougall 1969; Starcher 1980). The collagens and collagen-like proteins in ESM are of interest for skin care products.

Eggshell membranes have also been shown to contain glycosaminoglycans, such as dermatan sulfate and chondroitin sulfate, and sulfated glycoproteins including hexosamines, such as glucosamine (Picard 1973). ESM has a high content of protein and moderate quantities of glucosamine (up to 1% by dry weight), chondroitin sulfate (up to 2%), hyaluronic acid (up to 2%), and collagen (type I, up to 25%). The glycosaminoglycans (GAGs) are of high interest, as they play key roles in connective tissue (Kjellen and Lindahl 1991). Glucosamine, hyaluronic acid, and chondroitin sulfate are important GAGs in ESM (Nakano 2003; Long et al. 2004). Other components identified in eggshell membranes are hyaluronic acid (Long et al. 2004), sialic acid (Nakano 2003), desmosine and isodesmosine (Starcher 1980), ovotransferrin (Gautron et al. 2001), and enzymes such as lysyl oxidase (Akagawa 1999), lysozyme (Hincke et al. 2000), and β-*N*-acetylglucosaminidase (Ahlborn 2006). With the high protein and enzyme content and naturally occurring GAGs in ESM, scientists and nutritional supplement companies have speculated that it could present a viable alternative to traditional joint disorder and osteoarthritis treatments.

More than 300 proteins are found in ESM. These include fibrous structural proteins made up of collagens and keratins that are generally resistant to conventional gastric proteases. Also abundant are lysozyme, ovotransferrin, ovocleidin, clusterin, ovokeratin, ovodefensin, and many more (Makkar 2016). Many of these proteins and peptides have antimicrobial, antioxidant, and immunomodulatory properties. Among those include lysozyme, ovotransferrin, ovalbumin, globulins, ovomucins, and defensins (Miksík et al. 2007). Many of these proteins are functionally similar to some milk proteins which confer postnatal protection to newborns, help maturation of gut, and shape their microbiome (Lawrence and Pane 2007; Rose and Hincke 2009). Antimicrobial peptides not only provide protection against a wide range of microbes including bacteria and fungi but also can function as adjuvants enhancing immunity against foreign antigens (Brown and Hancock 2006). It should be noted that the membrane components have not yet been wholly characterized; there are likely a number of compounds that have yet to be identified in the membrane. Some of these yet undetected elements may contribute to benefits or improvements seen in joint health or in other uses. Furthermore in view of the need for alternatives to antibiotics in meat animal production (Seal et al. 2013; Thacker 2013), exploring the potential of egg by-products to improve immunity and disease resistance in production animals also makes sense. Factors present in the ESM appear to help modulate immunity and performance of chickens when provided as posthatch nutrient supplements (Makkar 2016).

7 Efficacy (in Humans) for Treating Joint Inflammation

The discovery of eggshell membrane as a natural source of combined collagen, glucosamine, chondroitin, and hyaluronic acid has prompted the evaluation of this material as a potential treatment for joint and connective tissue pain. There is a growing interest in ESM supplementation as a treatment for joint pain, as it does not present the side effects of conventional treatments such as from nonsteroidal anti-inflammatory agents. Clinical reports (Ruff et al. 2009a, b) investigated the timing and effectiveness of ESM supplementation in joint and connective tissue along with osteoarthritis in human patients experiencing severe pain and limited range of motion. These patients received daily 500 mg doses of oral ESM for 4–8 weeks. Rapid (7–10 days) and continuous effects were seen in terms of reduced pain and stiffness, as well as improved flexibility. In these investigations, there were no reports of adverse effects with supplementation. Other reports (Ruff et al. 2009a, b) have shown positive results of 500 mg ESM taken once daily, significantly reduced both joint pain and stiffness compared to placebo at 10, 30, and 60 days. Further reports also have shown ESM to help with exercise-induced joint issues and pain or from osteoarthritis (Ruff et al. 2018; Danesch et al. 2014).

8 Efficacy (in Animals) for Treating Joint Inflammation and Modes of Action

The use of ESM for treating joint inflammation in humans has prompted the same use for animals. Studies in animals have helped elucidate the modes of action of ESM. ESM has been investigated for anti-arthritis activity in rats (Sim et al. 2015).

Arthritis was induced by monosodium iodoacetate and treated by administering ESM. Nitric oxide and cytokines including IL-1β, IL-6, PGE_2, TIMP-1, LTB4, and hs-CRP in serum were decreased in comparison with the controls. The cartilage of patella volume increased significantly. ESM treatment suppressed cartilage deformation and preserved cartilage volume compared to untreated controls. At least part of this, chondroprotection may result from the anti-inflammatory properties of ESM. Serum levels of matrix metalloproteinases (MMP-2 and MMP-9) known to degrade cartilage were also substantially reduced. Other animal studies have also seen a reduction of pro-inflammatory cytokines when ESM has been administered (Ruff and DeVore 2014).

Additional studies (Ruff et al. 2015) have shown that nuclear factor kappa-light-chain-enhancer of activated B-cells (NF-κB) plays role in how ESM works in the body. NF-κB is a signaling protein found in the cytoplasm of nearly all human and animal cell types and is a primary regulator of immune function. ESM hydrolysates significantly activated NF-κB, and increased NF-κB activity might translate into the in vivo efficacy that has been observed with ESM via an "oral tolerance" mechanism. Oral tolerance refers to the phenomenon of a reduced peripheral immune response (tolerance) that results from the repeated exposure of the mucosal immune system in the gut to ingested protein antigens. Oral tolerance to immunogenic peptides that are repeatedly ingested is believed to result from immune surveillance within the gut-associated lymphoid tissue as a way for the body to prevent an inappropriate or unnecessary immune response to proteins normally consumed in the diet. Immune tolerance to cartilage components, particularly type II collagen, from oral supplementation with ESM (which contains types I, V, and X collagen), is a possible explanation for observed reduction in C-telopeptide type II collagen (CTX-II) formation observed with ESM supplementation. It should be noted that CTX-II is a marker of collagen degradation observed in osteoarthritis. Further research has also shown (Wedekind et al. 2017) that oral supplementation with ESM substantially suppressed swelling due to inflammation and markedly lessened cartilage damage, pannus formation, and periarticular bone resorption histologically in rats. In addition, ESM can promote nerve regeneration, which can stem from osteoarthritis (Farjah 2013).

ESM efficacy for joint use has been investigated in other animals besides rats. These animals include cranes (Bauer et al. 2014), camels (Dierenfeld et al. 2014), and horses (Wedekind et al. 2015). Similarly, a chondroprotective effect from ESM treatment in dogs is also seen with naturally occurring joint disease. There were no serious adverse events reported during the study, and subject dog owners reported that ESM was well tolerated by their pet (Ruff et al. 2016). Supplementation with ESM, ~13.5 mg/kg (6 mg/lb) taken once daily, significantly reduced joint pain and improved joint function rapidly as assessed by the Canine Brief Pain Inventory questionnaire. ESM demonstrated a lasting improvement in joint pain leading to an improved quality of life at 6 weeks. Moreover, a profound chondroprotective effect was demonstrated following 6 weeks of supplementation with ESM.

9 ESM as an Alternative to Antibiotics for Growth Promotion in Production Animals

The animal studies previously mention have showed significant anti-arthritis activity when using ESM. However, there are additional uses for ESM that are starting to be recognized. Chief among these new uses of ESM is an alternative to antibiotics used for growth promotion in production animals. There is increasing public and scientific concern about the use of antibiotics as feed additives in animal production. This concern is fueled by the emergence of antibiotic resistance in many human pathogenic bacteria, the release of contaminating residues into the environment (water, soil, etc.), and the risk that growth-promoting antibiotic residues may occur in foods of animal origin. This concern has resulted in the ban of the use of antibiotics as growth promoters in production animals in Europe in 2006. In 2015, the FDA approved a new Veterinary Feed Directive which is an updated guideline that gives instructions to pharmaceutical companies, veterinarians, and producers about how to administer necessary drugs through the animal's feed and water. The FDA has asked drug companies to voluntarily edit its labels to exclude growth promotion as an indication for antibiotic usage. FDA regulations on off-label use prohibit using a drug off-label for non-therapeutic purposes, which would make using the relabeled drug for growth enhancement illegal. The new guidelines took effect on 1 January 2017 (FDA 2017). This has prompted the search for alternatives to antibiotics. Products such as probiotics, prebiotics, bacteriophages, fecal extracts, yolk antibodies, and organic acids have been used to satisfy this need. However, another surprising item to add to the list is eggshell membranes. Research (Makkar 2016) has shown that feeding 0.5% levels of eggshell membrane not only improved the body weight of chickens but also modulated immunoglobulin parameters pro- and anti-inflammatory genes and reduced serum corticosterone levels under endotoxin challenge conditions. In view of the need for alternatives to antibiotics in meat animal production, exploring the potential of egg by-products as nutritional modulator of immunity during posthatch period appears logical.

10 Nutritional Effects of Eggshell Membrane Supplements on Chicken Performance and Immunity

ESM contain a variety of proteins and peptides which help in the development of embryo and provide protection to it. Many of the peptides and proteins associated with ESM have antimicrobial, immune-modulatory, and adjuvant properties. In view of the need for alternatives to antibiotics in meat animal production (Seal et al. 2013; Thacker 2013), exploring the potential of egg by-products to improve immunity and disease resistance in poultry or other production animals makes sense. It was hypothesized (Makkar 2016) that the membrane by-products from egg, provided as posthatch nutritional supplements to chickens, may improve their performance and immunity. To explore its effect, three groups of broiler chicks were fed with feed containing 0%, 0.2%, and 0.4% ESM from day 1 posthatch through 14 days and regular feed thereafter. The chickens in the ESM treated groups showed a statistically significant increase in body weight with no impact on relative organ weights. Compared with controls, the white blood cell and lymphocyte percentage increased in chickens fed 0.4% ESM, whereas the monocyte percentage decreased at both levels of ESM. Except for the serum protein which increased in ESM fed birds, no other metabolic clinical chemistry variables showed any significant change. Both IgM and IgG(Y) levels were elevated, and corticosterone levels reduced in chickens fed ESM supplemented diets. These results suggested that ESM supplements during the early phases of growth may improve immunity and stress variables and enhance their growth performance without any detrimental effect on other physiological parameters.

These studies also showed that the blood corticosterone levels were reduced in chickens fed ESM diets, suggesting a lower levels of stress in these birds, although the mechanism for its decrease is not understood. Stress and inflammation can also cause a loss of body weight and present other signs of sickness such as lethargy that was not observed in ESM fed birds. Low levels of stress can also imply better feeding behavior (Bunnett 2005) that would contribute to increase in BW. IgM is an antibody that fights infection, prevents inflammation, reacts with a variety of foreign antigens including pathogen associated molecules, activates complement, foreruns, and stimulates IgG response. Similarly, an increase in the levels of IgG in ESM fed chickens also suggests a modulation of adaptive immune response. These antibodies play vital roles for protection against a variety of microbial pathogens. Whether the antibody response to ESM is transient or it establishes a lasting resistance to certain infection needs to be verified. The ESM supplement appears to have beneficial effect in chickens while it reduces stress and modulates immunity without sacrificing the growth potential of the birds.

Additional studies were done (Makkar 2016) to determine if ESM could decrease the harmful effects of liposaccharide (LPS) in older chickens. LPS control birds and ESM plus LPS fed birds at 5 weeks of age were used in the study. The ESM was also treated with ethanol to inactivate bacterial factors. The effects of LPS were evaluated at 4 and 24 h of treatment. ESM supplement caused a numerical but nonsignificant weight gain and consistently decreased the blood corticosterone levels. LPS caused a significant loss in body weight at 24 h following its administration, but the ESM supplemented birds showed significantly less body weight loss compared with the control fed birds. The white blood cell, heterophil/lymphocyte ratio, and the levels of IgG were low in chickens fed ESM supplement diet compared with the control fed group. LPS challenge increased the expression of pro-inflammatory cytokine gene IL-6, but the ESM fed birds showed its effect curtailed also, favored the upregulation of some anti-inflammatory genes compared with control fed chickens. Posthatch supplementation of ESM appears to modulate immunity and increase their resistance to endotoxin. The data suggested that ESM supplementation of feed is beneficial to posthatch poultry, and it curtails the harming effects of LPS against common infections. In conclusion, these results show that an ESM supplement can be a sustainable feed additive to improve immunity and health physiology of poultry. Future use of ESM in other production animals as an alternative to antibiotics will be of obvious interest.

11 Other Veterinary Uses of ESM

While ESM has been shown to have efficacy in joint inflammation and as an antimicrobial agent, there are even further uses. This includes uses in human functional cosmetics as an antiaging ingredient to help prevent wrinkle formation since ESM may decrease collagenase activity. The cosmetic effects of ESM such as skin whitening, wound healing, and UV protection appear to help human skin function (Kimoon et al. 2012). ESM may also help retain skin moisture thereby improving the protective ability of the skin. As such, it may be possible that ESM may find new as a material for skin repair for veterinary purposes as well.

12 Conclusion Remarks and Future Directions

ESM, like many nutraceuticals, is one of the newer ingredients on the market that can have multiple uses. ESM was initially found to have efficacy in joint products but has now been found to have efficacy in growth promotion in production animals. ESM supplements during the early phases of growth may improve immunity and stress variables

while enhancing growth performance without any detrimental effect on other physiological parameters. What additional veterinary uses ESM has in the future remains to be seen. But it is clear that ESM will be playing a bigger role as an alternative to antibiotics and as a growth promoter while continuing to be used for fighting inflammation in joints.

Egg Derived Ovotransferrins and Lactoferrins

Jamil Talukder

Abstract

Proteins and minerals are integral parts of the biological system that harmonize and sustain life. Minerals such as iron binds with protein and is called transferrin and it plays a crucial role in animals. Ovotransferrin (OVTF) and lactoferrin (LF) are avid iron-binding glycoproteins with a molecular weight of 76 and 80 kDa, respectively. They belong to the transferrin family, have a wide range of biofunctions, and are a major component of the mammalian innate immune system. OVTF is present in egg whites, and LF is abundantly present in the colostrum, milk of different species (humans, bovines, and mice), neutrophils, and other body secretions. OVTF shows about a 50% sequence homology with mammalian serum transferrin and LF. The protective effects of OVTF and LF range from direct antimicrobial activities against a large panel of microorganisms to anti-inflammatory and anticancer activities. These extensive activities are made possible by mechanisms of action that utilize not only the capacity of OVTF and LF to bind iron but also the interactions with molecular and cellular components of both host and pathogen. This chapter aims to summarize the current understanding, though incomplete, of the many ways that LF and OVTF influence the complex immune machinery and the known and putative mechanisms that may explain biological functions.

1 Introduction

Since the discovery of iron-binding proteins, OVTF and LF are thought to be the most polyvalent found in vertebrates. Vertebrates have a robust immune system to protect themselves from infectious pathogens and other invaders. The immune system is a highly complex and potentially harmful biological system in which iron-binding proteins not only play antimicrobial roles but also seem to actuate strategic levers to modulate host defense. LF itself has been the object of more than 3000 studies reporting its activities in host defense as well as the mechanisms to explain them. LF appears to have the ability to stimulate the immune system to counteract pathogenic invaders and injuries while preventing overreactions which are harmful to the host. LF is produced by epithelial cells in most exocrine secretions such as seminal fluid, pancreatic exocrine secretions, tears, saliva, and uterine secretions and in milk, where its concentration in humans may vary between 1 and 7 g/L (Bennett and Kokocinski 1978). LF receptors (LFR) are expressed in different tissues including cells of the innate immune system and may locally deliver the molecule to inflammatory sites (Legrand 2012). Neutrophils [polymorphonuclear neutrophils (PMNs)], which represent more than one-half of total white blood cells, produce LF and store it in secondary granules. Upon activation of PMNs, which begins at the very first steps of adhesion to the activated endothelium, LF is released in the blood, where its concentration may rise to 200 mg/L (from about 1 mg/mL under normal conditions), especially in inflamed tissues (Maacks and Wood 1989). Talukder and Harada (2007) demonstrated that bovine LF protects against lipopolysaccharide-induced diarrhea by modulating nitric oxide and prostaglandin E_2 in mice. Furthermore, Talukder et al. (2002) discovered the receptor-mediated transport mechanism of LF in the intestinal cells which are transported into the cerebrospinal fluid via systemic circulation in newborn (Talukder et al. 2002) and young calves (Talukder et al. 2003). In addition, microglial

R. C. Gupta et al. (eds.), *Nutraceuticals in Veterinary Medicine*, https://doi.org/10.1007/978-3-030-04624-8_17

cells, which act as the resident macrophages in the brain, also release LF during inflammation (Fillebeen et al. 2001).

Egg white is the main source of various egg proteins including OVTF. In order of their abundance, the main egg white proteins are ovalbumin (54%), OVTF (12%), ovomucoid (11%), and lysozyme (3.5%), each of which has numerous functional characteristics (Abeyrathne et al. 2013). The minor proteins in egg white include avidin (0.05%), cystatin (0.05%), ovomacroglobulin (0.5%), OVTF (0.8%), ovoglycoprotein (1.0%), and ovoinhibitor (1.5%) (Kovacs-Nolan et al. 2005a, b). The first name given to OVTF was conalbumin. However, after finding that iron can be attached to the protein structure, it was renamed OVTF (Williams 1968).

2 Characteristics of OVTF and LF

OVTF is an acidic glycoprotein with an isoelectric point of 6.0. The overall structure of OVTF is similar to that of human LF and rabbit serum transferrin. It is being folded into two homologous lobes, each containing two dissimilar domains with one Fe^{3+} and one CO_3^{2-} bound at a specific site in each interdomain cleft. It is comprised of 686 amino acids with 15 disulfide bonds to form the 76 kDa structure (Abeyrathne et al. 2014). OVTF carries and transports iron in the animal body and exists in two distinct forms, (1) holo- (iron bound) and (2) apo- (iron-free), each with significantly different physicochemical characteristics (Wu and Acero-Lopez 2012). OVTF is made of two main lobes. The *N*-terminal lobe consisting of amino acid 1–329 and the C-terminal lobe consisting of amino acid 330–686 (Giansanti et al. 2012; Superti et al. 2007). Each lobe contains a site to bind with one mole iron and is further divided into two domains: C1 and C2 and N1 and N2 (Superti et al. 2007). OVTF is capable of binding with other metal cations such as, in order of affinity, $Fe^{3+} > Cr^{2+}$, $Cu^{2+} > Mn^{2+}$, Co^{2+}, and $Cd^{2+} > Zn^{2+} > Ni^{2+}$ (Tan and Woodworth 1969). This protein resembles 50%, 49%, and 51% with LF, human LF, and human transferrin, respectively. Most of the similarities can be found in the C-terminal lobe (Jeltsch et al. 1987). Transferrins are different in their structure of adhered N-glycan (highly mannose) and in the pI, which may influence their biofunctions (Jiang et al. 2014).

LF possesses a greater iron-binding affinity, and it is the only transferrin with the ability to retain this metal over a wide range of pH values, including a resistance to proteolysis. The most striking physicochemical feature of LF is its very high affinity for iron. In both LF and related transferrins, two Fe^{3+} ions are bound very tightly (K ~ 1022 M) but reversibly to LF, with two synergistically bound CO_3^{2-} ions (Aisen and Leibman 1972; Baker 1994). It contains ~ 700 amino acids, with a high homology among species. It is comprised of a simple polypeptide chain folded into two symmetrical lobes (the N-lobe and C-lobe), which are greatly homologous with one another (33–41% homology). The two lobes are connected via a hinge region containing parts of an α-helix between amino acids 333 and 343 in human LF (Öztaş Yeşim and Özgüneş 2005), which confers flexibility to the molecule (Haridas et al. 1995). The polypeptide chain includes amino acids 1–332, comprising the N-lobe, and 344–703, comprising the C-lobe. The chain is also made up of α-helix and β-pleated sheet structures that create two domains within each lobe (domains I and II) (Mazurier and Spik 1995). Each lobe can bind a metal atom in synergy with the carbonate ion (CO_3^{2-}). LF is capable of binding Fe^{2+} or Fe^{3+} ions, but it has also been observed to be bound to Cu^{2+}, Zn^{2+}, and Mn^{2+} ions (Baker et al. 2004). Because of its ability to reversibly bind Fe^{3+}, LF can exist free of Fe^{3+} (apo-Lf) or associated with Fe^{3+} (holo-Lf), and it has a different three-dimensional conformation depending on whether it is bound to Fe^{3+} (Wally and Buchanan 2007). Apo-LF has an open conformation, while holo-LF is a closed molecule with greater resistance to proteolysis (Öztaş Yeşim and Özgüneş 2005). Because of the common structural framework among LFs, it is possible to model their conformations using crystallographic data from other LF species (Fig. 1a). The amino acids directly involved at the iron-binding site in each lobe are Asp60, Tyr92, Tyr192, and His253, while Arg121 is involved in binding the CO_3^{2-} ion (Fig. 1b). LF is a basic, positively charged protein with a pI of 8.0–8.5. The primary structure of LF shows the number and position of Cys residues that allow the formation of intramolecular disulfide bridges. Asn residues in the N- and C-terminal lobes provide several potential N-glycosylation sites (Khan et al. 2001; Anderson et al. 1987).

3 OVTF and LF Receptors

The receptors of OVTF and LF play an important role in the internalization of these metalloproteins. They also facilitate absorption of iron ions. It has been shown that gene expression increases with age in the duodenum and decreases in the jejunum (Liao et al. 2007; Bharadwaj et al. 2009). The moonlighting glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH) has been demonstrated to function as a receptor for LF (Rawat et al. 2012).

4 Genes of OVTF and LF

The Chicken Gene Nomenclature Consortium reported that OVTF genes of *Gallus gallus* are located on chromosome 9 (assembly name, GRCg6a) with a mean length of 7398 bp. Counts and length of annotated features are provided for each

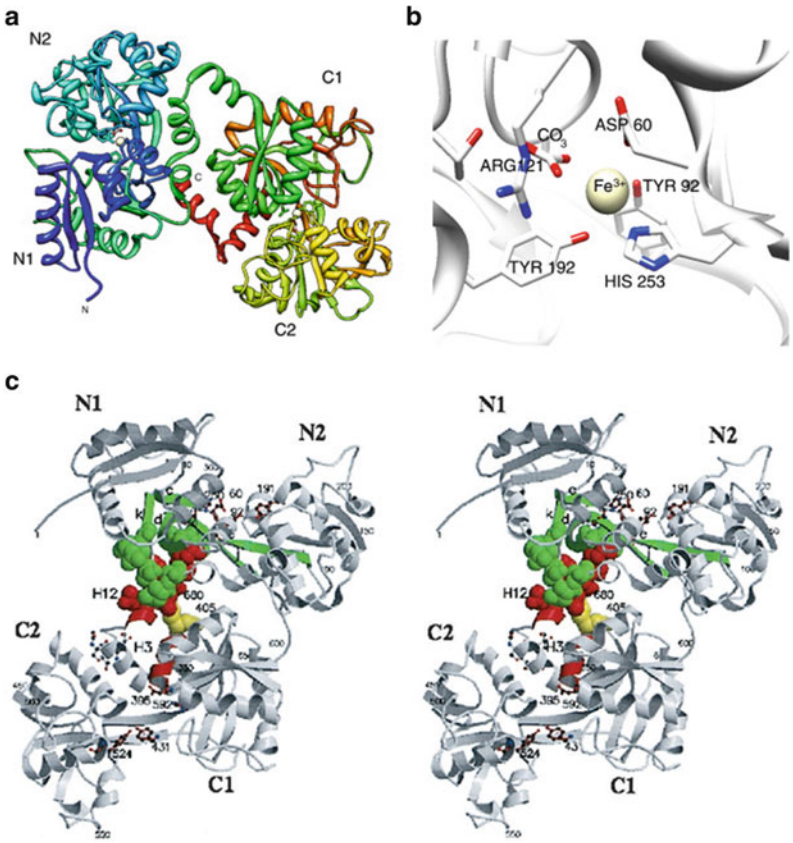

Fig. 1 Predicted structure of LF and OVTF: (**a**) Two-lobe, four-domain polypeptide, (**b**) canonical iron-binding pocket site of lactoferrin. Fe^{3+} (cream), CO_3 (gray and red), and (**c**) two-lobe, four-domain polypeptide of OVTF

assembly gene and pseudogene numbers 24,373; protein coding, 17,477; noncoding, 6534; transcribed pseudogenes, 22; non-transcribed pseudogenes, 240; and genes with variants, 10,544, along with 49,661 mRNAs. The number of transcripts per gene is 2.68, and the number of exons per transcript is 12.8.

LF gene polymorphism between species is much more diverse than the intraspecific polymorphism. About 60 gene sequences of LF have been characterized in 11 species of mammals (Kang et al. 2008). In most species, stop codon is TAA and TGA in *Mus musculus*. Deletions, insertions, and mutations of stop codons affect coding, and their length varies between 2055 and 2190 nucleotide pairs. There are differences in amino acid sequences: 8 in *Homo sapiens*, 6 in *Mus musculus*, 6 in *Capra hircus*, 10 in *Bos taurus*, and 20 in *Sus scrofa*. This variation may indicate functional differences between different types of LF (Kang et al. 2008). In humans, the LF gene is located on the third chromosome in the locus 3q21-q23. In oxen, the coding sequence consists of 17 exons and has a length of about 34,500 nucleotide pairs. Exons of the LF gene in oxen are of similar size to the exons of other genes in the transferrin family, whereas the sizes of introns differ within that family. Similarity in size of exons and their distribution in the domains of the protein molecule indicates that the evolutionary development of the LF gene occurred via duplication (Seyfert et al. 1994). The studying of polymorphisms of genes that encode LF helps in selecting livestock breeds that are resistant to mastitis (O'Halloran et al. 2009).

5 Bioavailability of OVTF and LF

In order to maximize the functions of OVTF and LF, absorption in the digestive system and transportation of these molecules to the target organs or tissues are very crucial. The amount of literature available on the absorption of OVTF in the human body is limited. The majority of investigations have been carried out on its derived peptides. Evenepoel et al. (1999) reported that the amounts of cooked and raw egg proteins which escaped digestion and absorption in the small intestine of healthy volunteers were 5.73% and 35.10%, respectively. It has been perceived that a good amount of protein enters the intestine in various forms, and the majority of it is digested and reabsorbed along with ingested protein (Matthews 1971).

Immunohistochemical and physiochemical investigations on the transportation and absorption of bovine LF in the small

intestine of growing pigs showed that the absorption of LF was mediated by LF-mediated factors on the epithelial cell membrane (Kitagawa et al. 2003). Their results also showed that bovine LF was absorbed through transcytosis at the apical halves of the villi of small intestine as small vesicles via villus columnar epithelial cells. Moreover, it was demonstrated that LF is transported via the lymphatics and the portal vein into systemic circulation (Kitagawa et al. 2003). Talukder et al. (article under review) investigated the absorption of OVTF using rat intestinal epithelial cells. They observed that OVTF is taken up by IEC-6 cells on the transwell membrane as an intact protein from the apical surface and transported to the basolateral surface through the transepithelial exocytosis mechanism. Maximum internalization and exocytosis were observed at 90 min. These processes were time and concentration dependent. It is concluded that absorption and transepithelial transportation of OVTF are accomplished by receptor-mediated transcytosis in the intestinal epithelial cells (Shirkhani et al. 2018).

Mazurier et al. (1985) detected LF receptors with a molecular weight of 100 kD in the microvillus of the enterocyte membrane of human and rabbit small intestine. Immunohistochemical analyses of Kitagawa et al. (2003) demonstrated the presence of LF receptors on the apical villi, striated border, and basolateral membrane of enterocytes.

6 Functional Properties of OVTF and LF

It has been reported that OVTF and LF can demonstrate a wide range of biofunctions. The protective effects of these iron-binding proteins have been shown from anticancer, anti-inflammatory, and immune modulator activities to antimicrobial activities against a large number of microorganisms. The wide range of activities is made possible by the mechanisms of action involving not only the capacity to bind iron but also interactions with molecular and cellular components of both hosts and pathogens (Garcia-Montoya et al. 2012). Therefore, their application in functional foods makes them an attractive compound to enhance human and animal health. Figure 2 shows the shared physiological properties of OVTF and LF with other types of transferrin.

7 Antibacterial Activity

The primary role of LF is to sequester free Fe^{2+} and remove an essential substrate required for bacterial growth (Farnaud and Evans 2003). LF is considered to be a key component of the innate host defense system because it can respond to a variety of physiological and environmental changes (Connely 2001). The structural features of LF provide additional functionalities beyond the Fe^{3+} homeostasis function

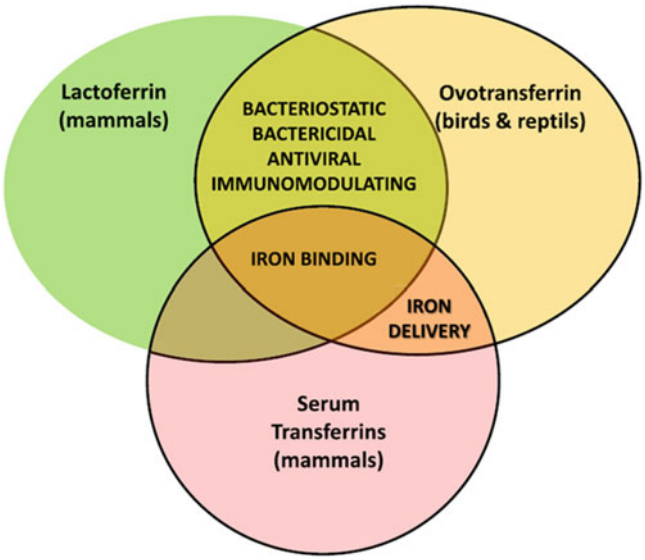

Fig. 2 Physiological properties shared between transferrin family proteins members

common to all transferrins. In particular, LF exhibits strong antimicrobial activity against a broad spectrum of bacteria (Gram positive and Gram negative), fungi, yeasts, viruses (Drago 2006), and parasites (Yamauchi et al. 2006). However, it seems to promote the growth of beneficial bacteria like *Lactobacillus* and *Bifidobacteria* (Sherman et al. 2004). It also exhibits anti-inflammatory and anticarcinogenic activities (Connely 2001) and has several enzymatic functions (Leffell and Spitznagel 1972). LF plays a key role in maintaining cellular iron levels in the body. Sequestering iron from bacterial pathogens is believed to be the sole antimicrobial action of LF because apo-LF possesses antibacterial activity (Kalmar and Arnold 1988; Yamauchi et al. 1993). It was later demonstrated that LF can also kill microorganisms through an iron-independent mechanism (Valenti and Antonini 2005) in which LF interacts directly with the bacterial cell surface (Kalmar and Arnold 1988; Bortner et al. 1989; Farnaud and Evans 2003).

The bacteriostatic characteristics of OVTF are promoted by adding a carbonate ion, enhancing the pH from 6 to 8 and immobilizing VOTF to Sepharose 4B by covalent linkage (Giansanti et al. 2012; Valenti et al. 1982). The most resistant bacterial species against OVTF are *Proteus* spp. and *Klebsiella* spp., whereas the most sensitive ones are *Pseudomonas* spp., *Escherichia coli*, and *Streptococcus mutans* (Valenti et al. 1982). Recently, the current authors observed that OVTF is a potent antimicrobial protein with the ability to kill different types of bacteria in in vitro and clinical applications (Talukder et al. 2018). Bacterial culture of a uterine swab demonstrated the presence of different types of bacteria including Gram positive, Gram negative, α- and β-hemolytic, rods, and cocci. Zone of inhibition studies with

different concentrations of OVTF demonstrated that 5% would be more than enough to kill all types of bacteria found in these studies.

8 Antifungal Activity

Mucosal surfaces can be infected by *Candida*, and it is considered to be analogous to a commensal organism that can also become an opportunistic pathogen. Kirkpatrick et al. (1971) conducted the studies with *Candida* spp. and attributed the antifungal effect of LF to its ability to sequester Fe^{3+} (Kirkpatrick et al. 1971; Viejo-Díaz et al. 2004; Garcia-Montoya et al. 2012). Both human and bovine LF as well as the LF-derived peptide lactoferricin have well-documented in vitro activity toward human pathogenic fungi, especially *Candida albicans* and several other *Candida* species. LF also has antifungal activity (Arnold et al. 1980; Bellamy et al. 1993), and it was observed that LF could kill both *C. albicans* and *C. krusei* by altering the permeability of the cell surface, as it does with bacteria (Wakabayashi et al. 1996; Kuipers et al. 1999). Bovine LF has been shown to be highly fungicidal for *C. tropicalis* and *C. krusei* and somewhat fungicidal for *C. albicans* and *C. guilliermondii*, while *C. glabrata* is almost resistant to LF (Xu et al. 1999). LF exhibited activity against *Cryptococcus neoformans* and *C. albicans* via cytoplasmic and mitochondrial membrane permeabilization (Kondori et al. 2011). Although LF's antifungal mechanism of action is through cell surface interaction rather than iron deprivation (Valenti et al. 1986), several reports demonstrate its ability to cause cell wall damage (Xu et al. 1999; Nikawa et al. 1993, 1995). In addition to direct interaction with the pathogen, Fe^{3+} sequestration is another important mechanism for fungicidal activity. Furthermore, Zarember et al. (2007) showed that Fe^{3+} sequestration by neutrophil apo-LF is important for host defense against *Aspergillus fumigatus* (Zarember et al. 2007). Additionally, the in vitro antifungal activity of two peptides (human LF (1–11 aa), bovine LF N1-domain) derived from human LF was compared, and dose-dependent antifungal activity was observed (Lupetti et al. 2008; van der Kraan et al. 2004). LF shows an interesting antifungal effect on body tinea caused by *Trichophyton mentagrophytes* against which it acts indirectly, facilitating clinical improvement of skin lesions after the peak of symptoms. Treatment of guinea pigs with bovine LF reduces fungal infection on the skin of the back and limbs in *Tinea corporis* and *Tinea pedis*, respectively (Wakabayashi et al. 2000). It has also been demonstrated that LF can mediate its antifungal activity through the stimulation of host cell immune mechanisms both in vitro and in vivo (Viejo-Díaz et al. 2004).

9 Antiparasitic Activity

The ecological niches of microbes often differ from one organism to another and make it difficult to have a clear mechanism and understanding of the antimicrobial activities of LF. The molecular mechanisms of LF as an antiparasitic activity are even more complex. Antiparasitic activities of LF usually involve interference with iron acquisition. This activity has also been shown using peptides derived from the full molecule (Weinberg 1994; Cirioni et al. 2000). There is also evidence supporting the occurrence of a similar mechanism during amebiasis, which is one of the leading causes of diarrhea in children under 5 years of age and is caused by *Entameba histolytica* (León-Sicairos et al. 2006a). In in vitro studies, apo-Lf demonstrated the greatest amebicidal effect against *E. histolytica* because it can bind to lipids on the trophozoite's membrane, causing membrane disruption and damage to the parasite (León-Sicairos et al. 2006b; López-Soto et al. 2010). LF appears to act as a specific iron donor and could be expected to enhance infection by other parasites such as *Tritrichomonas foetus* (Tachezy et al. 1996). It was reported that bovine LF bound to components of *T. brucei* and that bovine LF hydrolysate disrupted the sites responsible for binding to parasite proteins, causing Fe^{3+} deprivation (Tanaka et al. 2004). Other in vitro studies show that serum transferrin as well as human and bovine LF can bind the intracellular parasite *Toxoplasma gondii* responsible for toxoplasmosis in humans and animals. However, LF cannot prevent the parasite from entering the host. The mechanism of action in this case is inhibition of the intracellular growth of *T. gondii* in the host cells (Dzitko et al. 2007). In animal models, lactoferricin reduced infectivity of *T. gondii* and *Eimeria stiedae* sporozoites (Omata et al. 2001). The effect of LF on the hemoparasites *Babesia caballi* and *Babesia equi* depends on whether or not LF is bound to Fe^{3+} (Botteon et al. 2002). *B. caballi* was found to be significantly suppressed by apo-LF but was not inhibited by other types of LF, whereas none of the LF types had an inhibitory effect against *B. equi* (Ikada et al. 2005). In all these, LF demonstrates an additive or synergistic activity with clinically used antiparasitic compounds (Weinberg 1994; León-Sicairos et al. 2006a, b).

10 Antiviral Activity

Rotavirus and norovirus often cause gastroenteritis, a major illness prevalent in winter months. Rotavirus causes gastroenteritis only in children. Norovirus is an extremely important emerging human pathogen that causes a majority of gastroenteritis outbreaks worldwide. The in vitro anti-rotavirus effects of LF have been reported (Superti et al.

1997, 2001; Wakabayashi et al. 2014). The human norovirus remains difficult to study because of the lack of cell cultures and animal models. Instead, feline calicivirus and murine norovirus, which can be cultured and share a number of biochemical properties, similar genomic organization and primary RNA sequences with human norovirus, have been used as a virus surrogate to study human norovirus. A study using feline calicivirus showed that bovine LF inhibits the viral infection of Crandell-Reese feline kidney cells by binding to the cells and lactoferricin B inhibits the infection by binding to the virus (McCann et al. 2003). Bovine LF also decreased murine norovirus infection to murine macrophage cell line Raw264.7 through inhibition of the initial murine norovirus attachment to cells and the subsequent interference with murine norovirus replication (Ishikawa et al. 2013).

The induction of antiviral cytokine interferon (IFN)-α/β expression by LF was involved in the inhibition of viral replication in the infected cells. This is the first report that shows the inhibition of viral replication in the cells and the involvement of IFN-α/β. It has already been reported that oral administration of LF induces IFN-α/β in the small intestine of mice (Kuhara et al. 2006; Wakabayashi et al. 2006). From these findings, IFN-α/β may be a key mediator in the antiviral effects of orally administered LF (Wakabayashi et al. 2014), and the deduced antiviral mechanism of LF is illustrated in Fig. 3.

In a study of rotaviral gastroenteritis in children, daily intake of bovine LF-containing products ameliorated the severity of the disease, although there was no significant benefit in reducing infection incidence (Egashira et al. 2007). The addition of recombinant human LF and lysozyme to a rice-based oral rehydration solution had beneficial effects on children with acute diarrhea in whom rotavirus was identified as a pathogen in 18–19% of stool samples (Zavaleta et al. 2007). The daily administration of LF tablets to children reduced the incidence of noroviral gastroenteritis (Moriuchi and Moriuchi 2009). LF administration exhibited no decrease in diarrhea incidence, but decreased longitudinal prevalence and severity in children where norovirus was isolated as a pathogen in 35% of fecal samples (Moriuchi and Moriuchi 2009). LF inhibits the cytopathic effect of adenovirus in HEp-2 cells (Arnold et al. 2002; Di Biase et al. 2003; Pietrantoni et al. 2003), where the effect of bovine LF has been shown to be more potent than that of human LF. On the other hand, another investigation reported that human LF promotes the binding of adenovirus to human corneal epithelial cells and also infection of the cells by adenovirus (Johansson et al. 2007).

The anti-enteroviral activities of LF are indicated in poliovirus, enterovirus 71, coxsackievirus A16, echovirus 5, and echovirus 6 (Marchetti et al. 1999; Lin et al. 2002; Weng et al. 2005; Furlund et al. 2012; Pietrantoni et al. 2006; Ammendolia et al. 2007). Remarkably, bovine LF induced IFN-α expression of human neuroblastoma cells (SK-N-SH) and inhibited enterovirus 71-induced interleukin (IL)-6 production (Weng et al. 2005). The antiviral activity of bovine LF was not obvious in echovirus 9 (Lin et al. 2002).

Following enterovirus 71 infection, neonatal pups ingesting transgenic milk expressed recombinant porcine LF and showed significantly higher survival rate and heavier body weight compared to wild-type mice (Chen et al. 2008). However, oral supplementation of bovine LF at a dose of 70 mg/day did not show beneficial effects in the prevention of enterovirus 71 or rotavirus infection in children Yen et al. 2011). Herpes simplex virus type 1 and 2 (HSV-1 and HSV-2) establish lifelong latent infections in the host and can re-emerge periodically throughout life, primarily causing facial and genital herpetic lesions, respectively. The in vitro anti-herpes activities of LF have been studied in HSV-1 (Hasegawa et al. 1994; Marchetti et al. 1996, 1998; Siciliano et al. 1999; Seganti et al. 2001; Lampis et al. 2001; Jenssen et al. 2008; Marr et al. 2009) and HSV-2 (Marchetti et al. 1998; Jenssen et al. 2008; Shestakov et al. 2012). The effect of orally administered LF in HSV infection has been reported

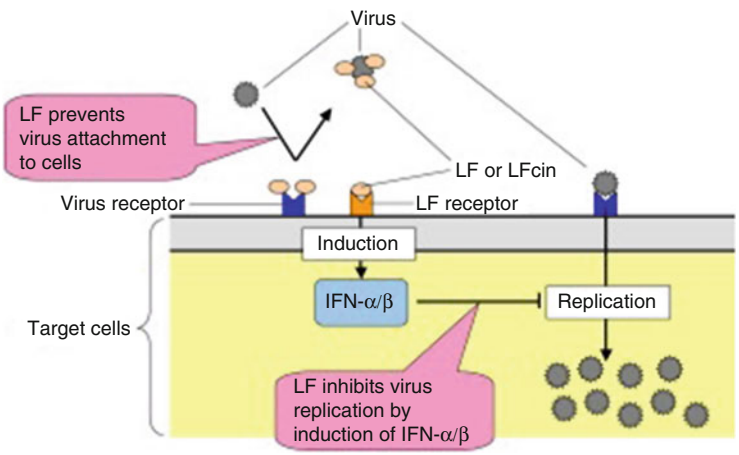

Fig. 3 Deduced mechanism of antiviral effect of lactoferrin (LF). LF or lactoferricin (LFcin) prevent virus attachment to the target cells by binding to the virus receptor on the target cells or binding to the virus. In addition, lactoferrin induces IFN α/β production and thereby inhibits virus replication after entry of the virus into the cells

by Wakabayashi et al. (2004) and demonstrated that LF administration prevents body weight loss and increases the production of Th1 cytokines, including IFN-γ, IL-12, and IL-18, after HSV-1 cutaneous infection in mice. These enhanced Th1 cytokine responses may help host protection against HSV-1 infection.

LF exhibits inhibitory activities against a wide range of viruses in vitro. The effects of LF via oral administration have been studied in various viral infections in animals and humans (Wakabayashi et al. 2014). Being a food component, LF is easily consumed by an individual to prevent these infections. Although the mechanism of action of LF has not been fully elucidated, direct antiviral activities exerted in the gastrointestinal tract and systemic immune modulation seem to be involved in these effects. Thus, LF is a promising candidate to prevent viral infection or diarrhea, and further studies are warranted to establish more reliable evidence.

11 Concluding Remarks and Future Directions

OVTF and LF have many biological functions; the host-protective effects range from direct antimicrobial activities against a large panel of microorganisms, including bacteria, viruses, fungi, and parasites, to anti-inflammatory, antioxidant, and anticancer activities. Thus, these metalloproteins have important therapeutic implications for humans and animals. Further basic and clinical studies will better clarify the usefulness of OVTF and LF.

Colostrum Antibodies, Egg Antibodies and Monoclonal Antibodies Providing Passive Immunity for Animals

Dan DuBourdieu

Abstract

Passive immunity can be provided to animals by several sources of antibodies including from colostrum, avian eggs, and monoclonal sources. These antibodies have been shown protect production and companion animals from a number of pathogens. This chapter reviews the immune system for the principles of immune response to antigens and the synthesis of immunoglobulins of the five classes of antibodies in the body. Colostrum antibodies are described for passive immunity protection in animals such as calves. Chicken egg antibodies are another source of antibodies for passive immunity. Therapeutic monoclonal antibodies are also used to provide passive immunity in the veterinary field.

Keywords

Passive immunity · Colostrum antibodies · Egg antibodies · Monoclonal antibodies

1 Introduction

The use of antibodies by veterinarians to maintain the health of animals has a long history. Fundamentally, when it comes to the immune system health of production and companion animals, there are little absolute differences in the intended purpose of the immune system. Mammals have the same basic immune system with minor differences between the species. Even the differences between birds and mammals are not so great since the purpose of the immune system is to keep infectious microorganisms, such as certain bacteria, viruses, and fungi, out of the body and to destroy any infectious microorganisms that do invade the body. How veterinarians take advantage of the immune system to maintain health can roughly be defined as taking advantage of the body's inherent method of maintaining health through adaptive immunity provided by vaccinations to generate antibodies inside the animal or by administering preformed antibodies to an animal through a process called passive immunity.

2 The Immune Response

Evolution has produced an amazing immune system in animals that utilizes various cell types and proteins to protect them from invasive organisms. This system has two broad categories: nonadaptive and adaptive. The nonadaptive immune system is mediated by cells that respond in a non-specific manner to foreign substances. This response includes phagocytosis by macrophages, secretion of lysozymes by lacrimal cells, and cell lysis by natural killer cells. The adaptive immune response is mediated by lymphocytes that produce a set of proteins called antibodies that are either secreted by or found on the surface of the lymphocyte. When the antibodies themselves are created within the animal following vaccination or from exposure to pathogens, the process is called adaptive immunity. When preformed antibodies from a host animal are given to another recipient animal, such as it offspring or even a completely different species animal, the process is called passive immunity.

3 Veterinary Vaccines for Active Immunity

Scientists have long taken advantage of the adaptive immune system by using vaccines.

Vaccines for animal diseases were the first to result from laboratory-based scientific investigation. French chemist Louis Pasteur developed a vaccine for chicken cholera in 1879, and one for anthrax of sheep and cattle in 1881.

R. C. Gupta et al. (eds.), *Nutraceuticals in Veterinary Medicine*, https://doi.org/10.1007/978-3-030-04624-8_18

The major goals of veterinary vaccines are to improve the health and welfare of companion animals, increase production of livestock in a cost-effective manner, and prevent animal-to-human transmission from both domestic animals and wildlife. These diverse aims have led to different approaches in the development of veterinary vaccines from crude but effective whole-pathogen preparations to molecularly defined subunit vaccines, genetically engineered organisms or chimeras, vectored antigen formulations, and naked DNA injections (Meeusen et al. 2007). It has also resulted in various guidelines for vaccinations of companion animals such as for dogs (Ford et al. 2017) and production animals such as swine (Alabama and Auburn 2018), in poultry (Stewart-Brown 2018), cow/calf (Missouri 2018), and other production animals. Successful veterinary vaccines have been produced against viral, bacterial, protozoal, and multicellular pathogens, which in many ways have led the field in the application and adaptation of novel technologies.

4 Passive Immunity

Whereas active immunity refers to the process of exposing the individual to an antigen to generate an adaptive immune response, passive immunity refers to the transfer of antibodies from one individual to another (Marcotte and Hammarström 2015). Passive immunity provides only short-lived protection, lasting from several weeks to up to 3–4 months, but is immediate. Nature intended passive immunity to occur when maternal antibodies are transferred to the fetus through the placenta or from breast milk to the gut of the infant. However, it can also be produced artificially when antibody preparations are derived from sera or secretions of immunized donors and are delivered via oral or systemic routes to nonimmune individuals. Passive immunization is a new approach to providing protection to animals against pathogens because of the emergence of new and drug-resistant microorganisms, diseases that are unresponsive to drug therapy and individuals with an impaired immune system who are unable to respond to conventional vaccines.

5 Antibodies

The immune system can respond specifically to millions of different molecules and is constantly challenged by huge numbers of antigens. A major feature of the immune system is that it can synthesize a vast number of antibodies. Each of these antibodies can bind to a different antigen. This binding is the basis for the molecular specificity of the immune response.

Antibodies are proteins produced by a type of terminally differentiated B lymphocytes. B cells take the B name from chicken bursa cells where they were first discovered (Gitlin and Nussenzweig 2015). Antibodies are produced in response to the presence of foreign molecules in the body. The antibodies circulate throughout the blood and lymph where they bind to the foreign antigens. Once bound, these antibody-antigen complexes are removed from circulation, primarily through phagocytosis by macrophages. This is the basis for antibodies protecting the animal against pathogens.

Antibodies are a large family of glycoproteins that share key structural and functional features. From a structure standpoint, antibodies look like a Y-shaped molecule (Fig. 1). Each Y contains four polypeptides. Two of the polypeptides are identical and called heavy chain. The other two, also identical, are called light chain and are connected by disulfide bonds. There are five classes of antibodies, IgG, IgM, IgA, IgE, and IgD, that are classified based on the number of Y-like units and the type of heavy-chain polypeptide they contain (Fig. 2).

6 Antibody Classes

IgM is the largest antibody, and it is the first to appear in response to initial antigen exposure. The spleen, where plasma cells responsible for antibody production reside, is the major site of specific IgM production (Capolunghi et al. 2013; Marchalonis et al. 2002). IgG is the main type of antibody found in blood and extracellular fluid allowing it

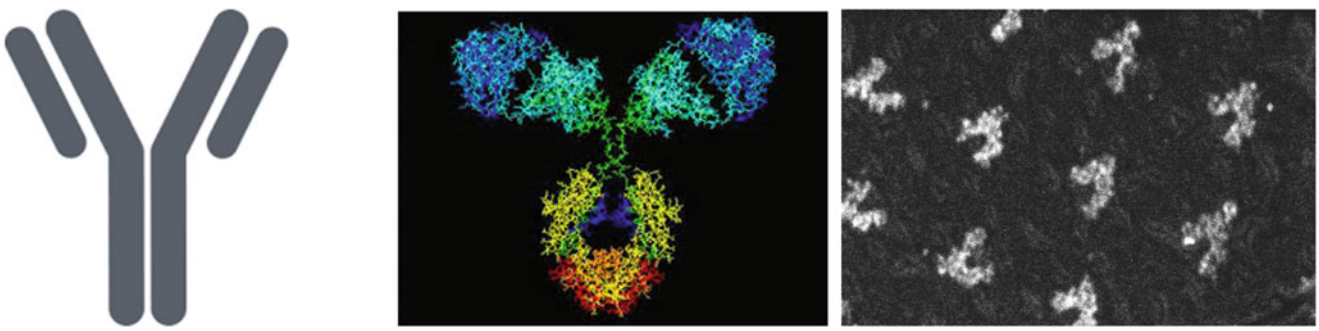

Fig. 1 Antibody structure as drawn, by protein model and by electron microscopy

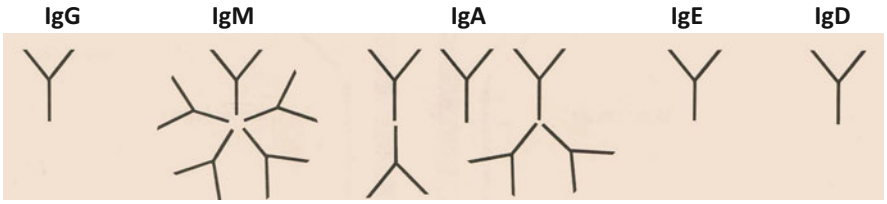

Fig. 2 Structures of the five classes of antibodies

to control infection within body tissues. Approximately 80% of all antibodies in humans and companion animals are of the IgG class. Immunoglobulin A (IgA) plays a crucial role in the immune function of mucous membranes. The amount of IgA produced in association with mucosal membranes is greater than all other types of antibodies combined (Fagarasan and Honjo 2003; Holmgren and Czerkinsky 2005; Snoeck et al. 2006). IgD was initially thought to be a recently evolved antibody class because it was only detected in primates, mice, rats, and dogs and not guinea pigs, swine, cattle, sheep, and frogs (Preud'homme et al. 2000). However, recent discoveries of IgD in ancient vertebrates suggest that IgD has been preserved in evolution from fish to humans for important immunological functions (Chen and Cerutt 2011). Immunoglobulin E (IgE) has only been identified in mammals. IgE's main function is immunity against parasites such as helminths (Erb 2007) like *Schistosoma mansoni*, *Trichinella spiralis*, and *Fasciola hepatica* (Watanabe et al. 2005; Pfister et al. 1983). IgE also has an essential role in type I hypersensitivity (Gould et al. 2003) which manifests in various allergic diseases, such as allergic asthma, most types of sinusitis, allergic rhinitis, food allergies, and specific types of chronic urticaria and atopic dermatitis (Mueller et al. 2016).

7 Antibody-Antigen Interactions

Antibodies bind antigens at the upper tips of the Y molecule. The region of antigen where binding occurs is called the epitope (Fig. 3).

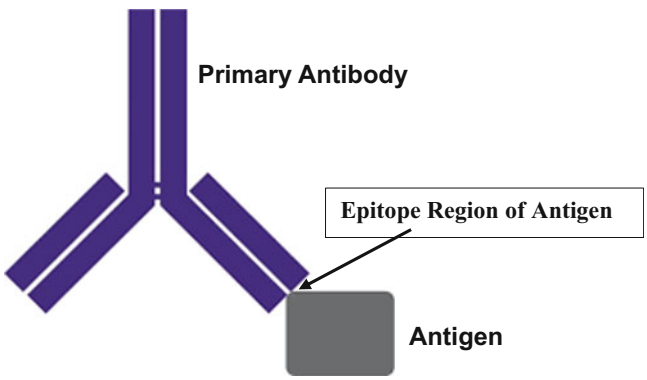

Fig. 3 Antibody binding to an antigen

Antibodies can bind to a wide range of chemical structures and can discriminate among related compounds. How well the antibody binds to an antigen is known as affinity. This affinity can range from low to high.

8 Colostrum and Passive Immunity

Mammals are born without a fully functional adaptive immune system even though the basic elements are present. When a mammal is born, it emerges from the sterile uterus into an environment where it is immediately exposed to a host of microorganisms. The gastrointestinal tract (GIT) acquires a complex microbial flora within hours. If it is to survive, the newborn animal must be able to control this microbial invasion. In practice, the adaptive immune system takes some time to become fully functional, and innate mechanisms are responsible for the initial resistance to infection. In some species with a short gestation period, such as mice, the adaptive immune system may not even be fully developed at birth. In animals with a long gestation period, such as domestic mammals, the adaptive immune system is fully developed at birth but cannot function at adult levels for several weeks. The complete development of active immunity depends on antigenic stimulation. The proper development of B cells and B-cell receptor diversity requires clonal selection and antigen-driven cell multiplication. Thus, newborn mammals are vulnerable to infection for the first few weeks of life. They need assistance in defending themselves at this juncture. Temporary help is provided by the mother in the form of colostrum, which contains antibodies. The passive transfer of immunity from mother to newborn is essential for survival.

Calves are born without an active immune system and rely on the consumption of antibodies for protection from disease such as scours and pneumonia. The cow provides its calf with nutrients for growth and development during gestation, but the cow cannot directly provide the calf with antibodies to protect it from diseases. Fortunately, immunoglobulins form an important component of the immunological activity found in milk and colostrum. While humans have a large amount of IgA in their colostrum, the colostrum from most other animals contains a high percentage of IgG (Hurley and Theil 2011) (Fig. 4). Immunoglobulins found in mammary secretions arise from systemic and local sources. In the case

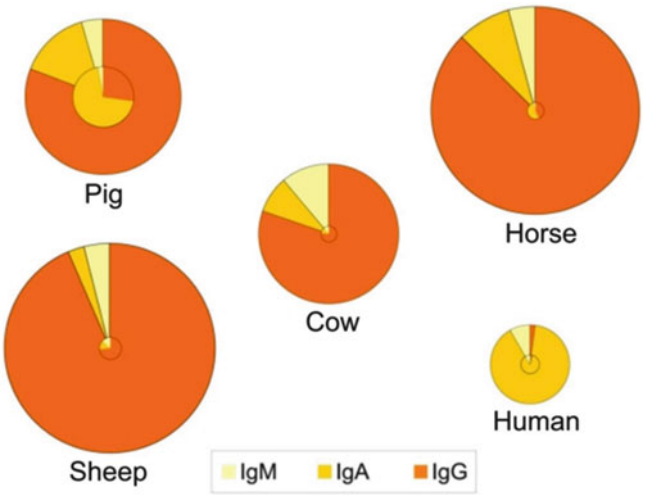

Fig. 4 Relative distribution of IgG, IgA, and IgM in colostrum (outer circle) and in milk (inner circle) of five species

of IgG in milk, the major portion comes from the serum (Mayer et al. 2005). While plasma cells producing IgG may occur within the mammary tissue, their contribution to the IgG in colostrum is minor compared with the IgG derived from serum.

The other major classes of immunoglobulins transported into colostrum and milk are IgA and IgM. Immunoglobulin A (IgA) is the major immunoglobulin in human colostrum and milk; however, it is also present in milk of most other species. Colostrum and milk IgA and IgM are found in the form of secretory IgA, or sIgA, and sIgM. Much of this is produced by plasma cells in the mammary tissue. The plasma cells are part of the gut-associated lymphoid tissue (GALT), the largest immune organ of an organism, which includes the Peyer's patches, lymphoid and myeloid cells in the lamina propria, and intraepithelial lymphocytes (Ishikawa et al. 2005). Interestingly enough, more than 70% of the immune system is located in the gastro intestinal tract, the site where many oral pathogens first interact with an animal (Vighi et al. 2008). GALT is a part of the mucosa-associated lymphoid tissue and works in the immune system to protect animals from invasion of pathogens in the gut. One of the physiological functions of the mucosa in the gut is for food absorption. However, of equal importance of the GALT is in the body's defense, due to its large population of plasma cells whose number exceeds the number of plasma cells in the spleen, lymph nodes, and bone marrow combined (Nagler-Anderson 2001).

Lymphocytes from the GALT system will move to the mammary gland and provide a direct link between the antigen exposure response in the mother's mucosa system and the secretory immunoglobulins of the mammary gland (Brandtzaeg 2010). As such, this means that maternal colostrum and milk will contain antibodies specific for pathogens that may be encountered by the neonate's intestine and other mucosal tissues. This provides a rationale for the observations that bovine colostrum from nonimmunized cows may also afford passive immune protection against human pathogens in both humans and animals (Li-Chan et al. 1994; Yolken et al. 1985) and opens the door to new technology to provide veterinarians another way to protect animals from pathogens that does not involve antibiotics.

Antibodies must be obtained by drinking colostrum within the first couple of hours after birth as part of the passive immunization system in order to maximize antibody absorption (Pakkanen and Aalto 1997). Like other animals, antibodies are generated by healthy cows as a result of every day exposure to infectious agents. Antibodies can also be the result of specific vaccination programs. The cow's natural antibodies to these infectious agents are passed from the cow to the calf through colostrum. The level of antibodies transmitted from the cow through the colostrum can be elevated by a pre-calving vaccination program (Thomas 2017).

When the calf drinks colostrum, the maternal derived antibodies are absorbed from the calf's GIT into the blood stream. Some of the immunoglobulins also remain in the gut where they can neutralize pathogenic bacteria and help prevent the development of diarrhea. The absorption of antibodies from the GIT into the bloodstream is called passive transfer. Failure of passive transfer (FPT) in dairy calves is defined by a blood IgG level of <10 mg/mL 24–48 h after birth (Stilwell and Carvalho 2011). Calves that experience FPT are more likely to become sick or die in the first 2 months of life than calves with adequate immunity. Many factors can contribute to FPT, but colostrum and the management of colostrum feeding are often involved. To successfully obtain passive transfer and provide the calf with protection from diseases, it is thought that the calf needs to consume a minimum of 150–200 g of immunoglobulins (Meganck et al. 2014).

The pathway between the gastrointestinal tract and the bloodstream is only open for a short window of time. Research shows that this pathway starts to close shortly after birth, and after 8–12 h, approximately 50% of the calf's ability to absorb colostrum antibodies is gone. It has therefore been recommended to feed calves as much colostrum as they want by bottle within 1–4 h after birth and at 12 h of age to substantially reduce the probability of FPT (Chigerwe et al. 2009; Trotz-Williams et al. 2008).

Colostrum also provides the calf with protein, energy in the form of fat and sugar, and vitamins (Quigley and Drewry 1998). Some vitamins do not cross the placental barrier, and colostrum is the primary source of these nutrients for the calf after birth. Energy is required for all metabolic functions including maintenance of body temperature. One of the leading causes of death in dairy calves is failure to initiate breathing and metabolic processes in the first hours of life. The

newborn calf only has a few hours of energy reserves in stored fat and therefore needs the energy from colostrum. Research also confirms that the sooner a calf consumes colostrum, the more maternal antibodies it can utilize.

The quality of colostrum is a major issue that the dairy industry faces on a regular basis. Generally speaking, quality of colostrum is related to the amount of antibody that is present. Colostral IgG concentration is an important factor that affects whether calves receive sufficient passive immunity (Godden et al. 2012). Unfortunately, the amount of IgG in maternal colostrum varies dramatically among cows (< 1–235 g/l) with 29.4–57.8% of samples that do not reach the desired amount of 50 g IgG/l (Gulliksen et al. 2008). Colostral quality is difficult to estimate by the farmer based on produced volume or appearance of the colostrum. There are many variables that impact colostrum quality, including nutrition, the time the cow is milked, heat stress, and stage of lactation. A study from Iowa State University suggests that a minimum 30% of dairy calves in the USA are currently being fed colostrum classified below industry standards for IgG content and are at a greater risk of FPT, mortality, and morbidity (Morrill et al. 2011).

Other production mammals such as piglets face the same issues as calves for colostrum quality. Studies have shown that on average 25% of pigs with a colostrum intake below 200 g usually die. In pigs with a colostrum intake below 100 g, mortality was as high as 65% (Devillers et al. 2011). Giving spray-dried bovine colostrum to other animals such piglets has been shown (Sty et al. 2006) to help protect against gut dysfunction and inflammation. It may be possible that using bovine colostrum for piglets could help supplement sow colostrum. Research has also been done in foals with an enhanced bovine colostrum supplementation (Fenger et al. 2016).

9 Colostrum Programs

Since up to 50% of cows have colostrum with an IgG level below 50 mg/mL, which will not prevent FPT, a variety of programs and protocols have been implemented by dairy producers. High-quality maternal colostrum is still the gold standard for feeding newborn calves. However, colostrum supplement and replacer products can be valuable tools to increase calf immunity when colostrum supplies are limited or disease eradication is desired. Colostrum products that contain IgG are regulated by the USDA Center for Veterinary Biologics and are available in bolus, gel, and powder formats. Supplement products are unable to raise the blood concentration of IgG above the species standard, which is 10 mg/mL for calves. Any product that is able to raise serum IgG concentration above 10 mg/mL may be called a colostrum replacer (Penn State 2017). Supplements do not contain sufficient quantities of antibodies to raise the blood IgG level in calves beyond what average quality colostrum will do. Colostrum replacer contains greater levels of IgG and other nutrients and provides an effective, convenient method of providing passive immunity to calves when maternal colostrum is not available.

Colostrum supplements available today are made from dried bovine colostrum or serum and contain 40–60 g of IgG per dose (9–13% globulin protein). The fat content of these products ranges from 0.5 to 15%. Spray-dried colostrum with high concentrations of immunoglobulin may be produced economically and used as an effective and convenient colostrum replacer in newborn calves (Chelack et al. 1993). Numerous products designed to replace colostrum are now on the market. These products are made from bovine colostrum or serum and contain 100–150 g of IgG per dose. These products also provide fat, protein, vitamins, and minerals needed by the newborn calf, although the amount varies between products. A summary (Pennsylvania State University 2017) of treatment means from 26 published studies investigating colostrum products indicated that replacer products provided an average of 157 g of IgG, with an absorption efficiency of 31%, and serum IgG of 12 mg/mL. Supplement products (fed in addition to colostrum) provided 136 g of IgG with 19% absorption efficiency and resulted in serum IgG of 9 mg/mL.

It has been recognized that while antibodies found in colostrum can certainly reduce diseases in animals via passive immunity when given to a newborn, they will only work if the colostrum donor animal has been exposed either naturally to the disease or given a vaccine to the disease, in order to have specific antibodies produced. Bovine colostrum that is typically spray-dried for supplements or replacer will contain only the antibodies that the cow may have encountered naturally. Therefore, the colostrum used may not have specific antibodies against particular diseases that a producer might be interested in. The animal industry has recognized this issue and has developed methods to produce specific antibodies in high titer against specific diseases that can be delivered in colostrum products. This is achieved by hyperimmunizing animals such as cows against specific animal diseases, collecting colostrum and processing it into powders such as by freeze-drying methods and then giving to a newborn animal in gels or boluses. A number of diseases including bacterial diseases like *E. coli* (Selim et al. 1995) and viral diseases such as rotavirus and coronavirus (Combs et al. 1993) or *coccidial* diseases such as *giardia* or *cryptosporidia* (Graczyk et al. 1999; Fayer et al. 1989; Naciri et al. 1994) have been researched for hyperimmunized colostrum efficacy. The hyperimmunized colostrum is collected, processed, and given to newborn calves. To varying degrees of success, these hyperimmunized colostrum antibodies have been proven to be successful in providing passive immunization.

Besides calves, research has been done in a variety of production animals using bovine or other sources of colostrum. For example, lambs have been supplemented with ewe colostrum as well as hyperimmunized serum from sheep against *E. coli* (Pommer 2010). Other research has examined vaccination of cows with clostridial antigens and passive transfer of clostridial antibodies from bovine colostrum to lambs (Clarkson et al. 1985). Piglets have also been given passive protection against porcine epidemic diarrhea by hyperimmune bovine colostrum (Shibata et al. 2001).

Specific antibodies in a hyperimmunized colostrum-derived product can be used while complementing early colostrum feeding and can be delivered at the same time as colostrum. There are some advantages to this strategy as specific immunoglobulins immediately fight at the gut level to protect against diseases that destroy the intestinal lining while also allowing for antibodies to be absorbed into the bloodstream. It's important to protect the intestinal lining because if the cells that line the digestive tract become damaged, milk cannot be digested or absorbed by the calf.

10 Vaccination of Newborn Animals While Receiving Colostrum

Besides the quality of the colostrum itself, researchers first believed that calves could not be vaccinated effectively while they had circulating maternal antibodies from the colostrum in their system. Preweaning calves can respond to vaccination stimulation as early as 1 month of age. The maternal antibodies absorbed from colostrum, however, cannot distinguish between the antigens of a natural challenge and the antigens in a vaccine. Therefore, colostrum antibodies can interfere with the immune response to a vaccination (Niewiesk 2014). Work continues to be done to develop ways to circumvent maternal antibody interference.

Vaccination of calves in the face of maternal antibodies (IFOMA) often does not result in seroconversion as maternally derived immunity interferes with the activation of adequate antibody responses to vaccination. However, it can prime T- and B-cell memory responses that protect calves against clinical disease when maternal immunity has decayed. The activation of B- and T-cell memory responses in calves vaccinated IFOMA varies and is affected by several factors, including age, level of maternal immunity, type of vaccine, and route of administration. These factors influence the adequate priming of humoral and cell-mediated immune responses and the outcome of vaccination. Failure to adequately prime immune memory after vaccination IFOMA could result in lack of clinical protection and an increased risk of viremia and/or virus shedding (Chamorro et al. 2016).

There is obviously some controversy about whether newborn calves should be vaccinated (Cook et al. 2003). It is thought that the process of the calf mounting an immune response to a vaccine requires energy that could better be used to fight off disease and gain weight and the response could actually be detrimental to the early health of that calf. On the other hand, while maternal antibodies can block response to vaccination, sometimes they do not (Woolums 2007). The exact immunologic outcome in calves vaccinated IFOMA can vary, and this variation likely depends on many factors. These factors are not well characterized but likely include the nature of the vaccine administered, number of doses administered, age of the calf and level of maternal antibody present in the calf, and the means by which a protective response is defined. Guidelines for vaccinating newborn animals such as calves require additional research to clarify the IFOMA vaccination reactions.

11 Antibody Products

Fortunately, producers also have the option of using antibody products in order to generate immediate protection in situations where colostrum quality is poor. Antibody products complement colostrum feeding because they can be fed at the same time. These products are available in bolus, gel, and powder form. They also are included in some colostrum replacer and supplement formulas for added value. Typically, the antibody products are from hyperimmunized cows, and the specific antibody is found in the colostrum. The colostrum is processed and typically fractionated into a semi-purified preparation of antibody that is freeze-dried and put into capsules or boluses. Because antibody boluses can be fed in conjunction with colostrum, they can be a tool to help the calf not only achieve adequate passive transfer but also provide enough specific antibodies to protect against the most common early calf hood diseases.

Antibody products do not require the calf to react to a vaccine in order to develop antibodies. Rather specific antibodies against various diseases are already present, measured, and verified to be at a high enough level to protect the calf from scour-related diseases, and they can be fed as close to birth as possible. United States Department of Agriculture (USDA)-approved antibody products are available on the market that can be fed in conjunction with colostrum and provide the calf with immediate immunity. These antibodies go to the gut to immediately bind and neutralize diarrhea antigens while also being absorbed into the blood stream for extended protection (Combs et al. 1993; Chamorro et al. 2014). Another advantage of this approach is that providing specific antibody can potentially avoid vaccine stimulation.

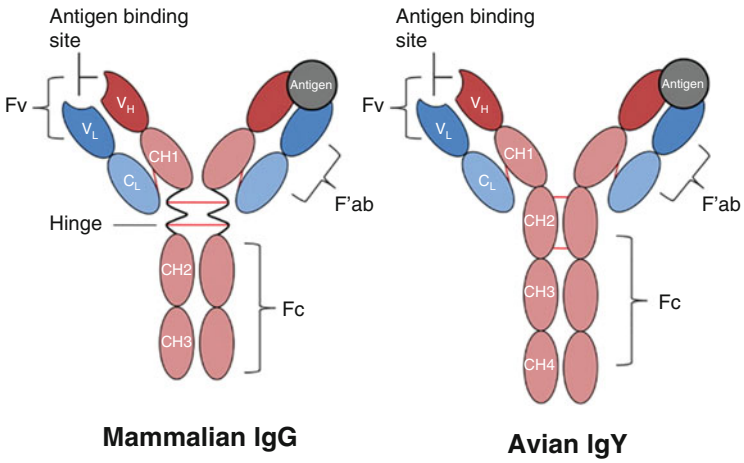

Fig. 5 Structure of mammalian IgG compared to avian IgY

Avoiding vaccine stimulation can allow a calf to conserve its minimal supply of fat and nutrients that are critical to get the calf through its first few days of life.

12 Passive Immunity by Egg Antibodies

Cows pass their immunity to their offspring by colostrum, and various colostrum products are on the market to achieve passive immunity. Additional sources of antibody products can be utilized in a similar manner to achieve passive immunity. These are from avian sources such as chickens. In birds, passive transfer of immunity occurs through the egg. By hyperimmunizing chickens over a period of time with inactivated multivalent bacterial or viral vaccines, this procedure results in the production of polyclonal immunoglobulins of the IgY class (specific to avians) directed against the stimulating organisms.

Oral consumption of the "immune" eggs containing specific IgY antibodies protects the animal against the specific organism(s) with which the hen was stimulated. Unfortunately, the eggs really cannot be cooked since heat dentures the antibodies found in the eggs. Other physical parameters such as an acidic pH will also destroy the antibodies to a certain extent. However, enough orally administrated IgY may survive passage through the GIT and, after excretion, still retain a great deal of its antigen-binding ability indicating that orally administrated IgYs are useful for passive immunity.

13 Eggs as a Natural Source of Immunoregulatory Factors

Just as immune protection is transferred in utero in mammals or passively by a lactating mother via colostrum, hens passively transfer protection to their young by secreting immunoglobulin and other immune factors into their eggs for use by the hatching chick. The transfer of chicken immunoglobulins from the hen's serum to the yolk and from the yolk to the chick is analogous to cross-placental transfer of IgG from the mammalian mother to its offspring. While IgM and IgA are found in chicken eggs, the principle immunoglobulin is IgY which is found in the yolk of the egg (Hamal et al. 2006). IgY (Y stands for yolk) is an immunoglobulin class specific to avians and analogous in function to that of mammalian immunoglobulins. IgY has a similar structure as mammalian IgG with some minor differences in the heavy chains (Fig. 5).

Both eggs and milk (including breast milk) contain naturally occurring antibodies, and there are reports of immunomodulatory factors in milk as well (Li et al. 2017). However, immunoglobulin levels in eggs can be significantly higher than levels found in serum or milk (Woolley and Landon 1995). This may not be surprising since mammals have a considerably longer time of weeks or months during which they may passively transfer immunoglobulin and immune factors, while the hen has a single opportunity (the egg) to transfer all necessary survival components to its offspring. All the aspects that the chick needs to survive must be in the egg. Because egg products are a common source of protein in human diets and eggs contain antibodies and immune factors, it was obvious to utilize egg antibodies to provide passive immunity to animals. As such, this has resulted in a number of commercial egg antibody products on the market for production animals as well as companion animals to prevent various diseases. With few exceptions, oral consumption of specific antibodies has been reported (Diraviyam et al. 2014) to protect both humans and animals. Furthermore, in vitro studies with specific IgY antibodies have been found to inhibit processes associated with bacterial growth, adhesion to intestinal cells, and toxin production (Sugita-Konishi et al. 1996).

Meta-analysis has demonstrated the beneficial effects of IgY (Diraviyam et al. 2014) for a variety of animals. This

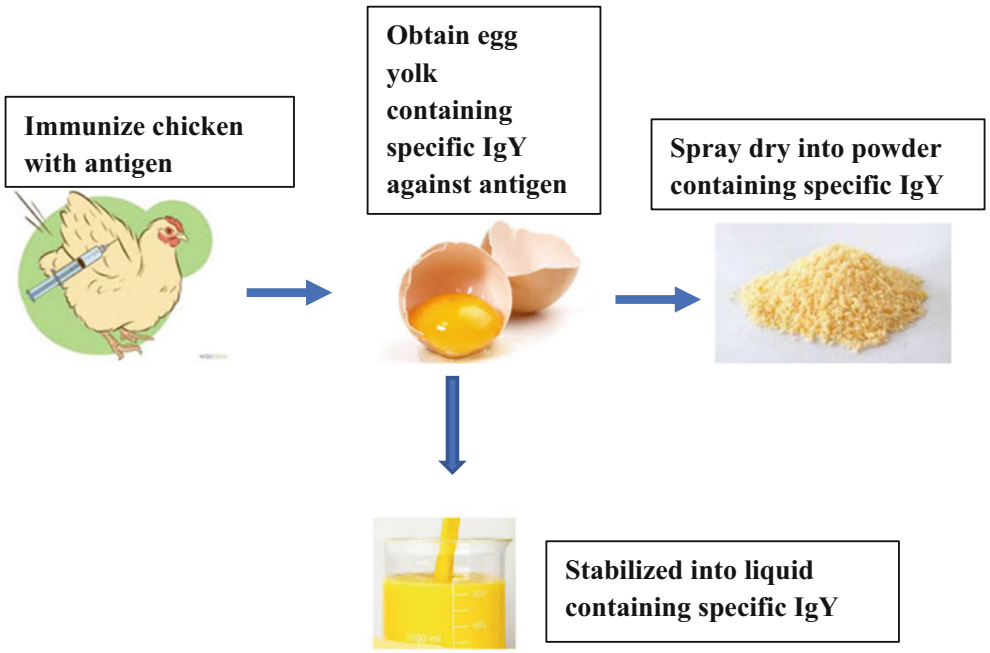

Fig. 6 Vaccination for specific antibodies and processing egg yolk strategies

analysis supports the opinion that IgY is useful for prophylaxis and treatment. Currently, the oral passive immunization using chicken IgY has been focused as an alternative to antibiotics for the treatment and control of diarrhea. IgY has been demonstrated to be effective in controlling and preventing diarrhea in humans and in animals including piglets (Cui et al. 2012; Vega et al. 2012), mice (Buragohain et al. 2012), poultry (El-Ghany 2011; Farooq et al. 2012), and calves (Cook et al. 2005; Germine et al. 2011; Vega et al. 2011).

Most commercially available chickens are immunized at birth to protect them from avian diseases. The only difference between such supermarket eggs and "immune" eggs is that the latter are from chickens that have received additional proprietary vaccinations with other inactivated pathogens known to be the etiologic agents of animal infections. A wide range of bacteria, viruses, and coccidia have been used in vaccines for producing commercial IgY products. A partial list includes *Shigella dysenteriae*, *Staphylococcus epidermidis*, *Escherichia coli*, *E. coli* K99, *Salmonella enteritidis*, and *S. typhimurium*, *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Haemophilus influenzae*, species of *Streptococcus*, *Salmonella Dublin*, *Salmonella anatum*, *Clostridium Perfringens* type A and type C toxoids, rotavirus types 1 and 2, coronavirus, reovirus, parvovirus, and *Cryptosporidium parvum* (Schade et al. 2005). Only the chicken (not the egg) is exposed to inactivated pathogens. Immunoglobulins and other immune factors are passively transferred to the egg from the serum for use by the chick and, more importantly, for passive immunity for other animals.

After appropriate times following vaccination, eggs are collected from the specially designated chicken flocks, washed and broken, and the yolk and egg white are typically dried to a fine proteinaceous powder. Various processes have been developed to help minimize heat damage to egg antibodies and immunoregulatory factors during the spray-drying procedure. However, spray-drying eggs can denature the IgY to an extent, due to at least some heating during the process. Keeping the egg away from heat is an optimal way of maintaining IgY titer levels and efficacy. While freeze-drying is an expensive option for maintaining antibody titer levels, simply feeding fresh immunized eggs is another method which exists. This is to keep the immunized eggs in a stabilized liquid (DuBourdieu 2014). This stabilized liquid format is a practical and inexpensive delivery method that allows the specific IgY to be delivered in watering systems to production animals or incorporation into other delivery formats such as soft chews that can be readily given to companion animals (Fig. 6).

The effective mechanism by which avian IgY's work is effective is by the same mechanism that mammalian IgG antibodies work in the animal to provide passive immunity. For example, bacteria *E. coli* strain K88 typically causes problems in production animals that result in diarrhea and possible death. Therefore, a vaccination program is used in chickens to create specific anti-*E. coli* K88 IgY antibodies. These specific antibodies found in the yolk of the egg are given orally to animals to prevent *E. coli* K88 from causing disease. This occurs when specific anti-*E. coli* K88 IgY antibodies bind to the pathogenic bacteria. This binding blocks the ability of the pathogen to bind to the mucin layer

in the GI tract of the animal. The pathogens are flushed out of the GI tract with the feces since they have been rendered unable to bind.

The total immunoglobulin content of eggs from hyperimmunized hens is identical to the total level of immunoglobulins found in conventional table eggs. However, the quantities of immunoglobulins to selected antigens are different in the two varieties of eggs. Additionally, both the table egg and the "immune" egg contain immunoregulatory factors, but eggs from hyperimmunized chickens may contain many times greater concentrations of individual factors as compared to regular eggs. Besides immunoglobulins, eggs contain a number of bioactive components, including phospholipids, cholesterol, lutein, zeaxanthin, and proteins, that possess a variety of pro- and/or anti-inflammatory properties. Two major categories of immune components are found in "hyperimmune" egg: (1) the immunoglobulins with neutralizing specificities against the stimulating pathogens and (2) the immunoregulatory factors that modulate cellular functions. The immunoglobulins provide local protection against gastrointestinal intoxication. The immunomodulatory mediators act directly on gastrointestinal surfaces and circulate systemically, affecting every immune, physical, metabolic, and neuroendocrine pathway in the body. These may have important implications for the pathophysiology of numerous chronic diseases and immune responses to acute injury (Andersen 2015). Given the essentiality of pro-inflammatory responses in normal immune defense against pathogens, further research into the role of egg intake on immunity is warranted and may lead to further commercial uses of eggs and IgY technology.

14 Monoclonal Antibodies in Veterinary Use

Biological medicine in humans, an intervention pioneered in the last 30 years, is now on the horizon for companion animals. This strategy includes the use of monoclonal antibodies (mAbs) to selectively target proteins such as cellular receptors or soluble molecules involved in disease pathogenesis. Such treatment holds the potential for targeted therapies of chronic diseases such as osteoarthritis, atopic dermatitis, or lymphomas in dogs and cats.

Monoclonal antibodies are antibodies that are made by identical immune cells that are all clones of a unique parent cell. Monoclonal antibodies have monovalent affinity, in that they bind to the same epitope. In contrast, polyclonal antibodies bind to multiple epitopes and are usually made by several different plasma cell lineages (Fig. 7).

Given almost any substance, it is possible to produce monoclonal antibodies that specifically bind to that substance; they can then serve to detect or purify that substance. This has become an important tool in biochemistry, molecular biology, and medicine. Therapeutic mAbs can be used medically to block disease-relevant proteins (e.g., cytokines or receptors on cells) and cancer and have gained significant use in humans. They can also be used to target viruses or bacteria and aid in their destruction and elimination. Veterinary medicine is only now incorporating this tool.

Despite the success of mAbs in human medicine, there are considerably fewer in the pipeline for veterinary medicine. This may be due to uncertain regulatory guidance in both Europe and the USA. These regulatory documents are written from the perspective of human medicine-based risk assessment and development. It is recognized that this may present a challenge to veterinary mAbs manufacturers to achieve the extent of characterization/quality control testing typically required for human mAbs. (EMA 2017). Regardless, the pet medicine industry is making strides to put mAbs into the market through basic research.

Early human therapeutic mAbs contained a high proportion of mouse-derived sequences (fully mouse or mouse/human chimeric mAbs) that were recognized by the human immune system as foreign. This immune response triggered production of anti-mAbs, leading to reduced therapeutic efficacy. Subsequently, the design of humanized and fully human mAbs has resulted in a vast reduction in their immunogenicity, although most therapeutic mAbs may have some remaining immunogenicity that is not followed by apparent adverse clinical manifestations. These same issues hold true

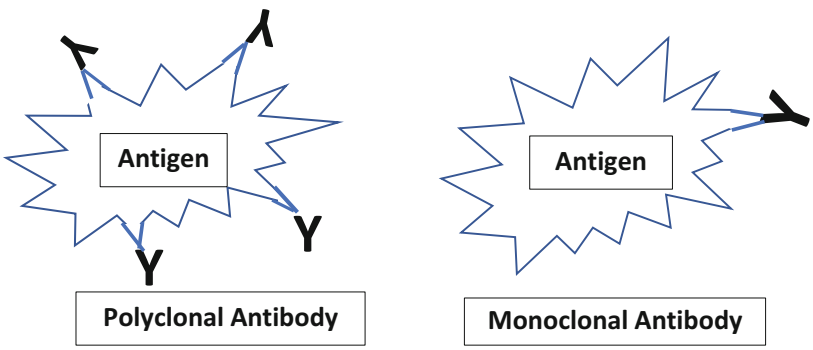

Fig. 7 Polyclonal antibody compared to monoclonal antibody binding of antigens

for making veterinary mAbs and utilizing canine mAbs for dogs that helps efficacy. It has been found that caninized anti-IgE mAbs reduce IgE hypersensitivity in mite-sensitized beagles (Gearing et al. 2013). Caninized anti-nerve growth factor mAb (Webster 2014) significantly reduced pain scores (Webster et al. 2014) in dogs, and mAbs that neutralize the pruritogenic cytokine IL-31 in dogs reduced the pruritic response for 3 weeks after injection (Dunham et al. 2014).

One of the aspects regarding commercializing therapeutic antibodies involves regulation from the USDA. In 2015, two USDA-approved monoclonal antibody treatments for B-cell and T-cell lymphomas in dogs were granted. These mAbs fight lymphoma by targeting the protein CD20, which is commonly expressed in B-cell lymphoma (Ogilvie et al. 2014; Bulman-Fleming et al. 2014). While these particular mAbs were not commercially successful, they are part of a new approach for using therapeutic antibodies in veterinary medicine. Other companies are developing veterinary mAbs for cancer, allergies, and chronic inflammatory disease such as atopic dermatitis and for the control of pain associated with osteoarthritis in dogs and cats (Webster et al. 2014). The first mAb approved for veterinary use was in the European Union (BMJ 2017). It treats the clinical signs of atopic dermatitis in dogs, including itch and inflammation, for up to 1 month. The mAb treatment works by mimicking the activity of natural antibodies to selectively bind to and neutralize interleukin-31 (IL-31), a key protein involved in cell communication which triggers itching associated with atopic dermatitis in dogs. Because it neutralizes IL-31, it has been demonstrated not to interfere with the immune response, meaning that it does not induce unintended immunosuppression or enhancement.

Most therapeutic mAbs are delivered via intravenous, intramuscular, or subcutaneous injection. This is because antibodies can't be delivered orally because of breakdown in the stomach by acids or other factors found there. Various encapsulation methodologies are required in order to overcome this basic issue, and these methods should be forthcoming. Once injected, most therapeutic mAbs, like natural antibodies, have a long half-life (about 21 days). The absolute half-life for each is unique, depending upon its concentration, distribution of its target, and, if the mAb is directed to a cell-surface receptor, clearance and elimination of the target receptor. Therapeutic mAbs have two main safety advantages: (1) they have very specific targets, and (2) they don't have intracellular activity. As a result, there are few anticipated side effects and reactions although they can occur (Catapanoab and Papadopoulosc 2013). mAbs are eventually eliminated via intracellular catabolism in the lysosome, where they are broken down into peptides or amino acids that can be either reused for synthesis of new proteins or excreted via the urine.

15 Concluding Remarks and Future Directions

Antibodies for veterinary use have great potential for the future. Passive antibody therapy in the treatment of infectious diseases is a concept which dates back more than 120 years, to the 1890s, when the use of serum from immunized animals provided the first effective treatment options against infections with *Clostridium tetani* and *Corynebacterium diphtheriae* (Hey 2015). However, due to the discovery of penicillin by Fleming in 1928, and the subsequent introduction of the much cheaper and safer antibiotics in the 1930s, serum therapy was largely abandoned. But in more recent times, the broad and general use of antibiotics in human and veterinary medicine has resulted in the development of multiresistant strains of bacteria with limited or no response to existing treatments and thus a need for alternative treatment options. This situation can be partially attributed to the overuse of antibiotics as growth promoters for production animals and other indiscriminate use.

The combined specificity and flexibility of antibody-based treatments in providing passive immunity makes them very valuable tools for designing specific antibody treatments to infectious agents. These attributes have already caused a revolution in new antibody-based treatments in oncology and inflammatory diseases, with many approved products for human use. However, only very few mAbs are approved for veterinary use. mAbs therapies are expensive, and this has been a barrier for their development in the presence of inexpensive antibiotics. The use of antibiotics as growth promoters came to an end in 2017 in the USA with the rest of the world already limiting their use for this purpose manner (FDA 2015). This opens the door to new technologies and antibodies from monoclonal sources, chicken eggs, cow colostrum, or other sources to be among the chief contenders for limiting diseases in a safe manner and potentially to act as growth promoters. For that purpose, antibodies and antibody-derived treatments offer very attractive tools and attributes to neutralize infectious agents or modulate the immune system to enable effector cells to escape immunosuppressed conditions and contribute to the elimination of infections. The ability to raise antibodies to any target, and the ability to modulate effector functions, half-life, and size of the treatment units, makes antibodies ideal for tailoring treatments for specific infectious agents. However, more research into the use of antibodies as growth promoters will need to occur.

One area that researchers are looking to make better use of antibody treatments for veterinary use includes more use of mAbs. It has been predicted that minimal amino acid changes are needed to adapt an antibody from one species to another

to avoid immune rejection. Using libraries of genetic information and algorithms to make sure that key amino acid sequences are recognized as "self" or "native" by the target species' immune system can reduce the chance of undesirable immune reactions. This will increase the advantages typical of mAbs for potency, safety, and a prolonged elimination half-life. Therefore, these second- and third-generation mAbs will be at the forefront of veterinary antibody technology along with IgY technology.

Molecular targets for therapeutic mAbs, IgY, and colostrum IgG in animals should (1) be involved in clinical signs or disease mechanism and (2) not have redundant pathways compensating for blockade of the intended target. The validity of blocking a molecule or eliminating a cell type must also be weighed against the importance of this protein or cell for desirable normal body functions. It is possible to speculate on uses of these antibodies in companion animals. These might include immune-mediated hemolytic anemias/thrombopenias, myasthenia gravis, and autoimmune blistering diseases such as pemphigus, among other conditions. For cancer, the use of mAb or IgY therapy targeting B-lymphocytes will be valuable for B-cell lymphomas in dogs and cats. In allergic diseases, the use of mAbs to inhibit production of IgE via its promoting cytokines such as interleukins IL-4/IL-13, their cytokine receptors, or IgE itself might be beneficial in dogs and cats with IgE-mediated atopic dermatitis or food allergies. The itch sensation itself could be altered, at least theoretically, by antibodies targeting itch-promoting cytokines such as IL-31, nerve growth factor, thymic stromal lymphopoietin, or neuromediators involved in itch transmission. In arthritis therapeutic mAbs that inhibit pro-inflammatory cytokines (TNF-alpha, IL1, etc.) or their receptors are likely to be of benefit in treating dogs and cats with arthritis. The usefulness of anti-NGF mAbs as an analgesic must be confirmed. In autoimmune diseases, the use of mAbs specific for B-lymphocyte surface proteins could theoretically lead to reduced production of autoantibodies.

Veterinary vaccines have had, and continue to have, a major impact not only on animal health and production but also on human health, through increasing safe food supplies and preventing animal-to-human transmission of infectious diseases. The continued interaction between animals and human researchers and health professionals will be of major importance for adapting new technologies, providing animal models of disease, and confronting new and emerging infectious diseases. One area of research where more information is needed is on factors that limit efficacy of vaccination IFOMA, particularly in calves <1 month old. This is a complex issue. However, research continues to evolve in the area of newborn calf vaccinations.

Passive immunity provided by chicken egg antibodies will gain increasing use in production animals. There is no doubt that chicken Abs can be produced and used, with minor modifications, in similar ways to mammalian Abs. It can also be said that, depending on the circumstances, the use of IgY Abs often has significant advantage over the use of mammalian Abs. However, from a realistic point of view, IgY Abs probably will not be able to completely replace the use of IgG Abs in diagnostic systems in the near future (Schade et al. 2005). Chickens have the potential to be used to complete the spectrum of animals that have been used for Ab production. However, a prerequisite is to make IgY technology more popular and to convince the scientific community of its significant advantages. An interesting possibility for the future is the production of chicken mAbs. These would combine the advantages of mAbs with the advantages of chicken Abs. It is to be expected that studies on the therapeutic or prophylactic use of IgY Abs will be intensified in the future. In particular, because of the increasing resistance of microorganisms to antibiotics, research on all aspects related to the development of specific IgY against pathogenic microorganisms will have to be intensified.

In conclusion, the next decade will see continued development of therapeutic mAbs, IgYs, and colostrum antibodies for production and companion animals in both treatment and prevention. These highly specific molecules are likely to prove beneficial to uniquely target disease mechanisms without the side effects associated with broad-spectrum pharmacotherapy. While vaccines will continue to play a very important role in maintaining the health of animals by active immunity, antibodies that provide passive immunity will be an increasing part of the arsenal available to veterinarians to promote growth in production animals in a safe manner and to maintain health in companion animals.

Prebiotics, Probiotics, Synbiotics, and Antimicrobials

Prebiotics and Probiotics in Feed and Animal Health

Arturo Anadón, Irma Ares, Maria Rosa Martínez-Larrañaga, and Maria Aŕanzazu Martínez

Abstract

The ban of antimicrobial growth promoters (AGP) has been a challenge for animal nutrition, increasing the need to find alternative methods to control and prevent the colonization of pathogenic bacteria. The elimination of antibacterials in animal nutrition has had adverse consequences on the production, health, and welfare of animals. Much research has been focused on the development of antibiotic alternatives to maintain or improve animal health and performance. Modulation of the gut microbiota with zoo-technical feed additives such as prebiotics and probiotics for host protection to support animal husbandry, including livestock, poultry, and fish farming, is the key to maximize productivity and maintain animal health and welfare. This chapter describes the classes of available prebiotics, probiotics, and synbiotics alternatives to increase productivity and aid performance in several food-producing animals. For farm animals, optimal combinations of various alternatives coupled with good management and husbandry practice, better housing conditions, and improvement of biosecurity measures are essential.

Keywords

Prebiotics · Probiotics · Synbiotics · Feed · Animal health · Animal welfare

1 Introduction

The concept of improving animal health and welfare through enhanced gut health has been known in food animal production for decades; however, only now are the tools available to identify microbes in the intestine associated with improved performance (Ballou et al. 2016). Preserving the integrity of the intestinal barrier is also critical for animal health and welfare. As well as ensuring nutrient absorption, the intestinal barrier is important in protecting the animal immune system (i.e., mucus production, prevention against bacteria and toxins entering the bloodstream). The more important objective of animal husbandry now is to deliver foods safe for human consumption while taking into account animal welfare and respect for the environment (Gaggìa et al. 2010).

Prebiotic and probiotic approaches require using microbial food supplements that benefit the host by improving intestinal microbial balance (Gibson and Roberfroid 1995). Dietary administration of spore-forming bacteria can restore the natural balance of the animal gut microflora and return the gut to its normal nutritional, growth, and health status (Fuller 1989). Researchers have used the term synbiotic to describe the use of prebiotic and probiotic mixtures that may benefit animal or human gastrointestinal (GI) systems (Kolida and Gibson 2011).

2 Gastrointestinal Microbiota and Microbiome

The microbiota is considered a "super-organism" and is an integral part of the gastrointestinal tract (GIT). This concept refers to the close relationship between microbes residing in the GIT and the animal host developed during the long course of evolution (Ley et al. 2008). The GI microbiota is a complex population of microorganisms that are significant in health and disease. Numerous functions benefiting the host are ascribed to the gut microbiota of mammals, such as the digestion and fermentation of carbohydrates, production of vitamins, maintenance of normal intestinal villi function, regulation of immune responses, and protection from pathogenic bacteria. The functions of microbiota include "nutrition" [fermentation of nondigestible substrates (i.e., carbohydrates) to generate short-chain fatty acids (SCFA)],

absorption of ions, production of amino acids and vitamins K, B_9, B_{12}, "protection" (the barrier effect that prevents invasion by nonnative microbes), and trophic effects on the intestinal epithelium and immune system, that is, the development and homeostasis of local and systemic immunity (Guarner 2007). Moreover, the intestinal bacteria are important in GI health. Resident commensal organisms (normal microflora, indigenous microbiota) promote gut health through the induction of mucus production and enterocyte turnover (Kamada et al. 2013) and also are important in host immunity, nutrient absorption, and metabolism. The resident commensal organisms of the gut flora both protect against invading organisms (e.g., enterotoxigenic *Escherichia coli* strains) within the GIT and are responsible for (1) the synthesis of vitamins; (2) the bioconversion of toxic compounds to nontoxic residues; (3) the stimulation of the immune system; (4) the maintenance of gut peristalsis and intestinal mucosal integrity, and (5) the provision of a barrier against colonization by pathogens. These effects as produced by resident commensal organisms may be mediated through direct competition for nutrients, stimulation of antimicrobial peptide production by the enterocyte, and host immunomodulation (Sancak et al. 2004).

Bacteria also promote self-tolerance by inducing hyporesponsiveness to the resident commensal organisms (Seepersadsingh et al. 2004). These important functions of health can be significantly impaired by bacterial dysbiosis (i.e., altered gut bacterial composition), which occurs when bacteria populations within the GIT become unbalanced. Dysbiosis is likely caused by an altered environment within the GIT, such as changes in pH, motility, oxygen level, and the presence of blood, and has been associated with the pathogenesis of many inflammatory diseases and infections.

The GI microbiota of domestic animals is a dense, large, and complex bacterial community, composed of bacteria, protozoa, fungi, Archaea, and viruses. The microbiota colonizes the gut with metabolic activity that affects the physiology and pathology of the host mucosal immune system. The microbiota located in the GIT of mammals can be considered a "metabolically active organ" whose composition and functions have been characterized for better understanding of the major contribution of the gut microbiota to animal nutrition. The GI microbiota is complex. Bacterial species of the genera *Lactobacillus* and *Bifidobacterium* have been shown to supply beneficial host effects of their metabolic function and end-products. Homeostasis regulation by the microbiota enhances its beneficial components, so it could be possible to treat various intestinal disorders and maintain host well-being (O'Hara and Shanahan 2007). Faecal microbial transplantation thus might be a novel therapy for dysbiosis in veterinary medicine (Redfern et al. 2017).

The GI microbiota promotes the supply, digestion, and fermentation of plant polymers in herbivorous animals and the absorption of nutrients, improves growth performance and prevents pathogen colonization, and maintains normal mucosal immunity. The importance of the GI microbiota and the host–microbe crosstalk is highlighted by the results of studies using germ-free animals.

In chickens, diet and environment affect the GIT microbial status. The microbiota of chickens varies according to factors such as diet, location, and age. Microbial richness and diversity increase with age, with dramatic changes in the microbial community as chickens grow older. Most studies examined the effect of time on the chicken caecum microbiota, as this is the organ with the greatest diversity and abundance in the entire intestinal tract. However, microbial diversity of the chicken microbiota is relatively low compared to the intestinal microbiota of other animals, which is attributed to the rapid transit of food through the digestive system, with short retention times. For example, a typical retention time for a 29-day-old broiler chicken is between 4 and 5 h, compared to humans, where the average is 20 h (Clavijo and Vives Flórez 2018).

Dirty litter and other animal management parameters affect GIT microbial composition both directly by providing a continuous source of bacteria and indirectly by influencing the physical condition and defence of the birds. Animals reared under conditions that prevent bacterial colonization display impaired intestinal immune system development and function (O'Hara and Shanahan 2007). This aspect demonstrates that there is a symbiotic relationship between host and microbiota. The intestinal microbiota is a highly complex milieu of more than 600 species, which may be present at levels up to 10^{11} colony-forming units of bacteria per gram of intestinal contents. Data show that bacterial densities in the ileum and caecum of broiler chickens 1 day after hatching already reach 10^8 and 10^{10} per gram of digesta, respectively. The numbers of microbes reach 10^{11} per gram of caecal digesta and 10^9 per gram of ileal digesta during the first 3 days post hatching and remain relatively stable for the following 30 days (Apajalahti et al. 2004). More than half the 640 species found in chickens represent previously unknown bacterial genera composing a healthy microbiota crucial for the health of the host.

The intestinal environment consists of microbiota, the mucosal immune system, and the gut structure and function, which affect host health and animal productivity. These aspects of the intestinal environment are all influenced by diet; thus, better understanding of the relationships between nutrition, the intestine, and host health is important for optimizing animal production. Because the GIT, particularly the large intestine (i.e., colon and caecum), is the most important site of fermentative activity, the importance of microflora activity (i.e., fermentation) must be clarified in relationship to host health. Although the intestinal contents pass through the human small intestine in only 2–4 h, the large bowel transit time is normally 20–80 h, so there is more

than enough time for the development and activity of the microflora (Williams et al. 2001).

As indicated previously, the intestinal tract, in addition to absorption and digestion, is also the body's largest organ of host defence. This organ represents the largest surface area in contact with the antigens of the external environment, and the dense wall-to-wall of the gut microbiota overlying the mucosa normally accounts for the largest proportion of the antigens presented to the resident immune cells and those stimulating the pattern recognition receptors such as toll-like receptor (TLRs) and NOD-like receptors (NLRs). Part of the intestinal mucosal barrier function is formed by a common mucosal immune system, which provides communication between the different mucosal surfaces of the body (Sekirov et al. 2010). The gut microbiota is intimately involved in numerous aspects of normal host physiology, from nutritional status to behavior and stress response, acting as a microbial organ. The indigenous microflora is host- and location specific, very complex in composition, and generally possesses properties that are beneficial to the host. Therefore, a major concern of antibiotic use is the long-term alteration of the normal healthy gut microbiota and horizontal transfer of resistance genes, which could result in a reservoir of organisms with a multidrug-resistant gene pool (Da Costa et al. 2013). Many environmental factors can affect the composition and function of gut microbiota in livestock animals. Feeding practices, animal diets, farm management, and productivity constraints also influence microbial balance in the GIT and consequently affect feed efficiency, digestive health, and animal welfare (Chaucheyras-Durand and Durand 2010).

In this regard, piglet weaning represents a critical period during which the still immature gut microbiota confronts a radical diet change, leading to increased susceptibility of the young animals to pathogen colonization. Multiple stressors encountered at piglet weaning induce transient anorexia, intestinal inflammation, and unbalanced gut microbiota (Gresse et al. 2017). The circumstances of piglet weaning transition often cause GI infections (e.g., colibacillosis diarrhea), and the potential use of feed supplements to achieve better animal health, welfare, and productivity through manipulation of the GIT microbial ecosystem has gained considerable attention.

Data from the rumen environment suggest it is home to a diverse population of microbes encompassing all three domains of life: Bacteria, Archaea, and Eukarya. Of the three domains of life inhabiting the rumen, the bacteria are predominant (10^{10}–10^{11} cells per gram of rumen content). Viruses are the most abundant biological entities, participating in microbe balance within an ecosystem and facilitating horizontal gene transfer.

Most feed ingredients of plant origin contain considerable amounts of fiber redefined to be soluble and insoluble nondigestible carbohydrates with three or more monomeric units, lignins that are intrinsic and intact in plants, and certain isolated and synthetic nondigestible carbohydrates with three or more monomeric units (Gibson et al. 2017). Insoluble fibers have traditionally been regarded as an inert nutrient diluent with little or no nutritive value in monogastric animal diets; however, they have further functions such as (1) improving gut health, (2) enhancing nutrient digestion, and (3) modulating animal behavior. It is suggested that monogastric animals need fiber because their gut development requires physical stimulation by hard, solid particles of feed (Hetland et al. 2004). So, Choct et al. (1996) demonstrated that addition of soluble non-starch polysaccharides (NSP) to a broiler chicken diet drastically increased volatile fatty acid (VFA) production in the ileum, which was easily reversed when the NSP were depolymerized with an enzyme. The VFA levels in the ileum were negatively correlated with apparent metabolisable energy and starch digestion. The microbiota also degrades polysaccharides that are not digestible by the host, thus increasing the nutritive value of the diet (Choct 2009). The functions of microbiota in pathogen exclusion and the synthesis of vitamins, minerals, and other biologically active compounds are well documented (Patterson and Burkholder 2003).

The link between nutrition and the microbiota is well established. Diet is considered as one of the main drivers in shaping the gut microbiota over the lifetime. The intestinal function and gut microflora of broiler chickens are influenced by cereal grain and microbial enzyme supplementation (Shakouri et al. 2009), dietary fat content, feed form, and NSP-degrading enzymes (Torok et al. 2008). The GIT of chickens harbor microbiomes important in (1) growth and development, including the production of energy-rich SCFA; (2) promotion of GIT villus and crypt morphology; (3) nutrient utilization, including reduction in luminal viscosity and deconstruction of dietary polysaccharides; (4) nutrient absorption; and (5) well-being of their chicken hosts, including detoxification. During the deconstruction of dietary polysaccharides, GIT bacteria produce SCFA. The composition and proportions of these SCFA vary depending on microbial composition, which is to some degree adaptable, and fine-tuned by the composition and structure of the fiber component of the chicken's diet. Acetate is the primary SCFA produced in most GIT environments, including the chicken, followed by propionate and butyrate. The chicken GIT is inhabited by various bacteria, methanogenic archaea, fungi, and viruses (Yeoman et al. 2012). The chicken GIT microbiome produces enzymes enabling the deconstruction of dietary polysaccharides (Beckmann et al. 2006). These enzymes are critical to host nutrition because chickens, similar to most animals, lack the genes for glycoside hydrolase, polysaccharide lyase, and carbohydrate esterase enzymes that are necessary to facilitate this process (Yeoman et al. 2012).

The gut "microbiome" (i.e., the natural intestinal microbial communities of the host, which refers to genetic elements

or the genome of the intestinal microbiota) contains more than 100 times the number of genes in our human genome and confers on us functional features that we have not evolved ourselves (Turnbaugh et al. 2007; Gibson et al. 2017). The GI microbiome is a diverse consortium of bacteria, archaea, fungi, protozoa, and viruses that inhabit the gut of all mammals. The microbiomes exist within greater systems that are organic in nature, including human, animal, plant, and invertebrate) or inorganic, such as soil, water, manufactured products, and the constructed environment. Dysfunctional microbiomes are associated with reduction in animal productivity, such as increases in antimicrobial resistance in livestock and poultry. Studies in humans and other mammals have implicated the microbiome in a range of physiological processes that are vital to host health including energy homeostasis, metabolism, gut epithelial health, immunological activity, and neurobehavioral development. The microbial genome confers metabolic capabilities exceeding those of the host organism alone, making the gut microbiome an active participant in host physiology (Barko et al. 2018).

Supporting an optimal gut microbiome may also prove beneficial in animal science as a means to manage stressful situations and to increase the productivity of farm animals. The microbiome and its genetics are an underestimated influence on animal health and growth. Although there remains a paucity of data about the intestinal microbiome in small animals, recent studies have helped characterize its role in host animal health and associated disease states (Barko et al. 2018). Microbiome characterization has progressed rapidly in recent years as DNA-based profiling technologies have verified and replaced traditional culture-based techniques. Using those newer techniques, it was found that 90% of the bacteria in the chicken GIT represent previously unknown species (Apajalahti et al. 2004).

As with humans, the microbiomes of plants and animals are necessary in plant and animal growth and development. Plants are constantly confronted by both abiotic and biotic stresses that seriously reduce their productivity. Recent evidence shows that a combination of abiotic and biotic stress can have a positive effect on plant performance by reducing susceptibility to biotic stress. Such an interaction between both types of stress suggests crosstalk between their respective signaling pathways. This synergistic or antagonistic crosstalk may include the involvement of phytohormones, transcription factors, kinase cascades, and reactive oxygen species (ROS). In certain cases, such crosstalk can lead to cross-tolerance and enhancement of plant resistance against pathogens (Rejeb et al. 2014).

Animal microbiomes are investigated and manipulated along with modern agricultural practices to increase productivity. The rumen microbiome reportedly contains up to 28,000 different viral genotypes obtained from each environment, with prophage sequences outnumbering potential lytic phages by approximately 2:1: the most abundant bacteriophage and prophage types are associated with members of the dominant rumen bacterial phyla Firmicutes and Proteobacteria (Berg et al. 2012). Viruses have been shown to be a driving factor in the evolution of microbiomes in various environments with important roles in controlling the numbers of microbes in an ecosystem, naturally selecting phage-resistant microbes, and facilitating horizontal gene transfer (Rohwer and Thurber 2009; Parsley et al. 2010).

The microbiome of a mature sow could contain between 10 and 100 trillion organisms. Every organ contains its own specific microbiome (lungs, skin, intestinal tract, etc.) (van Haandel 2016). There are different species of microbiomes and, within the species, there are genetic variations. The microbiome of the pig intestinal tract is dominated by two major groups, Firmicutes and *Bacteroides*, with the composition varying moderately from the beginning to the end of the GIT (Jensen 1998; Niu et al. 2015). The gut microbiome in young pigs is dramatically shaped by the composition of dietary glycans, reflected by the different functional capacities of the microbiome before and after weaning. Before weaning the microbial flora appears to be milk oriented. During the weaning phase the pig and its microbiome are subjected to a drastic period of transition, but during the nursing phase the microbial population is rather stable. After weaning (day 28 and beyond), populations of *Bacteroides* and *Enterobacteriaceae* decline and populations of *Lactobacillaceae*, *Ruminococcaceae*, *Veillonellaceae*, and *Prevotellaceae* increase (Frese et al. 2015). The microbiome adapts its bacterial composition to changes in the living environment or substrates in the diet (Lallès et al. 2007). The microbiome is in continuous symbiosis with its host, containing pathogens and other bacteria that are perfectly in balance in a healthy animal.

Little is known about the acquisition and development of the intestinal microbiome in dogs and cats, limited to a handful of studies in kittens and puppies. To date, only one longitudinal study of developing kittens has been published (Deusch et al. 2015). As in humans, the early faecal microbiome is characterized by a high degree of interindividual variation, and that intraindividual diversity and compositional stability increase with age. Also, similar to humans, the relative abundance of *Lactobacillus* and *Bifidobacterium* decreased with age, whereas *Bacteroides* and bacterial genes associated with the ability to metabolize complex carbon sources increased with age. However, there was no major change in bacterial gene repertoires between weeks 30 and 42 in these kittens (Barko et al. 2018).

Relative to the poultry microbiome and food safety, it should be highlighted that *Salmonella* affects people in many countries each year, giving rise to hospitalizations and deaths. This aspect is addressed by researchers who

studied the development of the chick microbiome from hatch to 28 days. The microbiome of growing chicks develops rapidly from days 1 to 3, and the microbiome is primarily *Enterobacteriaceae*, but Firmicutes increase in abundance and taxonomic diversity starting around day 7. Predicted metagenomic content suggests that, functionally, treatment may stimulate more differences at day 14, despite the strong taxonomic differences at day 28. These studies found that both vaccination and prebiotic use (i.e., microbial nutrients) with the chick diet help reduce the persistence of *Salmonella* in the challenged birds (Ballou et al. 2016). The GI microbiome in poultry differs ecologically from that of mammals in that colonization occurs primarily from the surrounding environment and individuals of the same age are reared in close proximity rather than in direct contact with adults. Colonization of poultry by microbes from environmental sources may have important biosecurity and management implications if human pathogens are transferred from environmental reservoirs through the poultry supply chain to consumers (Oakley et al. 2013). The microbial communities associated with agricultural animals are important for animal health, food safety, and public health. The use of high-throughput sequencing (HTS) to characterize the poultry microbiome across a series of farm-to-fork samples demonstrates the utility of HTS in monitoring the food supply chain and identifying sources of potential zoonoses and interactions among taxa in complex communities (Oakley et al. 2013). Similar approaches with other poultry and livestock may help prevent other food-borne diseases.

Growth performance that may differ between chicken breeds could be associated with the GIT microbiome. However, there may always be variation among individuals, probably because of initial bacterial colonization at posthatch. It was reported that the jejune microbiota was dominated by lactobacilli (more than 99% of jejune sequences) and showed no difference between birds with high and low feed conversion ratios (FCR), whereas the caecal microbial community displayed higher diversity with 24 unclassified bacterial species, significantly differentially more abundant between high- versus low-performing birds (Stanley et al. 2012). Many broiler chickens and microbiota studies contain only data from males or the sex of the broiler chickens was unknown. This sex bias in the literature might influence our understanding of the microbiota development in chickens, and therefore the sex of the chicken should always be reported (Stanley et al. 2012).

The genetic codes of a number of commensal bacteria, including *Lactobacillus acidophilus* and *L. johnsonii* (Pridmore et al. 2004), which produced SCFA, have recently been sequenced; this will facilitate future studies on microbial gene expression and improve our understanding of interactions between the host and the microbiome.

A healthy gut is the key to a healthy animal. An infected gut (i.e., by coccidiosis or by necrotic enteritis) is not a healthy gut, and is not efficient in digesting and transporting nutrients (Choct 2009). Thus, a balanced and diverse microbial composition is essential for optimal digestion and nutrient uptake. The most important tool for good gut health is to provide the best feed possible that meets the nutritional needs for the age category and stage of production.

The brain–gut–microbiota axis comprises an extensive communication network between the brain, the gut, and the microbiota (Wiley et al. 2017). Development of a diverse gut microbiota is crucial for multiple features of behavior and physiology, as well as many fundamental aspects of brain structure and function. Appropriate early-life assembly of the gut microbiota is also believed to influence subsequent emotional and cognitive development. If the composition, diversity, or assembly of the gut microbiota is impaired, this impairment can have a negative impact on host health and lead to disorders. Recent advances in DNA sequencing technology show that changes in the gastrointestinal microbiome are associated with diseases including inflammatory diseases, asthma, obesity, diabetes, cardiovascular disease, immune-mediated conditions, and even potentially neuropsychiatric illnesses including anxiety and depression (Wiley et al. 2017). Microbiomes represent one source of human and animal genetic and metabolic diversity. For example, aging predisposes humans and animals to a natural degeneration in GI function, epithelial barrier integrity, GI microbiota composition, and immune system function (adaptive and innate), elevating the risk of infections. Potentially pathogenic bacteria (i.e., enterobacteria and *Clostridia*) increase with aging, whereas *Bifidobacterium* species, which contribute to the protection of the intestinal tract, decrease. Little is known about the acquisition and development of the intestinal microbiome in dogs and cats. As in humans, the early faecal microbiome is characterized by a high degree of interindividual variation and that intraindividual diversity and compositional stability increase with age (Yatsunenko et al. 2012). Also similar to humans, the relative abundance of *Lactobacillus* and *Bifidobacterium* decreased with age, whereas *Bacteroides* and bacterial genes associated with the ability to metabolize complex carbon sources increased with age (Barko et al. 2018). In chickens, the microbiota varies according to diverse factors such as diet, location, and age. Dramatic changes have been described in the microbial community as chickens grow older. Most of the studies examined the effect of time on the chicken caecum microbiota (i.e., organ with the greatest diversity and abundance in the entire intestinal tract). However, the microbial diversity of the chicken microbiota is relatively low compared to the intestinal microbiota of other animals, which is attributed to the rapid transit of food through the digestive system, with short retention times; for example, a typical retention time for a

29-day-old broiler chicken is between 4 and 5 h, compared to humans, where the average is 20 h.

3 Classes of Alternatives to Antimicrobial Growth Promoters

The ban of antibiotic growth promoters (AGPs) has been a challenge for animal nutrition, increasing the need to find alternative methods to control and prevent the colonization of pathogenic bacteria (Anadón et al. 2006). Although the EU has banned antibiotics that are applied as growth promoters, they are still regularly used for therapeutic reasons. When antibiotics are used, the intestinal microbiota becomes unbalanced, and restrains the future intestinal health of the animal. Better intestinal health will have a positive impact on FCR and uniformity across all species. An ideal alternative should have the same benefits as AGP, ensure optimum animal performance, and increase nutrient availability (Huyghebaert et al. 2011). Considering the proposed mechanism of action of AGPs (microbiome and immunomodulating activities), a practical alternative should possess both these properties in addition to having a positive impact on FCR and growth (Huyghebaert et al. 2011; Seal et al. 2013). Applications of prebiotics and probiotics are needed not only for health- and welfare-promoting properties and performance, but also to displace the application of antibiotics in animal feed. Prebiotics and probiotics are regarded as components of strategies to reduce or even eliminate routine antimicrobial use in animal production and are seen as potential alternatives to in-feed antibiotics. Modulation of the gut microbiota with prebiotics and probiotics as the new feed additives for host-protecting functions to support animal health and welfare is an important issue in animal production.

3.1 Prebiotic Concept: Prebiotic Effects

Prebiotics are products that confer health benefits. Found naturally in many foods, prebiotics are also isolated from plants, or synthesized from lactose or sucrose by enzymatic methods, and promote the selective growth of certain indigenous gut bacteria. A prebiotic was defined by Gibson and Roberfroid (1995) as "a non-digestive food ingredient that beneficially affects the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon, and thus improves host health." These authors revised this concept and proposed a new prebiotic definition "as a selectively fermented ingredient that allows specific changes; both in the composition and/or activity in the GI microbiota that confers benefits upon host well-being and health" (Gibson et al. 2004; Roberfroid 2007). The latest definition equalizes "prebiotic" and "bifidogenic" and includes in the definition the "prebiotic index" (i.e., gives the absolute increase of the faecal bifidobacteria concentrate per gram of daily consumed prebiotics). As the prebiotic effects, or rather "bifidogenic effects," depend on the type and concentration of the prebiotic and on the *Bifidobacterium* concentration in the intestine of the host, therefore there is not a simple dose–effect relationship. Other investigators have proposed definitions that preferentially emphasized one or more different functional characteristics. FAO (2007) describes prebiotics as "non-viable food components that confer a health benefit on the host associated with modulation of the microbiota." The definition arose from observations that particular dietary fibres bring about a specific modulation of the gut microbiota, particularly increased numbers of *Bifidobacterium* or *Lactobacillus* spp., and that a decrease in potential harmful bacteria is a sufficient criterion for health promotion.

The selectivity for bifidobacteria may be promoted by the ingestion of substances such as fructo-oligosaccharides (FOS) and inulin, *trans*-galactosylated oligosaccharides, and soybean oligosaccharides (Mitsuoka et al. 1987). Recently, an expert consensus document updated the definition of a prebiotic (target-associated microbiota) as a substrate that is selectively utilized by host microorganisms, conferring a health benefit (Gibson et al. 2017). Prebiotics as substrate are nondigestible feed ingredients that influence the microbiota in a manner favourable for host health by stimulating growth or activity of potentially positive microbial flora in the large intestine (Patterson and Burkholder 2003), Thus, a prebiotic is a substrate that is selectively utilized by the host microorganisms conferring a health benefit (Gibson et al. 2017). All prebiotics are fibre, but not all fibres are prebiotics. Beneficial animal health effects must be documented for a substance to be considered a prebiotic. Prebiotics for use by animals in which microbial-focused strategies to maintain health and prevent disease are as relevant as for humans (Gibson et al. 2017).

During the past two decades, prebiotics have been recognized for their ability to manipulate host microbiota for the benefit of the host. Prebiotics include a diversity of non-starch polysaccharides (NSP) or oligosaccharides including mannan-oligosaccharide (MOS), fructans (FOS and inulin), oligofructose, galactans [galacto-oligosaccharide (GOS)], malto-oligosaccharide, lactulose, lactitol, gluco-oligosaccharide, xylo-oligosaccharide, soya-oligosaccharide, isomalto-oligosaccharide (IOS), and pyrodextrins.

Nondigestible in the small intestine, FOS could be utilized only by a few bacterial species, notably *Bifidobacterium*, and including such oligosaccharides in the food increased the count of bifidobacteria in the intestine. It should be stated that is difficult to test the selective stimulation of individual bacterial strains among the more than 400 cultivable and nonculturable bacterial strains in the human gut; for that

reason, the prebiotic effect has been defined as "the selective stimulation of growth and/or activity(ies) of one or a limited number of microbial genus(era)/species in the gut microbiota that confer(s) health benefits to the host" (Roberfroid et al. 2010). The diversity of bacterial species in the gut is one of the most important factors for the establishment of a stable ecosystem in the intestinal tract. Young birds have fewer bacterial species in the intestinal tract than do adult birds, so their gut microflora are more susceptible to disturbances than that of the adults (Mead 1989). A stable flora is essential for an animal to resist infections, particularly in the gut.

Although the concept of prebiotics has been developed over time, to be considered as an effective prebiotic, it is proposed that a candidate prebiotic must fulfill the following criteria, which are to be proven by in vitro and in vivo studies: (1) nondigestibility (i.e., resistance to low pH gastric acid, enzymatic digestion, and intestinal absorption in the upper part of the GIT), (2) good fermentation by the large intestinal microbiota; this can be investigated by measuring breath hydrogen or fecal recovery of the administered carbohydrate after a single prebiotic meal, and (3) selective stimulation of growth and activity of intestinal bacteria (i.e., measuring bacterial counts in faecal samples, or intestinal content, before and during exposure to the test material in batch or multi-chamber fermentation systems) that has associated health-promoting effects (Macfarlane et al. 2006; De Vrese and Schrezenmeir 2008).

Prebiotics are nonabsorbable carbohydrates, such as inulin, galacto-oligosaccharides (GOS), and FOS that promote growth and metabolic activity of presumably beneficial gut bacteria, most notably species of *Bifidobacterium* and *Lactobacillus*. These products may confer health benefits through the production of SCFA, including lactate and butyrate, which may reduce cytokine production within the intestinal mucosa (Sartor 2004).

Prebiotics undergo fermentation by beneficial microflora in the large intestine, providing sources of energy for the microflora. Only the carbohydrates [i.e., inulin and oligofructose (OF), (*trans*-galacto-oligosaccharides (TOS or GOS), or lactulose], which are not digestible but can be fermented by the intestinal flora (Gibson 1999), fulfill this criterion.

The "probiotic approach" adds one or two species to a spectrum of hundreds of species in the gut flora, but the "prebiotic approach" aims at fertilization of the intestinal ecosystem. Functional imitations of the naturally occurring prebiotics GOS and FOS stimulate intestinal growth of bifidobacteria as a marker of probiotics in a dose-dependent manner (Patterson and Burkholder 2003; Gaggìa et al. 2010).

In common terms, prebiotics are "food components" for live microorganisms that are considered beneficial for health and well-being, and it is scientifically accepted that prebiotics are valuable dietary additions for modulating the growth and activity of specific bacterial species in the colon that are considered health supporting (Gibson et al. 2010). An example of feed ingredients for animals is the eubiotic lignocellulose, which influences microflora that it does not digest but traverses to the large intestine where bacteria ferment it (Metzler and Mosenthin 2008).

A different substrate in the large intestine contains a diverse gut microflora. In pig faecal and turkey excreta samples, the amount of volatile fatty acids (VFA) (i.e., acetic acid, propionic acid, butyric acid, total VFA) and lactate can be high when the animals receive lignocellulose A and B. Dry matter digestibility was found to be about 75%, 28%, and <5% for swine/turkey diet, and lignocellulose A and B, respectively. Lignocellulose A resulted in a greater amount of gases, VFA, and lactate compared to product B. Lignocellulose A can be used as an alternative source of fiber to maintain the health and function of the digestive tract (Youssef and Kamphues 2018). The inclusion of lignocellulose in the chicken diet, in particular at a dose of 0.5%, promotes the growth of *Lactobacillus* spp. and *Bifidobacterium* spp., and reduces the number of *Escherichia coli* and *Clostridium* spp. as well as enhancing the concentration of SCFAs (i.e., acetic acid and propionic acids) and lactic acid, which suggests the prebiotic effect of lignocellulose on the broiler chicken GIT, although lignocellulose does not have a substantial effect on the pH of ileal and caecal digesta (Bogusławska-Tryk et al. 2015; Choct 2009; Mancabelli et al. 2016).

Although prebiotics are defined as "a nonviable food component that confers a health benefit on the host associated with modulation of the microbiota" (Pineiro et al. 2008), there are some limitations as to which food components actually count as prebiotics. The compounds need to be resistant to hydrolysis and absorption by the upper GIT so that they can reach the target organisms in the lower GIT. It is desirable that these compounds be substrates more or less only for those microorganisms that one intends to support. It has been argued that only fructo-oligosaccharides and inulin meet these criteria (Roberfroid 2007); however, numerous other compounds have been included in lists of prebiotics such as galacto-oligosaccharides, soy oligosaccharides, xylo-oligosaccharides, pyrodextrins, isomalto-oligosaccharides, lactulose, pectin oligosaccharides, lactosucrose, sugar alcohols, gluco-oligosaccharides, levans, resistant starch, and xylosaccharides.

Prebiotics are nondigestible feed ingredients (i.e., carbohydrates) that selectively promote the development of one or more species of microorganisms in the GIT of humans or animals. Oligosaccharides are the main components: the range is diverse and may be based on any of the hexose monosaccharides, including glucose, fructose, galactose, and mannose (Durst 1996) with a degree of polymerization

between 2 and 20 monosaccharides. Grain legumes are the most common natural sources of oligosaccharides (e.g., raffinose, stachyose, verbascose). "Synthetic" oligosaccharides are derived from the direct polymerization of disaccharides or from the fractionation of both vegetable and microbial cells. Oligosaccharides such as arabinogalactose, arabinoxylan, and rhamnogalacturonan, which are derived from polysaccharides of soybean (with about 3–5% galacto-oligosaccharides), wheat, and fruit, respectively (Van Craeyveld et al. 2009), are generally referred to as nondigestible oligosaccharides.

Some of the nondigestible oligosaccharides currently added to animal feed across different animal species are mannose oligosaccharides (MOS), fructose oligosaccharides (FOS), lactulose and galacto-oligosaccharides (GOS), chito-oligosaccharides (COS), arabinoxylan oligosaccharides (AXOS), xylo-oligosaccharide (XOS), *trans*-galacto-oligosaccharide (TOS), glucan, yeast cell wall, inulin, inactivated yeast bacteria, galactomannan, galactoglucomannan-oligosaccharide-arabinoxylan complex (GGMO-AX), levan, polydextrose, peptidoglycan, chitin, galactomannan-oligosaccharides (GMOS), acidic oligosaccharides (AOS), arabinogalactan, phosphorylated mannans (MAN), arabinoxylan, and mannobiose (Anadón et al. 2016a). These substances influence the intestinal ecosystem by, for instance, improving lactic acid fermentation.

Prebiotics compounds can reduce risk for certain conditions and promote better health; they have a long history of safe use and are known for their health benefits for humans including an increase in the bioavailability of minerals, modulation of the immune system, prevention of GI infections, modification of inflammatory conditions, regulation of metabolic disorders, and reduction of the risk of cancer (Roberfroid et al. 2010). For a dietary substrate to be classed as a prebiotic, at least three criteria are required: (1) the substrate must not be hydrolysed or absorbed in the stomach or small intestine; (2) it must be selective for beneficial commensal bacteria in the large intestine such as the Bifidobacteria; and (3) fermentation of the substrate should introduce beneficial luminal (systemic) effects within the host (Manning and Gibson 2004). The oligosaccharide β-glucans are thought to stimulate performance because of their immunomodulatory effects. Their main action is to enhance phagocytosis and proliferation of monocytes and macrophages (Novak and Vetvicka 2008). As macrophages have a crucial role in immunomodulation, the interaction of glucans with macrophages can have very large effects on the host. Recent reviews have elaborated the action of glucans on immune stimulation (Novak and Vetvicka 2008). Studies with broiler chickens have documented significant health benefits from using immune-modulating β-1,3- or 1,6-glucans (from yeast cell walls obtained from *S. cerevisiae*) as a feed ingredient. However, changes in thymus and liver relative weights and villus morphology of broilers were observed (Morales-López et al. 2009).

Prebiotics are a special form of dietary fiber, are not affected by heat, cold, acid, or time, provide a wide range of health benefits, and beneficially affect the host by selectively stimulating growth, activity, or both, of one or a limited number of bacteria species already resident in the colon (Nagpal and Kaur 2011). Prebiotics are specialized plant fibers which beneficially nourish the good bacteria located in the large bowel or colon. Prebiotics are used to increase bifidobacteria or lactobacilli towards being the numerically predominant genus in the colon, properly improving colonization resistance.

Prebiotic compounds are able to modulate both the luminal and mucosal microbial composition and activities and beneficially regulate host–microbe interactions. Moreover, the changes of gut microbiota composition (especially the number of bifidobacteria) contribute to modulate human metabolic processes associated with obesity and diabetes type 2 (Roberfroid et al. 2010). The prebiotics induce not only changes in the intestinal microbiota and the mucosal surface of the colon but the trans-epithelial transport of the SCFA, stimulating shifts of fluid to and from the lumen; furthermore, the transport of cationic minerals is stimulated by the lowered pH of the lumen. The intraluminal colonic propionate induces the nonneuronal release of acetylcholine synthesized by the epithelial crypt cells to the serosal surface, especially in the distal colon, and this was associated with modifications of the electrical parameters of the mucosa and chloride excretion (Yajima et al. 2011).

The proposed mechanisms of action for prebiotics include blocking receptor sites for pathogen adhesion, immunomodulation, production of antimicrobial compounds on fermentation, and modifying gut morphology (Pourabedin and Zhao 2015). Immunomodulation by prebiotics is thought to result from activation of innate immunity by the interaction of the sugars with certain receptors present on the surface of dendritic cells and macrophages, which can then stimulate production of cytokines, proliferation of lymphocytes, and the activity of natural killer (NK) cells (Saad et al. 2013).

Most prebiotics for the gut require an oral dose of 3 g/day or more to elicit an effect (Roberfroid et al. 2010). Products containing dosages lower than this level should not be called prebiotics, unless such a low dose has been proven to elicit selective effects on the microbiota with concomitant health aspects (Gibson et al. 2017).

3.1.1 Application to Benefit Animals

Prebiotics have been studied and used for companion animals and animal husbandry, including livestock, poultry, and aquaculture. The inherent differences among animal species with regard to the living environment, anatomy and physiology,

dietary composition, and reliance on the gut microbiota for energy must be considered when evaluating the effect of prebiotics on animal health (Stevens and Hume 1998, Gibson et al. 2017). Most prebiotics appear to stimulate acid lactic and bifidogenic bacteria. The functions described for prebiotics are that they attach to pathogens, serve as substrates for fermentation, increase osmosis in the lumen of the intestine, and may also indirectly stimulate the response of macrophages and the production of SCFAs and modulate the immune system (Patel and Goyal 2012).

Poultry

Poultry, which are used primarily for the production of meat or eggs, include land fowl species (for example, chickens, turkeys, quail) and waterfowl species (for example, ducks, geese) which respond to prebiotics although most have a fairly short midgut and hindgut that includes a short, straight colon and twin ceca. Dietary prebiotics, including inulin, yeast cell wall extracts, lactulose, and GOS are usually fed at concentrations up to 0.2% (weight/volume) of diet (Bednarczyk et al. 2016). Prebiotics provide substrates for microbial fermentation in the gut, resulting in the production of SCFA, an energy source for enterocytes. Fermentation of dietary fibers by commensal bacteria in the gut leads, in general, to production of SCFA in the hindgut that can be easily absorbed and contribute to the energy sources for the animal host. Many prebiotics, including fructo-oligosaccharide and mannan-oligosaccharide, increase levels of beneficial bacteria such as *Lactobacillus* and *Bifidobacterium* spp. and decrease levels of pathogens such as *Escherichia coli* (Fukata et al. 1999; Xu et al. 2003; Baurhoo et al. 2007). Terminal restriction fragment length polymorphism (T-RFLP) and denaturing gradient gel electrophoresis analysis have been used to demonstrate that FOS and MOS affect the composition of the bacterial population and *Lactobacillus* species profiles in broiler chickens. These microbial changes did not affect performance, indicating that numerous microbial compositions may facilitate a high level of performance under these conditions (Geier et al. 2009).

Compared to probiotics, the risks of undesirable side effects in the host are lower. Prebiotics are macromolecules that are either derived from plants or synthesized by microorganisms. MOS, derived from the outer cell wall layer of *Saccharomyces cerevisiae*, has been studied extensively as a prebiotic supplement in poultry diets.

Two kinds of prebiotics have been described for use in aviculture. Most of those currently used are nondigestible synthetic oligosaccharides that contain one or more molecules of a sugar, or a combination of simple sugars such as glucose, fructose, xylose, galactose, and mannose. MOS found in the cell walls of yeasts have proved to be most important as they contain compound proteins and glucan (Rehman et al. 2009). The other kind of prebiotic described corresponds to lactose and lactose derivatives such as lactulose and lacto-sucrose (van Immerseel et al. 2002). Lactulose is a nondigestible, synthetic disaccharide that shows prebiotic effect in broiler chickens diets, improving body weight and FCR, increasing villi height, goblet cell numbers, total SCFA concentrations, and *Lactobacillus* counts (Calik and Ergün 2015). Other prebiotics found to have beneficial effects in poultry include lignin, inulin, and palm kernel extract.

Several studies of prebiotics in chickens provide evidence of positive effects for oligosaccharides of mannose or fructose in inhibition of the pathogens *Salmonella* and *E. coli* (Chambers and Gong 2011; Stanley et al. 2014). Conflicting results obtained with or without oligosaccharides that occur naturally in feed ingredients (e.g., the raffinose series oligosaccharides) present an unclear scenario regarding the effect of their inclusion in diets for broiler chickens (Iji and Tivey 1998); however, their nutritional impact cannot be separated from other anti-nutritive components in the diet.

Prebiotics in poultry indicate their usefulness in controlling or reducing the growth of *Clostridium perfringens* implicated in necrotic enteritis. Fucosyllactose, a functional oligosaccharide present in human milk that protects against infection by enteric pathogens, seems to favour coaggragation with pathogens instead of pathogen contaminant being eliminated by the mucosal lining of the poultry intestine (Lee et al. 2012). The addition of various levels of MOS to the broiler chicken diet significantly increased their body weight and improved FCR with increased intestinal villi height, improved immuno-competence in the intestine, altered jejunal gene expression, and influenced intestinal microbiota. FOS, which is derived from plants, has also been shown to possess significant prebiotic effects and improve performance in broiler chickens. Another class of prebiotics includes IOS showing their efficacy in improving weight gain and FCR when fed to broiler chickens (Mookiah et al. 2014). In pigeons, dietary administration of MOS induced changes of gut morphology and lowered the pH of excreta, reflecting a reduced bacterial challenge in the intestine; thus, MOS has potential as a prebiotic strategy in birds (Abd El-Khalek et al. 2012).

A number of characteristics should be taken into consideration when selecting prebiotics for poultry, including resistance to gastric acidic environment, intestinal/pancreatic enzyme hydrolysis, and absorption across intestinal epithelium. The most important characteristic of a standard prebiotic is the ability to selectively enrich beneficial microorganisms associated with health and well-being. Thus, the majority of the beneficial effects of prebiotics are thought to be mediated predominantly through altering the intestinal microbiota (Pourabedin and Zhao 2015). Prebiotics also prevent pathogen colonization either by binding directly or by competitive exclusion by promoting the growth of

beneficial microbes or by stimulating them to produce bacteriocins and lactic acid (Spring et al. 2000). In particular, MOS acts by binding to type 1 fimbriae of enteric pathogens and prevents their adhesion to intestinal epithelial cells (Spring et al. 2000) and acts as adjuvants, and help boost the host immune responses (Ferket et al. 2005). Overall, prebiotics also act by beneficially altering luminal or systemic aspects of the host immune system.

The fermentation of prebiotics by microflora also leads to the production of SCFAs that act as energy sources for intestinal epithelial cells and thus maintain the integrity of the gut lining (Ferket et al. 2005). Several studies have revealed that synbiotic treatment was more efficacious than an individual prebiotic in reducing pathogen transmission and infections in poultry.

Pigs

Different types of chemically defined or undefined dietary compounds are added to the diet of pigs to test their influence on GI microbiota or on the health status improvement during challenge with pathogens. When added to the pig diet, fermentable and nonfermentable fiber appears to have a significant positive impact on growth and gut health: it seems to influence the total digestion and fermentation processes, contributing to a different equilibrium particularly in the large intestine of monogastric animals. Prebiotics such as oligosaccharides of fructose, mannose, and chitin protect piglets against high environmental stressors (for example, antibiotics) and pathogen loads, including faecal *Escherichia coli* shedding, and reduced infection-associated responses to *Salmonella enterica* serovar typhimurium infection or porcine reproductive and respiratory syndrome virus (Liu et al. 2008; Che et al. 2011). Symbiotic applications could be beneficial as significant improvement of growth performance parameters in suckling and in growing pigs was observed (Modesto et al. 2011).

Feeding fiber-rich diets to pregnant sows at the end of their lactation period shows a positive impact as these additives continuously stimulate the GI tract and have a positive influence on the duration of partus (i.e., a shorter duration of partus increases piglet survival rates).

Refined functional carbohydrates (RFCs) are the components harvested from yeast cells (*S. cerevisiae*) using specific enzymes during the manufacturing process to ensure a high level of bioavailability and uniformity. This proprietary enzymatic hydrolysis yields MOS, β-glucans (1,3/1,6), and D-mannose. These compounds are naturally present in all yeast cells but are not readily bioavailable. The method of processing used to refine the yeast cells influences the size and structure of these liberated components, which in turn affect bioavailability and functionality. Research shows that each RFC has a specific mode of action and outcome when fed to various livestock species, including dairy, beef, and poultry. RFCs also have been shown to positively influence the immune response of nursery pigs. RFCs act as a prebiotic by feeding the beneficial bacteria found in the intestine while blocking sites for attachment by pathogens.

Ruminants

Calves are born in a pre-ruminant state and function as non-ruminants until the rumen and other compartments of the stomach fully develop (Quigley et al. 1997). During the first few weeks of life, or longer in the case of veal calves maintained on low-roughage diets (that is, low in fibrous material), prebiotics can be used to increase growth, improve FCR, reduce the incidence and severity of scours (diarrhea), or reduce the incidence of respiratory diseases (Quigley et al. 1997; Ghosh and Mehla 2012; Roodposhti and Dabiri 2012).

The use of prebiotics in cattle has been limited by the ability of ruminants to degrade most prebiotics; however, enhancement in rumen-protective technologies may allow these feed substances to be used in feedlot and dairy cattle, considering also that several classes of nondigestible oligosaccharides are found in the plant cell wall in nature including plants normally used for livestock feeding (Callaway et al. 2008). However, the prebiotics used in pre-weaned calves are cello-oligosaccharides, galactosyl lactose, yeast cell wall extracts, and MOS.

Horses

Horses are large non-ruminant herbivores that rely heavily on microbial fermentation for energy, with more than half of their maintenance energy requirement coming from microbial fermentation occurring in their enlarged caecum and colon (Stevens and Hume 1998). As their typical diet is high in roughage and feedstuffs that are consumed throughout the day, prebiotic interventions might improve the effectiveness of fermentation (Morgan et al. 2007; Respondek et al. 2011). Commonly used prebiotics have stimulatory effects on lactic acid bacteria (i.e., *Lactobacillus*, *Bifidobacterium*, *Enterococcus*). Many of these bacterial strains have been used successfully as equine probiotics. These indigestible prebiotics serve as a substrate for lactic acid bacteria (LAB), potentially improving the microbiota of the large intestine. There have been a limited number of equine digestibility studies using prebiotics as digestive aids. Similar to studies using probiotics, the results are variable. When *S. cerevisiae* fermentation products were supplemented in conjunction with low-quality forage, the apparent digestibility of dry matter, crude protein, and neutral detergent fiber was greater,

indicating prebiotic supplementation is more effective when high-starch, high-fiber, or low-quality forage diets are fed.

Starch intake after supplementation the diet of the horse with short-chain fructo-oligosaccharides (scFOS) (Respondek et al. 2011) or MOS have beneficial effects in preventing digestive disorders associated with both prebiotics. Furthermore, use of scFOS in horses reduced disruptions in colonic microbial populations after an abrupt change in diet and altered faecal VFA concentrations towards propionate and butyrate (Coverdale 2016).

Dogs and Cats

Dogs and cats evolved as Carnivora, eating diets high in protein and fat but low in fibre. They are non-ruminants with short, simple GIT that have little capacity to ferment nondigestible substances, which action occurs predominantly in the colon (Stevens and Hume 1998). Nevertheless, some health benefits have been achieved with prebiotic administration such as reduced infections, improved insulin sensitivity, and better faecal consistency (Respondek et al. 2008; Verbrugghe et al. 2009). Most studies have investigated the effects of dietary supplementation with prebiotics on the bacterial flora in healthy dogs and cats. FOS supplemented at 0.75% dry matter produced qualitative and quantitative changes in the faecal flora of healthy cats (Sparkes et al. 1998a, b).

Compared with samples from cats fed a basal diet, increased numbers of lactobacilli and *Bacteroides* species and decreased numbers of *E. coli* were associated with the FOS diet. However, bacteriological examination of the duodenal juice in these same cats showed wide variation in the composition of the duodenal flora, across sampling periods, which was not affected by FOS supplementation. In a separate trial, healthy cats fed a diet containing short-chain GOS and FOS had greater faecal *Bifidobacterium* species populations and butyrate concentrations versus the control (Kanakupt et al. 2011). Further, healthy Beagle dogs fed a 1% FOS diet over a 3-month trial showed inconsistent faecal excretion of species of *Lactobacillus* and *Bifidobacterium* (Willard et al. 2000). There is a single report evaluating the effects of GOS on the faecal microbiota in healthy cats and cats with inflammatory bowel disease (IBD) (Biagi et al. 2013). Using a randomized, double-blinded, cross-over feeding trial, oligonucleotide probes targeting specific bacterial populations showed no significant differences in the faecal microbiota of IBD cats and healthy cats fed the same diet. Overall, interanimal variation was moderately high whereas a trend of increased *Bifidobacterium* species levels was observed with GOS supplementation.

Farmed Aquatic Species

Farmed aquatic species include finfish and shellfish. Although anatomy varies among carnivorous (e.g., turbot), omnivorous (e.g., catfish), and herbivorous (e.g., sturgeon) species, all fish have a fairly simple and short GIT. The short length and simple structure (lack of special adaptations) of the fish gut results in the rapid transit of digested material, limiting the time available for microbial or prebiotic activity. The prebiotics are indigestible fibers that increase beneficial gut resident commensal bacteria, resulting in improvement of the host health. Prebiotics are found to stimulate the growth of species of intestinal bacteria in aquatic species. Effective prebiotic doses in aquatic host species are in the range of 1% to 3% (weight/volume) of diet (Li et al. 2007; Hoseinifar et al. 2013, 2014). The beneficial effects of prebiotics result from the by-products generated from their fermentation by gut commensal bacteria. Prebiotics such as FOS, MOS, inulin, or β-glucan are called immunosaccharides. These additives directly enhance innate immune responses including phagocytic activation, neutrophil activation, activation of the alternative complement system, and increased lysozyme activity, among others, in farmed aquatic fish (Table 1). Immunosaccharides directly activate the innate immune system by interacting with pattern recognition receptors (PRR) expressed on innate immune cells (Kyu Song et al. 2014). They can also associate with microbe-associated molecular patterns (MAMPs) to activate innate immune cells. Proper immune responses are important not only for combating pathogens but also for appropriate weight gain. Many studies have indicated that immunosaccharides are beneficial to both finfish and shellfish (see Table 1).

The prebiotic mannan-oligosaccharide improves growth and enhances digestive enzymes such as protease and amylase (Xu et al. 2009).

4 Probiotics

Prebiotic and probiotic approaches both demand the use of microbial food supplements that beneficially affect the host by improving its intestinal microbial balance (Gibson and Roberfroid 1995). Probiotics are another feed additive that

Table 1 Prebiotics as immunostimulants in aquaculture

Oligosaccharides	Polysaccharides
• Fructo-oligosaccharides (FOS) • Mannan-oligosaccharide (MOS) • Mannan-oligosaccharide (MOS) + β-glucan • Galacto-oligosaccharide (GOS) • Arabinoxylan-oligosaccharide (AXOS)	• Inulin • β-Glucan • Chitin/chitosan

is gaining acceptance as a potential alternative to antibiotics to improve production efficacy in livestock, poultry and aquaculture. Probiotics have been defined as "mono- or mixed cultures of living microorganisms which beneficially affect the host by improving the properties of the indigenous microbiota" (Fuller 1992). Probiotics are defined as "live microbial feed additive that beneficially affects the host animal by improving its intestinal balance; probiotics, sometimes used interchangeably with the term direct-feed microbial (DFM), used in the US for products that are given to animals. Microorganisms used in animal feed in the European Union (EU) are mainly bacterial strains of gram-positive bacteria belonging to the types *B. licheniformis*, *B. subtilis*, *Enterococcus* (*E. faecium*), *Lactobacillus* (*L. acidophilus*, *L. casei*, *L. farciminis*, *L. plantarum*, *L. rhamnosus*), *Pediococcus* (*P. acidilactici*), and *Streptococcus* (*S. infantarius*); some other probiotics are microscopic fungi such as strains of yeast belonging to *Saccharomyces cerevisiae* and *Kluyveromyces* (Anadón et al. 2006). *Bacillus* and *Lactobacillus* bacteria differ in many characteristics, and *Bacillus* and the yeasts are not usual components of the gut microflora. Although most of the species and genera are apparently safe, particularly lactobacilli and bifidobacteria, certain microorganisms may be problematic, particularly the enterococci, which may harbour transmissible antibiotic-resistant determinants and bacilli, especially those belonging to the *Bacillus cereus* group that are known to produce enterotoxins and an emetic toxin (Anadón et al. 2006). For example ***Bacillus cereus* var. *toyoi* NCIMB 40112/CNCM I-1012) as a feed additive was withdrawn in the EU in 2015 for all animal species authorized previously**.

To date, reported performance enhancement in domestic animals has primarily been obtained through the application of one specific species or a mixture of probiotic strains within a species (Williams et al. 2001). For humans, specific microbial strains could have an important role in colonization resistance in the intestinal, respiratory, and urogenital tracts, cholesterol metabolism, inhibition of carcinogenesis by stimulating the immune system and lactose metabolism, absorption of calcium, and synthesis of vitamins (Anadón et al. 2016). For farm animals, the most important claims are growth promotion, improved FCR, health control such as prevention of intestinal disturbances (especially in young animals), pre-digestion of anti-nutritional factors (e.g., trypsin inhibitors, phytic acid, glucosinolates) (Havenaar et al. 1992), and welfare promotion.

Livestock probiotics commonly feature various strains of *Bacillus*, *Lactobacillus*, *Enterococcus*, and *Saccharomyces* yeast. There is still much to learn about their interactions with pathogens, but it is understood that certain strains of *Bacillus* have been proven to decrease growth of certain species of pathogenic bacteria including *E. coli*, *Clostridium*, *Streptococcus*, and *Salmonella*. Probiotics help prevent and control GI pathogens or improve the performance and productivity of livestock animals through various mechanisms. The selection of suitable probiotic strains is absolutely essential because such strains must not carry antibiotic resistance genes. Other genes that should, of course, be absent in probiotic strains are those that code for the production of toxins or compounds that can interfere in any way with an animal's well-being and productivity (Anadón et al. 2016; Joerger and Ganguly 2017).

A few genetically modified strains have been tested with the aim of improving animal performance. For example, *Lactococcus lactis* was engineered to express the epidermal growth factor EGF-LL in an effort to boost the performance of early-weaned piglets (Bedford et al. 2012), and the yeast *Pichia pastoris* was modified by the introduction of the *Clostridium perfringens* alpha toxin gene in an attempt to induce immunity against *C. perfringens* in broiler chickens (Gil de los Santos et al. 2012).

A suitable probiotic organism should be able to resist processing and storage, survive in the gastric acidic environment, adhere to the epithelium or mucus in the intestines, produce antimicrobial compounds, and modulate immune responses. However, not all probiotic strains exhibit all these properties and the most suitable probiotic strains or their combinations that will achieve maximum beneficial effect should be selected. Protection of probiotic organisms during their passage through the upper alimentary tract, such as a microencapsulation, should be considered to ensure viability and colonization in the intestine (Anadón et al. 2016b).

Probiotics or active microbials can help modulate the microflora, and slow-release butyrates can have a positive effect on intestinal integrity. Butyrate seems to have a positive influence on epithelial cells, leading to better epithelial cell proliferation and differentiation. Apart from better water and nutrient absorption, this leads to an improved barrier and pathogen control and seems positively to influence the immune system (Eeckhaut et al. 2008).

Probiotics are live organisms that, when ingested in sufficient quantities, transfer a health benefit to the host. Common probiotics include members of the *Lactobacillus* and *Bifidobacterium* genera and organisms such as *Saccharomyces cerevisiae*. Probiotic activity could be related to genera, species, or strains. The efficacy of single-strain and multi-strain probiotics for livestock has been investigated: the beneficial properties include removal or competitive exclusion of pathogens, enhanced immune system development and responsiveness, and production of beneficial compounds and metabolic by-products (Patterson and Burkholder 2003).

For probiotics, two main mechanisms of action have been suggested, summarized as follows: (1) nutritional effect, characterized by reduction of metabolic reactions that

produce toxic substances, stimulation of indigenous enzymes, and production of vitamins and antimicrobial substances; and (2) health or sanitary effects, distinguished by increase in colonization resistance, competition for gut-surface adhesion, and stimulation of the immune response (Guillot 2003); the latter effect acting as 'bio-regulators of the gut microflora' and reinforcing the host natural defences. In this latter mechanism there is an increase in cell-mediated immune response, TLR signalling, antibody production, and decrease of cellular apoptosis, among others (Khan et al. 2016). Host intestinal epithelial cells and dendritic cells have certain receptors [e.g., TLRs, nucleotide-binding oligomerization domain (NOD) proteins] activated by probiotic MAMPs such as fimbriae, flagellae, lipopolysaccharide, lipoteichoic acid, and peptidoglycan. Activation of these receptors leads to induction of signal transduction pathways in the host cell for transcription of genes coding for chemokines and cytokines, which can subsequently stimulate host systemic and mucosal immunity (Hardy et al. 2013). Interleukin 12 (IL-12), a proinflammatory cytokine, and interleukin (IL-10), an antiinflammatory cytokine, are of particular interest with respect to probiotics. Immunostimulatory probiotics induce IL-12 proliferation, which in turn increases the potency of NK cells and induces T-helper pathways. Immunoregulatory probiotics induce IL-10 proliferation, which then induces the T-regulatory pathway (Yaqoob 2014). Probiotics have also been known to alter the gut epithelial architecture. The mucus layer, composed of a class of glycoproteins known as mucins, forms the first line of host defence along with the gut epithelium. Studies have shown that certain probiotic species increase the expression of mucin 2 (MUC-2) and mucin 3 (MUC-3) genes, which code for the synthesis of mucins by goblet cells. Increased mucus production in the gut prevents the adherence and subsequent colonization of the intestinal epithelium by pathogenic bacteria (Hardy et al. 2013). Probiotics can also maintain the integrity of epithelial tight junctions by upregulating genes that code for junction proteins, which are responsible for tight junction signalling, as well as the restoration of mucosal integrity (Syngai et al. 2016). It was reported that *Lactobacillus rhamnosus GG* produced soluble proteins which protect the intestinal epithelial tight junctions and the barrier function from hydrogen peroxide-induced disruption by the activation of protein kinase C isoforms and the mitogen-activated protein kinase (MAPK)-dependent mechanism (Seth et al. 2008).

The delivery of certain living microorganisms during food animal production, with a variety of microorganisms used being LAB, various *Bacillus* species, and the yeast *Saccharomyces cerevisiae*, have been particularly used in the pig industry. The establishment of a beneficial LAB population at birth may lead to healthier animals: this may be most readily achieved by treating sows, which provides an amplification step and floods the neonatal pig environment with desirable bacterial strains (Kenny et al. 2011). Dietary supplementation with DFMs are used to promote health in livestock and poultry resulted in energy repartitioning to the immune system and an increase in antibody production independent of changes in whole-body metabolism or growth performance (Qiu et al. 2012).

Dietary feeding of probiotic-supplemented feed reduced intestinal inflammatory cytokine expression and enhanced growth performance in poultry (Higgins et al. 2011). Moreover, *Bacillus subtilis* strain PB6, provided as a powder preparation, may have preclinical antiinflammatory effects in an acute mice model, reducing symptoms of inflammatory bowel disease that are dependent on immunomodulatory responses (Foligné et al. 2012).

Probiotics would therefore have a role in the balance of gut microflora, increasing resistance to pathogenic agents, both through a strengthening of the intestinal barrier and by stimulating the immune system directly.

Competitive Exclusion Probiotics operate by "competitive exclusion," meaning that when adequate populations of probiotic bacteria are present, they reduce the ability of pathogenic bacteria to get out of control and overwhelm the host. The available probiotics can be classified into (1) 'colonising' species, such as *Lactobacillus* and *Enterococcus* spp., and (2) free-flowing 'noncolonizing' species, such as *Bacillus* spp. (spores) and *S. cerevisiae*. Competitive exclusion describes the treatment of day-old chicks with an undefined microbiota derived from adult animals, resulting in colonization resistance against pathogenic microorganisms (Huyghebaert et al. 2011).

Current feed additive products designed for microbiotal manipulation of food animals with live microorganisms (or with products directly derived from the culture of these organisms) fall into two categories. The predominant group (first category) attempts to improve or maintain animal health status under the conditions encountered in modern animal husbandry practices without making specific claims to target pathogens that are of concern to human health. The second category (smaller group) claims to establish or modify intestinal microbiota that have a direct measurable effect on pathogens of concern to humans, such as *Salmonella enterica* and *Clostridium jejuni*. The two categories are not mutually exclusive because healthier animals are expected to be less susceptible to colonization with certain human pathogens or to carry fewer of these pathogens. Similarly, the microbiota changes designed to inhibit food-borne pathogen colonization can also improve overall animal health and lead to gains in body weight. The number of probiotic products put on the market that claim to be directed against pathogens or are "competitive exclusion" products is exceedingly small compared to products that claim to improve FCR, growth, immune system function, or resistance to stressful events (Joerger and Ganguly 2017). The ecological definition of

"competitive exclusion" states that two species competing for the same resources cannot coexist stably. Therefore, one of the competitors will always dominate the other, leading to an evolutionary modification, a shift to another niche, or extinction. The intestinal microbiota competes with the colonizing pathogenic bacteria and can reduce the adhesion and colonization of pathogens in the intestine. This reduction might be a consequence of different mechanisms, perhaps the physical occupation of space, competition for resources in a given niche, or direct physical or chemical confrontation with the potential colonizer (Chaucheyras-Durand and Durand 2010; Clavijo and Vives Flórez 2018). In birds, competitive exclusion is the process by which favourable bacteria exclude bacteria that may be detrimental to the animal or that are of public health interest, such as *Salmonella* spp. The exclusion of *Salmonella* implies preventing the establishment of harmful bacteria in the gut. The aim is to provide, early in a bird's life, good bacteria having optimal ability to establish and maintain themselves in the gut environment. Thus, administering bacterial mixtures of *Salmonella* spp. from faecal or caecal sources of broiler chickens was more protective than administering single bacterial isolates or a combination of only a few isolates (Kerr et al. 2013). In practice, it is mainly used as a prophylactic measure aimed at increasing the resistance of chicks and poults to *Salmonella* infection. It does imply that the young birds being treated are *Salmonella* free, because the good bacteria are not likely to be able to displace *Salmonella* if it has had the opportunity to become established first in the gut. To achieve this, is imperative to administer the treatment immediately posthatch, before the chicks or poults can be exposed to *Salmonella* spp. The main mode of action of "competitive exclusion" is the establishment of a physical barrier (good bacteria culture attaching to the gut wall) between the intestinal wall and the lumen of the gut. Establishment of favourable bacteria increases the production of VFA and lactate, which lower the gut pH. The lower pH and high VFA concentration produces a hostile environment for unwanted bacteria, such as *Salmonella* spp. and *E. coli* (Lutful Kabir 2010).

4.1 Probiotic Application in Different Animal Species

The International Scientific Association for Probiotics and Prebiotics has defined probiotics "as a mixture of live microorganisms which when administered in adequate amounts confer a health benefit on the host" (Smith 2014). Before explaining the mechanisms and benefits provided by these microorganisms, it is important to specify why, if a microorganism is to be considered a probiotic, it should meet a range of requirements: (1) not pathogenic; (2) can adhere to epithelial cells; (3) can colonize and reproduce itself in the host; (4) able to survive passage through the GIT; (5) is resistant to gastric acidity and bile content; (6) produces metabolites that inhibit or kill pathogenic bacteria; and (7) has undergone trials in vitro and in vivo that demonstrate its benefits. Finally, a probiotic should remain viable under processing, production, and storage conditions (Kabir 2009). The following benefits are expected from administering probiotics (Syngai et al. 2016): (1) stimulation of the development of beneficial microbiota; (2) reduction and prevention of colonization by enteric pathogens; (3) modulation of immunological activity; (4) stimulation of epithelial health; (5) increased digestive capacity; and (6) aid in maturation of intestinal tissue. Probiotics can influence the immune system both directly and indirectly. Direct influence is exerted by different species of *Lactobacillus* that increase cytokine and antibody levels (Haghighi et al. 2006; Brisbin et al. 2011).

Poultry

Numerous probiotic strains have been tested for use for poultry to improve performance, prevent pathogenic colonization, and improve immunity. Probiotics such as *Lactobacillus johnsonii*, *Bacillus subtilis,* and a multi-strain *Lactobacillus johnsonii* FI9785 modified the intestinal microbiota by reducing levels of pathogenic bacteria such as *Salmonella enteritidis* and *Clostridium perfringens* in neonatal broiler chicks (La Ragione et al. 2004; Higgins et al. 2008). Also, a multi-strain probiotic significantly increased the numbers of lactobacilli and bifidobacteria in the caeca of broiler chickens (Mountzouris et al. 2007).

Probiotics for poultry may contain one or more strains of microorganisms and may be given either alone or in combination with other additives in feed or water. The use of probiotics in broiler chickens to control *Salmonella* spp. was effective when hatched chicks were fed a suspension of the intestinal contents of adult chickens (Nurmi and Rantala 1973). However, this first proposed use of "probiotic" proved to have serious limitations, principally the potential transfer of diseases along with the beneficial microorganisms. For this reason, subsequent research has focused on developing defined probiotics capable of being cultivated and administered as pure cultures (Smith 2014). A range of probiotics has been developed, obtained in various ways and for which dosage and time in the cycle in which they are administered also varies. Novel application strategies such as spraying the probiotic on chicks or embryonated eggs are also studied, and potential methods such as in ovo application are being evaluated (Cox and Dalloul 2015).

A variety of bacteria species (*Bacillus*, *Bifidobacterium*, *Enterococcus*, *Lactobacillus*, *Streptococcus*, and *Lactococcus* spp.) and yeast species (*Saccharomyces* spp.) have been tested and used as probiotics in poultry. The majority of the conducted research was specifically aimed at investigating the effects of probiotics in reducing the numbers of pathogenic microorganisms in the GIT. However,

a considerable amount of research also examined the effects of probiotics on improving growth and performance in poultry without apparent disease. Supplementation of diets with a single strain of *Lactobacillus* sp. (*L. casei*, *L. fermentum*, *L. bulgaricus*, *L. reuteri*) was shown to improve body weight and feed efficiency in broiler chickens. Similar results were shown when broiler chickens were given multiple strains of *Lactobacillus* sp. Probiotics based on *Bacillus* sp. (*B. coagulans*, *B. subtilis*, *B. licheniformis*, and *B. amyloliquefaciens*) were also successfully employed in poultry diets and shown to have growth-promoting effects.

Different trial studies have shown that chickens treated with probiotics produce a greater number of antibodies in response to a given antigen (Brisbin et al. 2010). Probiotics may also have indirect effects, promoting the growth of other bacteria. For example, *Lactobacillus agilis* and *Lactobacillus salivarus* can stimulate butyrate-producing microbiota and reestablish microbiota balance (Meimandipour et al. 2009). Another benefit of probiotics is competing with pathogenic microorganisms such as *Salmonella*, *Enterobacter sakasaki*, and *Clostridium difficile*, which have a high capacity of adhesion to the intestinal mucosa (Collado et al. 2005).

Strains of probiotics that help to reduce these levels of adhesion include bacteria of the genera *Bifidobacterium* (Collado et al. 2005) and *Lactobacillus* (Servin and Coconnier 2003). However, this ability is highly dependent on the source of the microorganism, as bacteria from the intestines of chickens show a greater capacity to adhere to the mucosa and, therefore, to displace pathogenic microorganisms (Collado et al. 2005).

The inhibitory effects of probiotic bacteria on undesirable microorganisms might result from the production of metabolites such as hydrogen peroxide (H_2O_2), diacetyl, bacteriocins, and organic acids. A purified bacteriocin produced by *Lactobacillus salivarius* NRRL B-30,514 was used to treat chickens, causing a clear reduction in the numbers of *C. jejuni* in their intestines (Stern et al. 2006). Other compounds that assist in the exclusion of human pathogenic microorganisms are organic acids such as lactic, acetic, or propionic acid, which diminish pH levels in the intestine and reduce the speed of pathogen multiplication (Blajman et al. 2015).

The effectiveness of probiotics depends on several factors, such as the composition of the mixed rations, the time when they are administered, and the origin of the microorganisms. It seems that the effectiveness of probiotic cultures is greater when they contain a larger number of genera (Chambers and Gong 2011). Similarly, origin affects effectiveness, as strains that come directly from chicken intestines are more effective than those from other sources. Additionally, the probiotic composition may be beneficial for one breed of chicken but not for others. Another factor affecting the effectiveness of probiotics is the time point at which they are administered. When probiotics are administered at an early stage of the cycle they will have positive effects only up to week 6, showing greater diversity and abundance of *Lactobacillus* and a significant reduction in the presence of chicken pathogens compared to the control (Nakphaichit et al. 2011). It has also been suggested that the administration of probiotics has a greater effect on pathogenic microorganisms following a change in diet or after antibiotic therapy (Zulkifli et al. 2000).

Lactobacillus is the most commonly used probiotic; its reported benefits include increased weight gain, improved feed utilization effectiveness, and reduction in mortality (Zulkifli et al. 2000; Kalavathy et al. 2003; Timmerman et al. 2006). The probiotic model has been used widely in broiler chickens for the control of *Salmonella*, and it has been reported that employment of these cultures led to reductions in colonization by this pathogen, an effect that is also correlated with increased weight gain and improved conversion of feed into body mass (Chambers and Gong 2011).

Pigs

Weaning as currently practised is one of the most critical periods for pigs, being characterized by a drop in food consumption, leading to severe anorexia, increased susceptibility to digestive disorders, growth delays, and microbial infections. The change in food substrate also leads to significant changes in the functionality of the intestine. *Saccharomyces cerevisae* yeasts, their cell walls or extracted fractions (mannan-oligosaccharides, β-glucans), seem to constitute positive alternatives. Their use in porcine diets can contribute to improving growth performance, stimulating the immune system, maintaining the balance of digestive microflora, and preventing bacterial adhesion to intestinal epithelial cells. Yeasts or yeast products might be potential alternatives to antibiotic growth promoters for swine.

The effect of including the yeast *S. cerevisiae* or its cell wall fraction in diets for weanling piglets for growth performance, nutrient utilization, and some morphological and immunological parameters has been evaluated. Two diets were supplemented with 1 g/kg of live yeast or yeast cell walls for an experiment lasting 5 weeks. Overall, increases in weight gain and in final body weight were observed, and the feed:gain ratio tended to improve with yeast diets. The inclusion of yeasts or yeast cell walls reduced the number of intraepithelial lymphocytes, and increased VFA production and the percentage of acetate, having beneficial effects on the productive performance of piglets after weaning (Lizardo et al. 2008).

Effects of *S. cerevisiae* [strain CNCM I-4407, 10(10) cfu/g] has been studied on postweaning diarrhea, immune response, and growth performance in weaned piglets orally challenged with enterotoxigenic *Escherichia coli* strain O149:K88. The live yeast was fed to sows and their piglets

in the late gestation, suckling, and postweaning periods. Sows were fed a basal diet without or with supplementation (i.e., 1 g/kg of live yeast) from day 94 of gestation and during lactation until weaning of piglets (day 28). Suckling piglets of the supplemented sows were orally treated with 1 g live yeast in porridge carrier three times a week until weaning. Weaned piglets were fed a basal starter diet without or with supplementation (i.e., 5 g of live yeast/kg feed for 2 weeks). Significantly lower daily diarrhea scores, duration of diarrhea, and shedding of pathogenic *E. coli* bacteria in faeces were detected in the supplemented piglets. Administration of live yeast significantly increased IgA levels in piglet serum. Evidence indicates that decreased infection-related stress and decreased severity of diarrhea in yeast-fed weaned piglets positively affected their growth capacity in the postweaning period. Thus, dietary supplementation with live yeast *S. cerevisiae* to sows and piglets in late gestation, suckling, and postweaning periods can be useful in the reduction of the duration and severity of postweaning diarrhea caused by *E. coli*. Decreased infection-related stress and severity of diarrhea in yeast-fed weaned piglets can positively affect growth performance in the pre-weaning period. The results from this study suggest that live yeast *S. cerevisiae* (strain CNCM I-4407) could be an alternative for prevention and treatment of postweaning diarrhea. In addition, *S. cerevisiae* can decrease inflammatory responses induced by F4+ enterotoxigenic *E. coli* in porcine intestinal epithelial cells.

Enterotoxigenic *E. coli* are pathogenic gram-negative bacteria that infect several species of farm animals, including pigs. Enterotoxigenic *E. coli* infection and enterotoxic secretion can induce intestinal inflammation and diarrhea, resulting in reduced growth rate, increased mortality, and economic loss (Fairbrother et al. 2005). Probiotic yeasts may provide protection against intestinal inflammation induced by enteric pathogens. In piglets, infection with F4+ enterotoxigenic *E. coli* causes inflammation, diarrhea, and intestinal damage. The yeast strains *S. cerevisiae* (strain CNCM I-3856) and *S. cerevisiae* var. *boulardii* (strain CNCM I-3799) were investigated for decreased expression of pro-inflammatory cytokines and chemokines in intestinal epithelial IPI-2I cells cultured with F4+ enterotoxigenic *E. coli*. Results showed that viable *S. cerevisiae* inhibited ETEC-induced TNF-α gene expression whereas *Saccharomyces boulardii* did not. In contrast, killed *S. cerevisiae* failed to inhibit the expression of pro-inflammatory genes: this inhibition was dependent on secreted soluble factors. *S. cerevisiae* culture supernatant decreased the TNF-α, IL-1α, IL-6, IL-8, CXCL2, and CCL20 enterotoxigenic *E. coli*-induced mRNA. Furthermore, the *S. cerevisiae* culture supernatant filtrated fraction at 10 kDa displayed the same effects, except for TNF-α.

Inclusion of *Lactobacillus sobrius* in pig diets may be significantly effective in the reduction of *E. coli* F4 colonization and may improve the weight gain of infected piglets (Konstantinov et al. 2008). Also, a multi-strain probiotic containing *L. acidophilus*, *L. bulgaricus, B. subtilis*, and *S. cerevisiae* significantly increased ileal and colonic bifidobacteria levels and decreased the levels of colonic coliforms.

Ruminants

The yeast *S. cerevisiae* has been used as an alternative to antimicrobial feed additives in ruminants for more than 15 years. Production responses showed improved live weight gain in beef cattle and increased milk yield and fat production in dairy cows. However, responses were highly variable and apparently influenced by diet composition and animal physiological stage. The yeast is generally available in two different DFM forms: yeast culture products and live yeast cell products. Ruminant animals, including cattle, sheep, and goats, principally depend on microbial degradation of their feed rather than on direct enzyme degradation, as in most non-ruminants. The enlarged foregut of ruminant livestock (reticulorumen) allows a large and diverse microbial population to gain access to feedstuff before the products of this fermentation and the microbial cells enter the absorptive regions of the GIT (Russell 2002).

The rumen is a symbiosis pathway between the ruminant host and microbes. It is known that microorganisms are involved in the animal host in supplying protein, vitamins, and short-chain organic acids. In the cattle rumen, for example, live yeast can improve milk yield and weight gain by microbial activity stimulation, although this stimulation might depend on certain microbial species. Cattle feed supplemented by live yeast *S. cerevisiae* Sc47 (0.5 or 5 g/day) modifies bacterial diversity and population and changes in the fermentation pattern and physicochemical parameters in the rumen which can modify microbiota composition. In this study the improvement of zootechnical parameters goes together with a shift in the mannin fibrolytic group (i.e., *Fibrobacter* and *Ruminococcus*) (Pinloche et al. 2013).

Early-lactation high-producing dairy cows have a nutrition strategy with the objective to provide adequate energy and rumen-undegraded protein to support high requirements in regard to milk production increase; most of the time, cows are in negative energy balance (Julien et al. 2015). Therefore, it should be important to use live yeast as a feed additive for the dietary rumen-degradable protein level, increasing the feed energy with a certain amount of grain (Julien et al. 2015).

Inclusion of live yeast stabilizes the rumen environment through higher pH values and enhances fibre digestion (Campanile et al. 2008). These key results certainly explain why the impact of live yeast supplementation has been studied primarily on energetic metabolism, in relationship to the dietary forage:concentrates ratio (Lascano et al. 2009). The

consensus was that the effects of live yeast were enhanced when animals consumed a highly concentrated diet or during an abrupt dietary transition (Chaucheyras-Durand et al. 2008). However, some studies have considered the potential effect of live yeast on ruminal ammonia nitrogen metabolism, more specifically on protein degradation or microbial proteosynthesis. In studying the interaction between live yeast and dietary rumen-degradable protein level, Julien et al. (2015) concluded that the rumen-degradable protein content of diet-fed lactating dairy cows could directly impact the acidogenic capacity of the diet: tanned soybean meal was less acidogenic than soybean meal when used as the main protein source. The positive effect of live yeast on ruminal pH in cows receiving a highly acidogenic diet and therefore suffering from subacute ruminal acidosis (SARA) is already known, as live yeast could modulate dietary N digestion in early-lactating dairy cows whose diet had an inadequate rumen-degradable protein content. In fact, live yeast seemed to have a post-ruminal effect on N digestibility even more pronounced than the quantity of bypass N, that is, with sources of protected dietary protein. In both cases, live yeast used as a dietary feed additive permits a better utilization of diet in dairy cows (Julien et al. 2015), and, moreover, increased ruminal total VFA.

Heat stress negatively affects the productivity and longevity of dairy cows. Heat stress has reduced intake and increased reliance on glucose, so feeding strategies capable of improving diet digestibility are plausible for improving post-rumen nutrient flow and performance. Advances in management such as cooling systems and nutrition strategies may attenuate the negative effects of heat stress, but the economic loss from reduced milk production, reproductive efficiency, and animal health during warm seasons is a major issue for the dairy industry worldwide (St. Pierre et al. 2003). The effect of live yeast (*S. cerevisiae*) on digestion and performance of lactating cows during the warm summer months of southeastern Brazil was evaluated (Salvati et al. 2015) using treatments with *S. cerevisiae* equivalent to 25×10^{10} cfu of live cells and 5×10^{10} cfu of dead cells top-dressed to the diet in the morning. A trend was observed for increased plasma glucose with yeast (62.9 vs. 57.3 mg/dl), lowered respiratory frequency (48 vs. 56 breaths/min), and increased plasma niacin content (1.31 vs. 1.22 μg/ml), although the cows had similar rectal temperature. Ruminal lactate and butyrate as proportions of ruminal organic acids were reduced by yeast. Plasma urea nitrogen was increased by yeast over 24 h. Yeast treatment produced a higher blood pH compared with the control, 7.34, and 7.31, respectively. Yeast supplementation improved the lactation performance of dairy cows under heat stress, although this improvement apparently involved regulation of body homeothermia rather than improved digestibility (Salvati et al. 2015).

In high-yielding dairy cows, live yeast *S. cerevisiae* differs from sodium bicarbonate to stabilize ruminal pH (Marden et al. 2008). Early-lactating Holstein cows were supplemented with 150 g/day of sodium bicarbonate or 5 g/day of live yeast during a 21-day experimental period. Total VFA, acetate, and propionate were greater with both additives, but butyrate remained constant; and mean total lactate concentrations decreased 67% with *S. cerevisiae*. The conclusion was *S. cerevisiae* prevented accumulation of lactate and allowed better fiber digestion, whereas sodium bicarbonate seemed to act only as an exogenous buffer.

Moreover, a bio-energetic–redox approach to the effect of *S. cerevisiae* on ruminal pH during induced SARA in dairy cows was described by Marden et al. (2013). The capacity of *S. cerevisiae* at 4 g/cow/day in optimizing ruminal pH was evaluated to understand its mode of action during induced acidosis in the cows. The beneficial effects of live yeast on concentrations of VFA and proportion of propionate in ruminal fluid were higher compared to the control diet. The proportion of butyrate decreased, from 15.8% to 14.2% total VFA, and lactate concentration decreased by 55% on average. Stabilization of ruminal pH (>6) is the outcome of *S. cerevisiae* ability to scavenge oxygen after feeding a high-starch diet. Live yeast seems to act on the reducing power of the ruminal milieu by decreasing oxygen partial pressure and thereby enhancing the activity of anaerobic bacteria.

Horses

Intensive management practices in the horse industry present a unique challenge to the microbiome of the large intestine. Common management practices such as high-concentrate diets, low forage quality, meal feeding, and confinement housing have an impact on intestinal function, specifically large intestinal fermentation. The microbiome of the equine large intestine is a complex and diverse ecosystem, and disruption of microbiota and their environment can lead to increased incidence of GI disorder. In horses, whose targeted digestive compartment is the caecum-colon, probiotic distribution appears particularly relevant in case of stress (e.g., transportation) or during distribution of a high-concentrate diet (Coverdale 2016). Research concerning the use of probiotics in horses to improve hindgut fermentation and diet digestibility has been limited. Most studies used live yeast culture (*S. cerevisiae*) supplemented to a variety of diets. Despite a lack of evidence for colonization with the supplemented strain of *S. cerevisiae*, improvements in cell wall digestibility were evident regardless of diet. In particular, when added to high-starch diets, *S. cerevisiae* supplementation appears to mitigate some of the disruptions, such as reduced fiber digestibility, that occur in the hindgut. Maintenance of fiber digestion is of particular interest when horses consume high-concentrate diets for the purpose of athletic

performance or maximum production (lactation, growth, etc.).

Probiotics, or direct-fed microbials, have been widely used in horses for treatment and prevention of GI disease. Introduction of these live, beneficial microorganisms orally into the intestinal tract has yielded variable results. However, it is difficult to compare data because of variations in choice of organism, dosage, and basal diet. Although there are still many unanswered questions about the mode of action of successful probiotics, evidence indicates competitive inhibition and enhanced immunity. A variety of microbial species have been tested in the horse as probiotics, such as *Lactobacillus* spp., *Enterococcus* spp., *Bifidobacterium* spp., and *Saccharomyces* spp. (Coverdale 2016). Diets containing *Lactobacillus acidophilus* had limited effects either on reducing the risk of acidosis associated with feeding high-starch concentrates to horses or on nutrient digestibility. Live yeasts have been demonstrated to elicit an increase in fibre digestibility in the colon and to modulate the balance of hindgut bacterial communities, with a decreased risk of lactic acidosis (Jouany et al. 2008). Use of these products has resulted in improved fibre digestibility in horses offered both high-starch and high-fibre diets.

Rabbits

Intensive breeding of rabbits can alter the environment, causing physiological stress, and increasing the frequency of enteric diseases, subsequently causing high mortality and decreased reproductive and productive performance of rabbit does (Combes et al. 2013). Application of probiotics as dietary supplements could control enteric diseases. Thus, some probiotics exert a barrier effect against pathogenic microorganisms by preventing their development and colonization within the digestive tract (Vanderpool et al. 2008). The most frequently examined microorganism related to probiotics has been *S. cerevisiae* yeast, known to improve growth performance in cross-breed rabbits. The effect of live yeast supplementation in the diet of rabbit does on their mortality and reproductive performance and the performance of their progeny was studied in two groups differing in diet during two reproductive cycles. Natural mating was performed 11 days after kindling and kits were weaned at 28 days of age. The addition of 1 g *S. cerevisiae*/kg of diet enhanced fertility and reduced mortality of rabbit does, while improving the viability rate of kits at birth; no difference was observed during the second lactation. However, diet supplemented with the tested probiotic had no effect on other reproductive performance traits in rabbit does (Belhassen et al. 2016).

Dogs and Cats

Lactobacillus spp. and *Enterococcus* spp. were studied as probiotics for dogs and *Bifidobacterium* spp. for cats.

Aquaculture

Probiotics intended for aquatic usage must take into account the relationship an aquatic organism has with its direct environment. Gram-negative facultative anaerobic bacteria are dominant in fish and shellfish digestive tracts; however, the intestinal microbiota may often change with the intrusion of microbes from water and food (Chaucheyras-Durand and Durand 2010). Thus, a large number of probiotics developed in aquaculture probably are bacteria directly originating from the aquatic environment. However, most probiotics commonly used in aquaculture are prokaryotic bacteria or yeast such as *Lactobacillus* spp., *Pediococcus* spp., *Bacillus* spp., *Vibrio* spp., and *S. cerevisiae*. Yeast species have also been used as probiotics and for delivery of enzymes in animal feeds. A number of eukaryotic microorganisms are able to survive passage through the acidic conditions and bile salts of the GIT to the intestine. Because these microorganisms may be beneficial for host health, feed utilization, and growth performance, they could also be used as alternative probiotics. Probiotics can target fish eggs and larvae, fish juveniles and adults, crustaceans, bivalve mollusks, and also live food such as rotifers, *Artemia*, or unicellular algae (Verschuere et al. 2000). Growth-promoting effects through better feed utilization and digestion, as well as biological control of pathogen colonization, are the most important expected benefits of probiotic applications (Chaucheyras-Durand and Durand 2010). Disease outbreaks caused by *Vibrio* spp. or *Aeromonas* spp. have been recognized as a significant constraint on aquaculture production (Verschuere et al. 2000), particularly in the shrimp subsector, where vibriosis is currently one of the main diseases identified (Castex et al. 2008). Some probiotics have been shown to protect rainbow trout against skin infections caused by *Aeromonas bestiarum* and a eukaryotic pathogen, *Ichthyophthirius multifiliis* (Pieters et al. 2008).

The effects of dietary probiotic *S. cerevisiae* microencapsulated with guar gum in the striped catfish (*Pangasianodon hypophthalmus*) for a 120-day culture period demonstrated that *S. cerevisiae*-supplemented diets significantly improved growth performance, including growth rate and FCR. *S. cerevisiae* had no effects on hematological parameters and blood chemistry but increased the humoral immune parameters including total immunoglobulin, lysozyme, and alternative complement activities (Boonanuntanasarn et al. 2018).

In Asian sea bass, the mixture of *L. casei* M15, *L. plantarum* D8, *L. pentosus* BD6, *L. fermentum* LW2, *Enterococcus faecium* 10–10, *B. subtilis* E20, and *S. cerevisiae* P13 improved either growth performance or disease resistance. A diet containing 10^9 cfu (kg diet)$^{-1}$ probiotic mixture is recommended to improve the growth and health status of Asian sea bass (Lin et al. 2017).

The effects of dietary substitution of fishmeal with live yeast, *S. cerevisiae*, and increasing water temperature on the

diversity and composition of gut microbiota of rainbow trout were described. The trout were reared in water temperatures of either 11 °C (cold) or 18 °C (warm) for 6 weeks. Feeding live yeast mainly increased yeast load in the trout gut, whereas increased water temperature significantly altered the bacterial diversity and abundance of the gut microbiota. Live yeast can replace 40% of fishmeal without disrupting bacteria communities in the gut of rainbow trout, although increased water temperature from seasonal fluctuations or climate change may cause a gut dysbiosis that jeopardizes farmed fish health (Huyben et al. 2018).

Honey Bee

Honey bees (*Apis millifera*), as pollinators in agriculture, have a critical role in global food production. Worldwide, 75% of the crops traded on the global market depend on pollinators to some degree. Bees are often the most important crop pollinators and honey bees are the pollinators most widely used. Studies show that a diversity of pollinators can improve crop yield or fruit quality. Restoring and maintaining pollinator diversity is thus very important for agriculture as well as for natural vegetation. Recently, honey bee populations in the US, Canada, and Europe have suffered unexplained annual losses from a phenomenon known as "colony collapse disorder." Several members of the *Apis mellifera* microbiota (*Acetobacteriaceae*, *Bifidobacterium*, *Lactobacillus*, *Simunsiella*) produce SCFA such as lactic and acetic acids as waste products during the metabolism of carbohydrates (Vasquez et al. 2012). Honey bees possess an abundant, diverse, and ancient LAB microbiota in their honey crop with beneficial effects for bee health, defending them against microbial threats. This microbiota will become central to studies on honey bee health, including colony collapse disorder, and act as an exemplar case of insect–microbe symbiosis. Honey bee species plus related apid bees show one of the largest collections of novel species from the genera *Lactobacillus* and *Bifidobacterium* ever discovered within a single insect, suggesting a long (>80 million years) history of association. Bee-associated microbiota highlight *Lactobacillus kunkeei* as the dominant LAB member. Prophylactic practices that enhance LAB, or supplementary feeding of LAB, may serve in integrated approaches to sustainable pollinator service provision (Vasquez et al. 2012).

SCFA can be absorbed through the rectal wall in insects, and the majority of the pollen and bacterial biomass within an adult *A. mellifera* is contained inside the rectum (Bradley 2008). Overwintering *Apis* may obtain additional nutrition from these rectal bacteria, as consumed food is stored for longer periods of time within the rectum during winter months (Lindström et al. 2008). The probiotics *Lactobacillus* and *Bifidobacterium* have evolved in synergy with bees and are important in defending their host.

5 Synbiotics

A synbiotic is a combination of one or more probiotics and prebiotics. Prebiotics may enhance the survival of probiotic strains, as well as stimulating activity of the host endogenous bacteria. Synbiotics are additives that combine the use of probiotics and prebiotics such that they act synergistically (Alloui et al. 2013). The use of synbiotics was based on the concept that a mixture of probiotics and prebiotics beneficially affect the host by improving the survival and implantation of probiotic organisms and by selectively promoting the growth or metabolism of beneficial bacteria in the intestinal tract (Gibson and Roberfroid 1995). It was suggested that clinical effects vary from modest to significant from a single strain of probiotics < multi-strain probiotics < or < single-strain/single-fiber synbiotics < multi-strain/multi-fiber synbiotics. A combination of a prebiotic and probiotic, termed a synbiotic, is thought to exert synergistic effects to maintain gut health. Specifically, the probiotic fraction is thought to promote the growth of pathogenic bacteria. Moreover, synbiotics help to reduce the concentration of undesirable metabolites, including nitrosamines, to inactivate carcinogens, and to prevent constipation and diarrhoea of diverse aetiology in human beings (Bengmark and Martindale 2005). Compared with the use of individual components, synbiotics seem to modulate beneficially the composition of the gut microbiota by increasing beneficial bacteria (i.e., lactobacilli and bifidobacteria) and reducing other less desirable bacteria (i.e., coliforms, enterococci) (Modesto et al. 2011).

Poultry

Few research trials have been conducted to demonstrate the effects of synbiotics on broiler chicken performance. Supplementation of diets with a synbiotic product compared with basal diets supplemented with probiotic (homofermentative and a heterofermentative *Lactobacillus* sp.) was shown to significantly improve body weight, average daily gain, feed efficiency, and carcass yield percentage of synbiotic products compared with controls or probiotic-fed broiler chickens (Awad et al. 2009). Synbiotics were also shown to beneficially alter their intestinal microbiota composition and increase villi height and crypt depth in the intestinal mucosa. The increase in the villus height and villus height:crypt depth ratio was associated with improvement of growth performance for both synbiotics and probiotics (Awad et al. 2009). Significant increase in weight gain and a decrease in the FCR was reported when birds were fed diets with a combination of IOS and a multi-strain probiotic (consisting of 11 strains of *Lactobacillus* spp.). A combination of these dietary additives as a synbiotic on caecal bacterial populations and concentrations of caecal volatile fatty acids

and nonvolatile fatty acids of broiler chickens were also evaluated (Mookiah et al. 2014).

Dogs and Cats

There are sparse data on the use of synbiotics in dogs and cats. In one study, the effect of a multispecies symbiotic on the faecal microbiota was investigated in healthy dogs and cats (Garcia-Mazcorro et al. 2011). The symbiotic (containing 5×10^9 colony-forming units of a mixture of seven probiotic strains and a blend of FOS + arabinogalactans) was fed daily for 21 days, with changes in faecal microbiota analysed by culture-independent analyses targeting 16S rRNA bacterial genes (e.g., 454-pyrosequencing). Synbiotic ingestion led to increased abundance of some probiotic species in the faeces; however, no significant changes in bacterial species composition were identified.

Aquaculture

One example of synbiotics in aquaculture is the combination of prebiotic oligosaccharides and probiotic bacteria. An evaluation of the acute-phase response in rainbow trout (*Oncorhynchus mykiss*) fed functional diets supplemented with pre- and probiotics (i.e., mannan-oligosaccharides and *S. cerevisiae*, respectively) and challenged by either *Vibrio anguillarum* or chronic stress via maintenance under high stocking densities suggests that both supplements have high immunostimulatory potentials for farmed fish. In juvenile rainbow trout (*Oncorhynchus mykiss*) fed functional diets supplemented with either pre- or probiotics (0.6% mannan-oligosaccharides and 0.5% *S. cerevisiae*, respectively) or the mixture of both shows a dynamic shift of the microbiome composition and the microbiome modulation dynamics by functional diets based on mannan-oligosaccharides (Goncalves and Gallardo-Escarate 2017).

In Nile tilapia (*Oreochromis niloticus*), encapsulated and freeze-dried *S. cerevisiae* JCM 7255 improved intestinal structure and growth performance. Intraepithelial lymphocytes in the proximal intestine were significantly greater than in the control, and reduced cumulative mortality after the oral streptococcal challenge was also seen (Pinpimai et al. 2015).

In juvenile pacu (*Piaractus mesopotamicus*) stressed and experimentally infected with *Aeromonas hydrophila*, the efficacy of a commercial product (Glucan-MOS®) derived from the yeast *S. cerevisiae*, containing two combined products, β-1,3- or 1,6-glucans and mannans, fed during 30 days, in periods before intensive management, improved growth and innate immunity. The supplementation of 0.1% Glucan-MOS® improved weight gain, feed conversion, and the protein efficiency ratio compared to a control diet. The 0.2% and 0.4% Glucan-MOS® diets were sufficient to increase the respiratory burst of leukocytes and lysozyme activity, the number of thrombocytes, neutrophils, and monocytes in the blood after stressful handling and bacterial challenge, and minimized stress response as shown by decreased cortisol and glucose levels when compared to the control. The 30-day period was sufficient to stimulate growth performance, improve nutrient utilization, minimize stress response, and modulate innate immunity responses (Pereira Soares et al. 2018).

6 Concluding Remarks and Future Directions

There is great potential for the use of prebiotics and probiotics as alternatives to antibiotics to improve performance and reduce pathogenic load in the intestines of animals. The intestinal microbiota is complex and it is not clear how bacteria provide benefit to the host. Modulation of the intestinal bacteria towards a "healthy" community by specialty carbohydrates supporting beneficial bacteria (so-called prebiotics) or by feeding live bacteria (so-called probiotics) is currently undergoing active research. Microbial community analysis has become more accurate, providing reliable data that bacteria in the GIT can be modulated in a number of ways. Although the mechanisms by which antibiotics enhance health and productivity have not been fully elucidated, new research tools, for example, metagenomics and other genome-enabled technologies, may provide new ways to elucidate the ecology of the gut microbiome, host–pathogen interactions, immune development, nutrition, and health. Careful consideration must be given when selecting combinations of prebiotics and probiotics to be used as synbiotics, and research trials should be conducted according to the guidance approved by the regulatory authorities to demonstrate their synergistic effect compared with the use of either product alone and depending on the intended use, and finally according to the quality, efficacy, and safety requirements. The inclusion of specific prebiotics will not be of any benefit without the presence of the targeted, beneficial bacteria products and will not succeed if the environment into which they are introduced is unfavourable. The growth enhancement and health improvement of domestic animals achieved by promoting the growth of certain microbes in the GIT with prebiotics or probiotics is a beneficial and rational strategy, but their use in some production systems such as aquaculture is just beginning. Limited research concerning the use of probiotics in horses to improve hindgut fermentation and diet digestibility also produced contrasting results. Probiotic bacteria have a positive effect on GI function on different species. Yeast species have also been used as probiotics, and for delivery of enzymes in animal feeds; development of genetically engineered yeast and bacterial cells expressing new

substances as antibacterials may have potential as probiotics (Biliouris et al. 2012). In many of these studies it is unclear how much of the positive response obtained with probiotics can or should be considered in the context of their effect on preventing health problems of improving health and welfare and how much to their direct effect on diet utilization. These approaches have been utilized in production systems of food animals for promoting health, but assessing their effectiveness and mechanisms of action is needed. The target of such nutraceutical products is to improve GI health by selecting for beneficial microflora and suppressing known intestinal and food-borne pathogens. If the growth requirements of the bacteria differ, it is possible in theory to shift the microbial community from harmful to nonharmful bacteria by changing the diet and consequently the gut dynamics. Specific species can be selected for resistant feed components, which escape digestion by the host but are readily available for the metabolic machinery of the target microbes. Direct-fed microbials (probiotics) are targeted to improve GI health, but these are likely to be effective only if their growth requirements are fulfilled. In fact, a synbiotic product, which contains both a probiotic strain and a prebiotic favouring the growth of that strain, may be a good solution in many cases.

Synbiotics in Animal Health and Production

Jitendra K. Malik, Atul Prakash, Anil K. Srivastava, and Ramesh C. Gupta

Abstract

This chapter describes the current knowledge on the effects of synbiotics on the health and performance of farm and companion animals. The mechanism of action, beneficial effects, and demonstrated study results proving the efficacy of synbiotics in poultry, cattle, pigs, and companion animals are presented. Synbiotics are now being considered important tools to help maintaining animals in good health and improving growth performance. The majority of studies dealing with synbiotics have been conducted in poultry, but increasing research has been focused on other animal species. The administration of synbiotics in animals is favorable for the beneficial intestinal microbiota which play several and significant roles including production of various nutrients for their host, prevention of infections caused by intestinal pathogens, and modulation of immunological response. Thus, modification of the microorganisms present in the gastrointestinal tract in order to attain, restore, and maintain positive balance in the ecosystem and activity of the intestinal microbiota is essential for the improvement of health and performance of animals. Synbiotics comprising of both most appropriate probiotic microorganisms and synergistic prebiotics may be still more effective and beneficial for animal health and production.

Keywords

Synbiotic · Animal · Gut microbiota · Health · Performance

1 Introduction

Synbiotics are generally considered as nutritional supplements combining probiotic and prebiotic in a form of synergism. Thus, a synbiotic product can enhance the isolated beneficial effects of probiotic and prebiotic. Probiotics are defined as live strains of strictly selected microorganisms which, when administered in adequate amounts, confer a health benefit on the host (FAO 2002). Probiotics are nonpathogenic microorganisms which favor the growth of beneficial intestinal bacteria over that of harmful ones. Prebiotics are nondigestible food ingredients that beneficially affect the health of host by selectively stimulating the growth and/or activity of a selected group of microorganisms living in the colon. An important basis for using a synbiotic is that a true probiotic uses the prebiotic as a food source that facilitates in extending the survival of probiotic microorganisms in the digestive system which would not be possible without otherwise. Without the necessary food source for the probiotic, it will have a greater intolerance for oxygen, low pH, and temperature. By harnessing both the advantages of the prebiotics and probiotics into synergy, the number of good microorganisms increases many folds in the digestive system (Sekhon and Jairath 2010; Malik et al. 2016). Thus, a suitable combination of both probiotic and prebiotic in a single product should ensure a better effect, compared to their alone activity. In addition to the improved survival of beneficial microorganisms added to food or feed, synbiotics also stimulate proliferation of specific native bacterial strains present in the gastrointestinal tract (Gourbeyre et al. 2011). The health effects of synbiotics may be associated with the individual combination of a probiotic and prebiotic. Taking into account a large number of possible

combinations, the application of synbiotics for the modulation of gut microbiota in humans and animals appears promising (Scavuzzi et al. 2014; Kearney and Gibbons 2018; Markowiak and Śliżewska 2018).

Some of the widely used probiotic microorganisms include *Lactobacillus rhamnosus*, *Lactobacillus reuteri*, bifidobacteria, and certain strains of *Lactobacillus casei*; *Lactobacillus acidophilus* group; *Bacillus coagulans*; *Escherichia coli* strain Nissle 1917; certain enterococci, particularly *Enterococcus faecium* SF68; and the yeast *Saccharomyces boulardii*. Lactic acid bacteria (LAB) including species of *Lactobacillus* serve both as agents of food fermentation and potentially impart health benefits (Pandey et al. 2015; Malik et al. 2016). Probiotic microorganisms contained in feed supplements for use in animals include *Lactobacillus* sp. (*L. brevis*, *L. casei*, *L. crispatus*, *L. farciminis*, *L. fermentum*, *L. murinus*, *L. gallinarum*, *L. paracasei*, *L. pentosus*, *L. plantarum*, *L. reuteri*, *L. rhamnosus*, *L. salivarius*), *Bifidobacterium* sp. (*B. animalis*, *B. longum*, *B. pseudolongum*, *B. thermophilum*), *Enterococcus faecalis*, *Enterococcus faecium*, *Lactococcus lactis*, *Leuconostoc citreum*, *Leuconostoc lactis*, *Leuconostoc mesenteroides*, *Pediococcus acidilactici*, *Pediococcus pentosaceus*, *Streptococcus infantarius*, *Streptococcus salivarius*, *Streptococcus thermophilus*, *Sporolactobacillus inulinus*, *Bacillus cereus*, *Bacillus licheniformis*, *Bacillus subtilis*, *Propionibacterium freudenreichii*, *Saccharomyces cerevisiae* (*boulardi*), *Saccharomyces pastorianus*, *Kluyveromyces fragilis*, *Kluyveromyces marxianus*, *Aspergillus oryzae*, and *Aspergillus niger* (EFSA 2013a, b, 2017; Markowiak and Śliżewska 2018). With more advanced and focused research efforts, new genera and strains of probiotic microorganisms are continuously emerging.

Some of the sources of prebiotics include soybeans, inulin sources (like Jerusalem artichoke, chicory roots, etc.), raw oats, unrefined wheat, unrefined barley, yacon, nondigestible carbohydrates, and in particular nondigestible oligosaccharides. Commonly known prebiotics include fructooligosaccharides (FOS), galactooligosaccharides (GOS), galactooligosaccharides/ transgalactosylated-oligosaccharides (GOS/TOS), inulin, isomaltooligosaccharides (IMO), lactulose, pyrodextrins, and soy oligosaccharides (SOS). The emergent prebiotics are genti-oligosaccharides, glucooligosaccharides, lactosucrose, levans, pectic oligosaccharides, resistant starch, sugar alcohols, and xylooligosaccharides (XOS) (Anadon et al. 2010; Pandey et al. 2015). Prebiotics most commonly used in livestock nutrition are FOS, GOS, inulin, IMO, XOS, mannan oligosaccharide (MOS), lacticol, lactulose, and cereal fiber (Malik et al. 2016; Olveira and González-Molero 2016; Markowiak and Śliżewska 2018). Fermentation of FOS in the colon increases the numbers of bifidobacteria in the colon as well as absorption of calcium and fecal weight. In addition, it leads to decrease in gastrointestinal transit time. The increase in colonic bifidobacteria produces compounds to inhibit potential pathogens, by lowering blood ammonia levels and by producing vitamins and digestive enzymes (Malik et al. 2016).

In view of the decline in the use of antibiotic growth promoters in the animal industry, there is increasing awareness for search and exploiting potential of antibiotic alternatives. Among various alternative agents, probiotics, prebiotics, and synbiotics ought to have beneficial effects to maintain or improve animal health and performance. The significant increase of short-chain fatty acids (SCFAs), ketones, carbon disulfide, and methyl acetate following the intake of synbiotics has been suggested for their potential health-promoting effects (Vitali et al. 2010). In the last few years, studies on synbiotics have started to emerge, with the main focus being their applications in enhancing health and preventing diseases, improvement of other production indices such as growth rate, absorption of nutrients, and quality of meat, milk, and eggs. Synbiotics lead to improvement of survival of the probiotic microbiota during the passage through the upper intestinal tract. With more efficient implantation in the colon as well as a stimulating effect of the growth of probiotics and ubiquitous bacteria, synbiotics contribute to maintain the intestinal homeostasis and deliver specific health benefits. Compared with probiotics and prebiotics, synbiotics are the least investigated substances with respect to animal health and performance. This chapter describes the current knowledge on the effects of synbiotics on the health and performance of poultry, cattle, pigs, and companion animals. The mode of action, beneficial effects, and demonstrated study results proving the efficacy of synbiotics in farm and companion animals are presented.

2 Synbiotics for Animals

Intestinal microorganisms are known to play a significant role in the immunological, physiological, nutritional, and protective functions of the host and can be influenced by the type of food. The use of synbiotics as alternative additives for livestock and poultry feed is likely to produce greater health effects and offer more additive benefits in growth performance, feed conversion ratio, hematological, and biochemical parameters than the individual use of probiotic and prebiotic of these additives. Furthermore, synbiotics could increase the digestibility and availability of many nutrient elements such as vitamins, mineral elements, and proteins (Uyeno et al. 2015; Hamasalim 2016; Malik et al. 2016; Markowiak and Śliżewska 2018).

Synbiotic is designed not only to present beneficial microorganisms populations but also to promote proliferation of autochthonous-specific strains in the intestinal tract. Although studies on the effects of synbiotics on livestock health and performance are yet limited, it is worth mentioning that the health effects will likely depend on the synbiotic

combination and synbiotics seem promising for the modulation of the gut microbiota composition (Scavuzzi et al. 2014).

2.1 Synbiotics for Poultry

Although few research trials have been conducted to demonstrate the effects of synbiotics, the findings of in vivo studies are promising, and recent developments and applications of synbiotics have focused on assessing the beneficial effects of synbiotics on poultry health and performance (Gadde et al. 2017). The effects of some synbiotics investigated on growth response, intestinal microbial ecosystem, immune functions, and other indices of broiler chickens are presented in Table 1.

The combination of probiotics and prebiotics could improve the survival and persistence of the health-promoting microorganisms in the gut of birds because of availability of its specific substrate for fermentation (Yang et al. 2009; Adil and Magray 2012). Synbiotics may have a significant effect on absorption and utilization of feed, daily body weight gain, and quality of meat and eggs. The clinical benefits of synbiotics include inhibiting proliferation of pathogenic bacteria, protecting the intestinal barrier, modulating immune function, and combating diarrhea in chickens. Mohnl et al. (2007) demonstrated that the synbiotic product increased body weight and feed conversion ratio and reduced feed intake and mortality in comparison to controls. The synbiotic had a comparable growth-stimulating potential as antibiotic growth promoter avilamycin in broiler chickens and might be a promising alternative to the use of antibiotic growth promoters in broiler production. A synbiotic product containing *Lactobacillus* sp. with the addition of lactose was shown to improve the body weight gain and feed conversion ratio in *Salmonella*-challenged turkey poults (Vicente et al. 2007). Similarly, dietary inclusion of *Bacillus subtilis* plus FOS improved the average daily growth and the feed conversion ratio, as well as reduced the incidence of diarrhea and mortality of broiler chickens in comparison to birds treated with a tetracycline antibiotic aureomycin. The combination of *Bacillus subtilis* and FOS produced much better improvement on cecal micro-ecosystem in broilers than their alone administration. Also the combination had better effects on reducing diarrhea rate and promoting growth than they were given individually. The synbiotic had selective effects on increasing cecal concentration of beneficial bacteria such as *Lactobacillus* and decreasing concentration of harmful bacteria such as *Escherichia coli* and *Salmonella*, whereas treatment with aureomycin had nonselective effects on cecal microflora which inhibited all bacteria (Li et al. 2008).

Dietary inclusion of synbiotic containing a combination of *Bifidobacterium lactis* bacteria and GOS for 40 days resulted in a significant increase of *Bifidobacterium* and *Lactobacillus* count and in population of total anaerobic bacteria in the fecal microbiota of the broiler chickens (Jung et al. 2008). McReynolds et al. (2009) evaluated the effects of probiotic (*Enterococcus faecium*, *Pediococcus acidilactici*, *Bifidobacterium animalis*, *Lactobacillus reuteri*) in association with a prebiotic containing, but not limited to, FOS and essential oil plant extracts on chicks given an immunosuppressant vaccine, inoculated with *Clostridium perfringens* and in dietary conditions favorable to necrotic enteritis development. Both probiotic and prebiotic resulted in reduction of *Clostridium perfringens* counts, a decrease in the intestinal lesions, and lower mortality. It was suggested that the synbiotic could be used as potential alternatives to help control *Clostridium perfringens* and necrotic enteritis. Erdoğan et al. (2010) showed that addition of synbiotics to the diet produced a decrease of cecal coliform organism counts, which might be due to the positive effects of probiotics and prebiotics on gut microbial ecology.

The positive impact of administration of synbiotics on the performance and ileal microbiota of chickens has also been substantiated in recent studies. The application of *Saccharomyces cerevisiae* with MOS significantly increased the weight gain as well as population of LAB and yeast in the ileal and cecal content of broiler chicks. The population of *Escherichia coli* was significantly decreased in the ileum and cecum. Dietary inclusion of *Saccharomyces cerevisiae* without MOS also produced these effects, but the effects were more pronounced following combined administration (Koc et al. 2010). Since MOS is not enzymatically digested in the small intestine, bacteria bound to MOS likely exit the intestine without attaching to the epithelium (Spring et al. 2000). The enhancement of intestinal morphology and nutrient absorption following the administration of synbiotics appears to contribute to the improved performance of broiler chickens (Awad et al. 2008; Hassanpour et al. 2013). Tayeri et al. (2018) compared the effects of antibiotics, probiotics, prebiotics, and synbiotics on the performance and carcass characteristics of broilers. The birds fed with synbiotic had greater relative gizzard and spleen weights and lighter kidneys and also had thinner walls of the caudal gut segments. Dietary supplementation of the synbiotic also reduced the feed conversion ratio, compared with the control and antibiotic flavomycin treatment. Thus, there were significant performance and health benefits of using probiotics, prebiotics, and synbiotics for broilers, rather than antibiotics.

Feed restriction for long period may induce a great stress on birds. Synbiotics have been shown to ameliorate the negative effects of feed restriction on broiler performance. Accordingly, the effects of synbiotics with and without feed restriction have been investigated on performance, hematological indices, and carcass characteristics of broiler chickens. Diets supplemented with *Bacillus licheniformis* and *Bacillus subtilis* plus MOS, with and without feed restriction, improved broiler performance, without affecting blood

Table 1 Effects of some synbiotics on health and growth performance of poultry

Synbiotic	Main outcome	References
Lactobacillus (*L.*) *acidophilus*, *Enterococcus faecium*, *L. plantarum*, *Pediococcus acidilactici* plus MOS	Reduced the mortality from necrotic enteritis caused by *Clostridium perfringens*	Hofacre et al. (2003)
Enterococcus faecium plus FOS	Prevented necrotic enteritis caused by *Clostridium perfringens* as expressed by reduction of signs, mortalities, lesions, and intestinal count and improved performance indices	El-Ghany (2010)
Biomin®IMBO[a]	Improved body weight gain and feed conversion ratio and protective effect against coccidiosis	Ghasemi et al. (2010)
L. acidophilus, *L. casei*, *L. plantarum*, *L. bulgaricus*, *Bifidobacterium* (*B.*) *bifidum*, *Streptococcus thermophilus*, *Streptococcus faecium*, *Torulopsis* sp., *Aspergillus oryzae* plus inulin	Increased weight gain and ameliorated toxic effects of aflatoxins	Hashem and Mohamed (2009)
Lactobacillus, *Bifidobacterium* plus oligosaccharides derived from yeast cell wall, and other ingredients	Improved the antibody response to Newcastle disease virus and infectious bronchitis virus vaccines	El-Sissi and Mohamed (2011)
Saccharomyces cerevisiae plus MOS	Increased weight gain, reduced the number of *Escherichia coli* in the small intestinal and cecal digesta, and higher villus height in the duodenum, jejunum, and ileum	Abdel-Raheem et al. (2012)
B. longum subsp. *longum* PCB133 plus GOS	Reduced *Campylobacter jejuni* concentration in poultry feces	Baffoni et al. (2012)
Biomin®IMBO[a]	Increased the numbers of lactobacilli and reduced *Escherichia coli* and total coliform populations in the intestine	Dibaji et al. (2014)
Multi-strain probiotic consisting of 11 *Lactobacillus* strains plus IMO	Increased the cecal populations of lactobacilli and bifidobacteria and decreased the cecal *Escherichia coli* and improved the performance and increased the cecal volatile fatty acids	Mookiah et al. (2014)
Biomin®IMBO[a]	Enhanced the humoral immune responses following vaccination against Newcastle disease, infectious bronchitis, and infectious bursal disease	Talebi et al. (2015)
L. acidophilus, *L. casei*, *Streptococcus faecium*, *Bacillus subtilis* plus yeast-derived carbohydrates	Exhibited a balanced T-helper (Th)-1/Th-2 response locally and a more Th-2-dependent response systemically	Yitbarek et al. (2015)
Biomin®IMBO[a]	Improved body weight gain, feed conversion, intestinal morphology, and intestinal microbial ecology and the highest antibody response to Newcastle disease vaccine	Al-Sultan et al. (2016)
L. acidophilus, *L. casei*, *Streptococcus faecium*, *Bacillus subtilis*, *Saccharomyces cerevisiae* plus yeast-derived carbohydrates	Improved humoral immunity by increasing IgG concentration in serum and modulated the adaptive antibody-mediated immune response against infectious bronchitis virus	Alizadeh et al. (2017)
B. longum PCB133 plus XOS	Reduced the cecal *Campylobacter jejuni* and *Campylobacter* sp. upon lifelong administration of the synbiotic in broiler chickens infected with *Campylobacter jejuni* strain M1	Baffoni et al. (2017)
L. reuteri, *Enterococcus faecium*, *B. animalis*, *Pediococcus acidilactici* plus FOS	Increased body weight, enhanced performance, and protected against *Salmonella enterica* Enteritidis infection	Luoma et al. (2017)
L. casei, *L. acidophilus*, *B. thermophilum*, *Enterococcus faecium* plus MOS	Improved specific growth rate, growth efficiency, energy efficiency ratio, protein efficiency ratio and decreased serum cholesterol concentration	Ashayerizadeh et al. (2011)
L. acidophilus, *B. thermophilus*, *B. longum*, *Streptococcus faecium* plus prebiotics	Increased serum overall total antioxidant capacity, paraoxonase and ceruloplasmin activity and decreased serum total oxidant status and homocysteine concentrations	Anwar et al. (2012)
Bacillus subtilis, *Bacillus licheniformis*, *Clostridium butyricum* plus yeast cell wall, and XOS	Increased average daily gain and breast yield, decreased feed/gain ratio and abdominal fat, and lowered malondialdehyde content in the thigh muscle, resulting in the production of meat with a favorable quality and oxidative stability	Cheng et al. (2017)
L. acidophilus, *L. casei*, *B. bifidum*, *Streptococcus faecium*, *Aspergillus oryzae* plus IMO	Decreased serum levels of total cholesterol at 36 weeks of age, low-density lipoprotein cholesterol, alanine aminotransferase and alkaline phosphatase, heterophil percentage, and heterophil to lymphocyte ratio and increased lymphocyte percentage at 36 and 52 weeks of age	Tang et al. (2017)
L. acidophilus, *L. casei*, *B. bifidum*, *Streptococcus faecium*, *Aspergillus oryzae* plus IMO	Decreased the egg yolk cholesterol and total saturated fatty acids and increased total unsaturated fatty acids, total omega	Tang et al. (2015)

(continued)

Table 1 (continued)

Synbiotic	Main outcome	References
	6, and polyunsaturated fatty acids including linoleic and alpha-linolenic acid levels in eggs	
Biomin®IMBO[a]	Improved egg weight, egg production, and egg mass; higher values of shell thickness, Haugh unit, and shell percentage; increased feed conversion ratio; and decreased serum cholesterol	Abdel-Wareth (2016)
Biomin®IMBO[a]	Improved growth performance, intestinal morphology, and nutrient absorption; increased villus height/crypt depth ratio and villus height in ileum; and reduction in ileal crypt depth	Awad et al. (2008)
Biomin®IMBO[a]	Increased average daily body weight gain, carcass yield percentage, feed conversion rate and villus height/crypt depth ratio, and villus height in both duodenum and ileum	Awad et al. (2009)
L. acidophilus, *Enterococcus* ssp. plus MOS	Improved weight gain and feed/gain ratio until 21 days old	Murarolli et al. (2014)
Biomin®IMBO[a]	Increased the consumption of metabolizable energy and crude protein and higher production index, live weight, and feed efficiency	Aziz Mousavi et al. (2015)
L. plantarum, *L. delbrueckii* subsp. *bulgaricus*, *L. acidophilus*, *L. rhamnosus*, *B. bifidum*, *Streptococcus salivarius* subsp. *thermophilus*, *Enterococcus faecium* plus MOS	Increased ileal villus height, crypt depth, and villus surface area	Sohail et al. (2012)
L. plantarum, *L. acidophilus*, *L. bulgaricus*, *L. rhamnosus*, *B. bifidum*, *Streptococcus thermophilus*, *Enterococcus faecium*, *Aspergillus oryzae*, *Candida pintolopesii* plus MOS	Improved mean body weight gain and feed efficiency and ameliorated the effects of cyclic heat stress on relative weights of the spleen, bursa, intestine, and ceca	Sohail et al. (2013)
Bacillus subtilis plus XOS and MOS	Increased daily weight gain; feed efficiency; villus height; and villus/crypt ratio in duodenum, jejunum, and ileum; intestinal mucosa secretory IgA content; and antioxidant capabilities	Min et al. (2016)
Saccharomyces cerevisiae, *Enterococcus faecium*, *Bacillus subtilis*, *Bacillus licheniformis* plus β-glucans, MOS and FOS	Increased body weight, decreased mortality adjusted feed conversion ratio, and necrotic enteritis-associated mortality with no decrease in the severity of intestinal lesion scores in broiler chickens challenged with *Clostridium perfringens*	Krueger et al. (2017)

[a]Biomin®IMBO (*Enterococcus faecium* plus prebiotic derived from chicory and immune-modulating substances derived from sea algae)

parameters and carcass yield. Feed restriction and addition of the synbiotic resulted in a decreased visible fat of the carcass. The use of synbiotic was recommended as an anti-stress factor in feed restriction and to increase weight, improve feed conversion rate, and reduce feed cost of production (Abdel-Hafeez et al. 2017).

The addition of synbiotic to broiler diets not only improved the growth performance but also had a positive impact on blood lipid profile and meat quality (Ghasemi et al. 2016). The synbiotic was shown to improve overall body weight gain or feed conversion ratio and decreased serum cholesterol as well as low-density lipoprotein cholesterol concentrations. The 2-thiobarbituric acid-reactive substances content in thigh meat after 30 days of storage at 4 °C was linearly decreased as the synbiotic inclusion concentrations in the diets increased. Dietary synbiotic also decreased the proportion of monounsaturated fatty acids and increased n-6 polyunsaturated fatty acid concentration in thigh meat, whereas the fatty acid profile of breast meat was not affected by synbiotic supplementation.

In an interesting study, Calik et al. (2017) evaluated the effect of intra-amniotic administration of synbiotic comprising of *Enterococcus faecium* and inulin and its continued supplementation in the diet on the performance, intestinal epithelium integrity, and cecal microflora of broiler chickens. The administration of an intra-amniotic synbiotic to embryonated eggs on day 17 of incubation had no effect on the hatchability or hatching weight of the birds. However, it resulted in a positive effect on villus height and goblet and proliferating cell nuclear antigen-positive cell counts. Intra-amniotic synbiotic injection followed by dietary supplementation with the synbiotic was found to significantly increase *Lactobacillus* colonization and decrease coliform population in the broiler cecum. Furthermore, cecal butyric acid concentration increased proportionally to the cecal *Lactobacillus* count with dietary supplementation of the synbiotic.

In addition to the improved growth performance, synbiotic supplementation was also shown to enhance the general immune function of broiler chickens. Chen et al. (2018) investigated the effects of dietary synbiotic supplementation as an alternative to antibiotics on growth performance,

intestinal morphology, immunity, and oxidative status of broilers. Supplemental synbiotic increased the average daily gain and gain:feed ratio of broilers, as well as the relative weight of the thymus and the secretory immunoglobulin A level in the jejunum and ileum. Dietary synbiotic inclusion promoted the ratio of ileal villus height to crypt depth and reduced the ileal malondialdehyde accumulation of broilers. The synbiotic-induced effects were comparable with that of dietary inclusion of the antibiotic chlortetracycline. It was suggested that dietary synbiotic supplementation may be used as an alternative to the antibiotic. Similarly, Naghi Shokri et al. (2017) reported that chickens fed diet supplemented with synbiotic exhibited better feed conversion ratios at the 14–28 day period and higher average daily gain and duodenal villus height/crypt depth ratio at 42 days than those fed the control diet. Supplemental synbiotic produced a marked increase in the serum antibody titer against infectious bursal disease and infectious bronchitis vaccines.

On the contrary, some of the trials conducted with dietary inclusion of synbiotics did not show that broiler performance was affected. The oral administration of GOS alone or in combination with a *Bifidobacterium lactis*-based probiotic had no significant effect on growth, feed consumption, and feed conversion ratio in broilers (Jung et al. 2008). Dietary inclusion of a combination of probiotic (*Bacillus licheniformis*, *Bacillus subtilis*) and a MOS derived from the cell walls of the yeast (*Saccharomyces cerevisiae*) had no significant effect on body weight gain, feed intake, carcass weight, and carcass yield, but feed conversion ratio was significantly improved (Midilli et al. 2008). Similarly, feeding of diet supplemented with synbiotic did not influence feed intake, feed conversion efficiency, body weight gain, and small intestine weight of broilers (Erdoğan et al. 2010). Dietary supplementation with a combination of commercial probiotic (PrimaLac) and prebiotic (TechnoMos) was found to have no significant effect on daily feed intake, daily body weight gain, feed conversion ratio, carcass traits, intestinal morphology, and bacterial populations of the ileum of broiler chickens (Salehimanesh et al. 2016). The morphometric parameters of the different intestinal wall layers of broiler chickens were not influenced by feeding a combination of probiotic product containing anaerobic bacteria, lactose-fermenting enterobacteria, *Enterococcus* sp. and *Lactobacillus acidophilus*, and MOS. Also the synbiotic did not improve intestinal integrity and broiler performance (Fernandes et al. 2014). Mookiah et al. (2014) reported that synbiotic consisting of 11 *Lactobacillus* strains plus IMO did not show a twofold synergistic effect on the performance, cecal bacterial populations and concentrations of cecal volatile fatty acids (VFA), and non-VFA of broiler chickens compared with those of probiotic or prebiotic alone. The differences in the effects of synbiotics on growth performance and other indices may be attributable to variations in the strain of probiotics and/or type of prebiotics selected, methods of preparation, the dietary supplementation level, and duration of use, diet composition, bird age, and hygiene condition. Also in several cases, the environmental and the stress status of the birds are not reported or considered, as the experimental settings are often too far from farm conditions (Gaggia et al. 2010; Wang et al. 2018).

Calcium ions deficit in bones leads to the deterioration of skeleton structure and reduction of bone strength. The necessity of using bioactive foods and ingredients in feed stimulating the assimilability of minerals in poultry is particularly important when the birds grow intensely and is very heavy (Kwiatkowska et al. 2017). Although prebiotics, probiotics, and synbiotics have been shown to modulate mineral absorption and bone mineral content, synbiotics are the least investigated substances with respect to a bone-health-promoting potential. Studies performed in animals and humans have revealed positive outcomes of prebiotics on mineral absorption and metabolism and bone composition and architecture. This effect of dietary prebiotics is promoted by high dietary calcium content up to a threshold level and an optimum amount and composition of supplemented prebiotics. The underlying mechanisms include increased solubility of minerals due to increased bacterial production of SCFAs, an enlargement of the absorption surface by promoting proliferation of enterocytes mediated by bacterial fermentation products, and increased expression of calcium-binding proteins. With the increased expression of enterocytes as well as calcium-binding proteins, more minerals are absorbed, the health of the gut is improved, and the body is enabled to maintain stronger bone structure with the supply of calcium (Scholz-Ahrens et al. 2007). On the other hand, the probiotic microorganisms produce phytase enzyme that is used to free up more minerals from phytate bondage for absorption. The probiotic microorganisms are also able to hydrolyze glycoside bonds in nutrients that otherwise cannot be broken down by the intestines; as a result both the probiotic bacteria and the host animal benefit with the increased availability of minerals (Parvaneh et al. 2014). Probiotics have an independent effect on facilitating mineral absorption, and synbiotics can induce additional effects. The increase in calcium absorption levels has been reported to coincide with an increase in bone density values (Weaver 2015).

Feeding of diet containing *Bacillus subtilis* and/or inulin increased the content of ash, calcium, and density of the tibia of Lohmann white laying hens. In addition, the supplementation also increased egg production and egg weight and improved the quality of eggshells, including thickness and content of calcium and decreased eggshell deformations. The improvements in performance and eggshell quality following dietary inclusion of the synbiotic were found to be directly related to the colonization of beneficial microflora along with an increase in the villi-crypts absorptive area. The positive

effects of the synbiotic on eggshell quality indices can probably be attributable to the stimulation of mineral availability (Abdelqader et al. 2013). A favorable effect of synbiotic on the accumulation of calcium has also been demonstrated in Japanese quails, in which the content of calcium and phosphorus in the tibia following the use of a commercial synbiotic (Biomin®IMBO) was dependent on the sex of the bird, and significant results were evident in males only (Vahdatpour et al. 2014). The beneficial effects of the use of dietary synbiotic in the nutrition of Hy-Line W-36 layers on eggshell characteristics have been reported by Cesari et al. (2014). Prebiotic (skim milk powder containing 54% lactose) added to a diet containing *Lactobacillus acidophilus* D2/CSL resulted in significant improvements in egg quality characteristics, in terms of specific gravity, shell thickness, Haugh unit, and percentage of shell. Such positive effects could be due to the increased production of SCFAs in the intestine of hens fed with the combination of probiotic bacteria and lactose.

The beneficial microorganisms inhabit the gastrointestinal tract of chickens instantly after hatching, and this development occurs through contact with maternal feces. But in artificial hatching, despite the use of feed additives, the settlement of the intestinal beneficial microorganisms is delayed. Hence, administration of the given substance directly into the egg has been used, and the results are promising (Maiorano et al. 2012; Sławińska et al. 2014a, b). Compared to dietary prebiotic administration, in ovo injection increases the population of beneficial microflora on the day of hatch and leads to a high and stable level of bifidobacteria throughout the broiler chickens growing period (Villaluenga et al. 2004). Furthermore, very low doses of the substances are effective when injected in ovo.

In ovo administration of selected synbiotics is a promising approach for enhancing the chicken immune system as it combines merits of probiotics and prebiotics and by early administration into the embryo and supports development of their immune organs. In ovo administration of *Lactococcus lactis* IBB SL1 plus raffinose family oligosaccharides (RFO), *Lactococcus lactis* IBB SC1 plus RFO, or *Lactobacillus acidophilus* and *Streptococcus faecium* plus lactose into the developing chicken embryo provided stimulus for the immune system stimulation of the growing chickens, but its efficiency depended on chicken genotype. *Lactococcus lactis* probiotics survived in the chicken guts throughout their lifespan (Sławińska et al. 2014a). In ovo administration of synbiotics has also been shown to activate the immune system in adult chickens. Sławińska et al. (2014b) investigated the effects of in ovo administration of *Lactococcus lactis* subsp. *lactis* IBB SL1 plus RFO, *Lactococcus lactis* subsp. *cremoris* IBB SC1 plus RFO, and *Lactobacillus acidophilus* and *Streptococcus faecium* plus lactose on immune-related gene expression in adult chickens. The intestinal tissues had downregulation of expression for the cytokines interleukin (IL) IL-4, IL-6, IL-12p40, IL-18, interferon (IFN)-β, and IFN-γ and 1 chemokine (IL-8) in the cecal tonsils of synbiotic-treated chickens. In spleen which is the peripheral part of the immune system, the expression of IL-4 and IL-6 was upregulated, suggesting that in ovo administration of synbiotics activates the immune system in adult chickens. In ovo administration of *Lactococcus lactis* subsp. *lactis* 2955 plus inulin was associated with downregulation of immune-related gene expression in the cecal tonsils and spleen of broiler chickens. The magnitude of that downregulation increased with age and was most likely caused by stabilization of the gastrointestinal microbiota (Płowiec et al. 2015).

Synbiotics (*Lactococcus lactis* subsp. *lactis* IBB SL1 plus inulin and *Lactococcus lactis* subsp. *cremoris* IBB SC1 plus transgalactooligosaccharide [TGOS]) injected in ovo into the air cell on the 12th day embryonic development have been demonstrated to increase the total activity of pancreatic enzymes amylase and trypsin, whereas lipase activity was increased by *Lactococcus lactis* subsp. *cremoris* IBB SC1 plus TGOS in the growing chickens. The most pronounced changes were observed at the end of the investigated rearing period on day 34. The in ovo injected synbiotics caused no deterioration in the posthatching condition of the chicken liver, as determined by measurement of the activity of marker enzymes serum alanine aminotransferase and serum aspartate aminotransferase. Although treatment with the synbiotics did not change the feed conversion ratio, but *Lactococcus lactis* subsp. *lactis* IBB SL1 plus inulin significantly increased final body weight of chickens (Pruszynska-Oszmalek et al. 2015).

In ovo administration of synbiotics may also be an effective method to increase body weight, improve the SCFAs cecal profile, and increase the villus length: crypt depth ratio in the jejunal mucosa (Miśta et al. 2017). These effects were more pronounced following administration of *Lactococcus lactis* subsp. *lactis* IBB SL1 plus inulin compared to another synbiotic *Lactococcus lactis* subsp. *cremoris* IBB SC1 plus TGOS. In addition, in ovo administration of these two synbiotics at day 12 incubation has been shown to modulate the central and peripheral lymphatic organ development in broilers. *Lactococcus lactis* subsp. *cremoris* IBB SC1 plus TGOS decreased the cortex/medulla ratio in the thymus and slowed the development of the cortex in bursal follicles on day 21 posthatching, with consequent impacts on the primary lymphatic organs. The synbiotic treatment also stimulated formation of germinal centers in the spleens of 21- and 35-day-old chickens, indicating enhanced B-cell proliferation in secondary lymphatic organs. It produced an age-dependent increase in the spleen/bursa of Fabricius ratio (Madej et al. 2015). In another study, *Lactococcus lactis* subsp. *lactis* IBB SL1 plus inulin as well as *Lactococcus lactis* subsp. *cremoris* IBB SC1 plus TGOS delivered *in ovo* were shown to have a

stimulatory effect on the gut-associated lymphoid tissue development after hatch (Madej and Bednarczyk 2016).

The biological effects of synbiotics depend exclusively on careful selection of bioactive probiotic and prebiotic. Dunislawska et al. (2017) presented a workflow associated with in vitro selection of synbiotics and its consequences for the downstream animal study, including abundance of intestinal microbial communities, performance parameters, and molecular responses of the immune system. Based on in vitro findings on hatchability and growth curve, they designed two synbiotics, namely, *Lactobacillus salivarius* IBB3154 plus GOS and *Lactobacillus plantarum* IBB3036 plus RFO. Both synbiotics delivered in ovo had beneficial effects on the overall status of broiler chickens characterized by low mortality and high production parameters, and microbial populations of *Lactobacillus* sp. and *Enterococcus* sp. were higher in the ileum. Of the two synbiotics, *Lactobacillus salivarius* IBB3154 plus GOS caused significant upregulation of IL-6, IL-18, IL-1β, IFN-γ, and IFN-β in the spleen on day 21 and IL-1β on day 7, whereas IL-12, IL-8, and IL-1β on day 42 and IFN-β on day 14 were downregulated in cecal tonsils and were more potent in establishing a beneficial shift in the microbiota composition in the gastrointestinal tract.

In a recent study, Kolodziejski et al. (2018) demonstrated that incretins are involved in the action of synbiotics or that they may even be their target in poultry. In ovo injection of two different synbiotics *Lactobacillus salivarius* IBB3154 plus GOS and *Lactobacillus plantarum* IBB3036 plus RFO led to a lowering of the level of incretins glucagon-like peptide 1 (GLP-1) and gastric inhibitory polypeptide or glucose-dependent insulinotropic peptide (GIP) in blood serum of broiler chickens. Both synbiotics downregulated GLP-1 and GIP mRNA expression in the duodenum and GLP-1 receptors in the pancreas. Furthermore, *Lactobacillus plantarum* IBB3036 plus RFO increased trypsin and lipase activities in the duodenum content, simultaneously decreasing amylase activity, which is likely to promote digestion of proteins and lipids. The in ovo delivery of these synbiotics was also found to significantly affect gut structure which should contribute to improvement in nutrient absorption by the gut (Sobolewska et al. 2017).

2.2 Synbiotics for Ruminants

The current use of probiotics in young preruminants generally targets the lower intestine and represents an interesting means to stabilize the gastrointestinal microorganisms and reduce the risk of colonization of pathogens and ultimately support the beneficial effects including balancing the gut microbiota as well as in animal nutrition and health. On the other hand, prebiotics have been shown to have specific beneficial effects in calves including blocking of colonization of pathogens in the gut, reduction in the incidence and severity of enteric disease, and prevention of adhesion of *Enterobacteriaceae*, particularly *Escherichia coli* and *Salmonella*, to the intestinal epithelium and may ultimately improve growth performance. However, the beneficial health effects with both probiotics and prebiotics seem to be minimal when calves are generally healthy. Probiotics in adult ruminants mainly improve fiber digestion by rumen microorganisms and have positive effects on various digestive processes, particularly cellulolysis and the synthesis of microbial proteins (Heinrichs et al. 2009; Uyeno et al. 2015). Application of synbiotics may assist in decreasing acidosis and stabilizing rumen pH, improving immune function, interfering with pathogen infections, and consequently improve animal health and production efficiency.

As compared to probiotics and prebiotics, studies on synbiotics on the cattle health and performance have received only minimal attention. The efficacy and suitability of the use of synbiotics have been generally assessed on the basis of weight gain, feed intake, and utilization and on status of health (Radzikowski 2017; Markowiak and Śliżewska 2018). In preruminant calves, *Enterococcus faecium* plus lactulose produced beneficial effects on the growth performance. The ileal villus height, the depth of the crypts in the cecum, and the surface area of lymph follicles from Peyer's patches were decreased by the synbiotic treatment (Fleige et al. 2007). Addition of combination of *Streptococcus faecium* and MOS to dairy calf diets was shown to improve fecal consistency and to reduce the fecal score of calves without reducing in the number of scour episodes (Morrison et al. 2010). Preruminant calves fed milk containing synbiotic consisting of probiotic (multi-strain probiotic containing seven bacteria strains and two yeast strains) and prebiotic (*Saccharomyces cerevisiae* cell wall polysaccharides) resulted in an increase in average daily weight gain and a decrease in the number of pathogenic *Escherichia coli* bacteria in feces of calves. However, application of the synbiotic had no significant effect on white blood cell count, plasma IgG1 level, and cell-mediated immune response (Roodposhti and Dabiri 2012). Similar results have been demonstrated by Marcondes et al. (2016) in Holstein Californian calves following symbiotic complex supplementation. The synbiotic-fed calves attained higher average daily weight gain and exhibited increased digestibility of dry matter and neutral detergent fiber and improved animal health. In addition, a combination of commercial probiotics and prebiotics has also been shown to eliminate morbidity and mortality losses associated with Shiga toxin-producing *Escherichia coli* infections in dairy calves (Baines et al. 2013).

Supplementation of feed with a synbiotic product consisting of *Lactobacillus casei* subsp. *casei* and dextran increased the resistance of Holstein dairy cows to adverse

environmental conditions such as high temperature and humidity. The synbiotic improved the milk production and total amounts of fat, protein, and solid nonfat, as a result of a positive change in the bovine intestinal microbiota and a greater resistance to infectious diseases. The cows evaluated also showed a reduction in the number of somatic cells and a decrease in the incidence of mastitis. (Yasuda et al. 2007).

2.3 Synbiotics for Pigs

Studies on the effects of synbiotics on pig health and performance are scarce. The effects of some synbiotics investigated on pig health and performance are presented in Table 2. Postweaning diarrhea is one of the major concerns related to gut health of nursery pigs and is often caused by infection of enterotoxigenic *Escherichia coli* (Sun and Kim 2017). A few studies have been performed to determine the potential usefulness of synbiotics to prevent postweaning diarrhea in pigs. Nemcová et al. (1999) demonstrated the synergistic beneficial effect of *Lactobacillus paracasei* plus FOS on the fecal microbiota of weanling piglets. Animals fed with synbiotic exhibited an increase of total anaerobic and aerobic count and increased number of *Lactobacillus* and *Bifidobacterium*, whereas the bacterial count of *Enterobacteriaceae* and *Clostridium* was decreased in the feces of the weanling pigs. In a later study, Nemcová et al. (2007) reported that the administration of combination of *Lactobacillus plantarum*, maltodextrin, and FOS increased acetic acid concentrations in the ileum and colon and was found to be most effective in inhibiting the counts of *Escherichia coli* O8:K88 adhering to the intestinal mucosa of the jejunum and colon of conventional piglets.

Piglets fed diet containing 0.5% synbiotics (mixture of 0.2% oligofructose plus 0.3% probiotics) exhibited higher average daily weight gain and had a significantly decreased number of total coliform bacteria in the colon, whereas the population of bifidobacteria was significantly increased in the ileum and colon (Shim et al. 2005). Lee et al. (2009) in a 16-day study assessed the effect of synbiotics on growth performance, nutrient digestibility, emission of harmful gases, and fecal microbial population in weaning pigs. Supplementation with the synbiotic product containing a combination of a probiotic originating from anaerobic microflora and a prebiotic (MOS, lactose, sodium acetate, and ammonium citrate) resulted in improved digestion of nutrients, decreased emission of harmful gases, and enteropathogenic bacteria in early-weaning pigs. Growing pigs fed diet supplemented with prebiotics, and 0.2% probiotics from anaerobic bacteria for 15 days showed higher dry matter and crude protein digestibility, decreased fecal ammonia and amine gas emissions, and increased fecal acetate gas emission. Although the growth performance was not affected, fecal *Escherichia coli* population was lower in pigs fed the synbiotic (Chu et al. 2011).

Krause et al. (2010) demonstrated the efficacy of synbiotic consisting of a 50:50 mixture of probiotic *Escherichia coli* strains UM-2 and UM-7 and prebiotic raw potato starch

Table 2 Effects of some synbiotics on health and growth performance of pigs

Synbiotic	Main outcome	References
Lactobacillus (*L.*) *paracasei* plus FOS	Increased fecal counts of *Lactobacillus* sp., *Bifidobacterium* sp., total anaerobes, and total aerobes and significantly decreased *Clostridium* and *Enterobacterium* counts	Bomba et al. (2002)
L. salivarius 1B 4/11 plus lactitol	Positive synergistic effect of the combination as compared with the use of individual components in modulating the cecal microflora in vitro and improved feed efficiency when fed to weaned pigs	Piva et al. (2005)
L. acidophilus ATCC 4962 plus FOS, inulin, and mannitol	Decreased plasma triacylglycerol, total cholesterol, and low-density lipoprotein cholesterol and reduced deformation of erythrocytes in hypercholesterolemic pigs	Liong et al. (2007)
Bacillus subtilis, *L. casei*, *Pichia anomala* plus oligosaccharides	Improved apparent nutrient digestibility, decreased diarrhea rates, and increased fecal counts of LAB and fecal lipase activity	Fan et al. (2015)
Enterococcus faecium, *L. salivarius*, *L. reuteri*, *Bifidobacterium thermophilum* plus inulin	Beneficial effect on the gut microbiota; decreased relative abundance of *Escherichia* in the ileum, cecum, and colon; and increased bifidobacterial numbers in the ileum	Sattler et al. (2015)
L. plantarum—Biocenol™ LP96 (CCM 7512), *L. fermentum*—Biocenol™ LF99 (CCM 7514) plus flaxseed	Decreased lactate dehydrogenase leakage in the blood serum and tissue extracts and likely improvement in the immune status and the integrity of jejunum mucosa during infection	Andrejčáková et al. (2016)
Enterococcus faecium NCIMB 11181 plus lactulose	Decreased *Proteobacteria* abundances, increased the average population of *Lactobacillaceae*, and large decreases in the proportions of *Enterobacteriaceae* in feces	Chae et al. (2016)
L. plantarum—Biocenol™ LP96 (CCM 7512), *L. fermentum*—Biocenol™ LF99 (CCM 7514) plus flaxseed	Positive effects on the blood serum levels of total lipids, the ratio of n-3 polyunsaturated fatty acids (PUFAs)/n-6 PUFAs, and gut health and adaptation process after weaning	Sopková et al. (2017)

(RPS) in young pigs challenged with enterotoxigenic *Escherichia coli* (ETEC) K88. The synbiotic produced a beneficial effect on piglet growth performance and resulted in a reduction of diarrhea and increased microbial diversity in the gut. It has been suggested that microcin produced by probiotic *Escherichia coli* can limit the growth of competitors in an inflamed intestine, including commensal *Escherichia coli* and adherent-invasive *Escherichia coli* (Krause et al. 2010; Sassone-Corsi et al. 2016; Liao and Nyachoti 2017). The prebiotic effect of RPS may be attributable to the starch granules which are much larger than those of cereal grains and consequently reach the distal small intestines and colon, where they modify fermentation. In another study, the potential of *Lactobacillus plantarum* JC1 (B2028), lactulose, and their combination to control postweaning colibacillosis in pigs was evaluated using an ETEC K88 oral challenge (Guerra-Ordaz et al. 2014). Lactulose, a nondigestible and synthetic disaccharide, not only improved the average daily gain but also increased lactobacilli, the percentage of butyric acid in the colon, and the ileum villous height and decreased the pig major acute-phase protein in serum. On the other hand, the probiotic increased the numbers of *Lactobacillus plantarum* bacteria in the ileum and colon and the total lactobacilli in the colon and showed a trend to reduce diarrhea. The concentrations of ammonia in ileal and colonic digesta were decreased, whereas the villous height and number of ileal goblet cells increased. The positive effects of *Lactobacillus plantarum* and lactulose were combined in the synbiotic treatment, resulting in a complementary synbiotic having a potential to control postweaning colibacillosis in piglets.

The Göttingen minipig seems to be a suitable model for gut microbiota research in pigs. Tanner et al. (2015) investigated the impact of *Bifidobacterium thermophilum* RBL67 (RBL67) alone and combined with FOS on the gut microbiota of Göttingen minipigs. During the treatments and at the time of killing of animals, RBL67 was consistently detected in feces, cecum, and colon after feeding RBL67 and synbiotic diets. At the time of killing of animals, significantly higher *Bifidobacterium* numbers in the cecum and colon of synbiotic-fed minipigs were measured compared with RBL67, suggesting that the synbiotic combination represents a valuable strategy to increase probiotic bacteria levels and survival in gastrointestinal tracts for feed and food applications.

2.4 Synbiotics for Companion Animals

The prebiotic component within a synbiotic product should support the growth of the probiotic and enhance its proliferation within the gastrointestinal tract. Obviously, prebiotic additives have to be chosen depending on the probiotic strain. Although combinations of prebiotics with dietary probiotics have not been adequately explored in the domestic canine and feline species, such information might have implications for the design and production of synbiotic formulations for companion animals. Ogué-Bon et al. (2010) conducted in vitro tests to evaluate the synergistic potential of prebiotics FOS, GOS, and inulin and probiotic strains *Bifidobacterium bifidum* 02450B, *Bifidobacterium longum* 05, *Lactobacillus plantarum* 115400B, *Lactobacillus acidophilus* 14150B, *Lactobacillus acidophilus*, and *Lactobacillus rhamnosus*. It was shown that the synbiotic combination GOS plus *Bifidobacterium bifidum* 02450B induced greater modulation of canine fecal microbiota compared with GOS alone. In another in vitro study, the association between commercially available probiotic strains (*Lactobacillus plantarum* 115400B, *Lactobacillus acidophilus* 14150B, *Lactobacillus acidophilus*, *Lactobacillus rhamnosus*, *Bifidobacterium longum* 05, and *Bifidobacterium bifidum* 02450B) and commercially available fiber blends (rice bran, citrus pectin, barley, and maize starch) was investigated. Rice bran was shown to be capable of increasing SCFAs production and stimulating the growth of probiotic strains. Since rice bran is commonly used as a fiber supplement in the pet food industry and could therefore add a prebiotic effect to the known dietary effects tied to the use of this type of fiber, which include increasing the fecal mass and providing a laxative action. Rice bran on its own had the same effect on the fecal counts of bifidobacteria and lactobacilli and concentrations of SCFAs as the various synbiotic combinations, thus indicating lack of synergistic effect between the probiotic strains and fiber source used (Ogue-Bon et al. 2011; Pinna and Biagi 2014).

In a recent study, Salavati Schmitz and Allenspach (2017) tested the growth properties of *Enterococcus faecium* NCIMB 10415 E1707, *Enterococcus faecium* NCIMB 30183, *Bifidobacterium longum* NCIMB 30182, and *Bifidobacterium infantis* NCIMB 30181, with the addition of FOS, MOS, and FOS plus gum Arabic in vitro. The *Enterococcus faecium* NCIMB 10415 E1707 which is most commonly used probiotic strain for small animals was not influenced by any of the prebiotics used. The growth of bifidobacteria was enhanced with commonly used prebiotic oligosaccharides, whereas the addition of gum Arabic had a stronger effect on growth acceleration than FOS alone, suggesting that bifidobacteria might be interesting probiotic candidates in small animals.

Besides in vitro studies, the effects of *Lactobacillus acidophilus* NCFM, FOS, or their combination have been investigated on concentrations of gut microbial populations, fermentative end products, and nutrient digestibilities in healthy adult dogs. *Lactobacillus acidophilus* plus FOS containing synbiotic was proved to be beneficial in healthy dogs. Supplementation of FOS alone enhanced gut microbial ecology by increasing concentrations of beneficial microbial populations (e.g., bifidobacteria, lactobacilli) and decreasing

concentrations of potential pathogens (e.g., *Clostridium perfringens*). It also enhanced indices of gut health by increasing fecal butyrate and lactate concentrations and decreasing several putrefactive compounds present in feces. On the other hand, *Lactobacillus acidophilus* enhanced some beneficial microbial populations and increased total tract nutrient digestibility. *Lactobacillus acidophilus* plus FOS resulted in effects of larger entity on the concentration of bacterial metabolites. In particular, the synbiotic was effective in reducing the fecal concentrations of ammonia and putrefactive compounds including branched chain fatty acids, biogenic amines, phenols, and indoles to a greater extent as compared to administration of either probiotic or prebiotic alone (Swanson et al. 2002).

Although supplemental synbiotics may be useful in introducing beneficial bacterial populations and have potential to encourage proliferation of autochthonous-specific strains in the intestinal tract, there are limited studies using synbiotics as a supplement in the prevention or treatment of diarrhea in companion animals. Gagné et al. (2013) evaluated the effects of a synbiotic containing *Enterococcus faecium* SF68, *Bacillus coagulans*, and *Lactobacillus acidophilus* plus FOS and MOS and other ingredients on fecal quality, SCFAs concentrations, and the microbiome and its potential to reduce the episodes of diarrhea in training healthy sled dogs. Administration of synbiotic resulted in a significant rise in *Lactobacillaceae*, positive correlation between *Lactobacillaceae* and overall butyrate concentration, and improvement in fecal score which was associated with a decrease in the prevalence of diarrhea in dogs. In contrast, in a previous study, no changes in the major bacterial phyla were identified in healthy dogs and cats following administration of a commercial synbiotic containing a mixture of seven different probiotic species (*Enterococcus faecium* NCIMB 30183, *Streptococcus salivarius* subsp. *thermophilus* NCIMB 30189, *Bifidobacterium longum* NCIMB 30179, *Lactobacillus acidophilus* NCIMB 30184, *Lactobacillus casei* subsp. *rhamnosus* NCIMB 30188, *Lactobacillus plantarum* NCIMB 30187, *Lactobacillus delbrueckii* subsp. *bulgaricus* NCIMB 30186) and a blend of FOS and arabinogalactans daily for 21 days. The synbiotic had no adverse gastrointestinal effects during the study period. None of the evaluated serum (cobalamin, folate, IgA, trypsin-like immunoreactivity, and pancreatic lipase immunoreactivity) or fecal (IgA and α_1-proteinase inhibitor) markers of gastrointestinal and immune function were influenced by the synbiotic administration. However, administration of the synbiotic resulted in an increased abundance of probiotic bacteria in the feces of healthy dogs and cats (Garcia-Mazcorro et al. 2011). Lack of changes in the major bacterial phyla of the synbiotic-administered dogs and cats has been attributable to significantly less prebiotic supplied in the diet. It has been shown that to cause significant increases in the fecal microbiome of dogs such as *Lactobacillus*, at least 0.5–1% increase in soluble fiber is required (Swanson et al. 2002; Gagné et al. 2013).

Diarrhea is also the most common disease affecting kenneled dogs in animal shelters. In a recent study, Rose et al. (2017) assessed the efficacy of a synbiotic supplement on the incidence of diarrhea in a dog shelter in a randomized, double-blind, placebo-controlled trial. Supplementing healthy dogs entering an animal shelter with *Enterococcus faecium* NCIMB 10415 4b1707 plus a combination of FOS and acacia was demonstrated to significantly decrease the incidence of diarrhea. It was suggested that animal shelters can use synbiotic supplements to improve animal welfare and decrease costs involved in cleaning and housing animals as well as potentially decreasing veterinary intervention.

Studies addressing the efficacy of synbiotics in domestic cats with diarrhea are very scarce. Hart et al. (2012) examined the effect of a synbiotic formulation comprising of multispecies probiotics (*Enterococcus faecium* NCIMB 30183, *Streptococcus salivarius* subsp. *thermophilus* NCIMB 30189, *Bifidobacterium bifidum* NCIMB 30179, *Lactobacillus acidophilus* NCIMB 30184, *Lactobacillus casei* subsp. *rhamnosus* NCIMB 30188, *Lactobacillus plantarum* NCIMB 30187, *Lactobacillus delbrueckii* subsp. *bulgaricus* NCIMB 30186) plus two prebiotics in client-owned adult cats with naturally occurring chronic diarrhea. The synbiotic improved stool character, and the mean fecal score decreased from 6.0 to 4.4, representing a significantly firmer stool character. Following a 21-day course of synbiotic supplementation, 72% of owners perceived an improvement in diarrhea of their cats. This synbiotic product had no adverse effects and was found to be safe and well tolerated.

Although probiotic use is beneficial in the prevention of antibiotic-associated gastrointestinal signs (AAGS) in humans (Blaabjerg et al. 2017), little is known about efficacy of synbiotics in mitigating AAGS in cats. Stokes et al. (2017) conducted a randomized, double-blinded, placebo-controlled, two-way, two-period, crossover trial of prevention of clindamycin-induced gastrointestinal signs using a synbiotic (a commercial mixture of probiotics and prebiotics) in healthy research cats. Administration of the synbiotic 1 h after clindamycin administration decreased hyporexia and vomiting in cats. In addition, the clinical benefits of synbiotic administration persisted for at least 6 weeks after discontinuation, decreasing the severity of AAGS in cats that subsequently received clindamycin with placebo. However, synbiotic administration did not decrease antibiotic-associated diarrhea.

3 Concluding Remarks and Future Directions

In view of increasing consumer awareness and the ever-growing demand for animal products from antibiotic-free livestock production systems, synbiotics and other feed

additives are now being considered important tools to help in the improvement of animal performance and health and counteracting diseases. Although available data regarding effects of synbiotics on animal health and production are inadequate and require further studies, the majority of studies dealing with synbiotics have been conducted in poultry, but increasing research has been focused in ruminants, pigs, and pet animals. There are evidences to suggest that synbiotics are having favorable influence on the intestinal microbiota of animals and play role in the improvement of performance and maintenance of optimal health of farm and companion animals. High potential of synbiotic products is attributable to the concurrent use of probiotics and prebiotics with the ultimate aim, besides others to improve the survival and implantation of probiotic microorganisms and maintain favorable balance in the ecosystem in the gastrointestinal tract, which is crucial for the improved health and productivity of the host animal. Besides other favorable effects, improvement in the number of beneficial intestinal microorganisms and the reduction of the potential pathogen load, stimulation of immunological response, and increased production capacity have been demonstrated following administration of synbiotics in animals. They are also effective in improving the intestinal architect, blood indices, and absorption of minerals and nutrients. The use of synbiotics may reduce the demand for antibiotic-based growth promoters. Selection of most appropriate probiotic and prebiotic in synbiotic products and better understanding about the intestinal microbiota of animals will pave the way in designing more efficacious synbiotics. Further research is needed regarding preventive and therapeutic health benefits, mechanisms of action, optimal doses, duration of treatment, improved delivery systems, and augmentation of in vivo efficacy of synbiotics which may lead to the enhancement of their beneficial effects on animal health and production.

Enzymes in Feed and Animal Health

Arturo Anadón, Irma Ares, Maria Rosa Martínez-Larrañaga, and Maria Aŕanzazu Martínez

Abstract

Exogenous enzymes are potentially important alternatives to antibiotics for improving growth performance, particularly in poultry and swine, although research in other animals such as ruminants, fish, fur-bearers, and pets has been done in recent years. The value of added feed enzymes in promoting growth and efficiency of nutrient utilization in animal production is clearly recognized. This chapter covers several reaction conditions that need to be met for the enzyme to act, as well as feed enzymes and gastrointestinal microbiota, mode of action for enzymes, dietary substrates, and enzyme types to be used in animal feed (for example, phytase, and enzyme classes such as xylanases, β-glucanases, pectinases, amylases, and proteases) which improve the feed utilization of dietary components such as protein, amino acids, starch, lipids, and energy. Feed enzymes can affect gastrointestinal tract (GIT) microbial ecology by reducing undigested substrates and anti-nutritive factors and producing oligosaccharides in situ from dietary non-starch polysaccharides (NSP) with potential prebiotic effects.

Keywords

Veterinary nutraceuticals · Enzymes in feed · Poultry feed · Swine feed · Phytase · Glucanases · Amylases · Proteases

1 Introduction

Enzymes as feed additives for food production animals are biologically active proteins that facilitate chemical breakdown of nutrients to smaller compounds for further digestion and absorption (Thacker 2013). Enzymes added to feed are broken down in the digestive tract in the same way as other proteins. Enzymes are biologically active proteins that break specific chemical bonds to release nutrients for further digestion and absorption. The enzymes used in animal feed are commonly produced by bacteria (i.e., *Bacillus subtilis*), fungus (i.e., *Trichoderma reesei*, *Aspergillus niger*), or yeast (*Saccharomyces cerevisiae*). The potential benefits of various exogenous feed enzymes, derived from microbes (bacteria and fungi) through traditional submerged liquid fermentation or solid-state fermentation, have been used in poultry and swine feeds for the past several years, and their value for improving nutrient digestion and growth, and efficiency of utilization of dietary components (i.e., protein, amino acids, starch, lipids, energy) in feedstuffs, are well documented (Woyengo and Nyachoti 2011). The potential for use of enzymes in feed, as alternatives to antibiotics, to improve performance in poultry and swine is significant.

Enzymes extracted from microorganisms are of great importance in the manufacturing of animal feed. Currently, new molecular techniques are used to discover microbial enzymes that are used in animal feeds to improve their quality.

A number of efficacy trials indicate that the adverse consequences of discontinuance of the use of antimicrobial growth promoters (AGPs) could be compensated to some extent by administering enzymes to facilitate the digestion of polysaccharides. Specific enzymes added to the diet are able to depolymerize these polysaccharides. A variety of enzymes are obtained from plants, bacteria, and fungi but there is also a wide variety of enzymes marketed commercially for poultry feed additives, many of which are produced as recombinant proteins in yeast commercially and sold as a lysate. In poultry, feed enzymes generally increase its digestibility, which could be particularly beneficial to young animals; thus, young birds may benefit from a wide spectrum of enzymes, such as lipase, proteases, and amylases. The benefits of enzymes generally diminish with age category, and responses are usually greater during the broiler chicken

starter phase compared with the finisher phase. The aim of adding enzymes to poultry feed is to improve performance and profitability through enhanced digestion of dietary components. In attempts to reduce the ecological footprint, enzymes as proteases are an interesting option; the enzymes allows for more effective improvements to nutritional management, thus mitigating the risks and particularly in the "post-antibiotic environment." The different classes of feed enzymes commonly employed include phytase, carbohydrases in maize-based diets, xylanase (from *Trichoderma longibrachiatum*), cellulose (from *Aspergillus niger* and *Trichoderma longibrachiatum*), α-galactosidase, β-mannanase, α-amylase (from *Aspergillus oryzae*, *Bacillus amyloliquefaciens*, *Bacillus subtilis*) and pectinase, β-glucanase (from *Aspergillus niger*), proteases, and lipases. The most common reasons for enzyme supplementation include degrading feed components resistant to endogenous enzymes (i.e., β-glucanase, xylanase, mannanase, pectinase, galactosidase), inactivating ANFs (i.e., phytase), and supplementing endogenous enzymes that may be present in insufficient amounts (i.e., proteases, lipases, amylases) (Thacker 2013). It is thought that xylanases in wheat-based diets can improve the performance of chickens by initiating the breakdown of pentosans into smaller compounds and as a result reducing their viscosity properties.

Many other enzyme classes can significantly improve the utilization of feed such as xylanases, β-glucanases, pectinases, amylases, and proteases. In this respect, endo-1,4-β-xylanase may improve the nutritive value of wheat-based diets for poultry by degrading dietary arabinoxylans (Beg et al. 2001). However, a response of broiler chickens to supplementation of wheat-based diets with exogenous endo-1,4-β-xylanase is not always observed. It is thought that endoxylanase improves the apparent metabolizable energy value and nutrient digestibility of wheat-based diets and reduces the variability of wheat.

Although there initially may be concerns over using recombinant DNA-produced enzymes as feed additives for food-producing animals, recombinant synthesized enzymes such as phytases and carbohydrases are commercially produced and sold as feed additives in monogastric food animal production (Adeola and Cowieson 2011). Proteases added to broiler chicken feed were reported to have a beneficial effect by increasing the feed conversion ratio (FCR) and lowering levels of *Clostridium perfringens* in the ileum.

Enzymes are highly effective biological catalysts capable of accelerating chemical reactions millions of times over, acting on specific substrates or reactants. Chemically, they are proteins with a highly complex three-dimensional molecular structure. The protein nature of enzymes has important implications for their stability during high-temperature feed manufacture and transit through the gastrointestinal tract (GIT). As proteins, they can be denatured by heat and pH and they can also be subject to proteolysis by digestive enzymes. Enzymes are affected by the conditions of their surroundings (e.g., water concentration, temperature, pH) with respect to enzyme activity as well as stability.

The role of feed enzymes in improving the productive value of diets for single-stomached animals is based on several modes of action (Adeola and Cowieson 2011; Slominski 2011), namely, (1) hydrolysis of specific chemical bonds in feedstuffs that are not sufficiently degraded or indeed not at all by the animal's own enzymes (e.g., mixed salts of phytic acid); (2) elimination of the nutrient-encapsulating effect of the cell wall polysaccharides and therefore increased availability of starches, amino acids, and minerals; (3) breakdown of anti-nutritional factors (ANFs) that are present in many feed ingredients [e.g., non-starch polysaccharides (NSP) and phytic acid]; (4) solubilization of insoluble NSP for more effective hindgut fermentation and thus improved overall energy utilization; and (5) complementation of the enzymes (e.g., amylase, lipase, protease) produced by young animals in which, because of the immaturity of their own digestive system, endogenous enzyme production may be inadequate.

A unique feature of enzymes is their high substrate specificity. Each enzyme breaks down onto highly specific substrates at specific reaction sites. Thus, to achieve maximal benefits from enzyme addition, it is necessary to ensure that the enzymes are chosen on the basis of substrates in the ingredients used in feed formulations. Moreover, the enzymes need to meet several reaction conditions to act (Adeola and Cowieson 2011; Ravindran 2013):

1. *Moisture content*. Enzymes require an aqueous environment to initiate their activity; thus, moisture may be essential for the mobility of the enzyme, solubility of the substrate and enzyme, or both (Ravindran 2013). When ingested feed contains exogenous enzyme, the condition for humidity is quickly met and feed moves down the digestive tract (Svihus 2011).
2. *Temperature*. In general, enzyme activity increases up to 40 °C and then sharply decays because of the loss of structure through denaturing, which renders the enzyme inactive (Ravindran 2013). For example, in the bird body most enzymes are active in a range between 40 °C and 60 °C without being a limiting factor.
3. *pH*. In general, the most exogenous enzymes have an optimum pH of 4–6 (Ravindran 2013), but variation can appear between different enzyme sources, which may result in catalytic activity at both lower and higher pH. In poultry, the exogenous enzymes are active and degrade their substrates in the forestomach (i.e., crop, proventriculus, or glandular stomach, and gizzard or muscular stomach) before they are exposed to hydrolysis by endogenous proteolytic enzymes in the proventriculus site of acid secretion (Selle and Ravindran 2007).

Table 1 Average transit time and pH in different segments of the digestive tract of broiler chickens

Segment	pH	Transit time (min)
Crop	5.5	10–50
Proventriculus and gizzard	2.5–3.5	30–90
Duodenum	5–6	5–10
Jejunum	6.5–7.0	20–30
Ileum	7.0–7.5	50–70
Caecum/colon	8.0	20–30

The pH condition becomes the first physiological limitation for the activity and stability enzymes. The second limitation is the short interval between feed ingestion and the time to reach the lower ileum. The feed pH is typically close to neutral, the crop of the chicken is mildly acidic, the proventriculus and gizzard are acidic, and the intestine is mildly acidic at the proximal end, becoming mildly alkaline to neutral towards the distal part (see Table 1). Acid secretion of chickens is high relative to mammals, possibly because of the rapid digestive transit time. Under discontinuous feeding systems, the role of the crop of poultry resembles a food storage organ, not being essential for digestion, whereas in continuous feeding systems this function does not exist. A less-developed gizzard serves as a transit organ rather than a grinding organ, with implications for reduced retention time. There is evidence that meal feeding, instead of ad libitum access to feed, may markedly increase the retention time in the crop, together with a rapid moisturization and a reduction in pH (i.e., pH between 4 and 5). In the pig, the stomach pH is usually between 2 and 3.5, so that the enzymes have been developed to resist over a broad pH range, and exhibit thermostability, that is, are resistant to endogenous pepsin and trypsin, and viable under simulated gastric conditions (Thacker 2013).

4. *Enzyme concentration*. In theory, the reaction rate is directly proportional to enzyme concentration and increases when enhancing the concentration of the enzyme, because more available active sites exist, and this will continue until no more enzyme–substrate complex can be formed. In practice, however, because of other limitations within the digestive tract of animals, this linear relationship does not occur (Ravindran 2013).
5. *Substrate concentration*. In the presence of adequate enzyme concentrations, the reaction rate increases with augmenting substrate concentration until the maximum turnover is reached. The enzymes considerably vary with the reaction conditions needed and depend on their source (fungal vs. bacterial vs. yeast). Therefore, the source has a major influence on how closely particular enzymes are adapted to the prevalent conditions in the digestive tract and their effectiveness (Ravindran 2013).

Table 2 The effectiveness of a feed enzyme in the digestive tract of a bird

Prerequisites	
Enzymes	Source, specific catalytic activity, resistance to pepsin proteolytic action
Substrate characteristics	Concentration and accessibility
Digestive tract conditions	Moisture content, pH, temperature, and the time digesta remains in the tract, especially in the early gastric phase where most of the enzyme action occurs

The effectiveness of a feed enzyme in the digestive tract of a bird depends on several prerequisites (Table 2). An aqueous environment is needed for the enzymes to initiate their activity.

2 Feed Enzymes and Gastrointestinal Microbiota

Efficacy in animal feed applications depends very much on a different set of criteria based on the mechanism of action in animal nutrition (Bedford and Schulze 1998). The interaction between feed enzymes and the GIT microbiota/microbiome can be better understood from two points of view. On one hand are the effects of substrates by themselves on the digesta biochemical characteristics and GIT physiology (i.e., increased viscosity of soluble NSP, increased digesta transit time of soluble NSP, increased endogenous secretion and cell turnover (e.g., mucus), increased undigested fat, proteins, and starches, and on the other hand is the modification of these effects by feed enzymes [decreased viscosity, decreased transit time (NSPases), decreased endogenous secretion (NSPases, phytase), decreased undigested fat, protein, and starches (NSPases, phytase, amylase, proteases)] to the extent that the substrates are degraded or modified in the GIT (Kiarie et al. 2013), which explains feed enzymes acting on specific components of feed ingredients,which in most cases explicates the role of feed enzymes in modulating the gut microbiota.

Viscosity reduction can be effectively achieved with a single enzyme provided that it is active against the backbone of the polymer and not against a side chain. Because viscosity is, in part, a function of chain length, it is not necessary to degrade the polymer fully; relatively few breaks in the chain will substantially reduce or destroy a gel-forming capacity. Thus, problems, such as sticky droppings, which relate solely to gelation are relatively simple to alleviate with any enzyme preparation containing the necessary activity. For example, the problems of wet droppings associated with oats and rye-based diets to broiler chickens can be overcome by

inclusion of enzyme preparations rich in β-glucanase and endo-β-xylanase (pentosanase) activity, respectively.

The latest endo-β-xylanase improves litter quality as well. In conclusion, a close relationship exists between viscosity data obtained in vitro by extraction of soluble polysaccharide and those ANFs properties that can be reduced or eradicated by enzyme treatment (Annison 1991). The viscosity aspect is important because the rationale for the development and application of feed enzymes is to target certain dietary substrates (i.e., phytate and NSP) that are not degraded sufficiently or indeed not at all by the endogenous digestive enzyme array in the GIT. For instance, an accepted paradigm in broiler chickens is that increased intestinal viscosity from soluble NSP as indicated previously is the most important cause of for poor growth and feed utilization. Consequently, it has been suggested that feed enzymes might influence the intestinal microbiota through two main mechanisms: reducing the undigested substrates; and creating (in situ) short-chain oligosaccharides from cell wall NSP with potential prebiotic effects (Kiarie et al. 2013).

For feed digestion by enzymes, there is, however, a physiological limit to the extent that enzymes can improve digestion, and these barriers relate to pH and retention time within the GIT. The use of exogenous feed enzymes in poultry diets is becoming a norm to overcome the adverse effects of anti-nutritional factors (ANFs) that are present in plant-based feedstuffs such as phytic acid, NSP, and cell wall complex carbohydrates, and to improve digestion of dietary components and bird performance. The cell walls of cereal grains, legumes, and oilseed meals are made up of complex carbohydrates commonly referred to as NSP (Choct 2009). NSP are a complex group of components differing widely in chemical composition, physical properties, and physiological activity. NSP consist of a wide range of polymers including (hemi)cellulose, pectins, β-glucans (consisting of either a more soluble or a nonsoluble fraction), α-galactosides (raffinose, stachnyose, verbascose), and xylans (Thacker 2013). Many NSP have negative effects on growth and performance and reduce the nutritional value of feed ingredients in a number of ways: (1) they are indigestible by mammalian enzymes and therefore dilute the energy and nutrient content of the feed, and (2) NSP exhibit a so-called cage effect whereby normally highly digestible nutrients such as starch, fat, and protein are entrapped in a coating of NSP that prevent access of the endogenous enzymes to these substrates (Metzler et al. 2005). Further, certain NSP may increase intestinal viscosity. The anti-nutritive effects exerted by NSP are complex, but their viscous nature is considered a primary cause for their anti-nutritive effect in poultry. The increased bulk and viscosity of the intestinal contents decrease the rate of diffusion of substrates and digestive enzymes and hinder their effective interaction at the mucosal surface (Choct et al. 1996). In addition to the direct effect of viscous NSPs on gut physiology and morphology, there appear to be some indirect effects that have important implications for the efficient use of nutrients by the chicken (Dänicke et al. 1999). One such indirect effect may be related to stimulation of fermentation of NSPs by the gut microbiota, leading to volatile fatty acid (VFA) production in the small intestine. On a NSP-rich diet, the VFA concentration increases, mainly in the distal ileal lumen, because of excess fermentation combined with a proliferation of the fermentative microflora with a rather limited effect on the activity of the hindgut microbiota (Choct et al. 1999). Fermentation in the small intestine indicates competition with the host for digestible nutrients. Dietary NSP enzymes reduce the viscosity of the digesta in the small intestine, so that digesta passage and nutrient digestion rate increase, allowing less substrate and less time for the fermentation organisms to proliferate. This change may restore the normal and efficient endogenous enzymatic digestion of nutrients in the small intestine. The enzymes partially counterbalance the adverse effects of soluble NSP on performance (Bedford and Classen 1992). Additionally, NSP-degrading enzymes will also reduce the proliferation of pathogenic bacteria such as *Clostridium perfringens* (Jackson et al. 2003). Presently, all broiler chicken feed contains enzymes such as xylanases and β-glucanases that break down NSPs. Different cereal types contain variable NSP levels with concomitant differences in chemical composition. For example, maize contains almost exclusively insoluble NSPs, whereas wheat and barley contain NSPs of which the ratio of soluble to insoluble is about 1:6. This ratio is about 3:4 in rye, making this cereal one with particularly high levels of soluble NSPs (Choct 2002). Diet formulation has to be adjusted and conditions have to be created to ensure maximum response to added enzymes.

3 Mode of Action for Enzymes

It must be recognized that different feed enzymes (Table 1) have nonidentical modes of action. Despite their increasing acceptance as feed additives, the exact mode(s) of action of feed enzymes remains to be elucidated. The possible mechanisms of action of in-feed enzymes include the following: (1) increase in the digestibility of nutrients that are otherwise not degraded by host enzymes (e.g., phytic acid); (2) elimination of the nutrient-encapsulating effect of cell wall polysaccharides and increase in the availability of starches, amino acids, and minerals; (3) inactivation of anti-nutritional factors (e.g., phytic acid or soluble NSP) and reduced intestinal viscosity; (4) increase in the solubility of nonsoluble NSP and promotion of caecal fermentation; and (5) supplementation of endogenous enzymes that may occur in insufficient amounts, especially in young animals in which the digestive system is not fully developed (Choct 2009;

Kiarie et al. 2013). In addition to the enzymes, effects have been observed on nutrient digestibility; they are also thought to influence the composition of the gut microbiota. The enzyme-induced microbiota changes are mostly indirect and are thought to be mediated by two main mechanisms: (1) reducing the undigested substrates and (2) generating short-chain oligosaccharides from cell wall NSP with potential prebiotic effects (Bedford 2000; Bedford and Cowieson 2012; Kiarie et al. 2013). These mechanisms influence the nutrient supply and intestinal environment, thus altering selection pressures on bacterial species (Bedford and Cowieson 2012; Cheng et al. 2014).

The general consensus is that one or more of the following mechanisms are responsible for the observed benefits (Bedford and Partridge 2011): (1) degradation of specific bonds in ingredients that are not usually hydrolyzed by endogenous digestive enzymes; (2) degradation of anti-nutritional factors that limit nutrient digestion directly, increase intestinal digesta viscosity indirectly, or both; (3) disruption of endosperm integrity and release of nutrients that are bound to or entrapped by the cell wall; (4) shift of digestion to more efficient digestion sites; (5) reductions in endogenous secretions and protein losses from the gut, resulting in reduced maintenance requirements (Cowieson et al. 2009); (6) reduction in the weight of the intestinal tract and changes in intestinal morphology (Jaroni et al. 1999); and (7) changes in the microflora profile in the small intestine. The proven value of the addition of enzyme preparations, capable of hydrolyzing the mixed-linked β-glucan content of barley endosperm walls (part of a storage structure) to poultry diets containing barley (classed as a low-energy cereal) has stimulated interest in both the mechanism underlying the productive response and the application of enzymes to other cereals as an important component of farm animal diets. Cell walls having a structural function are intrinsically more resistant to degradation.

β-Glucanase alone is sufficient to disrupt barley endosperm walls: multi-enzyme preparations containing high levels of enzymes active against cellulose and arabinoxylan are required to maximize the release of protein from the aleurone layer (Mulder et al. 1991). The endosperm walls of maize, triticale, and wheat also contain arabinoxylans and glucans. The disruption of intact walls and release of entrapped nutrients is the major factor in any improvement in nutritive value ascribed to exogenous enzymes. β-Glucan and arabinoxylans, which, in varying proportions, form the endosperm wall of all cereals, act to restrict access to nutrients found in the endosperm. For that reason, enzyme additions in both young pigs and poultry support the digestibility values for fat, starch, and nitrogen.

As enzymes influence the amounts and form of substrate present within the gut, their use has a direct effect on the bacteria that make up the microfloral populations (Apajalahti et al. 2004; Vahjen et al. 1998); alteration of gut flora towards favourable bacterial species, which improves gut health, provides a protective effect on the overall health of the animal that arises, in part, from the influence of flora on immune function. Augmentation of endogenous digestive enzymes, which are either insufficient or absent in the bird, results in improved digestion, especially in newly hatched chicks with immature digestive systems.

4 Dietary Substrates and Enzyme Types

In birds, substrates in feed ingredients can be mainly classified into three groups: (1) substrates for which suitable enzymes are produced in their own digestive tract (e.g., starch, proteins, lipids) [some of these incomplete endogenous enzymes (i.e., 10–20%) of these substrates are not digested and are excreted]; (2) substrates for which enzymes are not produced by the bird and not digested (e.g., cellulose); and (3) substrates for which enzymes are not produced by the bird and, in addition not being digested, have anti-nutritive effects (e.g., β-glucans, pentosans, phytate). Pentosans (arabinoxylans) in wheat have an anti-nutritive activity in broiler chickens. In feed ingredients, the substrates (nutrients and antinutrients) exist as complexes, limiting the accessibility to enzymes (Ravindran 2013).

Despite advances, the chemistry and structure of most target substrates in feed ingredients are still poorly defined. It is known that the chemistry of NSP in different ingredients varies widely. Although basic quantitative information on the type of sugars making up the NSP is available for cereals, corresponding information for other ingredients is lacking. The high NSP and indigestible protein contents in cereal co-products can limit their inclusion in pig feed; however, supplemental NSP-degrading enzymes and proteases might allow high inclusion of such feedstuffs. The efficacy of enzymes can be greatly improved if the chemistry of the target substrates is more precisely understood. Matching an enzyme, however, does not guarantee the efficacy of the enzyme in degrading the substrate, and affinity must also be considered. Using three fungal xylanases (xylanase A derived from *Thermomyces lanuginosus*, xylanase B from *Humicola insolens*, and xylanase C from *Aspergillus aculeatus*), of different substrate affinities, showed that substrate specificity is dependent on the source of the enzyme. It may be concluded that wheats with low or normal metabolizable energy values vary in their responses to xylanase supplementation (Choct et al. 2004).

For an enzyme to be effective, an adequate enzyme-to-substrate ratio must be present in the diet. A complicating factor is that a particular substrate in one ingredient is not exactly the same as the one found in another ingredient. The substrates differ and the same substrate in different

Table 3 Type of commercial feed enzymes and target substrates

Enzyme	Target substrate	Target feedstuff
Phytases	Phytic acid	All plant-derived ingredients
β-Glucanases	β-Glucan	Barley, oats, and rye
Xylanases (carbohydrase)	Arabinoxylans	Wheat, rye, triticale, barley, fibrous plant materials
α-Galactosidases	Oligosaccharides	Soybean meal, grain legumes
Proteases	Proteins	All plant protein sources
α-Amylase	Starch	Cereal grains, grain legumes
Lipases	Lipids	Lipids in feed ingredients
β-Mannanases, cellulases (carbohydrase), hemicellulases, pectinases	Cell wall matrix (fiber components)	Plant-derived ingredients, fibrous plant materials

ingredients may respond differently to the enzyme. Such differences arise from the location of the substrate in the ingredient matrix, the presence of other limiting factors, and differences in accessibility or solubility. In the case of phytate it was shown that phytates from different ingredients are not similarly susceptible to dephosphorylation and that the reactive, and not total, phytate content is critical in determining the responses to supplemental phytase (Leske and Coon 1999). It was found, for example, that canola meal contained a relatively high level of total phytate, but a less reactive phytate, and does not respond well to added phytase (Ravindran 2013).

Feed enzymes are actually the most researched feed additive. The current usage of feed enzymes is very broad, given the number of feed enzymes (Table 3) and, within each enzyme, a large number of commercial products is available, varying in their source, enzyme activities, and characteristics (Ravindran 2013). Not surprising is the success of enzyme addition to broiler chicken diet containing barley, which has stimulated interest in the application of feed enzymes to other diets and diet ingredients, notably wheat and soybean.

Currently, four distinct categories of enzyme products are commercially available for use by the feed industry: (1) microbial phytases; (2) glycanases or glycan hydrolases (xylanases, β-glucanases) targeting viscous cereals (e.g., wheat, barley) (these enzymes degrade polysaccharides and show little or no activity against oligosaccharides); (3) enzymes targeting nonviscous cereals (e.g., corn, sorghum); and (4) enzymes targeting non-cereals (e.g., soybean meal, grain legumes). With the exception of microbial phytases, most other enzyme products contain a mixture of enzymes that may be produced by one or more organisms (Cowieson et al. 2006; Selle and Ravindran 2007). The most widely used feed enzymes are a mixture of a variety of glycanases, and the single-use degrading enzyme is phytase (Ravindran 2013). There is also evidence to suggest that preparations with multiple enzyme activities may provide a competitive strategy to improve nutrient utilization in poultry diets (Selle and Ravindran 2007). The combined application of enzymes may result in additive, sub-additive, or synergistic effects on nutrient utilization and animal performance (Ravindran et al. 1999; Juanpere et al. 2005). Such enzyme combinations, rather than pure single enzymes, represent the next generation of feed enzymes, because feed ingredients are exceedingly structurally complex. In the native stage, nutrients in raw materials are not isolated entities, but exist as complexes with various linkages to protein, fat, fiber, and other complex carbohydrates. For example, in wheat-based diets, merely targeting the arabinoxylans with xylanases may not provide full benefits (Ravindran 2013).

The benefits of simultaneous inclusions of a carbohydrase enzyme with predominantly xylanase activity and a microbial phytase in wheat-based broiler chicken diets, in terms of both protein and energy utilization and growth performance, have been reported (Ravindran et al. 1999; Zyla et al. 1999; Selle et al. 2009). It appears that the activity of one type of feed enzyme may be facilitated by the other, possibly in a reciprocal fashion, by providing greater substrate access, and also by reducing the anti-nutritive effects of the substrates and phytate) on nutrient utilization. It is thought that these anti-nutritional effects are manifested by depression in performance and wet droppings, connected with the high viscosity of NSPs. The simultaneous inclusion of phytase with α-galactosidases, protease, β-glucanase, and xylanase in corn-, barley-, or wheat-based diets has been investigated: it was found that the phytase in combination with carbohydrase and protease had additive effects in nutritionally marginal broiler chicken diets (Cowieson and Adeola 2005; Juanpere et al. 2005).

In this context, various enzymes, derived from microbes (bacteria and fungi) through fermentation, have been used in swine and poultry feeds for the past several years, and their value in enhancing growth and feed efficiency is widely known. The diverse classes of enzymes commonly employed include phytase, carbohydrases, and proteases. The enzymes do not directly attack bacteria, but only reduce substrates for the growth of bacteria.

5 Main Enzymes

5.1 Phytase

Phosphorus is the third most expensive nutrient in diets for non-ruminants; however, the majority (>65%) of the phosphorus in feedstuffs of plant origin is bound in mixed salts of phytic acids and is unavailable to the animal without

enzymatic dephosphorylation (Kiarie and Nyachoti 2009). The plant phosphate, to be unavailable to the animals, acts as an ANF by forming complexes with minerals such as calcium, zinc, and iron. Phytase, an activity derived from *Aspergillus ficuum*, is able to release phosphate from phytic acid (hexa-phosphorylated myoinositol). The requisite enzyme to hydrolyze phytic acids is insufficient in avian and mammalian pancreatic and intestinal secretions, present in some feedstuffs, and ubiquitous in microbial systems (Selle and Ravindran 2007, 2008). Phytic acid is the major storage form of phosphorus in plant seeds and is particularly abundant in cereals, where it occurs as crystals associated with protein bodies found principally in the aleurone layer (Graf 1986). Approximately two thirds of the phosphorus in feeds for pigs and poultry is present as phytic acid, which is unavailable to non-ruminants. So, monogastric animals (i.e., swine and poultry) poorly utilize the phosphorus present in phytate as they have little to no endogenous phytase activity. The application of phytase, either as a pre-treatment or as a feed supplement, allows diets to be formulated with substantially less supplemental inorganic phosphorus and reduces the discharge of faecal phosphorus to the environment. Consequently, to provide adequate phosphorus to non-ruminant farm animals it is necessary to include feedstuffs with high phosphorus bioavailability such as inorganic supplements (e.g., dicalcium phosphate) or animal-based feedstuffs (e.g., meat and bone meal) in the diet. It is known phytase has significant effects on the digestibility of calcium, phosphorus, and minerals as well as the intestinal mucin production and endogenous losses, all of which influence the nutrient supply and the intestinal environment, which will alter the selection pressure on bacterial species (Bedford and Cowieson 2012).

Nowadays, phytase dominates the market of feed enzymes and rapid growth has been associated with the acceptance of phytase in replacing inorganic phosphates (Kiarie et al. 2013). The use of phytases in improving phosphorus availability from plant feed ingredients is very well known in animal nutrition. A simple example is dietary phosphorus level and microbial phytases; if the diets contain excess amounts of phosphorus, then the chance of any animal response to phytase addition will be low. The use of microbial phytase is potentially useful and appropriate only for diets with suboptimal phosphorus levels and containing significant levels of plant-derived ingredients. The phytase feed additive is used to increase phosphorus absorption, to digest more than 30% more phosphate in its ratios, by pigs. Less of the mineral is therefore required in feed and less is wasted, thus reducing the emission of mineral phosphate in slurry and easing the burden in groundwater. It also offers substantial saving for natural resources of mineral phosphate. Phytase in pig rations can cleave phosphate output in manure and increase the digestion efficiency for phosphorus and other minerals in the diet including calcium, magnesium, and zinc.

The pollution potential from too high levels of phosphate in pig and poultry manure begins with the way in which phosphate is presented in most vegetable feed materials as phytate-phosphorus. This phytate-phosphorus can only be broken down for digestion through the activity of phytase enzymes.

These enzymes can be found in the stomachs of ruminants such as cows where they are naturally produced by microorganisms. But, in monogastric animals such as pigs and poultry, the enzymes are not present, or present only in very small amounts. A feeding pig on conventional rations excretes more than 60% of the phosphorus present in its feed and a breeding sow some 85%. When fed to growing slaughter pigs at the rate of about 100 g per tonne of feed mix, this phytase only offers around 33% reduction in phosphate excretion. Because it promotes more efficient digestion of dietary phosphorus, any supplementation of mineral phosphorus in feed can be reduced.

The addition of phytase enzymes to animal diets has the potential to improve the phytic acid-phosphorus utilization by the animal. Phytase enzymes catalyze the hydrolysis of feed grain and fiber phytic acid to myoinositol and phosphorus and thereby allow reduction in mineral phosphate supplementation and excretion. A wide variety of techniques follow before the phytase product is ready: screening, characterization, protein engineering, genetic modification, genomics, expression technology, fermentation, and testing. The next generation of the products is even better because they are more stable and less excess phosphate is released into the environment.

5.2 Carbohydrases

Carbohydrases include all enzymes that catalyze a reduction in the molecular weight of polymeric carbohydrate, but more than 80% of the global carbohydrase market is accounted for by xylanase and β-glucanase (Adeola and Cowieson 2011). Other commercially available carbohydrases include α-amylase, cellulose, β-mannanase, α-galactosidase, and pectinase. These carbohydrases have widespread application in the poultry industry but are used less commonly in feeds for swine.

The effect of carbohydrase supplementation on the performance of pigs is contradictory (Thacker 2013). Although positive effects on performance are observed, they are commonly associated with increases in nutrient digestibility, probably a result of increased accessibility of endogenous enzymes to nutrients as a result of inhibition of the "cage effect" as well as hydrolysis or partial hydrolysis of the NSP.

Hydrolysis of NSP results in increased sugar release in the large and small intestine and thereby stimulates the growth of lactobacilli, which produce lactic acid. Increased proportions of lactic acid promote gut health by suppressing the growth of coliforms such as pathogenic *E. coli*.

It is known that the response of pigs to carbohydrase supplementation is less consistent than has been observed with poultry, differences resulting from the physiology of the pig and the chicken. One clear difference is the pH in the gut. In the pig, the duration that feed is exposed to a low pH is significantly longer than in the chicken (Baas and Thacker 1996). It is possible that exposure to low pH in the stomach of the pig is either partially or totally denaturing the enzyme, accounting for the lower magnitude of responses obtained when carbohydrases are fed to pigs compared with poultry (Thacker 2013).

5.3 Proteases

Proteases have the capacity of breaking down proteins. The use of proteases in feed has not been analyzed as extensively as other enzyme classes, and in many cases the proteases investigated have been present as part of an enzyme mixture (e.g., *Bacillus* wild-type fermentations). Monogastric animals, such as swine and poultry, produce digestive proteases, for example, pepsin, trypsin, chymotrypsin, and carboxypeptidases, which digest feed proteins to a greater extent. Nevertheless, a fraction of the ingested feed protein is excreted in the faeces, representing an opportunity for an exogenous protease to improve the utilization of protein in chickens for fattening (Glitsoe et al. 2015). Protease reduces the proportion of indigestible amino acids in feedstuffs, resulting in a corresponding increase in digestible amino acids. Generally, the more indigestible the level of amino acid present, the greater the increase in digestibility when proteases are added. The greater the level of undigested protein, as measured by the level of digestibility of amino acids, the more variability a particular feedstuff will exhibit.

Protease is a very modern feed additive that supports better nutrition, health, and environmental conditions in pig production, which are closely interrelated through the mode of action of protease. The use of protease can contribute significantly to reduce nitrogen emissions during livestock production. Improved gut health, for example, also reduces the requirement for amino acids and energy. Nutritional benefits are based firmly on digestible amino acids, in terms of both animal requirements and availability from feedstuffs. Health benefits are linked to the potential to reduce dietary protein levels and therefore reduce the level of undigested proteins in the hindgut. Excess protein is a fermentation substrate that may produce breakdown products such as phenols, amines, ammonia, and indoles that in turn increase the pH, which are all undesirable outcomes. Likewise, anti-nutritional factors (ANFs), such as trypsin inhibitors, might set up conditions to predispose the growth of *Clostridium perfringens.* Higher ammonia levels in animal buildings could predispose animals to risks of respiratory disease.

Protease added to broiler chicken feed was reported to have a beneficial effect by increasing the FCR and lowering levels of *Clostridium perfringens* in the ileum. There are a wide variety of enzymes for poultry feed additives, many of which are produced as recombinant proteins in yeast used as a lysate. Production of enzymes by *Pichia pastoris* can serve as a potential source for biochemical or animal feed studies (Johnson et al. 2010), and dietary use of encapsulated lysozyme (Zhong and Jin 2009) as a feed additive in the diet of chickens significantly reduced the concentration of *Clostridium perfringens* and gastrointestinal lesions because of the organism in the ileum (Liu et al. 2012).

Abrupt piglet weaning around the fourth week of life causes a dramatic fall in the output of amylase and a significant check in the production of protease, whether measured as activity per unit pancreas weight or on a total pancreas basis (Lindemann et al. 1986). The weaned pig is ill prepared to digest the starch and protein found in a cereal-based weaner diet and could benefit from enzyme augmentation immediately after weaning (Owsley et al. 1986). However, recovery of endogenous enzyme production is rapid and the benefit of enzyme supplementation is likely to be short lived.

At weaning, the transition from highly digestible to less digestible sources of protein is worsened by a decrease in secretion of endogenous protease and changes in gut lining morphology. These changes include the reduction of villus height and crypt hyperplasia, which results in impaired absorption of nutrients and gut health issues. Therefore, additive protease supplementation can help piglets to digest proteins, which reduces the amount of undigested protein reaching the hindgut. Feeding exogenous protease additive to piglets can improve gut morphology when compared to nonsupplemented piglets. Thus, the integrity of tight junctions can be preserved, leading to a reduction in post-weaning mortality. By minimizing the levels of nondigested protein, protease enzyme also establishes the conditions for a healthier gut, reduced nitrogenous excretion, and lower protein diets, all of which have the potential to improve performance and reduce feed and production costs (Aehle 2007). This functionality is unique to protease, which is why it has been called the “next amino acid.” The indirect nutritional effects of protease enzyme provide some further health benefits. The potential reduction in putrefaction protein in the hindgut lessens the risk of generation of a range of harmful metabolites, such as 3-methylindole and hydrogen sulfide. The protease supplementation resulted in a significant increase in the thickness of the adherent mucus layer in the

GIT of broiler chickens and promoted the ability to survive with a coccidiosis infection.

It was observed that supplemental protease increased gut tensile strength, villus height, and crypt depth, and reduced epithelial thickness and goblet cell numbers (Cowieson et al. 2009). These morphological changes are indicative of enhanced gut integrity and resilience and are suggestive of beneficial effects of protease that extend beyond increased amino acid recovery. The presence of protease has been shown to enhance the numbers of lactobacilli and reduce the levels of *Escherichia coli* in the colon in both high- and low-protein diets.

A life cycle analysis was carried out to determine the environmental impact of protease in the whole broiler chickens production chain using the life cycle assessment methodology described in ISO 1404017 and 1404418. The study showed significant benefits for all the environmental impacts that were considered. The most important was the potential to reduce water and air pollution with nitrous compounds, which can lead to eutrophication and acidification. The greatest effects were observed when the protease was used in diets to compensate for reduced protein content (Oxenboll et al. 2011).

Low-protein diets reduce disease risk. The use of protease allows confidence in achieving compatible performance from lower protein diets and, hence, supporting a better environment and reducing risk from respiratory disease produced by *Pasteurella multocida*; a lower-protein diet produces manure with a much lower ammonia, hydrogen sulfide, and odor content.

In pig farming, it has been proposed to use "precision feeding techniques" as an essential approach to improve the utilization of dietary nitrogen, phosphorus, and other nutrients, and also to reduce nutrient excretion. For example, addition of enzymes (e.g., phytases) improves the environmental traits in comparison with the traditional feed formulation. The enzyme feed addition can promote the sustainability of the improving the environmental sustainability of pork production, animal well-being, and meat product quality by reducing nutrient excretion in swine operations with small increases in feeding costs (Pomar et al. 2009). Using these "precision feeding techniques," pigs are individually fed with a daily adjusted diet that can improve dietary nutrient efficiency. The estimated feeding costs can be reduced in an amount higher than 4.6%, and nitrogen and phosphorus excretion can both be reduced more than 38% (Pomar et al. 2009).

The role of protease, therefore, becomes increasingly important in improving the availability of multiple essential amino acids from feedstuffs. An additional benefit of protease is in reducing the negative effects of ANFs, such as trypsin inhibitors, on the efficiency of production. A further outcome is that gut mucin production may be reduced so that absorbed amino acids are used for useful protein building through lean gain or milk production and not for unnecessary production of intestinal mucin protein. Mucin production also uses energy that would otherwise be supporting protein building. Consequently, energy is used more efficiently, which makes this a doubly valuable result.

Protease additives reduce the proportion of indigestible amino acids in feedstuffs, resulting in a corresponding increase in digestible amino acids. Generally, the more indigestible level of amino acids present, the greater the increase in digestibility when proteases are added. A meta-analysis revealed that the improvement of amino acid digestibility was about 10% when the overall digestibility in a control diet was less than 70%. As the overall digestibility of the control diet improved, opportunity for the benefit from protease was reduced. At 90% dietary digestibility, the average response from protease was about 2% (Cowieson and Ross 2014). The apparent metabolizable energy was significantly increased by 49 kcal/kg and fat digestibility was improved by 1%. It is worth noting that the inherent digestibility in the control diet explained approximately 047% of the variance in the response.

Previously, following in vitro addition of protease, higher hydrolysis of allergenic proteins, glycinin, and β-conglycinin from soybean meal has been shown (Wang et al. 2004). It is important to note that nutrient levels in a diet affect the response to protease and that the best responses appear to occur when there are higher levels of indigestible protein and soy in the diet. Therefore, response to protease may be more consistent in the presence of phytase and xylanase. Furthermore, enzyme interactions with a corn source indicated the influence of extractable salt-soluble protein content of corn on accessibility to protein and starch. The magnitude of phytase responses was greater during the first week posthatch compared with broiler chickens at 4 weeks of age. Responses with exogenous enzymes cannot be assumed to be constant and are influenced by the source of corn used as well as the age of broiler chickens. One caveat with this particular study relates to the fact that between day 9 and 21 the birds were all fed the same enzyme treatments but a constant and different source of corn (Gehring et al. 2013).

5.4 Xylanase

Interestingly, xylanase added to a wheat-based diet alleviated the pathological effects of *Clostridium perfringens* in broiler chickens (Liu et al. 2012).

5.5 β-Galactomannans

The dietary inclusion of β-galactomannans has become a promising strategy to control and prevent intestinal infections. The effect of various β-galactomannan-rich products on intestinal morphology in chickens challenged with *Salmonella enteritidis* has been investigated, indicating the beneficial effects of these enzymes on intestinal morphology give more evidence of the positive effects of these supplements in poultry nutrition (Brufau et al. 2015).

6 Concluding Remarks and Future Directions

The potential for using enzymes in poultry diets to improve the nutritional value of feeds has been recognized for many years. The limitations on enzyme activity are imposed by the nature of the substrate and by the host animal. The scientific basis for enzyme addition is established for some feedstuffs although for others it is not. The β-glucanases and xylanases have been used as feed additives for more than 20 years and their ability to improve the FCR and weight gain of monogastric animals (poultry and pigs) has been demonstrated in numerous reports. The use of these feed enzymes has been restricted primarily to poultry and pigs where the majority of feed in intensive farming contains feed enzymes, although research focusing on supplemental enzymes for ruminants and fish, as well as fur and pet animals, has been also carried out during recent years. During the past years investigations into the mode of action of feed enzymes have continued rapidly, particularly in phytase research, where it is clear that the valuable benefit of this enzyme is not simply through the provision of phosphate, but also via the destruction of phytic acid, a potent anti-nutrient. Similarly, a better understanding between feed enzyme function and digestive physiology has positively influenced application recommendations for feed enzymes. The confirmation of feed enzymes reduces the environmental impacts of agriculture as a complex area needing consideration and specific studies. Feed enzymes are applied to improve feed utilization and their benefits include reduced feed cost, improved animal performance, and reduced environmental impact of animal production. Additionally, effects of feed enzymes on the microbiota or microbiome of the GIT need further research. Feed enzymes may cause an impact on GIT microbial ecology by reducing undigested substrates and anti-nutritive factors and producing oligosaccharides in situ from dietary NSP. Furthermore, investigations using specific enteric pathogen challenge models have demonstrated the efficacy of feed enzymes in modulating gut health. Because feed enzymes probably change the substrate characteristics along the GIT, subsequent microbiota responses will vary according to the populations present at the time of administration and their reaction to such changes. Nowadays, the role of major feed enzymes (for example, carbohydrases and phytase) on the gut health of poultry and swine species with a specific focus on the impact on GIT microbiota is of great interest. The application of genetic engineering in the process of enzyme production allows the development of enzymes targeted for specific purposes. Establishment of specific substrates (and therefore enzyme activity), substrate effects, factor affecting substrate importance, and the stability of enzyme cocktails are required to fully exploit this new engineering technology. However, before a feed enzyme can be put on the market, it must be submitted to a number of toxicological and safety examinations and fulfill the requirements of the registration procedures.

Nutraceuticals Used as Antibacterial Alternatives in Animal Health and Disease

Arturo Anadón, Irma Ares, Maria Rosa Martínez-Larrañaga, and Maria Aŕanzazu Martínez

Abstract

In the past decades, an accumulative amount of research has been concentrated on the development of alternatives to antimicrobials to maintain animal welfare and health and performance. A high level of internal and external biosecurity for farms, herds, or flocks is critical because they constantly receive and deliver biological material. Many efforts have been dedicated to demonstrate how viruses or bacteria are shed from poultry or pigs and transmitted among farms, herds, or flocks. A good external biosecurity is crucial to avoid introduction of new biological agents. To overcome the increased rate of mortality and morbidity resulting from the ban of in-feed antibiotics, a number of antibacterial alternatives have been designed. The classes of alternative substances described in this chapter include organic acids and short- and medium-chain fatty acids, phytobiotics and essential oils, antimicrobial peptides, bacteriophages and their endolisins, and immunomodulatory compounds (vaccines). Prebiotics and probiotics, and enzymes, are also notable alternatives to antibacterials but are described in two other chapters. These nutraceuticals are valuable tools in antibiotic-free production systems to support the intestinal health of the animal. Based on a literature search, it is evident that a long and growing list of compounds have been reported for their ability to replace antibacterials as feed additives in animal diets. Research is still needed in the area of nutraceuticals used as antibacterial alternatives in animal health because the perfect alternative to antibacterials does not yet exist. The mechanism of action for these compounds needs to be better defined. Regulations concerning feed additives in the European Union for these nutraceuticals used in animal production are also described.

1 Introduction

Antimicrobials have been used worldwide in animal husbandry including livestock, poultry, and fish farming for many decades because of their favorable economic effects in livestock production to maintain health and productivity. Antibiotics added in low doses (i.e., sub-therapeutic doses) to the feed of farm animals improved growth and performance (feed conversion ratio) and hence were known as "antimicrobial growth promoters" (AGP). Growth promotion involves the modification of the gut microflora population and changes in the host metabolism. Concerns exist that these practices in antibiotics use as growth promoters in animal feed contributed to the development of antimicrobial resistance, spreading drug-resistant pathogens in both farm animals and humans, posing a significant potential threat to public health.

The problems associated with the use of antimicrobials in food animals are growing worldwide without clear evidence of the need for or benefit from it, leading to increasing recognition that urgent action is needed. It is accepted that the prevalence of antibiotic resistance in the livestock sector is generally higher in animal species reared under intensive production systems. The prudent use of antimicrobials (also referred to as "judicious," "rational," or "antimicrobial stewardship") in animals is very important to help reduce the development of antimicrobial resistance (AMR) because, as in humans, inappropriate use can result in the development of resistant microorganisms, which can be subsequently transmitted from animals to humans (or vice versa) and to the environment. "Prudent or judicious" and "rational" terms are frequently used to suggest a responsible attitude to antimicrobial use, aimed at minimizing the development and spread of AMR while maximizing therapeutic efficacy.

R. C. Gupta et al. (eds.), *Nutraceuticals in Veterinary Medicine*, https://doi.org/10.1007/978-3-030-04624-8_22

Antimicrobial stewardship is a concept developed as an interdisciplinary approach to ensure the efficacy of antibacterials and their use in future generations. The core principles of the concept are the "5 R's": Responsibility (shared responsibility involves a drug-prescribing veterinarian and livestock producers), Reduction (avoid prophylactic and metaphylactic use and use antibacterials only for treatment outbreak), Refinement (combination of reliable diagnostics followed by correct use of antibacterials), Replacement (use of alternatives at the farmers' disposal, pre- and probiotics, organic acids and butyrate, secondary plant compounds), and Review (regularly checking the applied measures with the aim to eventually reduce antibiotic use to zero). The prudent use of antimicrobials is part of good veterinary and good animal husbandry practice and takes into consideration disease prevention practices such as the use of vaccination and improvements in husbandry conditions. The different applications of antibiotics in food animals have been described as prophylactic use, therapeutic use, and metaphylactic and sub-therapeutic use. The use of antimicrobials for mass medication, in sub-therapeutic doses or in other inappropriate manners, amplifies this risk. Thus, the European Commission in 2015 published guidelines for the prudent use of antimicrobials in animals that set out many potential factors to be considered in establishing policies and actions which reflect the multi-faceted, complex issues involved in tackling AMR. They define the prudent use of antimicrobials as leading to more rational and targeted use of antimicrobials, thereby maximizing their therapeutic effect and minimizing the development of AMR (EC 2015, 2018). Mixed opinions still exist on the transfer of antibiotic resistance genes from animal to human pathogens (Gadde et al. 2017). Several studies showed that there might be a link between the practice of using sub-therapeutic doses of antibacterials and the development of AMR among the microflora (Cosby et al. 2015). Because of the emergence of microbes resistant to antibiotics (AMR) that are used to treat human and animal infections, the European Commission (EC) decided to phase out, and ultimately ban since the 1 January 2006 decision taken on "precautionary principles," the marketing and use of antibiotics as growth promoters in animal feed (Anadón 2006). Since then, the use of antibacterials is only allowed on veterinary prescription for direct applications or as medicated feed. These restrictions are deemed necessary as antibacterials may lead to the selection of resistant bacterial strains in animals that could be transferred to humans, by direct contact or via foodstuffs, and subsequently lead to an impairment of the efficacy of antibiotics used in therapy of human infectious diseases (Anadón 2006).

The impact of phasing out animal growth promoters could be minimized provided that adequate attention is given to alternative disease prevention strategies and management factors, such as alternative husbandry practices in food animal production. Livestock performance and feed efficiency are closely interrelated with the qualitative and quantitative microbial load of the animal gut, the morphological structure of the intestinal wall, and the activity of the immune system (Huyghebaert et al. 2011). In the US, antibiotic use in livestock and poultry feeds is under great scrutiny as a result of increasing consumer awareness and the demand for livestock products from antibiotic-free production systems. In 2013, the US Food and Drug Administration (FDA) called for major manufacturers of medically important animal drugs to voluntarily stop labeling them for growth promotion in animals and revise the labels such that veterinary supervision is required for therapeutic uses (FDA 2013). The FDA continued to strengthen its agenda on promoting judicious use of antimicrobials in food-producing animals and published its final rule of the Veterinary Feed Directive (VFD) in early 2015, bringing the use of critically important antimicrobials (CIAs) (for example, third- and fourth-generation cephalosporins and/or fluoroquinolones) according to their degree of risk to man in feed under veterinary supervision, so that they are used only when necessary to ensure the health of the animals. Medicated feed containing antibacterial veterinary medicinal products shall not be used to supplement food-producing animals nor to enhance their performance. Particular issues should be considered before using CIAs. (1) Many of the antimicrobials used in animals are also used in humans. Some of these antimicrobials are critical for preventing or treating life-threatening infections in humans. (2) Special consideration is necessary to ensure the continued efficacy of such antimicrobials and to minimize the development of resistance. (3) Before using these antimicrobials in animals, consideration should be given to the following: these antimicrobials should only be used in situations for which a veterinarian has assessed, on the basis of antimicrobial susceptibility testing (AST) and relevant epidemiological data, that there is no non-critically important effective antimicrobial available. (4) In exceptional cases where the use of these antimicrobials under "off-label" (extra-label) use (cascade system) is unavoidable and legally permissible, prescription and final use should be sufficiently justified and recorded. Such use should be based on clinical grounds: that is, the prescribing veterinarian considers the use of a particular CIA necessary to avoid the suffering of diseased animals, and should also take into consideration ethical and public health concerns. The use of CIAs should be limited to cases where no other alternative is available (EC 2015).

Antimicrobial resistance is a well-documented knock-on effect of the overuse of antibiotics as a preventive method to maintain animal health and performance. The majority of

antibiotics used in animal husbandry are not used to treat sick animals, but are used to treat unhealthy production systems. For example, in dairy production (e.g., mastitis treatments are responsible for most antibiotics used on a dairy farm to control inflammation of the mammary gland and udder tissues, usually caused by bacterial infections), dairy cows receive on average two antibiotic treatments annually, one to prevent and one to treat mastitis. This practice often involves "blanket" use of antibiotics across all cows to prevent the occurrence of mastitis during the "dry" period; when dairy cows are rested between the end of one lactation and the start of the next (typically around 60 days), with penicillins, cephalosporins (e.g., cefquinome, a third-generation cephalosporin), or other β-lactam drugs. The most commonly used antibiotics for dry-cow therapy are older cephalosporins, with modern cephalosporins used by about 16% of farmers (Rose and Nunan 2016). Another area where antibacterials use is too high is in pre-weaned dairy calves reared at the dairy; antibiotics are added to the milk/milk replacer and to routinely treat diarrhoea. Similarly, beef calves that enter feedlots receive antibiotics for the treatment of clinical respiratory disease or to prevent liver abscesses that negatively impact growth with macrolide tylosin (Walker et al. 2012).

Growing swine receive antibiotics, commonly tetracyclines or tylosin, in their feed for disease prevention and growth promotion purposes. Finally, the most common use of antibiotics in poultry production is to support marginal baby chicks that have become contaminated in the yolk sac or at the navel during hatch. The systematic injection of antimicrobials (e.g., cephalosporins) into eggs or day-old chicks in hatcheries is often practiced but should be avoided entirely, unless justified for exceptional reasons. For example, the use of third- and fourth-generation cephalosporins in poultry (including eggs) should be prohibited, in accordance with the Commission's decision following the referral procedure of 13 January 2012 and in line with the European Food Safety Authority's (EFSA) scientific opinion on the public health risks of bacterial strains producing extended-spectrum beta-lactamases (ESBL) and/or AmpC β-lactamases in food and food-producing animals and due to the risk of AMR spreading to humans (EMA 2012). The prophylactic use of antimicrobials at this stage can be avoided by ensuring good hatchery hygiene and through good management of day-old chick production (e.g., temperature control, hygiene, and stimulation of drinking and eating) (EC 2015). For the newly hatched chick, access to feed is also very important. Neonatal nutrition is a critical component in the establishment of normal gut function, from digestion and absorption to barrier function and development of the immune system. The intestinal epithelium is constantly exposed to commensal or resident pathogenic microbes and antigens that are important for the development of immunity.

2 Impact of Phasing Out Animal Growth Promoters

Antimicrobials have many times been used indiscriminately, to the detriment of healthy animals. If antimicrobials are given to an animal with a healthy gut microflora, it is highly likely to result in digestive and microbial disturbances. In-feed prophylactic antibiotics are not used to treat individual sick animals but are used to treat sick and suboptimal production systems.

It is well known that after antibiotic human treatment results in severe disturbance of the intestinal microflora leading to diarrhoea and abdominal discomfort in a variable fraction of patients, depending on the age group and the antibiotic used; approximately 15–30% of patients experience a symptomatic recurrence after discontinuation of antibiotics. A treatment period with antibiotics only temporarily change the composition of the microbiota, causing environmental changes. In most cases, the cause of the diarrhoea is unknown but a varying proportion of the cases are caused by *Clostridium difficile*. The *C. difficile* toxins may cause anything from mild diarrhoea, which can be cured simply by terminating the antibiotic treatment, to the life-threatening disease pseudo-membranous colitis (Vanderhoof et al. 1999). Although these effects usually resolve with *Lactobacillus* probiotics as single species or combination probiotic products, in livestock these intestinal disturbances certainly come with a cost in terms of lost feed efficiency. So, the impact of phasing out AGP could be minimized with adequate use of alternative disease prevention strategies and management factors, such as alternative husbandry practices in food animal production (Huyghebaert et al. 2011).

The incidence of certain poultry diseases, such as (subclinical) "necrotic enteritis," also called dysbacteriosis, affects chickens and turkeys for fattening at the age of 2–16 weeks, proliferating at the age of 3–6 weeks. The subclinical necrotic enteritis leads to a slow but steady growth rate reduction. This poultry disease syndrome is clearly emerging in the EU simultaneously with the EU ban of AGP; both the incidence of bacterial enteritis and use of drug medication to treat this disease have increased. Necrotic enteritis is caused by specific gram-positive, facultative anaerobic bacteria, *Clostridium perfringens* (toxin-producing pathogen), mostly type A. The overgrowth of the toxin-producing strain of *C. perfringens* damages the intestinal wall, impairing wall functionality and chemical architecture, which reduces their capacity to absorb nutrients. Acute clinical necrotic enteritis in which the level of infection is severe may result in high mortality even in the absence of other symptoms. The most commonly recognized predisposing factors for necrotic enteritis include coccidiosis infection, high dietary levels of non-starch polysaccharides (NSP), and indigestible protein.

C. perfringens is a component of the normal gut flora and is found in litter, faeces, soil, dust, and in healthy animal guts. These spore-forming bacteria are extremely resistant against environmental influences and can survive in soil, feed, and litter for several years and even reproduce. The factors that create an intestinal environment favorable for *C. perfringens* promoting an infection with necrotic enteritis are as follows. (1) Feed: undigested non-starrch polysaccharides (NSPs) serve as substrate, and some cause higher production of mucus, also serving as substrate and providing ideal anaerobic conditions. Undigested proteins from high content in the diet also serve as substrates. (2) Stress: stresses such as feed change or high stocking density. (3) Immunosuppressive diseases (such as infective chicken anaemia, and Gumboro or Marek's) decrease resistance against intestinal infections and facilitate their colonization. Dysbacteriosis is commonly observed in broiler chickens with acute or chronic gastrointestinal (GI) disease; primary dysbiosis is defined as alterations in microbiota without an identifiable cause. Anatomical and physiological differences along the GI tract, differences between luminal and mucosa-adherent microbiota, and bacterial interactions between host and microbiota (via innate and adaptive immune system) can also take place on a functional level without obvious changes in the actual composition of microbiota (Suchodolski et al. 2005). Some pathogens exert pressure on the gut and prepare the way for *Clostridia*: *Cryptosporidia*, and *Salmonella* may result in an imbalance between commensals or residents and potentially pathogenic bacteria (*Clostridium perfringens,* among others) because of an oversupply of nutrients in the lumen, leading to interference of microbiota with mucosa and inflammation (Dibner and Richards 2005). Consequently, the gastrointestinal tract (GIT) becomes less functional, contributing to poor digestion of feed and flock performance. This condition of the gut may be synonymous with conditions such as "wet litter," "small intestinal bacterial overgrowth," "malabsorption," and "feed passage syndrome." In this syndrome, there is increased water content in the faeces and reduced digestibility with indigested residues visible in the faeces (Huyghebaert et al. 2011). Dry bedding might still have to be added to address the moisture already in the litter. Alternatives such as probiotics or slow-release butyrates are given via the feed before the wet litter problem arises, bringing some benefits in terms of feed conversion ratio (FCR) and uniformity. Avoiding "wet litter" can contribute to the air quality in the poultry house, improving conditions for workers and animals alike. Good intestinal health can prevent respiratory problems by way of drier litter.

Weaning is a critical event in the pig's life cycle, frequently associated with severe enteric infections and overuse of antibiotics, which raises serious economic and public health concerns. During the weaning period, piglets lose the benefit of passive immunity from the sow's milk and experience GI changes that accompany the change in diet, which causes them a degree of stress and leaves them vulnerable to secondary infections. Among the physiological and GI factors impacted by the weaning transition, gut microbiota disruption is likely to be recognized as a key leading to postweaning diarrhea. The pig gut microbiota is a very complex ecosystem showing dynamic composition and diversity that shifts over time and along the entire GI tract (Isaacson and Kim 2012). Colonization is initiated at birth and is shaped by consumption of the sow's milk, which provides nutritional advantages to the population of lactic acid bacteria, building a milk-oriented microbiome (Frese et al. 2015). *Escherichia coli* and *Streptococcus* spp. create an anaerobic environment favouring the establishment of other colonizers such as *Bacteroides*, *Lactobacillus*, *Bifidobacterium*, and *Clostridium* (Petri et al. 2010). During the suckling period, the brood and rearing mother further differentiate the fecal microbiota of piglets. This weaning period obliges a change to new strategies because now no protection comes from the mother. As a result of all these changes, some piglets will not eat for some period of time. Strategies have been developed to counteract the problems of this period because the feed is less digestible as it includes raw vegetable materials and it is often presented in a dry form. One strategy is to stimulate the development of the GI tract of the neonate by supplementation of the sow diet with certain biologically active substances and plants. The weaned piglet body must try to adapt to this new physiological condition by reducing the use of energy and protein and lowering the replacement rate of the intestinal epithelial cells, resulting in a shortening of the intestinal microvilli (Skrzypek et al. 2007): their stomach however is not prepared to receive large quantities of food. The time the food remains in the stomach will be shorter and the pH obtained will not be correct to activate protein enzymes to digest vegetable protein, and therefore the risk of diarrhoea will increase.

Weaning has a strong impact on the GI immune system as the moment of weaning results in three major changes for the piglet: (1) all the diet composition is changed drastically from easily digested milk to a less digestible solid-based diet; (2) the piglets are moved to a new environment; and (3) litters are mixed, which brings social stress to the animal. These factors have major impact on the piglet's health and performance and sometimes results in mortality. The gut microbiota dysbiosis, induced by abrupt changes in the diet composition and environment of piglets, emerges as a leading cause of "post-weaning diarrhea," and associated infections in piglets even if the exact underlying mechanisms remain unclear (Gresse et al. 2017). The change in diet composition might have an enormous impact on their feed and water intake, which results in a fasting period of 24 h or even 48 h. When a piglet is in a status of dysbiosis, there is an increased risk for post-weaning diarrhoea. Moreover, weaning is associated

with increased permeability of the intestinal epithelium, which increases the risk of pathogenic infections as it become easier for pathogens to cross the epithelium and enter the body (Gresse et al. 2017). For many years, the solution has been based on using antibiotics or zinc oxide as premix for medicated feedstuff, at a dosage of 100 mg/kg bw/day for 14 consecutive days, that is, 2500 mg/kg feed ppm, in pre-starter and starter diets, for the treatment or prevention and control of post-weaning diarrhea in piglets (EMA 2016a, b). According to recently published data, zinc as used in animal farming might increase the prevalence of antibiotic-resistant bacteria because of co-selection for antimicrobial resistance genes. Several published studies demonstrated, during in vivo experiments or by investigating environmental isolates, a correlation between high doses of zinc supplementation in food and the prevalence of antimicrobial-resistant bacteria (LA-MRSA) or of multi-resistant bacterial clones (*Escherichia coli*). The EMA-CVMP considers that (1) the environmental risks identified by the yearly accumulation of zinc in soil from the spreading of manure in agricultural land cannot be controlled with risk mitigation measures, and (2) the overall benefit–risk balance for veterinary medicines containing zinc oxide to be administered orally to food-producing species is negative, as the benefits of zinc oxide for the prevention of diarrhoea in pigs do not outweigh the risks for the environment. Overall, there is a risk of co-selection for resistance associated with the use of zinc oxide, but at the present time, that risk is not quantifiable (EMA 2016a, b). Among the non-antimicrobial alternatives there are essential oils, and prebiotics or probiotics, which are currently evaluated to restore intestinal balance and allow a better management of the crucial weaning transition (Gresse et al. 2017).

3 Biosecurity

Biosecurity is the term used in veterinary medicine to describe measures to prevent pathogens from entering farm premises or a group of animals (external biosecurity) or the spreading of pathogens within farm premises or groups of animals (internal biosecurity) (Amass and Clark 1999). Biosecurity generally refers to keeping infectious agents out of an animal operation or farm whereas biocontainment refers to keeping any infectious agent(s) present on a farm or within a region confined to that region (Turner 2018). Biosecurity is a kind of health animal production system or programme, which is critical to prevent the introduction of disease-causing organisms in a farm/herd/flock and prevent the spread within a farm/herd/flock, being part of sustainable livestock production practices. Biosecurity means taking steps to ensure good hygiene practices are in place so that the risk of a disease occurring or spreading is minimized. These measures should be practiced at all times and not just during a disease outbreak. The poultry industry has for a long time embraced the importance of biosecurity, and pig production has come far, whereas the importance of biosecurity has not been fully embraced in dairy and beef production. The level of biosecurity of a certain herd can be assessed by interviewing the farmer regarding biosecurity practices and collecting data by visual inspection. A high level of biosecurity is a demand, not only for farms located in pig-dense areas with high infection pressure, but for all farms because they constantly receive, and deliver, biological material (i.e., animals and feed). The risk-based weighted biosecurity scoring system translates questions regarding biosecurity into a score for a herd for its internal, external, and overall biosecurity status. This score aims at providing an objective, comprehensive, and quantitative description of the level of biosecurity and can be used to inform the farmer about possible areas for improvements, and to compare the biosecurity level with that of other farms/herds/flocks. Farmers are likely to be more motivated to implement biosecurity measures if such measures can be expected to be beneficial for their farm performance (Laanen et al. 2014), yet there are limited quantitative data available to link biosecurity and production parameters (Amass and Clark 1999; Laanen et al. 2013). Especially, studying these relationships on the basis of multiple country data has not been done previously. Biosecurity also has a role in maintaining the health of animals in farms and the challenges within farms to manage implementation of biosecurity protocols.

Antibacterials use, for example, in pig farming, is influenced by a range of risk factors, including herd characteristics, biosecurity level, farm performance, occurrence of clinical signs and vaccination scheme, as well as farmers' attitudes and habits towards antimicrobial use. Therefore, initiatives should be required to preserve antibiotic effectiveness while simultaneously ensuring food security in low- and lower- to middle-income countries.

The development of antimicrobial resistance is a normal evolutionary process for microorganisms, but the selection pressure created by the routine use of antibiotics accelerates this development. This problem threatens the achievements of modern medicine, as the pipeline for the development of new antibacterial drugs is nearly empty. Limiting the use of antimicrobial drugs in human and veterinary practice can minimize the development of resistance. In 2016, colistin-resistant *E. coli* was isolated from a commercial poultry farm in China. Following the discovery of a new colistin horizontally transferable resistance mechanism (*mcr*-1), and considering the rapidly increasing importance of colistin for the treatment of critically ill human patients, the European Medicines Agency (EMA) recommended that all countries should strive to reduce the use of polymyxins as much as possible because colistin is an antibiotic of last resort (EMA

2016a). In parallel, the EMA also recommended refusal of new marketing authorizations and the withdrawal of the existing marketing authorizations for veterinary medical products containing zinc oxide. The recommendation is primarily based on the risk for the environment in addition to the possible risk of co-selection for antimicrobial resistance associated with the use of zinc oxide (EMA 2016a, b).

Global efforts include the 2016 United Nations Political Declaration on AMR and the 2015 WHO Global Action Plan on AMR, which was subsequently adopted by the World Animal Health Organisation (OIE) and the Food and Agriculture Organization (FAO). AMR has also been addressed in the G7 and G20 forums. In addition, action plans on antimicrobial resistance, such as those launched by FAO, WHO, and the EU (EU 2017), are also enabling and motivating countries to provide supportive actions to reduce infections and thus the need for antimicrobials. The industry is clearly working together to ensure our farming systems are sustainable and healthy. According to this "European One Health Action Plan on AMR", the European Agencies' supportive actions will include infection prevention, biosecurity measures, and control practices in human healthcare and in animal husbandry, including aquaculture, to reduce infections and thus the need for antimicrobials (EU 2017). In biosecurity measures, one must monitor the following critical features.

3.1 Animal Welfare

The five freedoms proposed by FAWC (1993) encompassed (1) Freedom from thirst, hunger, and malnutrition; (2) Freedom from discomfort; (3) Freedom from pain, injury, and disease; (4) Freedom to express normal behaviour, and (5) Freedom from fear and distress, combined elements in welfare which are a very useful framework to identify the main welfare problems in a given production system and also as a starting point to select the main welfare indicators. The welfare of an individual is its state as regards its attempts to cope with its environment. Many of the behavioral changes and medical conditions associated with aging may impair the welfare of the animal as defined by the five freedoms (FAWC 1993). Animal welfare has a large impact on production efficiency and health. Although most of us know about all these stressors for animals, it is very common to come to farms, herds, or flocks where the management and stress factors leading to disease are not corrected, but the animals are fed antibiotics to reduce disease and poor performance. For example, several diseases may result in pain or interfere with the expression of normal behavior. In piglets, reducing stress particularly at the time of weaning by increasing the weaning age and optimal nutrition are also beneficial, particularly to reduce the need for antimicrobials to control post-weaning diarrhoea. In poultry, the subclinical necrotic enteritis that produces conditions such as "wet litter" is a constant challenge in broiler chicken production, strongly linked to "food pad" lesions and welfare concerns for air quality.

3.2 Disease Prevention

Animal diseases and infections should be prevented by ensuring biosecurity, following good production and good management practices, and implementing integrated disease control programmes to both minimize the occurrence of diseases and eradicate endemic disease (EC 2015). Nutritional solutions to prepare the gut for an influx of bacteria could be crucial. Biosecurity measures that ensure hygiene standards, and housing situations that adhere to the welfare and well-being of the animal, should be the highest possible. Disease prevention through biosecurity measures is believed to be an important factor for improvement of overall health status in animal husbandry. Better protected animals, in turn, diminish the need for preventative or sub-therapeutic medicine. Biosecurity measures can influence animal health for the better and reduce potential need for antimicrobials. So, implementation of biosecurity measures, good farming practices, and herd health planning that prevents infections reduce the need for antimicrobials (EC 2015).

3.3 Cleaning and Disinfection

Good biosecurity requires a disinfection protocol. A correctly implemented protocol can be a cost-effective method of reducing pathogenic organisms and is an important step in any biological risk management program. Every biosecurity protocol needs to include a correctly selected hygiene and disinfection agent, which must prevent the proliferation of pathogenic microorganisms. An effective disinfectant material reduces ammonia formation, absorbs excessive moisture, decreases the pH value of the litter, contributes to significantly better air quality through minimizing harmful emissions, and improves overall animal performance. Applied regularly, the disinfectant can improve biosecurity status and minimize the spread of disease. Hygiene and biosecurity measures, including measures designed to prevent the introduction of infections, include keeping separate clothes and boots for each unit; controlled or limiting access to minimize intra- and interspecies exposure to animals and transmission of pathogens (e.g., by arthropods and rodents); handwashing (e.g., before preparing or eating human food), with hand disinfection facilities (liquid soap, hot and cold water) available close to the workplace; ensuring quick removal of and prevention of access to dead animals; applying the 'all-in all-out' system in each unit; following a strict

schedule for cleaning and disinfection; and performing regular disinfection controls (EC 2015). One key action that stands above all in terms of preventing antibiotic resistance is establishing a better and healthier environment through improved hygiene and good biosecurity practices.

3.4 Good Hygiene Practices and Environment

In production systems with high density of animals or poor biosecurity, development and spread of infectious diseases is favoured, leading more frequently to antimicrobial treatment and prevention of those diseases and providing favourable conditions for selection, spread, and persistence of antimicrobial-resistant bacteria (Rose and Nunan 2016). The objective of reducing antimicrobials use is also in line with animal welfare, aiming to reduce the farm animal population density. Stocking density (an adequate welfare parameter), and hygienic conditions of housing, bedding material, temperature, humidity, and air quality, are just a few environmental conditions with a very large influence on production, health, and welfare of animals. Overstocking is very common, impacting environmental temperature and hygiene, and often reduces cleaning and disinfection between batches of animals. Overcrowding also imposes social stress on the animals as there may be insufficient eating and resting space. Overcrowding and very large numbers of animals facilitate disease transmission and pathogen mutation to greater virulence. Keeping stock densities low and avoiding excessive herd or flock sizes, and avoiding mixing within the herd or flock, or quarantining stock for an appropriate period before mixing, are important biosecurity measures (EC 2015). A period of quarantine and stabilization can help ensure that new stock are healthy and free from disease (Turner 2018).

A flawless environmental temperature is perfectly adapted to the age and weight of the animals. Good air quality and ventilation are essential to keep animals healthy and vigorous. Physical separation of sick and healthy animals, and handling and attending to the needs of healthy animals first, will help reduce disease transmission within a group of animals (Turner 2018). In birds, for example, ventilation must be managed adequately to minimize the negative impact from ammonia concentrations, dust, litter moisture, excessive humidity, or combustion gases. A warm, moist environment is also a perfect environment for pathogenic bacteria to thrive and propagate.

In laying hens, optimal hatchery equipment operation and optimal hatchery environment reduce the need for supportive antibiotics. The establishment and maintenance of good gut function is vitally important in reducing neonatal chick morbidity and mortality. Antimicrobials should not be used routinely on the arrival of day-old chicks at the farm. The prophylactic use of antimicrobials at this stage can be avoided by ensuring good hatchery hygiene and through good management of day-old chick production (e.g., temperature control, hygiene, stimulation of drinking and eating) (EC 2015).

In bovines and small ruminants, mass or group medication of cattle is rare, although veal calves can be subjected to group treatment using antimicrobials. Treatment given to cows at drying-off is of particular importance. These measures include (1) avoiding prophylactic use of antimicrobials in newborn calves (e.g., antimicrobials added to milk replacers) by implementing good farming practices (e.g., ensure high standards of hygiene); (2) developing preventive strategies (e.g., vaccinations, feeding colostrums to calves), especially for the allotment of veal calves and beef cattle; (3) avoiding the systematic treatment of cows at drying-off, considering and implementing alternative measures on a case-by-case basis; (4) establishing thorough hygiene measures and good farm practice and management strategies to minimize the development and spread of mastitis in dairy cows; (5) promoting rapid diagnostic tests (e.g., standardized tests with chromogenic media) for identifying mastitis-causing pathogens to minimize both intramammary and injectable antimicrobials in milking cows; and (6) avoiding feeding calves with waste milk from cows treated with antimicrobials (EC 2015). In dairy cows, hard flooring, inadequate bedding, and crowded conditions can increase the likelihood of dairy cows developing mastitis or lameness. Housing should therefore be designed around cow comfort, with good ventilation, suitable humidity, high-quality bedding, and good hygiene practices (Rose and Nunan 2016).

3.5 Immunity

Vaccines have proven to be very important and cost-effective in preventing the onset and spread of infectious diseases and thereby have great potential to reduce the incidence of AMR; thus, good systemic immunity is essential. The European Commission states in the "One Health Action Plan" (EU 2017) that vaccines should be boosted even further to decrease the use of antimicrobials in those sectors. However, immune-enhancing measures are not limited to vaccinations but include genetic selection, pathogen-free animals, nutrition, mycotoxin prevention, stress reduction, stocking density, and environmental factors. Biosecurity and increased use of vaccination were perceived to be the most promising alternatives to antimicrobials in industrial pig and poultry production, based on combined effectiveness, feasibility, and return on investment. In baby chicks, for example, training hatchery personnel to monitor factors critical to chick quality as well as training in vaccination technique enable poultry producers to start with healthy birds. When possible, alternative strategies for controlling disease that have been

proven to be equally efficient and safe (e.g., vaccines) should be preferred over antimicrobial treatment. Vaccination management should also include measures to avoid stress reaction and improvements for the availability of autogenous vaccines (EC 2015).

3.6 Management

Management is probably the best alternative, but it is not so easy to apply as it includes many different characteristics. Management has to ensure good hygiene and environment (e.g., when pigs are weaned and located in nurseries). The pigs have to find the feed and water as easily as possible, and feeders have to allow them to eat in groups, as they do during lactation. Probably the most important management improvement is teaching the pig how to eat feed. It is recognized that if pigs know how to eat and drink before weaning, the fasting period after is reduced and with it, all the derived problems. Training the young pig to eat should start very early on, during lactation (Oostindjer et al. 2011). Ensuring that animal feed is preserved and that water is clean and not contaminated will minimize the spread of disease within a group of animals (Turner 2018). Stimulating them to eat creep feed should include nutritional skills to formulate an attractive and digestible diet, but also allow them to take feed and water at the same time, as when they nurse from their mother. Liquid presentation in a concentration similar to the mother's milk can make training easier and increase feed intake while they are still lactating, allowing them to achieve their maximum genetic potential. This presentation before weaning is not simple as it must guarantee that the feed remains clean and attractive to the piglets. Weaning management in cases of recurrent weaning diarrhoea should be reassessed, considering in particular hygiene, age of pigs, use of 'all-in all-out' systems, reducing stress suffered by the animals, and alternatives to the prophylactic use of antimicrobials (EC 2015).

3.7 Nutrition

Feed business operators must comply with the legal requirements for feed hygiene, implement best practices in the production of safe and nutritionally balanced feed, and ensure adequate feed formulation. They must also ensure that all ingredients meet the required standards and that the manufacturing process does not allow the feed to be contaminated with deleterious agents, which could compromise the safety of the feed. Feed business operators producing medicated feed must be approved for its manufacture. They must follow all legal requirements for medicated feeds and may only produce medicated feed from authorized veterinary medicinal products and in accordance with a veterinarian's prescription. They must follow good manufacturing practices and ensure appropriate mixing to guarantee the homogeneity of antimicrobials in the feed as well as avoid cross-contamination and minimize the transfer of antimicrobials to subsequent batches of feed (Dorne et al. 2013; EC 2015).

Highly digestible diets have always been regarded as a good instrument to prevent digestive problems. The bioavailability of synthetic amino acids has made it possible to formulate low crude protein diets that are considered safer, but pig performance remains unaltered. Even low-protein diets will not totally prevent protein fermentation in the gut, as the digestibility of the protein will not be 100%. The inclusion of higher levels of fibre could help in maintaining intestinal stability. The type or what level of fibre would be most interesting in post-weaning diets but needs further investigation (Gloaguen et al. 2014). It must be highlighted that the colostrum fed to the piglet or calf during the first 24 h after birth is the most important meal of the animal's life as it is vital for the development of the gut. A hygienic environment and feed are crucial for young animals with underdeveloped immune systems.

Besides good nutrition and a proper anti-coccidial program, fattening chickens requires eubiotics to prevent wet litter problems and limit antibiotic usage. The synergistic effect of certain organic acids with essential oils is well known, and these are now widely used as "gut health enhancers." The combination of specific essential oil compounds and benzoic acid is particularly effective in improving nutrient utilization, therefore improving performance and reducing flock treatments.

The eubiotic approach must be included within a complete feed strategy accurately involving all the other critical nutritional components including micronutrients and enzymes. Nutrition is only part of the solution and needs to be integrated in a sustainable holistic approach including proper vaccination, farm management, and biosecurity.

3.8 Stress

Transport and trade in live animals impose high physiological stress on the animals and create a high risk of spread of diseases, and this creates a need for antimicrobial medication to protect the animals from disease. Current production systems have enabled live animal transport and trade to the detriment of the animals. Transport of young animals often includes prophylactic antibiotic medications. Antimicrobials are most often used in pigs to relieve weaning diarrhoea, intestinal infections associated with *Lawsonia intracellularis*, and respiratory diseases often associated with transport, plus the stress caused when pigs originating from different farms are brought together or when animals are housed with

inadequate ventilation, unsuitable feeding, or insufficient biosecurity measures (EC 2015). These production systems must minimize all unnecessary transport of animals during rearing. However, there are advantages in segregated production systems, and therefore more focus should be placed on minimizing stress and spread of disease through animal trade and transport and minimizing the length of transports. Stressful situations can weaken animal immune systems and make them more susceptible to infections; thus, to avoid stress, animal transport should be limited by minimizing transport time and avoiding overcrowding) (EC 2015).

4 Reducing Antibiotic Use

Prophylactic antibiotics have been used for various digestive tract challenges in animal production, such as necrotic enteritis in poultry, pre-weaning calf diarrhoea, and pre- and post-weaning diarrhoea in piglets. Thus, a focus on gut health is critical to achieving a sustainable, efficient production without the routine use of antibiotics. For example, butyric acid decreases the incidence of subclinical necrotic enteritis caused by *C. perfringens* (Timbermont et al. 2009). To reduce antibiotic use, the production system needs to be healthy, sustainable, and respectful of animal needs.

Reduced risk of contracting an infection can allow reducing the need for antimicrobial treatment of animals. A clear link between biosecurity and both production- and antimicrobial treatment-related criteria in pig herds has been demonstrated, indicating substantial differences in the current application of biosecurity in pig herds. Aspects of both external and internal biosecurity were positively associated with daily weight gain and negatively associated with FCR, respectively. Internal scores were negatively associated with disease treatment incidence, suggesting that improved biosecurity might reduce the prophylactic use of antimicrobials (Laanen et al. 2013). Reduced and prudent usage of antimicrobials in livestock production is an arguable point, mainly in relationship to public health. It is known that previously effective antibiotics are losing their power, and healthcare is approaching a situation similar to the "pre-antibiotic era". Antibacterials have been, and are, the best treatment options for serious bacterial disease. International, national, regional, and local antibacterial stewardship campaigns have been developed to encourage prudent and responsible use of antibiotics, limiting unnecessary exposure, with the ultimate desire of preserving their effectiveness for serious and life-threatening infections.

In June 2017, the EU adopted "the European One Health action plan against antimicrobial resistance (AMR)" (EU 2017). This policy was reinforced with the 2011 Commission action plan, notable for its "One Health approach," addressing AMR in both humans and animals. "One health" is a term used to describe a principle which recognizes that human and animal health are interconnected, that diseases are transmitted from humans to animals and vice versa and must therefore be tackled in both. The "One Health approach" also encompasses the environment, another link between humans and animals and likewise a potential source of new resistant microorganisms. The EU new one health action plan is based on three pillars: (1) making the EU a best practice region on AMR: better evidence and awareness; better coordination and implementation of EU rules; better prevention and control; better addressing the role of the environment; a stronger partnership against AMR and better availability of antimicrobials; (2) boosting research, development, and innovation on AMR: new economic models and incentives, better detection and control measures; new antimicrobials, rapid diagnostic tests, vaccines, and alternative therapies; AMR in the environment; and (3) shaping the global agenda on AMR: stronger EU global presence, partnering; stronger bilateral partnership for stronger cooperation; cooperating with developing countries; and developing a global research agenda (EU 2017). This new action plan will enable and motivate countries to provide supportive actions including infection prevention, biosecurity measures, and control practices in human healthcare and in animal husbandry to reduce infections and thus the need for antimicrobials.

The greatest flaw of animal production systems is that they have been designed and utilized in a way that requires antibacterials to maintain production and the health and welfare of animals. The majority of antibacterials used in animal production are not used to treat sick animals but rather treat unhealthy production systems. The goal to reduce antibiotic use should be rephrased to a goal to produce healthy production systems. The knowledge and tools to create these systems and many producers can demonstrate high productivity and cost-effectiveness in production systems that have eliminated prophylactic and metaphylactic use of antibiotics. In striving for a higher level of health and productivity, and providing the quality products that modern-day consumers are requesting, it is time for alternatives to antibiotics before taking action. A key to success in an antibiotic reduction programme is to assemble a team including veterinarians, nutritionists, consultants (governmental, academic, or industry), building engineer experts, owners, managers, and workers. This "One Health" term is globally recognized, having been widely used in the EU and in the 2016 United Nations Political Declaration of the high-level meeting of the General Assembly on antimicrobial resistance. The draft political declaration recognizes the "One Health approach," emphasizing that this requires coherent, comprehensive, and integrated multi-sectoral action, because human, animal, and environmental health are interconnected. Two key messages were raised by the Inter-Agency Coordination Group (IACG) on AMR: (1) antimicrobial resistance (AMR) is a global,

multi-sectoral issue that affects all countries and requires coherent, comprehensive action on human, animal, plant, and environmental health in the framework of a "One Health approach", and (2) a successful response to AMR will address not only antimicrobials but also diagnostics, vaccines, and alternatives to antibiotics for human and animal health (IACG 2018).

The reduction of antibiotic use in food animal production has become a significant aim of all livestock producers. Veterinarians and domestic animal producers, when using a veterinary drug, must apply the dosage form, route of administration, or dosage regimen as stated; the withdrawal period stated in the product labeling applies only to that particular formulation when administered via the recommended route and in accordance with the dose regime to ensure that animal products are not contaminated with drug residues. Alteration to any of these factors affects the pharmacokinetics behavior of the drug in the animal and invalidates the withdrawal period (Anadón et al. 2018). Concerns about the development and spread of resistant genes, regardless of the prudent and responsible use of antibacterials, have created a climate where overall antibiotic reduction has become a goal of food animal producers, retailers, and consumers alike.

The first step toward the objective of antibiotic reduction is better preventive disease strategies. Preventive use of antibiotics or use to enhance the performance of food-producing animals should in particular not be allowed. The period after weaning is known for regular antibiotic application and is a perfect target for antibiotic reduction. The World Organisation for Animal Health (OIE) and the European Commission (EC), as well as the WHO, have proposed strategies for the issue of antimicrobial resistance (EU 2017): (1) good governance and usage principles for antibiotics; (2) monitoring of antimicrobial usage and resistance; (3) nonspecific prevention, interventions at the production level to reduce risks of disease development on the farm (good housing and management to reduce environmental challenges and stress, correct nutrition, diets to biosecurity); and (4) specific prevention, disease- or pathogen-specific interventions to eliminate or reduce disease incidence and therefore avoid the need for antibiotics. This step could be focused on control of primary bacterial infections or control of viral diseases that can trigger more severe clinical outcomes. Veterinarians and farmers have a direct impact on implementation of prevention programmes to reduce antibiotic reliance using four main steps. (1) Diagnosis: Specialist veterinarians with a thorough understanding of the disease situation on a farm can collect samples and carry out testing to determine the cause of an infection or disease. Often such diseases are multifactorial and the whole farm should be considered in the analysis (infection chain). If a bacterial cause is found, the laboratory can test for the most appropriate antimicrobial treatment (i.e., conventional cultures and antimicrobial susceptibility testing, or C&AST): each bacterium can be reported as susceptible, intermediate, or resistant. More accurate is determination of the minimum inhibitory concentration (MIC), the lowest concentration of an antimicrobial that inhibits the growth of the bacteria. (2) Advice on control: Once the situation is fully understood, interventions can be implemented. Specific interventions, for example, may be curative treatment with an antibiotic using prudent use principles to stop the disease and suffering and mortality. Usage of appropriate vaccinations can result in less antibiotic use on the farm. General interventions are often as important, for example, minimizing exposure to pathogens (i.e., internal biosecurity: ventilation and hygiene to reduce the presence, load, and spread of pathogens) and good external biosecurity will avoid new pathogens entering the production system. A recent work study that measured levels of implementation of biosecurity measures in pig production in four EU countries (Postma et al. 2016b) also examined associations between biosecurity compliance and farm and production characteristics. The results suggested improvements in biosecurity. Improved biosecurity and management practices focused on prevention could reduce antimicrobial use and allow better overall health status and higher animal production and welfare. Prevention is better than a cure (Collineau et al. 2017). (3) Monitor treatment outcomes and antimicrobial susceptibility testing (AST) results by routine and periodic follow-up, with revision of disease control plans to optimize prevention, so a veterinarian can advise the best antibiotic treatment. (4) Education: Pork producers need to be informed of the best practices and to understand legislation and public health developments that impact their business.

In an effort to reduce antimicrobial use, there is an excellent opportunity to optimize production animal health, welfare, and productivity. Biosecurity, herd-level immunity, feeds and feeding systems, stress levels, individual pig health, and environmental conditions all influence animal health and productivity and all interact with each other. Many resources and information sources can assist an individual producer to optimize and maintain high levels of health and welfare in production systems that do not necessitate antimicrobial medication. European pig health experts recently ranked alternative solutions to antimicrobials into a consortium. The top five measures in terms of perceived effectiveness were (1) improved internal biosecurity; (2) improved external biosecurity; (3) improved climate/environmental conditions; (4) high health/specific pathogen-free/disease eradication; and (5) increased vaccination (Postma et al. 2015). These experts have indicated that biosecurity is the highest priority as an alternative solution to antimicrobials (Postma et al. 2016b). Higher levels of biosecurity in pig farms have been shown to be associated with higher levels of production and decreased antimicrobial use and resistance (Postma et al. 2016a). Good

developed immunity to various diseases is essential in industrial pig production. Vaccines have proven very cost-effective in preventing the onset and spread of infectious diseases and are therefore crucial in the modern health production system. On the other hand, stress can have a negative impact on the development of the intestinal barrier.

In animal production systems with a high density of animals or poor biosecurity, development and spread of infectious diseases is favoured, leading more frequently to antimicrobial treatment and prevention of those diseases (Davies et al. 2009), because these conditions favour the selection, spread, and persistence of antimicrobial-resistant bacteria. Some of these bacteria are capable of causing infections in animals and, if zoonotic, also in humans. Bacteria of animal origin can also be a source for transmission of resistance genes to human and animal pathogens. In many cases, such disease can be prevented by good husbandry, a good environment, and hygiene, rather than by the routine prophylactic use of antibiotics (Aarestrup 2004). Positive measures that can reduce disease in farmed animals include the following. (1) Switching to extensive production systems: High-welfare, free-range, and organic systems can achieve higher levels of animal health together with lower levels of antibiotic use than intensive production systems. Recent studies in the UK, Norway, and Sweden found that organic dairy farms, where preventive antibiotic treatment of dry cows is less likely to be used, achieve the same level of mastitis control as conventional farms that typically use routine prophylactic antibiotics (Van Borel and Sorensen 2004; Cogliani et al. 2011; Hovi et al. 2003). (2) Reducing stress: Stress can cause immunocompromise of the animals whereas reducing stress can improve immunocompetence and the ability of animals to fight disease. (3) Good weaning practices: If too early or poorly managed, weaning can cause stress and lead to disease (Davies et al. 2009). Later weaning helps to ensure that animals are more independent of their mother nutritionally, immunologically, and physiologically, which reduces stress and the risk of scouring. The "Alliance to Save our Antibiotics" use in the UK dairy sector has identified three potential measures to optimize animal welfare and immunity, to mitigate the risk of zoonotic diseases, and to reduce the need for antibiotics in this sector: (1) animals should be kept on pasture; (2) move to selective dry-cow therapy; and (3) maximize herd health, welfare, and hygiene (Rose and Nunan 2016).

Veterinarians are responsible for internal biosecurity, avoiding the spread of pathogens into farms or animal groups, as well as the implementation of disease vaccinations to reduce antibiotic use. Alternative measures, in particular preventive strategies, also reduce the use of antibacterial therapy. Herd-specific interventions to substantially reduce antimicrobial usage in pig production were followed without negative impact on overall farm performance. A median reduction of 47% of the antibiotic treatment from birth to slaughter time was achieved (more than 30% median antimicrobial expending reduction). During the study there were no significant changes in mortality, daily weight gain, and feed conversion ratio; on the other hand, there was a slight improvement in the number of weaned piglets per sow per year. Pork producers, veterinarians, and consultants could see reduction of antibacterial use policy as a chance to optimize production and disease prevention approaches improving farming sustainability and animal health and welfare (Collineau et al. 2017).

It has become prevalent to develop alternatives to in-feed antibiotics, as demanded by consumers and by legislation. When it comes to antibiotic-free animal production, veterinarians, nutritionists, and animal producers use several substances such as organic acids, enzymes, prebiotics and probiotics, and phytogenic feed additives to support the intestinal health of the animals.

5 Gastrointestinal Microflora

The gut is the largest internal organ and has the most extensive exposed surface within the body. It is a selective barrier with physical, chemical, immunological, and microbiological aspects where digested feed and water are absorbed but disease-causing agents should be kept under control. The gut is also the largest immune organ of the body and the location of 70% of the immune cells, being the body's first line of active defence against pathogens. A healthy gut is therefore not only a disease-free gut; but is also an effective digestive organ that can mount good protection against disease and cope with changes and stresses. The gastrointestinal (GI) microbiota are crucial in the host immune system, its physiological development, health, nutrition, and productivity. A healthy gut with a balanced microbial composition is critical for optimal digestion and nutrient uptake. The most important tool for good healthy gut is providing the best feed possible that meets the nutritional needs for the specific age and stage of production of the animal. Multi-phase feeding systems and precision feeding are valuable tools, not only for productivity but also for health. Appropriate feed for the various stages of development is very important, and weaning times and weaning systems in piglets and dairy calves should allow the animals to transition from milk to grain-based diets.

The presence of disease-causing microorganisms (pathogens) in the gut is not sufficient to cause disease. Trillions of microorganisms inhabit the intestinal tract (collectively called "the gut microflora"), forming a complex ecosystem that can influence the immune system both inside and outside the gut and the animal. When this gut microflora

is disturbed (dysbiosis), there is a microbial imbalance between the beneficial microflora and potential pathogens, and disease can occur. Dysbiosis therefore makes it easier for pathogens to damage gut structures and functions. Any dietary change leads to changes in the microflora, so dietary changes should always be gradual to allow the microflora to adapt. Probiotics and mannan-oligosaccharides have been shown to be beneficial for microflora and the gut structures, being valuable tools in antibiotic-free production systems.

The animal diet must incorporate eubiotic substances such as organic acids, probiotics, prebiotics, and essential oils to optimize GI functionality, either by acting on the intestinal barrier or tight junctions, or by modulating the microflora composition. For example, Short-chain fatty acids (SCFAs) reduce paracellular permeability in the caco-2 cell line, possibly from promotion of a more differentiated phenotype; if there is such an effect in vivo, it may have consequences for the biology and pathobiology of the colonic mucosa (Mariadason et al. 1997). Overall, the GI microbiota has great influence on the host immune system, its physiological development, health, and nutrition, and on animal productivity. The control of the microbial community of the GIT with the inclusion of feed additives embracing prebiotics, probiotics, phytobiotics, and phages can enhance animal growth and control of both human and animal pathogens. In fact, the gut of the young animal is exposed to bacteria from the environment through the mother, pen, and feed, nutrition being mother dependable. Good gut condition can help to overcame environmental, management, and nutritional stresses, helping animals to stay healthy. Weaning creates a stress point on the immature gut and can impact the microflora, so initial intakes are important. A diverse microflora, for instance, in chickens, can provide benefits such as pathogen competitive exclusion and natural disease resistance (Patterson and Burkholder 2003). In pigs, the gut microbiome in young animals may be modified by the composition of dietary glycans, resulting in a different functional capacity of the microbiome before and after weaning. Glycan degradation pathways differ significantly among diets (Frese et al. 2015).

Evidence suggests that eubiotics can be great contributors to optimal GI functionality, reducing the need for antibiotics. During the past few decades, the concept of gut health has been of increasing interest to animal nutritionists. However, the lack of a clear definition has redirected scientific efforts towards GI functionality, defined as a steady state where the microbiome and the host intestinal tract exist in symbiotic equilibrium, meaning that the welfare and performance of the animal is not constrained by intestinal dysfunction. Occasionally, pathogenic bacteria have a change to grow, immune barriers are disrupted, and the host animal becomes sick. Antibiotics use has an influence on microbial populations as it can kill both pathogenic and harmless bacteria. GI functionality embraces factors such as effective digestion, absence of gut disorders, a balanced intestinal microbiota, and optimal gastrointestinal chemical and physical barriers (Kamada et al. 2013).

An overall state of well-being, an effective immune system, and optimal inflammatory and oxidative status are also directly related to a healthy GI tract. A fully integrated approach needs to be adopted in which management and health practices include nutrition for success. Alterations in the composition of commensal bacterial communities are associated with enhanced susceptibility to multiple inflammatory, allergic, metabolic, and infectious diseases. Commensal bacteria-derived signals can influence the host immune response to invasive pathogens by acting as an adjuvant to boost the immune response to infection or by providing tonic stimulation to induce basal expression of factors required for host defense. Conversely, some pathogens have evolved mechanisms that can utilize commensal bacteria to establish a replicative advantage within the host. Thus, examining the dynamic relationship between the mammalian host, commensal bacteria, and invasive pathogens can provide insights into the etiology of pathogenesis from an infection (Abt and Artis 2013).

Eubiotics are becoming increasingly popular and are being used globally. The term “eubiotic” was introduced many years ago to encompass all the different product categories. Organic acids and essential oils act directly on gut flora modulation, leading to improved digestibility, whereas probiotics are notably able to enhance the resilience of young animals to enteric disease or stress by establishing, maintaining, or even restoring a balanced gut flora. Prebiotics act specifically in the hindgut, indirectly reducing pathogen pressure, enhancing gut morphology and modulating immune response. It is essential to understand the challenges that poultry and swine producers might face to propose the most relevant and efficient eubiotics combination. Their integrated use in animal feeding has great potential for animal nutrition.

Antibiotics are one of the most important medical discoveries of the twentieth century and will remain an essential tool for treating animal and human diseases in the twenty-first century. However, antimicrobial resistance (AMR) among bacterial pathogens and concerns over their extensive use in food animals has garnered global interest in limiting antibiotic use in animal agriculture.

There is worldwide concern over the present state of AMR among zoonotic bacteria that circulate among food-producing animals including poultry, beef and dairy cattle, goats, sheep, and aquacultural populations (Gyles 2008; Prescott 2008). Although antibiotic growth promoters (AGPs) have been successfully utilized during food animal production since their efficacy was first described during the 1940s, the exact modes of action are not fully understood and are probably multi-factorial. In recent years, many national

veterinary associations have produced "prudent and responsible use guidelines" to improve antimicrobial drug use and decrease resistance, but the impact of these guidelines is unknown. Within the evolving global movement for "antimicrobial stewardship" many aspects of antimicrobial use in animals can be improved, including infection control and reduction of use, with a view to reducing resistance and its spread and to preserving antimicrobial drugs for the future (Prescott 2008). Novel intervention methods including narrow-spectrum antimicrobials and probiotics that selectively target pathogenic organisms while avoiding killing of beneficial organisms are needed.

The urgent need for effective alternatives to AGPs to maintain current animal production levels without threatening public health should stimulate new research (Millet and Maertens 2011). Consequently, the discovery of additional antimicrobials from nature could lead to even more wide-ranging novel veterinary and medical alternatives to common antibiotics.

6 Antibacterial Alternatives in Animal Health

Alternatives to antibacterials are wide, but probably there is not one as powerful, consistent in results, and easy to use as are antibiotics. The following different alternatives to be explored here include management, feed formulation, vaccines, organic acids, enzymes, prebiotics, probiotics, and phytogenic feed additives.

6.1 Organic Acids

Organic acids and their salts are distributed in nature and have been applied widely worldwide for more than 50 years as feed additives (acidifiers) and drinking water supplements among a variety of candidates for the replacement and reduction of antibiotic consumption in animal production. These acids occur as normal constituents of animal or plant tissues and some, particularly short-chain fatty acids (SCFA), are produced naturally by the body as by-products in the hindgut of food animals and human through large intestinal bacterial fermentation of dietary fibres, starches, and sugar by the microbiota-bacteria, viruses and fungi that colonise the GI tract. SCFA and medium-chain fatty acids (MCFA) are primarily absorbed through the portal vein during lipid digestion (Huyghebaert et al. 2011). It has been common practice to add organic acids to animal feed; they may have significant benefits in poultry and swine production over the years because of their preservative effect and the positive influence on growth rate and FCR (Panda et al. 2009; Adil et al. 2011; Chowdhury et al. 2009). Organic acids have been used in rearing diets to improve growth rate and the FCR (e.g., 5% in piglets and 1–5% in pigs) during the early nursery period of piglets (Table 1). Dietary acids inclusion may be particularly beneficial when there is a problem with the enterobacteria *Escherichia coli* in the nursery period. The mechanism of action is unclear, but it may be related to a reduction in the pH in the upper intestinal tract, and therefore decrease potential pathogen proliferation of undesirable microorganisms in the stomach and small intestine. Acidification of the feed (sanitation effect of feed) and of the GIT through the proper use of acidifiers improves digestion and absorption and influences intestinal flora.

It can be assumed that drinking water is the most prominent risk factor for the spread of *Campylobacter* infection in broiler chicken flocks, and acidification in drinking water using organic acids could affect *Campylobacter* infection in young chicks. Organic acids in drinking water were able to keep the water free from *Campylobacter*. Animal welfare concerns about the consumption of acidified drinking water were taken into account by evaluating the lesions of the epithelium of the gastrointestinal tract. Consumption of acidified water showed no differences in number of damaged epithelial cells in the digestive tract. In crop and caecal contents of chickens, no difference of volatile fatty acid (VFAs) levels was observed between treatment and control groups (Chaveerach et al. 2004).

Research has shown that the beneficial effects of organic acids can be enhanced by using them as blends rather than a single acid, for example, in improving the FCR in chickens for fattening (Samanta et al. 2008). Blends of organic acids represent an array of pKa values and are used because of the broader spectrum of activity. The use of benzoic acid as an animal feed additive is not permitted at present. Nevertheless, results suggest that benzoic acid supplementation has a positive effect on both ammonia emission and feed conversion. Chemically, organic acid used in food-producing animals are listed in Table 2.

The mechanism of action of organic acids is not clearly understood, but it can be attributed to their antibacterial activity. Several possible mechanisms have been summarized: (1) reducing the pH level of the upper GI tract (crop, pro-ventriculus, gizzard) and associated physiological changes in the gut mucosa; (2) altering the gut microflora either by directly killing through cell-wall penetration or by indirectly modifying pH and reducing the numbers of pathogenic bacteria, increasing acid-tolerant beneficial species

Table 1 Organic acids used in food animals

Piglets	Acetic acid, citric acid, formic acid, fumaric acid, propionic acid, tartaric acid
Poultry	Citric acid, formic acid, lactic acid, malic acid, sorbic acid, tartaric acid

Table 2 Organic acids groups used in food animals

Monocarboxylic acids	Acetic acid, butyric acid, formic acid, propionic acid
Carboxylic acids	Citric acid, lactic acid, malic acid, tartaric acid

Table 3 Variables that influence antibacterial activity of organic acids

• Chemical formula
• pKa value of the organic acid
• Chemical form (esterified or not; acid salt, coated or not)
• Molecular weight
• The microorganism-related MIC value of the acid
• The nature of the microorganism
• Animal species
• Buffering capacity of the feed

such as *Lactobacillus* spp., and reducing competition for nutrients by the altered microbes; (3) increasing nutrient digestibility by elevating protein and dry matter retention, improving mineral absorption and phosphorus utilization; and (4) improving gut health through direct effects on epithelial cells (e.g., SCFA are a direct energy source for the growth of epithelial cells) (Gadde et al. 2017). Overall, variables that influence antibacterial activity (Huyghebaert et al. 2011) are listed in Table 3.

SCFA, with a chain length less than 6 carbon atoms, and mid-chain fatty acids (MCFA), with a chain length between 8 and 12 carbon atoms, are broadly used in animal nutrition. The fields of application and the effect of the respective acids vary widely; each organic acid can be used for different aims, and they have diverse properties according to their chemical characteristics. Feed supplements of mixtures of organic acid are used to make their spectrum broader and combine the good qualities of the different acids. However, synergistic effects can be created by targeted selection and combination of acids (Huyghebaert et al. 2011). The beneficial effects can be attributed to several factors such as the inclusion rates, the source of the organic acids, and the buffering capacity of other dietary ingredients. SCFA positively affect the microbiota and modulate immune responses in the gut. The antimicrobial action of organic acids in feed or drinking water occurs through lowering of pH, reduction of the feed buffering capacity, and a direct effect on the microbial population. Yet, more important is the activity of organic acids inside the animal GI tract.

The antimicrobial activity of organic acids depends on the pKa value of each acid. At a pH equal to the pKa value, half the acid present is dissociated. Strong organic acids (low pKa) at normal intestinal pH are mostly in a dissociated form. Thus, they are pH-reducing acids and have a bacteriostatic effect. Weak organic acids (high pKa) at normal intestinal pH are mostly in an undissociated form. This undissociated organic acid form is a requisite to approach the bacteria, can easily penetrate the lipid of bacteria cell membrane, where they dissociate and thus have a bactericidal effect. Inside the bacterial cell (pH is maintained near 7), with a pH above the pKa of the acid, it will lower the cytoplasmic pH, consequently inhibiting normal enzyme activity and causing cell leakage (Ricke 2003). There is a synergistic effect between strong and weak acids. The pH-reducing acids will ensure better action of the bactericidal acids because they promote weak acids to stay in the undissociated form. In this way, organic acids can cope with enteropathogenic bacteria, acting as modulators of the intestinal microflora. Cell enzymes are suppressed and energy depleted as bacteria try to maintain a neutral cytoplasm by pumping out protons. Antimicrobial activity of organic acids generally improves with higher pKa values. Organic acids with higher pKa values are more effective antibacterial compounds and their efficacy is generally improved with increasing chain length and degree of unsaturation (Huyghebaert et al. 2011): SCFA are weak acids with a pKa value below 4.8. In the hindgut, where the pH is close to neutral, they are present as anions and have lesser antimicrobial properties compared to MCFA. The microorganism-related MIC value of the acid is another factor determining its antimicrobial activity. *Clostridium perfringens* is susceptible to most MCFA with the lowest MIC value for lauric acid, whereas resistance occurs against fumaric, lactic, acetic, and propionic acids. The bacterial cell wall is less penetrated by these SCFA at intestinal pH, around 6, because of their lower pKa. It is very important to differentiate the antimicrobial action of organic acids as a preservative in feed or drinking water, from the effect on the complex microbial community along the intestine and on the integrity of the intestinal mucosa. In conclusion, organic acids may help the intestinal mucosa maintain its integrity; they reduce the buffering capacity of the diets helping to keep stomach pH low, resulting in increased pepsin activity and slowing of stomach emptying.

The antibacterial activity of organic acids is mainly against *Campylobacter* spp., *Escherichia coli*, *Salmonella*, *Clostridium perfringens*, and *Listeria monocytogenes* (Over et al. 2009). SCFA can also offer a way to resist or limit the effects of a *Salmonella* infection. Dietary supplementation of organic acids increased the counts of CD4 cells and T-cell receptor II lymphocytes, which corresponds to a faster immune response (Khan and Iqbal 2016). Organic acids are also being studied for their part in improvement of phytate phosphorus utilization in chickens (Rafacz-Livingston et al. 2005). SCFAs have been reported to upregulate genes involved in epithelial cell growth, division, differentiation, proliferation, and apoptosis (Hashemi and Davoodi 2011).

Butyric acid mainly has an impact on intestinal physiology development and recovery of intestinal integrity, but also provides indirect effects on animal metabolism beyond compromised digestive and absorptive capacity, intestinal

barrier function, and tight junction quality, which also deteriorate at weaning. Butyric acid induces the production of host defence peptides in mucus and repair of the intestinal tract architecture through increased cell proliferation, tight junction assembly, and immune cell regulation. Butyric acid stimulates the expression of tight junction proteins (Mariadason et al. 1997). At weaning of piglets, activation of the intestinal immune system and upregulation of genes of pro-inflammatory cytokines engender a significant inflammatory reaction, resulting in intestinal mucosal injury and dysfunction. The energy needs for an activated immune system increase more than 20%. The antiinflammatory properties of butyric acid and alkaloid-rich plant extracts can largely temper the inflammatory reaction, which contributes to an energy-saving and growth-promoting effect. Weaning stress is also related to increased reactive oxygen species (ROS). Glutathione, positively influenced by butyric acid, is critical in many biological processes as a major redox buffer in mammalian cells. The intensive renewal process of the intestinal cells (2–7 days) requires an adequate energy supply. SCFA and MCFA stimulate mitosis, maturation, and differentiation of intestinal mucosal cells and inhibit their apoptosis (Isaacson and Kim 2012).

Similar effects of growth performance improvement were seen when butyric acid was included in the broiler chicken diet (Panda et al. 2009). To guarantee the presence of butyric acid in the intestine, esterified forms of butyric acid are used. The esterified forms automatically bypass the stomach, and the butyric acid molecules are enzymatically released (mainly from di-and tributyrins) by lipase into the small intestine. Polar monobutyrins pass the hydrophilic membrane of pathogenic bacteria (*E. coli, Salmonella, Clostridium perfringens*), disturbing their metabolism and inactivating them.

Butyrate is one of the most important SCFAs. Butyrate is a very small molecule, easily absorbed in the stomach and the upper part of the small intestine. However, to improve gut health and integrity it must be delivered to the lower part of the intestinal tract. The solution to this problem lies in the use of butyric acid as a coated salt (i.e., sodium, potassium, or calcium salts) or partially esterified (e.g., butyric acid glyceride) to reach the lower part of the intestinal tract. Glycerides have the advantage over butyric acid salts that they are very easily absorbed, and very palatable because of the sweet taste of glycerol. This chemical form does not depress feed intake and does not have an odor. Another advantage of esterified fatty acids is the gradual release of the corresponding acid throughout the gut by the enzymatic activity of pancreas lipase. For supplementary butyrate to increase the levels achieved by endogenous production it must be protected from the digestive processes (i.e., coated forms of butyrate could provide the protection needed to go through the acidic stomach). Butyrate released in the first part of the intestinal tract also has an impact on colon inflammation, attributable to the action of the gut as a sensory organ which communicates through effector systems that include the enteroendocrine hormonal signalling system, gut innervation, the gut immune system, and local tissue defences. Butyrate is important in improving gut integrity and in the development and improvement of intestinal functions in mammals and birds. Butyric acid is released in the intestine, nourishing the gut mucosa, decreasing pathogen proliferation, and inactivating negative bacteria, greatly improving the quality of the intestinal microbiome and mucosal integrity (Castillo et al. 2006). Among the SCFA, butyric acid has received particular attention for its extraordinary beneficial effects on general health status. Butyrate is naturally present at high concentrations in the large intestine, as a product of bacterial fermentation, and in milk. It serves as an important source of energy for enterocytes, especially for colon epithelial cells. It also substantially increases epithelial cell proliferation and differentiation while reducing apoptosis of normal enterocytes. Butyrate seems to have a positive influence. In chickens, butyrate seems be involved in satiety management and the maintenance of colonic homeostasis. Various studies confirm a stimulating effect of butyric acid and MCFA on beneficial microflora in early-weaning pigs while decreasing the number of coliforms (*E. coli*).

The immense surface area of the intestinal mucosa is constantly in direct contact with the environment. The intestine is a selective barrier between animal metabolism and the luminal environment, providing adequate protection against invasion of pathogenic bacteria, but also ensures an efficient absorption of nutrients. To accomplish both functions requires simultaneously maintaining an exquisite balance between gut microbial components and adequate numbers of bacteria and their location. Any factor compromising the intestinal mucosal integrity will affect animal health and productivity (Mariadason et al. 1997). It is important to appreciate the particulars of how butyrate can support health against bacterial challenges and restore the equilibrium of the microbiota when it is perturbed, for example, by antibacterials. However, the effects of butyrate on the immune system are potentially involved in animal production. The gut is the largest immunologically active organ. SCFAs are a crucial link in maintaining a healthy microbiota and immune system against pathogenic invasion. In that way, the SCFAs act as a vital link between microbiota and host immunity.

The intestinal mucosal surface is an immunological component that protects the host from pathogenic invasion challenge, is tightly regulated with regard to its permeability, and can influence the systemic energy balance. The activation or suppression of the toll-like receptors (TLRs) by microbial signals can dictate the tone of the immune response, and the TLRs are implicated in regulation of energy homeostasis. The SCFAs are a group of molecules that can both modulate

the intestinal barrier and escape the gut to influence systemic health. As modulators of immune response, microbiota-derived signals influence functions of distant organs and can alter susceptibility to metabolic diseases (Spiljar et al. 2017). The immune system is constituted with innate and adaptive responses which rely on activation by the innate immune system, including specific responses by antibody formation. Innate immunity includes physical epithelial barriers (i.e., intestinal cells, and sentinel cells as macrophages and chemical messengers). The intestinal epithelial barrier, constituted of epithelial cells, tight junction proteins, and intestinal secretions, can prevent entrance of luminal substances and antigens throughout the paracellular space (Kamada et al. 2013). It is known that dysfunction of the intestinal barrier integrity induced by toxins and pathogens is associated with a variety of GI disorders including diseases. Butyrate modifies intestinal barrier function in IPEC-J2 cells through a selective upregulation of tight junction proteins and activation of Akt signaling pathways. Moreover, butyrate increases both mRNA expression and protein–junction (i.e., claudin-3 and claudin-4), influencing intracellular ATP concentration in a dose-dependent relationship (Yan and Ajuwon 2017). At the GI tract, butyrate has a regulatory capacity on trans-epithelial fluid transport, improves mucosal inflammation and oxidative stress status, fortifies the epithelial defense barrier, and adjusts visceral sensitivity and intestinal motility (Canani et al. 2011). It has been described as synergy supplied by the application of exogenous ketone and beta-hydroxybutyrate in combination with SCFA butyrate in the context of cellular and physiological outcomes (Cavaleri and Bashar 2018). Butyrate also exerts a beneficial effect on the immune system through antiinflammatory and anti-oxidant activity (Hodin 2000). Another important feature of SCFA in broiler chickens is its influence on the intestinal microflora. Supplementation of acetate, butyrate, and propionate increase from undetectable levels in 1-day-old broiler chicks to high concentration in 15-day-old-broiler chickens, after which they stabilize. The results indicated that significant negative correlations could be calculated between the number of *Enterobacteriaceae* and concentrations of undissociated SCFAs (van Der Wielen et al. 2000). Butyrate has been the most studied SCFA, being the preferred metabolite for colonocytes. On this basis, butyrate and glucose metabolism by colonocytes has been evidenced in experimental mouse colitis, and it was concluded that colonocyte metabolism of butyrate, but not of glucose, is deteriorated in colitis, which may be important in the interpretation of colitis pathophysiology (Ahmad et al. 2000). Preclinical evidence corroborates the SCFAs as modulator substances in colonic function and in multiple inflammatory and metabolic processes. SCFAs are also associated with autoimmune, allergic, and metabolic diseases (Gill et al. 2017).

6.2 Phytobiotics and Essential Oils

The need to reduce the use of antibiotics in livestock arising from increased concerns over the spread of AMR, has raised interest in phytobiotics. Phytogenic also referred as "phytobiotics", "botanicals", or "plant extracts", which are natural biologically active constituents that are derived from plants and incorporated into animal feed to enhance productivity (Windisch et al. 2008). Phytochemical medicines are recognized as useful and viable alternatives to chemotherapy because they are economical, effective, non-resistance-forming, renewable, and environmentally friendly. Dietary phytochemicals are small molecules with high structural diversity that cause selective stress to or stimulate the resident microbiota. SCFAs are correlated with specific microorganisms of the phylum of intestinal Firmicutes. Potentially effective plant extracts could be used in combination with antibiotics to lower the required antibiotic dose and increase their effectiveness (Shin and Park 2018).

Phytobiotics constitute a large number of compounds or variety of herbs, species, and products derived thereof, such as essential oils. A common feature of phytobiotics is that they are a highly complex blend of bioactive components. Phytobiotics are described as primary or secondary components of plants that contain bioactive constituents which exert a positive effect on the productivity and health of animals.

Phytobiotics have been exploited in animal nutrition in particular for their antimicrobial, antiinflammatory, anti-oxidative, and anti-parasitic activities. Primary components include the base nutrients, such as protein, fats, and carbohydrates; secondary compounds include essential (lipophilic or volatile) oils, bitters, colorants, and phenolic compounds (Grashorn 2010) that may be classified into four groups: (1) herbs (products from flowering, non-woody, and non-perennial plants); (2) botanicals (whole plants or processed parts); (3) essential oils (hydro-distilled extracts of volatile plant compounds); and (4) oleoresins (extracts based on nonaqueous solvents) (Clavijo and Vives Flórez 2017). Biologically active constituents of plants are mostly secondary metabolites, such as terpenoids (mono- and sesquiterpenes, steroids, etc.), phenolics (tannins), glycosides, and alkaloids (present as alcohols, aldehydes, ketones, esters, ethers, lactones, etc.) (Huyghebaert et al. 2011). Useful antimicrobial phytochemicals can be divided into several categories, such as phenolics/polyphenols, terpenoids/essential oils, and lectins/polyphenols (Windisch et al. 2008). Essential oils have two major classes of compounds, terpenes (e.g., carvacrol and thymol) and phenylpropenes (e.g., cinnamaldehyde and eugenol) (Omonijo et al. 2018). Flavonoids such as resveratrol, epigallocatechin gallate, and phenols such as galangin, puerarin, and ursolic

acid are proven to be effective as antimicrobial agents (Shin and Park 2018).

Many plants have beneficial multifunctional properties derived from their specific bioactive components. Large variations in composition result from (1) different factors (i.e., plant species, growing location, harvest conditions), (2) manufacturing (i.e., extraction/distillation, stabilization), and (3) storage conditions (i.e., light, temperature, oxygen tension, time). The challenge is to identify and quantify the multitude of actions and claims improving feed utilization, animal physiology, and health status.

A wide range of plants and their products are in this beneficial category and, based on their origin (part of the plant), can be broadly classified as herbs (flowering, non-woody, non-persistent plants from which leaves and flowers are used) or spices (non-leaf parts of plants, including seeds, fruits, bark, or root with intensive taste or smell) (Windisch et al. 2008). They can be used in solid, dried, and ground form or as extracts (crude or concentrate) (Gadde et al. 2017). A common feature of phytobiotics is that they are a very complex blend of bioactive components. The biologically active constituents are compounds derived from plants or parts thereof (leaves, roots, flowers, etc.) (Huyghebaert et al. 2011). The wide range of modes of action of different phytogenic activities can optimize nutrient digestibility and support intestinal health. Phytogenics can promote the growth of beneficial intestinal bacteria for the host and promote increased concentrations of SCFA in the ileum and colon while reducing potentially harmful bacteria and the production of protein-derivative catabolites.

Phytogenics, or plant-based compounds, are specifically essential oils of herbs and spices known to have a narrow range of biologically active properties that can be applied in modern animal production. Phytogenics are potent to improve nutrient utilization, stimulate digestive enzymatic activity (i.e., intestinal and pancreatic enzyme production), increase bile flow, and even show anti-oxidant, antimicrobial, antiinflammatory, and immunomodulatory effects as well as maintaining the gut growth (intestinal barrier functions) and health and feed palatability enhancement (Windisch et al. 2008).

Experimental data show the in vitro antimicrobial effects with respective minimal inhibitory concentration (MIC) values and spectrum of activity (Fu et al. 2007; Barbosa et al. 2009). The MIC of essential oils needed for killing enteric pathogens may not ensure the optimal feed intake in swine production. The lipophilic and volatile nature of essential oils creates a challenge in their effective delivery within the pig gut, and this challenge can be partially resolved by microencapsulation and nanotechnology (Omonijo et al. 2018). According to Adams (1999), antimicrobial activity is rather weak for ginger (*Zingiber officinale* Roscoe) and pepper (*Piper* spp.), medium for cumin (*Cuminum cyminum*), coriander (*Coriandrum sativum*) (also known as cilantro), oregano (*Origanum vulgare*), rosemary (*Rosmarinus officinalis*), sage (*Salvia officinalis*), and thyme (*Thymus vulgaris*), and strong for clove (*Syzygium aromaticum*), mustard (Lyrica), cinnamon (*Cinnamomum cassia*, *Cinnamomum zeylanicum, Cinnamomum verum*), and garlic (*Allium sativum*) (Table 4). Other biologically active plant extracts include soybean derivatives, *Allium* derivatives, carvacrol, *Curcuma longa* derivatives, *Astragalus* derivatives, *Capsicum* derivatives, *Achyranthes* derivatives, *Echinacea*, and *Origanum* derivatives.

Phytogenics are characterized by their plant-derived origin, being natural and proven to be safe. The phytogenic feed additives consist mainly of essential oils, bitter and pungent substances, saponins, flavonoids, mucilages, and tannins; it is evident that they are not only for sensorial stimulation but also stimulate various physiological processes. It is very well known that components used in phytogenics are generally approved in the EU for use in animal feed as "sensory

Table 4 Natural phytobiotic substances and chemical composition

Natural substances	Chemical composition
Cinnamon species Family Lauraceae	Monoterpenes (pineme, camphene, liminene), sesquiterpenes The main constituent of cinnamon bark oil is cinnamaldehyde
Coriander Family Apiaceae	Linalool (unsaturated terpene)
Clove Family Myrtaceae	Eugenol and β-caryiphyllene
Cumin (black) Family Apiaceae	*p*-Cymene (alkylbenzene related to a monoterpene)
Garlic Family Liliaceae	Allicin: the main constituents of garlic oil are allylpolysulfifes (diallyl sulfide, diallyl disulfide, diallyl trisulfide)
Ginger Family Ziniberaceae	6-Gingerol, 8-gingerol, 10-gingerol, methylgingerol, gingerdiol, dehydrogingerdione, gingerdiones, diarylheptanoids (curcuminoids), diterpene lactones, galanolactone)
Mustard Family Brassicaceae	Allylisothiocyanate
Oregano Family Lamiaceae	Carvacrol, *o*-cymophenol (monoterpenoid phenol)
Pepper Family Solanaceae	Capsaicin, dihydrocapsaicin, nordihydrocapsaicin, homocapsaicin, homodihydrocapsaicin
Rosemary Family Lamiaceae	Carnosic acid, carnosol, 12-*O*-methylcarnosic acid, rosmarinic acid, genkwanin, isoscutellarein-7-*O*-glucoside
Sage Family Lamiaceae	Cineol or eucalyptol (essential oil)
Thyme Family Lamiaceae	Thymol, monoterpene phenol derivative of cymene

additives" or "flavors" because of their flavor characteristics. However, it is important to understand which flavours or compounds might have a negative impact on feed intake by the animals and to know the acceptable dose, mask their taste, or replace them altogether in the formula. Composition of phytogenetic products and optimal inclusion feed levels must be based on the dose–response trials by animal species. Moreover, the bioactive components of herbs and species can have functional properties besides their flavouring properties.

Essential oils have been shown to have good potential as antibiotic alternatives in feeds for swine production. The combination of different essential oils and other compounds (synergistic effect) such as organic acids seems to be a promising approach to improve the efficacy and safety of essential oils in applications.

Although phytogenics, and especially essential oils, have demonstrated direct antibacterial effects, high concentrations are needed to guarantee such effects and are less attractive for economic or sensorial reasons. Nevertheless, small amounts of various plant-derived essential oils effectively reduce the production of virulence factors by bacteria, so-called quorum sensing (QS), resulting in reduced toxin production, adhesion factors, and biofilm formation. QS is a process of cell–cell communication that allows bacteria to share information about cell density and adjust gene expression accordingly. This process enables bacteria to express energetically expensive processes as a collective only when the impact of those processes on the environment or on a host will be maximized (Rutherford and Bassler 2012). Overall, the effects of essential oils on inflammation, oxidative stress, microbiome, gut chemosensing, and bacterial QS have led to better production performance of animals fed essential oils in a number of studies (Omonijo et al. 2018). Essential oils are aromatic oily liquids obtained from plant material and usually have the characteristic odor or flavor of the plant from which they are derived (Stein and Kil 2006). Typically mixtures of secondary plant metabolites, they may contain phenolic compounds (i.e., thymol, carvacrol, eugenol), terpenes (i.e., citric and pineapple extracts), alkaloids (capsaicine), lectins, aldehydes (i.e., cinnamaldehyde), polypeptides, or polyacetylenes (Thacker 2013). Many plants produce chemicals with therapeutic and protective properties, the isolation and concentration of which may produce potent compounds that could potentially improve animal health and performance. These phytogenics benefits are derived from improved intestinal health, including improved digestion, modification of digestive secretions, and support of the histology of the intestine (Diaz-Sanchez et al. 2015). In addition to herbs and spices, various essential oils (thymol; carvacrol; cinnamaldehyde; essential oils from clove, coriander, star anise, ginger, garlic, rosemary, turmeric, basil, caraway, lemon, and sage) have been used either individually or as blends to improve animal health and productivity (Gadde et al. 2017).

The principal use of phytobiotics in poultry and swine has been the administration of essential oils, which have been used for a long time in the preparation of feed as artificial flavors and preservatives. Most essential oils have been classified as Generally Recognized as Safe (GRAS), by the US FDA. These oils are characterized as being involved in antimicrobial activities and having growth-promoting properties. Several oils, including carvacrol and thymol obtained from oregano and eugenol from the clove plant, have been shown to inhibit a wide range of pathogenic bacteria (Dorman and Deans 2000). Several studies have reported controlled experiments in which oils have been used as feed additives to reduce the presence of different pathogens in the intestine, including, for example, *Salmonella* using capsaicin (Tellez et al. 1993; Vicente et al. 2007); *E. coli* (Jamroz et al. 2005); *Campylobacter* (Ali 2014), and *Clostridium perfringens* (Mitsch et al. 2004). These results suggest that the effectiveness of essential oils varies, principally because their active components can differ depending on the method of extraction, geographic origin, plant genotype, and storage time.

Plant extracts have been reported to alter the composition of the microbiota in poultry (Guo et al. 2004) and pigs (Castillo et al. 2006). Cinnamaldehyde, carvacrol, eugenol, and thymol have received the most interest for use in swine production. The exact mode of action of essential oils has not been established but the activity may be related to changes in lipid solubility at the surface of the bacteria. The hydrophobic constituents of essential oils allow them to disintegrate the outer membrane of *E. coli* and *Salmonella* and thus inactivate these pathogens (Stein and Kil 2006). Essential oils are aromatic, volatile, and oily liquids extracted from plant materials such as seeds, flowers, leaves, buds, twigs, herbs, bark, wood, fruits, and roots; essential oils containing phenolic compounds tend to have greater antimicrobial activity than oils containing other compounds (Brenes and Roura 2010). Based on the fact that essential oils appear to control pathogenic bacteria, several research groups have attempted to determine whether the inclusion of essential oils in swine diets can improve pig performance (Ragland et al. 2008). The results have been inconclusive; some trials have demonstrated positive results whereas others have reported no beneficial effects. Conclusive evidence for including essential oils in diets fed to swine was demonstrated by a trial that compared the performance of pigs fed an unsupplemented control diet with that of pigs fed a diet supplemented with antibiotics or a combination of thymol (*Thymus vulgaris*) and cinnamaldehyde (*Cinnamomum zeylanicum, Cinnamomum verum*) (Li et al. 2012). Weight gain, FCR, and fecal consistency of pigs fed essential oils was essentially equal to that of pigs fed antibiotics. In addition, total antioxidant capacity and levels of the cytokines

interleukin 6 (IL-6) and tumor necrosis factor-α (TNF-α) were altered by inclusion of essential oils. The variability could result from differences in the type of essential oils and dose used (Li et al. 2012). It appears that oils containing phenolic compounds have greater antimicrobial activity than those based on other compounds. In addition, if the dose used is too high, the strong smell can reduce feed intake and thereby limit pig performance (Stein and Kil 2006). Another important consideration is the stability of essential oils during pelleting.

Eucalyptus oil, a MCFA is obtained from the leaves of the eucalyptus, a tree in the plant family *Myrtaceae* that is cultivated worldwide. Eucalyptus oil has also been shown to stimulate the immune system by affecting the phagocytic ability of monocyte-derived macrophages (Serafino et al. 2008). In poultry, dietary inclusion of eucalyptus has been shown to improve production performance and stimulate the immunity of commercial laying hens (Abd El-Motaal et al. 2008).

MCFAs have been suggested as an alternative feed additive to antibiotics for piglets (Hong et al. 2012). MCFAs have shown antimicrobial activity against *Salmonella* (Rossi et al. 2010) and *E. coli* (Dierick et al. 2002). Feeding a blend of caprylic and caproic acids has been reported to improve performance and nutrient digestibility in 3- and 4-week-old weaned pigs during the first 2 weeks after weaning (Hong et al. 2012). A recent review in vitro study demonstrated the influence of various MCFAs on the growth of swine-specific pathogenic germs (Omonijo et al. 2018). The effects of essential oils on inflammation, oxidative stress, microbiome, gut chemosensing, and bacterial QS have led to better production performance of animals fed essential oils in a number of studies. It has been demonstrated that essential oils have good potential as antibiotic alternatives in feeds for swine production.

Bacteria cause many problems on pig farms. *Streptococcus suis* is a species of pathogenic gram-positive bacterial strains that represents a primary health problem in the swine industry worldwide. *S. suis* is also an emerging zoonotic pathogen that causes severe human infections clinically featuring varied diseases or syndromes such as meningitis, septicemia, and arthritis. Infections with streptococci are considered to be a prime reason for the high use of antibiotics in piglet production (Feng et al. 2014). Piglets are generally infected during or shortly after birth, with germs capable of entering the animal through even the tiniest wounds. The special feature of the dangerous streptococci is that they possess the ability to enter the bloodstream, where they settle in certain places in the body via the blood and reproduce. Once the pathogen has settled in the animal, it can cause a wide variety of disease patterns. With pneumonia, inflammation of the joints, and meningitis, streptococci can also cause sudden death. The aim must therefore be to minimize the germ pressure as early and as much as possible.

MCFAs are particularly important in animal nutrition because of their energy-supplying ingredients and antibacterial effect. These properties are highly interesting for use in pig farming. The pressure of infection on the animals, triggered by swine-specific pathogenic germs, is one of the main reasons for using antibiotic medications. Many in vitro studies displayed pronounced antibacterial effects following the use of MCFAs against both gram-negative and gram-positive bacteria. Lauric acid and glycerol monolaurate are considered to be particularly active antibacterial ingredients (Omonijo et al. 2018).

Salmonella invasion in intestinal epithelial cells is decreased and colonization of *Campylobacter jejuni* is reduced in broiler chickens when administered a mixture of MCFAs containing lauric acid. In particular, lauric acid has a strong antibacterial effect against *Clostridium perfringens* strains, significantly decreasing necrotic lesions in the gut. The MIC of the different additives were determined in vitro, showing that lauric acid, thymol, and cinnamaldehyde are very effective in inhibiting the growth of *Clostridium perfringens*. The efficacy of target-released butyric acid, MCFAs (C6 to C12, but mainly lauric acid), and essential oils (thymol, cinnamaldehyde, essential oil of eucalyptus) micro-encapsulated in a poly-sugar matrix to control necrotic enteritis was investigated. Combining butyrate and mid-chain fatty acids, such as lauric acid, gave the best protection against these lesions and can be used for controlling necrotic enteritis in broilers. These results suggest that butyric acid, medium-chain fatty acids, and essential oils may contribute to the prevention of necrotic enteritis in broiler chickens (Timbermont et al. 2010). MCFAs have a pronounced antimicrobial effect on a wide range of bacterial species, towards both gram-positive and gram-negative bacteria: this effect is higher than for SCFAs.

Micro-encapsulation of MCFAs is a process in which medium-chain fatty acids are nano-micronized to extremely small particles and then encapsulated. A product of eucalyptus extract mixed with caprylic and carpric acids and encapsulated with palm oil was tested in comparison with antibiotics or zinc oxide. The performance of pigs fed the eucalyptus–medium-chain fatty acid blend was essentially equal to that of those receiving antibiotics or zinc oxide. The performance-enhancing effects of the blend appeared to be mediated through improvements in nutrient digestibility (Han et al. 2011).

An alternative approach to support the intestinal health of farm animals may be found by combining the beneficial effects of phytogenic feed additives with the antibacterial effects of esterified SCFAs and MCFAs. Both SCFAs and MCFAs possess antimicrobial properties and influence the composition of the microbiota (Chaveerach et al. 2004; Solis

de Los Santos et al. 2008). SCFAs are produced by fermentation of indigestible oligosaccharides and may alter the pH of the intestinal environment, changing the relative proportions of susceptible bacteria, including *Salmonella* and *C. perfringens* (Chaveerach et al. 2004; Van Immerseel et al. 2006). MCFAs have potent antimicrobial properties in vitro and in vivo. For example, lauric acid has been shown to target *C. perfringens* (Skrivanova et al. 2005), whereas caprylic acid is effective against *E. coli* (Marounek et al. 2003) and *Campylobacter jejuni* (Solis de Los Santos et al. 2008).

A possible influence of phytogenics on the efficacy of antibiotics through combined administration would require a change in application recommendations of antibiotics and phytogenic feed additives. A trial evaluated to what extent this is the case.

Many antibacterials used in animals are applied via the waterline, where they are dosed in combination with other feed additives. Amongst those there are mixtures of secondary plant compounds with a proven antimicrobial efficacy against veterinary pathogenic bacteria. However, there is only sparse information available if and to which extent antibiotics and phytogenics influence each other. There are several scenarios possible: (1) no interaction (if the bacterial strain is sensitive to both, antibiotics and phytogenics, and they do not influence each other in their antimicrobial efficacy, then a combined application with their recommended dosages is possible without restrictions and limitations); (2) negative interaction (if the combined use of antibiotics with phytogenic feed additives attenuates the efficacy of antibiotics, a combined application would not be recommended); (3) positive interaction (if phytogenics increase the effectiveness of antibiotics, a combined application of both might generate a synergistic antimicrobial effect on certain veterinary pathogenic bacteria). There are reports on the adverse interactions of phytogenics with enzyme preparations (Sarica et al. 2005). An alternative approach to support the intestinal health of farm animals may be found by combining the beneficial effects of phytogenic feed additives with the antibacterial effects of esterified SCFAs and MCFAs. In a trial, this combination was shown to improve the efficacy of poultry performance, even under challenging conditions involving necrotic enteritis (Dahiya et al. 2006). In terms of performance, feeding the combination of the phytogenic feed additive and esterified SCFAs and MCFAs for 28 days was effective. The wide spectrum of modes of actions of phytogenic feed additives based on plant extracts show the synergistic effects of many different bioactives, which have not been reduced to the effects of a single lead substance.

Nonetheless, although the mechanisms of action of the most phytotherapeutic chemicals are not fully understood, their synergistic antimicrobial activity is generally assumed to be the result of bacterial membrane disruption by lipophilic compounds or their blockade of cell division by DNA synthesis inhibition (Chandar et al. 2017).

6.3 Antimicrobial Peptides

Antimicrobial peptides (AMPs) are widely distributed and are classified into two categories, non-ribosomally synthesized AMPs and ribosomally synthesized AMPs, according to the peptide synthesis mechanism. The non-ribosomal AMPs, mainly produced by bacteria, are synthesized by peptide synthetases and structural modifications (i.e., gramicidin, polymyxin, bacitracin, sugar peptide) (Cheng et al. 2014).

Reports have indicated the protective effect of antimicrobial peptides on animals. Gene-encoded natural antibiotics that have gained recent attention include host-derived antimicrobial peptides such as defensins and cathelicidins, which provide a protective response against bacterial infection and are a principal component of innate immunity in vertebrates (Sang and Blecha 2008). For instance, porcine host defense peptides are a large group of innate immune antimicrobial peptides that possess antibacterial activity (Sang and Blecha 2008). Cathelicidins are host defense peptides that were first described in mammals, and are also found in birds, that exhibit both antimicrobial and immunomodulatory activities (van Dijk et al. 2009, 2011) which could be used to control pathogens such as *Campylobacter jejuni* (van Dijk et al. 2012). Other peptides such as lactoferricin B, a 25-residue peptide derived from the N-terminal domain of bovine lactoferrin, and synthetic derivatives of this peptide cause depolarization of the cytoplasmic membrane in susceptible bacteria and have antimicrobial activity (Liu et al. 2011). Antimicrobial peptides such as cecropins (Boman 1991) and magainins (Zasloff 1987), a chimeric peptide, are derived from insects and amphibians, respectively. Cecropìn A added to the feed diet increased weight gain, feed intake, feed:gain ratio, and intestinal villus height while decreasing aerobic bacterial counts in both jejunal and caecal digests. Other antibacterial peptides are the bacteriocins, which are defined as ribosomally synthesized peptides secreted by various bacteria that have antibacterial activity against other similar or closely related bacteria. Bacteriocins produced by lactic acid bacteria (LAB) generally function to suppress competitor species that are primarily active against other gram-positive bacteria (Cotter et al. 2005). In the past, bacteriocins were used as food preservatives. Several bacteriocins have been indentified, such as nisin, lactacin, lactocin, helveticin, fermenticin, sakacin, lacticin, plantacin, and subticin, among others in genera including gram-positive and gram-negative bacteria as well as Archaea. In vitro tests show that bacteriocins have strong killing and suppressive effects on a variety of pathogens, including resistant pathogens. The

antibacterial spectrum of most bacteriocins is narrow, only effective to the related bacterial species. One of the most reported as a dietary supplement in poultry was divercin AS7 (produced by *Carnobacterium divergens* AS7), a lactic acid-producing bacterium isolated from fish, which has been extensively studied in broiler chickens for growth-promoting effect, digestibility, and modulatory effect on intestinal microbiota (Józefiak et al. 2012).

In addition, dietary nisin (produced by *Lactococcus lactis*) exerted a modulatory effect on the microbial ecology of the GIT with decreased counts of *Bacteroides* and *Enterobacteriacae*, but unchanged counts of *Clostridium perfringens*, *Lactobacillus* spp., *Enterococcus* spp., and total bacteria (Józefiak et al. 2013). Albusin B (produced by *Ruminococcus albus* 7), another bacteriocin added to poultry feed, also showed improved growth performance, increased intestinal absorption and *Lactobacillus* counts, modulated lipid metabolism, and activated systemic antioxidant defense (Wang et al. 2013). Overall, the use of antimicrobial peptides including bacteoricins have potential to enhance animal health and productivity.

6.4 Bacteriophages and Their Endolisins

Bacteriophages, which are highly species-specific viruses that kill bacteria, have been considered agents to treat bacterial infections through the production of endolysins and subsequent lysis of the bacterial cells. Bacteriophages can be considered safe antibiotic alternatives as they exhibit no activity against animal and plant cells. Bacteriophages (phages) have been utilized as treatment for bacterial diseases in Europe (Sulakvelidze 2005), particularly in poultry (i.e., to reduce mortality in poultry caused by *Staphylococcus gallinarum* and *Pullorum* (Atterbury et al. 2007) and in cattle (Smith et al. 1987). Preparations of bacteriophages are commercially available in many parts of the world. The FDA accepted the use of a bacteriophage preparation as a food additive (Bren 2007). An important extension to bacteriophage therapy is the use of phage lytic enzymes that digest the bacterial peptidoglycan, especially of gram-positive bacteria, as a novel class of alternative antimicrobials (Fischetti 2008; Schmelcher et al. 2012a). The phage lytic enzymes can be applied externally and have a variety of biochemical activities that can be fused into recombinant chimeric molecules which synergistically retain their parental activities to digest bacterial cell walls, thereby avoiding resistance development (Schmelcher et al. 2012b). Bacteriophages can replicate in host cells and are able to produce new lytic phages to keep pace with the mutation of pathogens. Many of these phage lytic enzymes are highly species specific (Simmons et al. 2010), and their cell wall-binding (CWB) domains can also be used for bacterial detection systems (Schmelcher et al. 2010). Phages can cause the release of toxins [e.g., endotoxin (lipopolysaccharides, LPS)], in large quantities from bacteria, especially gram-negative bacteria, which may account for several side effects on the host such as the development of an inflammatory cascade leading to multiple organ failure (Chen et al. 2014).

An important extension to bacteriophage therapy is the use of phage lytic enzymes that digest the bacterial peptidoglycan, particularly of gram-positive bacteria (Schmelcher et al. 2012a). Bacteriophages are defined as specific intracellular parasites of bacteria that multiply using the metabolic machinery of their hosts. There are two large kinds of phages: (1) virulent phages, with a lytic life cycle; and (2) temperate phages, with a lysogenic life cycle. In a lytic life cycle, the phage recognizes specific bacteria, injects its genetic material, and then uses the metabolic machinery of the host to replicate and assemble copies of itself. A process of cellular lysis mediated by the phage then frees the virions assembled within the interior of the cell. Once freed, these new virions can infect another cell, reinitiating the cycle. By contrast, in the lysogenic life cycle the phage recognizes the host cell, the injected DNA is incorporated into the bacterium genome, and replicates with it. Under certain conditions, this DNA can detach from the genome and initiate a lytic life cycle. As it leaves the bacterial genome, the phage DNA can take information with it which can be transferred to its next host. This process might impart undesirable characteristics to the new host, such as virulence factors or antibiotic resistance genes.

Phage therapy is defined as the use of phages to treat bacterial infections; the term is restricted to the employment of virulent phages. Its application to humans was described almost as soon as these viruses were discovered, in 1915 (Abedon et al. 2011). However, the bacteriophages use was displaced by the discovery of penicillin and continued only in some countries of the former Eastern Block (Summers 2012). Today, the problematic emergence of multi-drug-resistant (MDR) bacteria has provided a new focus on bacteriophages as a natural, nontoxic alternative treatment of bacterial infections. The advantages of phage therapy include that treatment with phages can target a specific group of bacteria, with the result that the normal microbiota is not affected, reducing, thereby, the risk of secondary infections associated with antibiotic therapies (Loc-Carrillo and Abedon 2011). Phage therapy is one of the strategies available to manipulate the gut microbiome; it has promising results and also has some advantages over the other technologies. Phages are considered to be more effective than antibiotics as they only multiply when their specific host is present, which implies that phages have the ability to increase their density in situ. Equally, following infection, once the concentration of the host has been reduced, the population of phages diminishes as well. Another important advantage is that phages can be

effective against sensitive bacteria as well as strains that are resistant to antibiotics (Nilsson 2014). Phages are able to target only certain groups of pathogenic bacteria without having any negative effect on the normal microbiota of a given niche (Sulakvelidze 2011), which, as has been shown throughout, fulfills important functions in the host.

The application of phages has been described for humans (Abedon et al. 2011), different models in animals, plants, and food (Cooper 2016). A bacteriophage cocktail that targets *Listeria monocytogenes* contaminants on ready-to-eat foods containing meat and poultry products was approved in 2006 by the US FDA (Sulakvelidze 2013). In spite of this, several studies have used bacteriophages in animals to control bacteria transmitted by foodstuffs. These models include the use of phages to control *Salmonella* and *Campylobacter* in broiler chickens (Wernicki et al. 2017). It is widely recognized that pathogens such as *Campylobacter* and *Salmonella* can be transmitted along the food chain and can be the source of human illness. In all cases, phages have been administered orally, either as a feed supplement, in water, or using a gavage after the birds have been challenged with a given concentration of the pathogen (Grant et al. 2016). Published studies show that the application of phages in higher concentrations than the targeted microorganism is more successful in reducing the presence of the latter (Bardina et al. 2012). It should also be considered that cocktails of phages are more effective than individual applications. Additionally, it has been demonstrated that treatment with phages is more effective when it precedes the exposure to the pathogen (Wong et al. 2014). On administration routes, even though most of the studies have been carried out using oral *gavages*, comparing the effectiveness of treatments conducted using a *gavage* with those in which phages were administered as a feed supplement, both approaches obtained reductions of 1.7 log10 and 2 log10 CFU/ml, respectively (Carvalho et al. 2010). In a different approach, an extremely interesting study showed that the application of phages alongside with probiotics is more effective in reducing *Salmonella* than applying each treatment separately (Toro et al. 2005).

Bacteriophages are viruses that are parasitic on bacteria, and have long been considered as one of the types of agents to treat bacterial infections. A bacteriophage cocktail that targets *Listeria monocytogenes* contaminants on ready-to-eat (RTE) foods containing meat and poultry products was granted approval during 2006, which was the first time that the US FDA accepted the use of a bacteriophage preparation as a food additive (Bren 2007). Preparations of bacteriophages are commercially available in many parts of the world to reduce mortality in poultry caused by *Salmonella gallinarum* and *S. pullorum*. Lytic phage has also been used to treat a fatal neonatal meningitis *E. coli* infection of rats (Pouillot et al. 2012). An important extension to bacteriophage therapy is the use of phage lytic enzymes (PLEs) that digest the bacterial peptidoglycan, especially of gram-positive bacteria, as a novel class of alternative antimicrobials (Fischetti 2008; Schmelcher et al. 2012a). PLEs can be applied externally and have a variety of biochemical activities that can be fused into recombinant chimeric molecules which synergistically retain their parental activities to digest bacterial cell walls, thereby avoiding resistance development (Schmelcher et al. 2012b). Many of these enzymes are highly species specific (Simmons et al. 2010), and their cell wall-binding domains can also be used for bacterial detection systems (Schmelcher et al. 2010). Currently, the main challenge for the promotion of phage preparations is the lack of data obtained from large-scale clinical trials, thus hindering their universal application. Regulatory loopholes remain another major hurdle. In addition to the inherent safety concern, neither the US FDA nor the EMA has an approval processing place that can easily accommodate the ever-changing combinations of phages that accompanies the need to continuously develop the product to stay one step ahead of evolving MDR bacteria (Miedzybrodzki et al. 2012).

Another alternative to the use of bacteriophages is the application of bacteriophage endolysins (or lysins) (glucosidase, amidase, endopeptidase, transglycosylase), which are lytic enzymes encoded by bacteriophages that decompose the bacterial cell wall peptidoglycan during the late stage of the phage reproduction lytic cycle, degrading bacterial peptidoglycan to facilitate the release of new phages from the infected bacteria. Endolysins can treat sepsis and a few gram-positive bacteria infections but is poor against gram-negative bacteria (Cheng et al. 2014). Endolysins can quickly kill susceptible strains with wider antibacterial spectrum than phages and the activities are easier to detect.

These enzymes present some advantages and disadvantages over living phages. The advantages are (1) lysins are not self-replicating, meaning they are more targeted and defined control; (2) resistance to these enzymes has not yet been reported; (3) they can be identified and used from temperate and virulent phages; and (4) lysins have the potential to be used in many environments (humans, animals, food, biofilms, etc.) (O'Flaherty et al. 2009). Among the important disadvantages of lysins are (1) there is a lack of effectiveness against gram-negative bacteria; and (2) bacteriocins are protein, therefore are susceptible to inactivation. Several reports on the antimicrobial application of endolysins along the food processing line have been carried out, mainly directed to *Staphylococcus aureus* and *Listeria monocytogenes* in dairy products (Oliveira et al. 2012).

It is also important to note that all other *Clostridium* species were resistant to lytic activity, demonstrating species specificity for *C. perfringens*. No other reports of lysins with potential use in broiler chickens were found, perhaps because

most of the food-borne contamination is caused by gram-negative bacteria (Zimmer et al. 2002).

It should be stressed that phage therapy still presents limitations, such as variability in the results obtained, which might be explained by different reasons: (1) the development of resistance to phages by target bacteria, (2) the low multiplicity of infection, (3) the inaccessibility of the target microorganism, and (4) the deactivation of phages by the host. The most important limitations to employ bacteriophages in producer farms is the lack of approval and regulation for their use with animals, and acceptance of the therapy by the producer community, given that it is a relatively new technology. However, if such approval is to be achieved, research into the effectiveness of phages in the commercial conditions of factory farming is still required (Grant et al. 2016).

Only one study using bacteriophages in broiler chicken flocks using *Campylobacter* phages is available (Kittler et al. 2013). The authors of this chicken study carried out three field trials, two in the same farm but in different sheds, and the third was carried out in another farm. The cocktail of four phages was supplied via drinking water to a final concentration of 10^5–10^7 CFU/ml. In the first trial, a reduction up to 3.2 CFU/g of *Campylobacter* load in the caecal content was achieved, compared to the control. However, no significant reduction was observed in the experimental groups of the other trials, indicating that additional research is required for large-scale application of the phages (Kittler et al. 2013).

Overall, bacteriophages represent a promising alternative for the control of *Salmonella* and *Campylobacter* in food-producing animals. However, replicable studies that demonstrate the effectiveness of the technology in intensive production systems are still required.

6.5 Immunomodulatory Compounds: Vaccines

Immunomodulatory compounds such as lactoferrin may also affect the microbiota. Lactoferrin was shown to affect the bacterial community in the caecum of poultry (Geier et al. 2011). In pigs, lactoferrin increased numbers of *Lactobacillus* and *Bifidobacteria* and decreased numbers of *E. coli* and *Salmonella* (Wang et al. 2007). Other compounds, including bacterial products such as bacteriocins (Shin et al. 2008) and immunomodulatory compounds, may also be important in modifying the intestinal microbiota.

One technique that appears to have considerable potential as an alternative to antibacterials in the presence of disease-causing organism is the use of egg yolk antibodies, usually referred to as IgY. The injection of the antigens induces an immune response in the hen, resulting in the production of antibodies. Approaches utilizing pathogen-specific antibodies in animal feeds are based on the fact that transfer of avian maternal antibodies from serum to egg yolk (the antibodies are deposited in the egg yolk) can confer passive immunity to embryos and neonates (Tini et al. 2002). Consequently, passive immunization by oral administration of specific antibodies is a possible alternative to antibiotic treatment to reduce gastrointestinal pathogens in animals. Specifically, based on treatment with specific antibodies targeting *E. coli* adherence-associated proteins (Cook et al. 2007), orally administered pathogen-specific antibodies may alleviate enteric diseases.

7 Regulations Concerning Feed Additives in the European Union

Article 5 of Regulation (EC) No. 1831/2003 (EC 2003) states that a feed additive (1) shall not have an adverse effect on animal health, human health, or the environment, (2) shall not be presented in a manner that may mislead the user, and (3) shall not harm the consumer by impairing the distinctive features of animal products, or mislead the consumer with regard to the distinctive features of an animal product (Anadón et al. 2018).

According to the Regulation (EC) No. 1831/2003, a feed additive is a substance, microorganisms, or preparations, other than feed material and premixtures, that is intentionally added to feed or water to perform, in particular, one or more specific functions that are enumerated in Article 5(3) of the Regulation (EC) No. 1831/ 2003 (EC 2003): (1) favorably affect the characteristics of feed; (2) favorably affect the characteristics of animal products; (3) favorably affect the color of ornamental fish and birds; (4) satisfy the nutritional needs of animals; (5) favorably affect the environmental consequences of animal production; (6) favorably affect animal production, performance or welfare, particularly by affecting the gastrointestinal flora or digestibility of feedstuffs; or (7) have a coccidiostatic or histomonostatic effect; and shall be allocated to one or more of the following categories:

Technological Additives Technological additives are defined as any substance added to feed for a technological purpose, including the following functional groups. (1) Preservatives: substances or, when applicable, microorganisms which protect feed against deterioration caused by microorganisms or their metabolites; (2) antioxidants: substances prolonging the storage life of feedstuffs and feed materials by protecting them against deterioration caused by oxidation; (3) emulsifiers: substances that make it possible to form or maintain a homogeneous mixture of two or more immiscible phases in feedstuffs; (4) stabilizers: substances which make it possible to maintain the physicochemical state of feedstuffs; (5) thickeners: substances which increase the viscosity of feedstuffs; (6) gelling agents:

substances that give a feedstuff texture through the formation of a gel; (7) binders: substances that increase the tendency of particles of feedstuffs to adhere; (8) substances for control of radionuclide contamination: substances that suppress absorption of radionuclides or promote their excretion; (9) anti-caking agents: substances that reduce the tendency of individual particles of a feedstuff to adhere; (10) acidity regulators: substances that adjust the pH of feedstuffs; (11) silage additives: substances, including enzymes or microorganisms, intended to be incorporated into feed to improve the production of silage; (12) denaturants: substances that, when used for the manufacture of processed feeding stuffs, allow the identification of the origin of specific food or feed materials.

Sensory Additives Sensory additives are defined as any substance that improves or changes the organoleptic properties of the feed and/or the visual characteristics of food derived from an animal, and include the following functional groups: (1) colorants: substances that add or restore color in feeding stuffs; substances that, when fed to animals, add color to food of animal origin; and substances that favorably affect the color of ornamental fish or birds; and (2) flavoring compounds: substances when included in feedstuffs increase feed smell or palatability (Anadón et al. 2018).

Nutritional Additives Nutritional additives supply a specific nutrient required by the animal for optimal growth. The following functional groups are included: (1) vitamins, pro-vitamins, and chemically well-defined substances having similar effect; (2) compounds of trace elements; (3) amino acids, their salts, and analogues; and (4) urea and its derivatives (Anadón et al. 2018).

Zoo-technical Additives Zoo-technical additives are defined as any additive used to favorably affect the performance of animals in good health or to favorably affect the environment, including the following functional groups: (1) digestibility enhancers, substances that, when fed to animals, increase the digestibility of the diet, through action on target feed materials; (2) gut flora stabilizers, microorganisms or other chemically defined substances which, when fed to animals, have a positive effect on the gut flora; (3) substances that favorably affect the environment; and (4) other zoo-technical additives. Commission Regulation (EC) No. 429/2008 (EC 2008) on detailed rules for the implementation of Regulation (EC) No. 1831/2003 as regards the preparation and the presentation of applications and the assessment and the authorization of feed additives is in application.

This Regulation (EC) No. 429/2008 (EC 2008) includes general provisions for safety and efficacy studies to be carried out in support of the application of feed additives. Specific guidelines have been prepared for the FEEDAP Panel of EFSA for feed additives that are already authorized for use in food in minor species, as nutritional additives in pets, and for other non-food-producing animals as well as for sensory additives other than flavoring compounds, technological additives (silage additives), technological additives other than silage additives, zoo-technical additives (enzymes, microorganisms), zoo-technical additives other than enzymes and microorganisms, and coccidiostats and histomonostats, among others (Anadón et al. 2018). Regulation (EC) No. 1831/2003 will establish a community procedure for authorizing the placing on the market and use of feed additives and to lay down rules for the supervision and labelling of feed additives and pre-mixtures to provide a basis for the assurance of a high level of protection of human health, animal health and welfare, the environment, and users' and consumers' interests in relationship to feed additives, while ensuring the effective functioning of the internal market. This regulation will not apply to processing aids and veterinary medicinal products as defined in Directive 2001/82/EC (EC 2001) Directive 2004/28/EC (EC 2004) amending Directive 2001/82/EC on the Community code relating to veterinary medicinal products with the exception of coccidiostats and histomonostats used as feed additives Regulation (EU) 2019/6 of the European Parliament and of the council of 11 December 2018 on veterinary medicinal products and repealing Directive 2001/82/EC recentely published. However, prebiotics (inulin, fructo-mannan-oligosaccharides, yeast cell walls rich in β-glucans) or SCFAs and MCFAs are considered as feedstuffs and not as feed additives and so fall under the scope of Regulation (EC) No. 767/2009 (EC 2009) concerning the marketing and use of animal feeds. However, the classification of a product as either a feedstuff or a feed additive remains unclear because of differences in the relative impact of technological processing (Huyghebaert et al. 2011). Botanical or herbal extracts, flavours, and etheric oils now fall within the scope of Regulation (EC) No. 1831/2003 (EC 2003). In general, unprocessed herbs are regarded as feed materials and do not need authorisation. Notified plant extracts or components are included in the "Community Register of Feed Additives" established as laid down by Article 17 of Regulation (EC) No. 1831/2003 (EC 2003). The Commission has established this Community Register, which is regularly updated, and it makes reference/links to the relevant authorization. This Register is composed of two parts: the first part, Annex I, contains the list of modifications to the Register and the current authorizations, and the second part, Annex II, contains a list of additives that will be withdrawn in the short term. Also included are those for which a date is indicated in the column "Expiry date of Authorisation." Those additives are no longer allowed to be placed on the EU market if that date is expired. The Community Register of

Feed Additives has only informative purposes and does not replace community legal acts. The community legal acts concerning the authorization of each additive entered in the Register constitute the legal basis for the market placement and use of each additive concerned. Thus, before November 2010, a complete scientific dossier for each notified etheric oil or component shall be submitted to European Food Safety Authority (EFSA), which provides guidance on scientific data needed to carry out a safety assessment for botanical agents (EFSA 2009, 2014).

Unresolved Issues

A significant area of attention is enhancement of biosecurity employed in animal production, which improves the efficiency of animal production and animal welfare.

There is a strong drive by consumers, regulatory agencies, scientific committees, and governments to reduce the use of antibiotics in food-producing animals. Feed and pharmaceutical companies provide an array of nutraceuticals to use as feed additives or veterinary drugs, all offering to replace antibiotics, but not all of these can deliver on that promise. It is very important to evaluate each feed additive or veterinary drug on its claims. A description of mechanism of action, efficacy, and advantages and disadvantages of use must be available, and clear proof of the compatibility of different additives in drinking water and feed must be shown. Benefits must be visible in farms, herd, or flock conditions in animal production: only those that perform on scientific grounds are true alternatives. Replicable studies that demonstrate the effectiveness and safety of the nutraceuticals as alternatives to antibacterials in intensive production systems are required. Researchers continue to investigate and fine-tune nutritional solutions for animal husbandry to positively influence animal health and welfare and productivity and decrease use of antibiotics on intesive farms. Most of these compounds produce inconsistent results and are rarely equal to antibacterials in their effectiveness. There is still much to learn about which type or what level of fibre would be best in post-weaning diets, as investigation continues: also needed is avoiding dysbacteriosis, postweaning diarrhoea, poor hatchery environment, and mastitis among other pathological findings.

Phage therapy has promising results and also have some advantages over other technologies, but research is needed for phage use at a productive scale. The most important limitation to use of bacteriophages in producer farms is lack of approval and regulation for their use with animals, and acceptance of the therapy by the producer community, given that it is a relatively new technology. However, if such approval is to be achieved, research into the effectiveness of phages in the commercial conditions of factory farming is still required.

The use of phytogenics in farm practice is limited. The mode of action of the plant extracts is poorly investigated either because these were studied primarily with regard to mixtures or because only a few studies are available.

Essential oils and organic acids have been extensively used and studied in food animals to improve feed safety, growth rate and feed conversion, but further research is required to confirm possible improvement of productive parameters and animal health and welfare. Moreover, there is a need to validate reliable biomarkers to measure the efficacy and safety of phytogenics.

Studies on antimicrobial peptides and their applications in poultry have mostly focused on potential protection against diverse pathogens causing infectious diseases rather than growth-promoting activities. However, a few research trials have investigated the effect of antimicrobial peptides on poultry growth performance, intestinal morphology, and gut microbiology as potential AGP alternatives.

A legal basis must exist for the market placement and use of new nutraceuticals. Regulatory activity to take into account the new development and innovation of nutraceuticals to be used in food animals must be based on scientific data.

Acknowledgments This work was supported by Project S2013/ABI-2728 (ALIBIRD-CM Program) from Comunidad de Madrid, and by Project Ref. RTA2015-00010-C03-03 from Ministerio de Economía, Industria y Competitividad, Spain.

Feed Additives in Animal Health

Amit Kumar Pandey, Prafulla Kumar, and M. J. Saxena

Abstract

Animal feed additives are used all over the world for various livestock including poultry for more reasons than one like to provide essential nutrients, increase palatability of the feed, improve their growth performance, as well as optimize the utilization of the feed. Animals with high growth performance need to maintain a high health status, and the use of proper additives is a predominant argument in such cases. With increasing industry standards and consumer awareness as well as demand for healthy food products of animal origin, there is an increased pressure on the industry for more natural and non-residual alternatives than the conventional feed additives used till recently as animal feed products. Consumer and animal welfare are primary concerns dictating the valuable alternatives of animal feed additives. Some of the alternatives seen for use as animal feed additives are probiotics, prebiotics, enzymes, and herbs. Such choice of feed additives is backed by scientific and empirical research on these alternatives as herbs and their extracts (botanicals) have been found to have a wide range of activity which cannot only stimulate feed intake but also stimulate endogenous secretions or have antimicrobial, coccidiostat, or anthelmintic activity.

Ban of antibiotic use as growth promoters, cost-effectiveness, and increased awareness about harmful residual effect cause herbal feed additive to gain importance in sustainable livestock production. Animal husbandry sector gets benefited by the use of number of feed additives such as ascorbic acid, prebiotic, probiotic, and herbal extracts. Medicinal properties of the herbs to improve antimicrobial, anti-inflammatory, antioxidant, digestibility, and immune-stimulant activity must be explored in the feeding of animals as well as safe food for human beings. Standardization of correct dosage regime of herbal feed additives for a particular function is the demand of situation so more research should be conducted in this direction.

Feed additives · Phytogenic product · Probiotics · Prebiotics · Enzymes · Herbs · Plant extracts · Quality control

1 Introduction

One of the greatest challenges faced by farm managers, livestock rearers, animal scientists, as well as nutritionists involved in animal feed industry or research domain is designing the balanced ration practices of high yielding animals along with maintaining the cost-benefit ratio. Also, to be taken in consideration is the fact that meat, dairy, and animal by-product costs are not stable and vary for various reasons, and one among them is the feed cost involved (Thornton 2010). Feed costs represent the largest input cost in animal husbandry practices (estimated to be 35–50%). In general there is an opinion that animals ate plants, or grass or some other "food" natural to their ilk, but in reality, in today's farms, feeding livestock and poultry is a complicated endeavor fraught with controversy and split opinions. Feed additives have been considered as a group or class of feed ingredients which in a non-nutrient role can cause the desired animal response. Such responses may include a shift in pH, growth, or modifying the metabolic response of the animal (Hutjens 1991). According to the European Commission, feed additives are products used in animal nutrition for purposes of improving the quality of feed and the quality of food from animal origin or to improve the animals' performance and health, e.g., providing enhanced digestibility of the feed materials. Several feed additives may contain various

nutrients such as sodium and protein which are part of sodium bicarbonate or yeast culture, respectively. Technically, feed additives are neither considered a requirement nor do guarantee high animal productivity or economic profitability in animal husbandry practices (Animal Feed Additives 2018, web source). There has been a rapid increase in the demand to be met from dairy and meat industry owing to increasing population pressure. Food security which is the second in the list of Sustainable Development Goals in form of "zero hunger" and 12th sustainable development goal which is "responsible consumption and production" are both sought after in animal feed industry up to a greater extent.

The importance of feed additives is gaining popularity day by day owing to the benefits that they can ascertain like growth promotion in animals, control over infectious diseases as well as enhancement of feed digestibility (Specialty Feed Additives Report 2016). There is a steadfast growth graph of animal feed additives market which is projected to grow in the future due to the rapid increase in demand for meat, meat products as well as dairy products around the globe (Animal Feed Additives Report 2014). The consensus of meat and dairy farmers has increased towards feed quality and certifications associated with them owing to frequent occurrences of epidemics such as bird flu, other diseases such as foot-and mouth-disease, and environmental concerns have led to increase in concern over animal health around the globe.

The top consumers of feed additives in the world are North America and Asia-Pacific. They account for more than 60% of the consumption of animal feeds in the world (Animal Feed Additives Report 2014). Asia-Pacific is estimated to be the fastest growing region in terms of revenue. Growth is particularly high in emerging economies such as India, China, and Brazil because of gradual increase in the income levels of population owing to increased industrialization and boom in service sector, and in the process it has given an uplift to the feed industry as well due to rising per capita meat consumption (Ruminant Feed Market Report 2018). Species wise the largest market coverage is of poultry feed additives which are followed by market share for feed additives for swine (Animal Feed Additives Report 2014). The main driving factors of the global market of animal feed additives can be classified as:

(a) Rise in global meat consumption
(b) Increasing awareness toward meat quality and safety
(c) Increasing mass production of meat
(d) Recent disease outbreaks in livestock

(Kearney 2010; Henchion et al. 2017).

The restraints of the market are increasing raw material cost and regulatory structure. However, increasing cost of natural feed products is creating an opportunity for feed additives as a cheap alternative. Leading manufacturers are focusing on the expansion of businesses across regions and setting up new plants for increasing their production capacity.

Though there are various definitions of feed additives, a comprehensive definition put forward by the European Commission is: "Feed additives are products used in animal nutrition for purposes of improving the quality of feed and the quality of food from animal origin, or to improve the animals' performance and health, e.g. providing enhanced digestibility of the feed materials."

With the tightening of the noose of regulatory authorities and stronger social media, there is hardly any scope to flout the norms set for industries. For any animal feed additives to be marketed, the process of scientific evaluation and validation to ascertain presence or absence of any harmful effects on human and animal health or environment needs to be performed in stringently (European Commission 2018). So, various domains such as health, environmental sustainability, regulatory requirements, and even climate change are a part of production, marketing, and post-utilization effects which are assimilated with the feed production industry.

2 Classification of Animal Feed Additives

Feed additives are classified into various categories according to different parameters. Feed additives can be of various types:

Based on European Commission regulations
Based on holistic approach
Based on their origin and function

Feed additives can be categorized as feed antioxidants, compound acidifiers, complex enzymes, mycotoxin adsorbent, mildew prevention, vitamins and electrolytes, L-carnitine hydrochloride, diluted chromium nicotinate, fattening agents, amino acids, antibiotics, binders, minerals, herbs, and premix. A widely recognized classification of animal feed additives based on European Commission regulations and guidelines is as below.

One additional class of feed additives used to include the technological interventions employed in feed additives is *Technological additives*.

2.1 Based on European Commission Regulations

2.1.1 Sensory Additives

This refers to a group of additives which improve the palatability (i.e., voluntary intake) of a diet by stimulating appetite, usually through the effect these products have on the flavor or color of the diet. For example, feed flavors or sweeteners such as vanilla extract may well encourage piglets to eat a ration.

2.1.2 Nutritional Additives

Additives provide specific nutrients for an animal for optimal growth. An example would be a vitamin, amino acid, or trace mineral. In most cases, such additives are simply concentrated forms of nutrients supplied in natural ingredients in the diet.

2.1.3 Zootechnical Additives

These additives improve the nutrient status and production of the livestock, not just by providing specific nutrients but also by assisting the more efficient use of the nutrients present in the diet. An example of such an additive would be an enzyme or direct-fed microbial product, both of which enhance the conditions of the intestinal tract, thus enabling more effective nutrient extraction from the diet. In this respect, they are often referred to as pro-nutrients, i.e., products which improve the nutritional value of a diet without necessarily providing nutrients directly. Other additives are used for environmental benefits that they provide to animal husbandry, and others are targeted for specific physiological functions.

2.1.4 Coccidiostats and Histomonostats

These additives control the health of poultry through direct effects. These compounds are used to control the intestinal health of poultry, and they directly act on the parasitic organisms inhabiting the intestines, and they are not classified as antibiotics (Feed additive classifications 2018).

2.1.5 Technological Additives

This classification refers to a group of additives which influences the technological aspects of the feed. These additives do not directly influence the nutritional value of the feed but may do so indirectly by improving its handling or hygiene characteristics. An example of such an additive would be an organic acid for the preservation of feed (Fig. 1).

2.2 Based on Holistic Approach

Apart from European classification, a more holistic classification provided by the Indian Council of Agricultural Research, Ministry of Agriculture, Government of India, is shown in Fig. 2.

Fig. 1 Classification of technological feed additives

2.2.1 Additives That Influence Feed Stability, Feed Manufacturing, and Properties of Feeds

(a) Antifungals
(b) Antioxidants
(c) Pellet binders

2.2.2 Additives That Modify Animal Growth, Feed Efficiency, Metabolism, and Performance

(a) Feed flavors
(b) Digestion modifiers
  I. Enzymes
  II. Prebiotics
  III. Buffers
  IV. Acidifiers
  V. Ionophores
  VI. Antibloat compound
  VII. Isoacids
  VIII. Salivation inducers
  IX. Probiotics
  X. Defaunating agents
(c) Metabolism modifiers
  I. Hormones
  II. Beta-adrenergic agents (repartitioning agents)
(d) Growth promotants
  I. Antibiotics

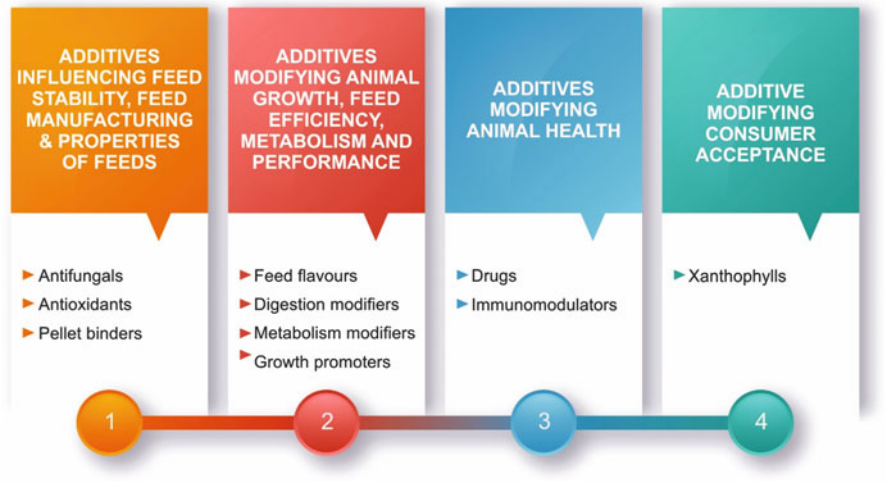

Fig. 2 Indian Council of Agricultural Research (ICAR)—classification of feed additives

II. Chemotherapeutic agents
III. Prebiotics and probiotics

2.2.3 Additives That Modify Animal Health

(e) Drugs
(f) Immunomodulators

2.2.4 Additives That Modify Consumer Acceptance

(a) Xanthophylls

Further to have a holistic classification to include all the types and subtypes of animal feed additives, including those included in the above classification based on the primary activity of function performed by a set class, we suggest the following detailed classification.

2.3 Based on Their Origin and Function (Fig. 3)

2.3.1 Additives That Enhance Feed Intake

Antioxidants

Antioxidants are compounds that prevent oxidative rancidity of polyunsaturated fats. Rancidity once develops may cause the destruction of vitamins A, D, and E and several of the B complex vitamins. Breakdown products of rancidity may react with lysine and thus affects the protein value of the ration. Ethoxyquin or BHT (butylated hydroxytoluene) can serve as an antioxidant in the feed.

Flavoring Agents

Flavoring agents are feed additives that are supposed to increase palatability and feed intake. There is a need for flavoring agents that will help to keep up feed intake.
When highly unpalatable medicants are being mixed:

- During attacks of diseases
- When animals are under stress
- When less palatable feedstuffs are being fed either as such or being incorporated in the ration

Fig. 3 Holistic classification of feed additives

Ruminants prefer sweet compounds. Additionally, cattle and goats respond positively to salts of volatile fatty acids. Horses will often refuse musty feed when there is so little mold that the owner fails to detect it.

2.3.2 Additives That Enhance the Quality and Acceptability of the Feed

Poultry owners will often enhance the yellow color by incorporating xanthophylls into broiler feed. Among various additives, arsanilic acid, sodium arsanilate, and roxarsone are added for the purpose.

Anticaking Agents

Anticaking agents are the anhydrous substance that can pick up moisture without themselves becoming wet. They are added to dry mixes to prevent the particles from clumping together and so keep the product free-flowing. They are either anhydrous salts or substance that hold water by surface adhesion yet themselves remain free-flowing:

- Salt or long chain fatty acids
- Calcium phosphate
- Potassium and sodium ferrocyanide
- Magnesium oxide
- Salts silicic acid—Al, Mg, Ca, and salt
- Sodium aluminum silicate
- Sodium calcium aluminum silicate
- Calcium aluminum silicate

Humectants

These are the substance which is required to keep the product moist, for example, bread and cakes. Anticaking agents immobilize moisture that was picked up. Humectants are not of much use in poultry feed.

Firming and Crisping Agents

These are substances that preserve the texture or vegetable tissues and, by maintaining the water pressure inside them, keep them turgid. It prevents a loss of water from the tissues.

Sequestrants

Certain elements—copper and iron—can act as prooxidant catalytic and therefore need to the immobilized. Sequestrants are compounds added to do this. These compounds should have an affinity to metal ions and should prevent the metal in becoming engaged in oxidative action. Most effective sequestrants ethylenediaminetetraacetic acid (EDTA) is a calcium salt of EDTA which works satisfactorily as a sequestrant without interfering with trace mineral metabolism.

Sweeteners

It is the common constitution of food but yet used as an additive, e.g., sugar. Some are poorly digestible and may cause digestive upsets. Saccharin is extensively used during World War I. It is a compound without any calorific value.

Additives such as humectants, firming and crisping agents, sweeteners, emulsifiers, stabilizers, acid, and buffers are not commonly used in poultry feeds.

2.3.3 Additives That Facilitate Digestion and Absorption

Grit

Poultry does not have teeth to grind any hard grain, most grinding takes place in the thick musculated gizzard. The more thoroughly feed is ground, the more surface area is created for digestion and subsequent absorption. Hence, when hard, coarse, or fibrous feeds are fed to poultry, grit is sometimes added to supply additional surface for grinding within gizzard. When mash or finely ground feeds are fed, the value of grit becomes less. Oyster shells, coquina shells, and limestone are used as grit.

Buffers and Neutralizers

During the maximum production stage ruminants are given high doses of concentrate feeds for meeting demands for extra energy and protein requirement of the animal. The condition, on the other hand, lowers the pH of the rumen. Since many of the rumen microbes cannot tolerate low pH environment, the normally heterogeneous balanced population of microbes become skewed, favoring the acidophilic (acid-loving) bacteria. The condition often leads to acidosis and thereby upsets normal digestion. The addition of feed buffers and neutralizers, such as carbonates, bicarbonates, hydroxides, oxides, salts of VFA, phosphate salts, ammonium chloride, and sodium sulfate, has been shown to have beneficial effects. Recently the use of baking soda ($NaHCO_3$) has been shown to increase average daily gain by about 10%, feed efficiency by 5–10%, and milk production by about 0.5 L per head per day.

Chelates

The word "chelates" is derived from the Greek word "chele" meaning "claw" which is a good descriptive term for the manner in which polyvalent cations are held by the metal-binding agents. Prior to union with the metal, these organic substances are termed as "ligands." Ligand + mineral = chelate element.

Organic chelates of mineral elements, which are cyclic compounds, are the most important factors controlling absorption of a number of mineral elements. A particular element in chelated form may be released in ionic form at the intestinal wall or might be readily absorbed as the intact chelate. Chelates may be of naturally occurring substances

such as chlorophyll, cytochromes, hemoglobin, vitamin B_{12}, some amino acids, etc. or may be of synthetic substances like ethylenediaminetetraacetic acid (EDTA).

Chelates as Feed Additives

Type I: Chelates that aid in transport and to store metal ions

Chelates of this group behave as a carrier for proper absorption, transportation in the circulatory system, and passing across cell membranes to deposit the metal ion at the site where needed. Among amino acids, cysteine and histidine are particularly effective metal-binding agents and may be of primary importance in the transport and storage of mineral elements throughout the animal body. Ethylenediaminetetraacetic acid (EDTA) and other similar synthetic ligands also may improve the availability of zinc and other minerals.

Type II: Chelates essential in metabolism

Many chelates of the animal body are holding metal ions in such a cyclic fashion which are absolutely necessary to be in that form to perform metabolic function. Vitamin B_{12}, cytochrome enzymes, and hemoglobin are some of the examples of this type. Hemoglobin molecule without its content of ferrous form of iron will be of no use in transporting oxygen.

Type III: Chelates which interfere with utilization of essential cations

There are some chelates found in the body which might have accidentally formed and are of no use to the subject. Rather, those chelates may be detrimental for the proper utilization of the element. Phytic acid-Zn chelate and oxalic acid calcium chelate are examples of this type.

2.3.4 Enzymes

Enzymes are the protein which has the property of catalyzing specific biochemical reactions. They are found in all plants and animals and are responsible for growth and the maintenance of health. Microorganisms also produce enzymes, and in recent years it has been possible to produce enzymes using microorganism on an industrial scale and extract and use these enzymes in a wide range of processes for the production of feed and natural products.

Poultry feeds are largely composed of plant and vegetable materials, and there are enzymes developed to degrade, modify, or extract the plant polymers found in some of the cereals and their by-products. The enzymes can be used to improve the feeding of poultry in the following ways:

- By improving the efficiency of the utilization of the feed
- By upgrading cereals by-products or feed components that are poorly digested
- By providing additional digestive enzymes to help poultry to withstand stress conditions, e.g., hot climates

Some of the cereals are compounds of polymers either of glucose (beta-glucan) or arabinose and xylose (pentosan or hemicellulose). These polymers are not well digested by poultry, and this can result in loss of energy in two ways. Energy may be lost because these polymers hinder the digestion of starch by coating starch granules and preventing the action of starch digesting enzymes in the intestine.

Energy may be lost because the animals own enzymes are not capable of degrading the polymers, and therefore they pass through the digestive system untouched. By adding microbial enzymes to the feed, these polymers can be degraded, and their energy value made available to the bird. The dual role of enzymes has been demonstrated in trials with barley-based feed supplemented with beta-glucanase, where the apparent increase in available energy was far in excess of that available in the beta-glucan of the barley. In this case not only was the problem of sticky dropping completely eliminated but the chicken's rate of growth was equivalent to that observed normally with feeds containing a higher energy density (e.g., wheat based).

Choice of Enzyme

- Because feed is normally composed of a single raw material of constant quality, it is important that the correct choice of enzyme product be made.
- Even in the case of a relatively well-defined problem such as that in barley, the use of multienzyme activity products has an advantage.
- The enzymes should fulfill the following criteria for practical application:
  - The enzymes must be active at the pH of the animals' digestive system and capable of surviving transit through the stomach.
  - They must be in a physical form in which they can be safely and easily mixed into all forms of animal feed.
  - The products should be of a high standardized activity that will remain stable both before and after incorporation into the feed or premix.

– The enzymes must be capable of surviving normal pelleting conditions.

2.3.5 Additives That Promote Growth and Production

Antibiotics

These are substances which are produced by living organisms (mold, bacteria, or green plants) and which in small concentration have bacteriostatic or bactericidal properties. They were originally developed for medical and veterinary purposes to control specific pathogenic organisms. Later, it was discovered that certain antibiotics could increase the rate of growth of young pigs and chicks when included in their diet in small amounts. Soon after this report, a wide range of antibiotics have been tested, and the following have been shown to have growth-promoting properties: penicillin, oxytetracycline (Terramycin), chlortetracycline, bacitracin, streptomycin, tyrothricin, gramicidin, neomycin, erythromycin, and flavomycin.

Increased weight gain is most evident during the period of rapid growth and then decreases. Differences between control and treated animals are greater when the diet is slightly deficient or marginal in protein, B vitamins, or certain mineral elements.

Mode of Action of Antibiotics

- Antibiotics "spare" protein, amino acids, and vitamin on diets containing 1–3% less protein, but balance experiments have often failed to show increased nitrogen retention. Growth stimulation has been greatest when the antibiotic penicillin supplement has been added to a ration containing no protein supplements of animal origin or to a ration low in vitamin B_{12}. Under hygienic conditions, growth increases are small.
- Intestinal wall of animals fed antibiotics is thinner than that of untreated animals which might explain the enhanced absorption of calcium shown for chicks.
- Reduce or eliminate the activity of pathogens causing "subclinical infection."
- Reduce the growth of microorganisms that compete with the host for supplies of nutrients.
- Antibiotics alter intestinal bacteria so that less urease is produced and thus less ammonia is formed. Ammonia is highly toxic and suppresses growth in nonruminants.
- Stimulate the growth of microorganisms that synthesize known or unidentified nutrients.

The following points should be kept in mind while using antibiotics for animal feeding:

- Antibiotics should be used only for:
  - Growing and fattening pigs for slaughter as pork or bacon
  - Growing chicks and turkey poults for killing as table poultry
- Antibiotics should not be used in the feed of ruminant animals (cattle, sheep, and goats), breeding pigs, and breeding and laying poultry stock.
- While adding antibiotics at the recommended level, care should be taken that they are thoroughly and evenly mixed with the feed.
- For best results, antibiotics should be used with properly balanced feeds. Also, the feeds containing antibiotics should be fed only to the type of stock for which they are intended.
- Antibiotics are not a substitute for good management and healthy living conditions or for properly balanced rations.

Probiotic and Prebiotic

The animal gut is composed of nearly a thousand different types of microorganisms, some of them are beneficial some are not. The gut microflora plays a very important role in health and disease condition of the living being. The healthy condition is due to the presence of beneficial bacteria which is also termed as probiotic or due to the intake of nutrients that stimulate the endogenous beneficial microbes (prebiotics).

A probiotic is defined classically as a viable microbial dietary supplement that beneficially affects the host through its effects in the intestinal tract (Sanchez and Rivas-Estilla 2006). Probiotics are live microbial feed supplements which are beneficial to the host animals and help to improve their intestinal microbial balance.

A prebiotic is defined as a nondigestible food ingredient that beneficially affects the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon (Gibson and Roberfroid 1995). Use of prebiotic causes change in the colonic microflora composition with dominance of a few of the potentially health-promoting bacteria, especially, but not exclusively, *Lactobacilli* and *Bifidobacterium* (Gibson and Roberfroid 1995). Prebiotics target animal-associated microbiota with the goal of improving health, whereas probiotics use live microorganisms.

Probiotics

The genera of bacteria which are most frequently used as prebiotics are *Lactobacilli* and *Bifidobacterium*, *Enterococcus faecium*, and spore-forming *Bacillus* spp., while some yeasts are also used such as *Saccharomyces*. There are several new uses of probiotics that were previously unthinkable. But the efficacy of these is not misunderstood and consider for the cure of everything. Probiotics are very specific and

strain dependent, and hence different strains are beneficial in different disorders. Some strains of probiotics may be detrimental to certain individuals, and it may worsen the condition of disease in certain individuals. Moreover, the investigation regarding the dose-dependence relationship is also very rare. Though numerous research have been conducted on probiotics in the past two decades, still there is much to be discovered.

They benefit the host by:

- Having a direct antagonistic effect against specific group of undesirable or harmful organism through production of antibacterial compounds, elementary, or minimizing their competition of nutrients
- Altering the pattern of microbial metabolism in the gastrointestinal tract
- Stimulation of immunity
- Neutralization of enterotoxins formed by pathogenic organism

Prebiotics

Prebiotics were recognized for their ability to manipulate host microbiota to the benefit of the host (Gibson and Roberfroid 1995). Prebiotics provide nutrients to favorable microorganisms raise by the host, including administered probiotic strains and indigenous (resident) microorganisms. Therefore, prebiotics are differing from most of the dietary fibers such as cellulose, xylans, and pectins which inspire the growth of a wide range of gut microorganisms. Currently, two main groups dominate the prebiotic category with their effects acting through enrichment of *Lactobacillus* and/or *Bifidobacterium* spp. thus resulting in increased growth rate and improved feed efficiency:

I. Fructans (fructooligosaccharides (FOS) and inulin)
II. Galactans (galactooligosaccharides or GOS)

2.3.6 Additives That Alter Metabolism

Hormones

These are chemicals released by a specific area of the body (ductless glands) and are transported to another region within the animal where they elicit a physiological response. Extensive use is being made of synthetic and purified estrogens, androgens, progestogens, growth hormones, and thyroxine or thyroprotein (iodinated casein) to stimulate the growth and fattening of meat-producing animals. There is concern, however, about possible harmful effects of any residues of these materials in the meat or milk for the consumers.

The whole question whether hormones should be used as growth promoters is still debatable, but it seems logical that with any feeding system, the economic advantages, however great, should never take precedence over any potential risk to human health. These substances may induce cancer in human beings if taken over a prolonged period through products of the treated animals. The use of such substances in poultry rearing has been prohibited by law in the USA.

Implant

Implants are hormone or hormone-like products that are designed to release slowly, but constantly, the active chemicals for absorption into the bloodstream. These are implanted subcutaneously in the ear [e.g., diethylstilbestrol (DES)].

2.3.7 Additives That Affect the Health Status of Livestock

Antibloat Compounds

Surfactants such as poloxalene are used as a preventive for pasture bloat, and several other products which have been shown to be highly effective to prevent bloat are also available in the market.

Antifungal Additives

Mold inhibitors are added to feed liable to be contaminated with various types of fungi such as *Aspergillus flavus*, *Penicillium cyclopium*, etc.

Before adding commercial inhibitors, all feedstuff should be dried below 10% moisture. Propionic, acetic acid, and sodium propionate are added in high-moisture grain to inhibit mold growth. Antifungals such as nystatin and copper sulfate preparations are also in use to concentrate feeds to prevent molds.

Anticoccidials

Various brands of anticoccidials are now available in the country to prevent the growth of coccidia which are protozoa and live inside the cells of the intestinal lining of livestock.

Anthelmintics

Under some practical feeding conditions, anthelmintics have also been used. The compounds act by reducing parasitic infections.

2.3.8 Phytogenic Feed Additive

Phytogenic feed additives are the products which are derived from plants to be used in animal feeding to improve the quality of feed, performance, and health of agricultural livestock and quality of food from animal origin. Since the last two decades, this group of feed additive gets immense interest among the farmers, especially for use in poultry and swine

farming. This increase in popularity is due to the increase in number of scientific publication in this field since 2000 which is also supported by the ban on the most of the antibiotic feed additives within the European Union (complete ban enforced in 2006), voluntarily withdrawal of the use of antibiotics as growth promoters by the USA, and growing discussion to restrict their use outside European Union. This ban and discussion is driven by the speculated risk for generating antibiotic resistance in pathogenic microorganisms.

Awareness among the people regarding the potential health hazards and environmental harm caused by the excessive use of synthetic pharmaceuticals including in-feed antibiotics as growth promoters and growth hormones and also public demand for organic foods have gradually changed the attitude toward these synthetic antibiotics (Greathead 2003; Rochfort et al. 2008).

Restrictions on the use of antibiotics as growth promoters have significantly increased the incidence of infection by pathogens, consequently having an inimical effect on the performance of livestock. This also intensifies the search for an alternative to the antibiotics as growth promoters and popularizes the phytogenic feed additive. Phytobiotics as a feed additive is a new member in the list of non-antibiotic growth promoters, such as probiotics, prebiotics, and organic acids, which are already well known in the field of livestock nutrition. The knowledge about their mode of action and aspect of the application is still rather limited, and it has a lot of potential in the coming time.

Phytogenic feed additive is a wide range of plant-derived products such as herbs, essential/aromatic oils, and oleoresins. They can be added to the diet of commercial animals to improve their productivity through enhancing feed properties, promoting animal's production performance, and improving the quality of products derived from these animals (Windisch et al. 2008).

Windisch et al. (2008) has also recommended some commonly used terms to classify different phytogenic compounds based on their origin and processing, including herbs (flowering, non-woody, and nonpersistent plants), spices (herbs with an intensive smell or taste commonly added to human food), essential oils (volatile lipophilic compounds), and oleoresins (extracts derived by nonaqueous solvents). The content of active substances and the chemical composition of phytogenic substance in the final products may vary widely depending on the plant parts used (seeds, leaves, etc.), geographical origins, and harvesting season (Burt 2004; Bakkali et al. 2008; Wendisch et al. 2008). Selection of particular part of a plant of particular species of a very particular geographical region is very important to get a specific needed effect. The active constituents of the same species of plant may vary depending on the different geographical region and climatic condition. These variations are the results of genetic and environmental interaction and a manifestation of biodiversity within the same plant species (Zhang et al. 2011).

Plenty of research studies have indicated the multiple roles of phytobiotics as a feed additive like growth promotion effects, antimicrobial activity, antioxidant activity, anti-inflammatory activity, etc. Based on the investigations, it seems that modulation of the gut environment and intestinal morphology in swine and poultry is the hypothesized mode of action of phytogenic feed additives (Stein and Kil 2006; Li et al. 2012) (Table 1).

Plant Secondary Metabolites (PSM)

The biological and therapeutic property of a medicinal plant is closely related to the phytochemicals in it. An extensive summary is required for a comprehensive overview of chemistry, biochemistry, and bioactivity of plant secondary metabolites because they are a very large group of compounds. Out of the more than 100,000 different compounds of natural origin that have been described, more than 80,000 are derived from plants (Hashemi and Davoodi 2010). These phytochemicals can further be classified into major groups such as alkaloids, tannins, saponins, steroids, essential oils, acids, etc.

Different classifications had been put forward to classify this broad range of phytogenic substances based on their source of origin, chemical composition, usage, mode of action, etc. Regarding classification of the phytogenic substances/phytobiotics with respect to biological origin, chemical composition, formulation, and purity, phytogenic substances comprise a very wide range and can further be classified into four groups as herbs (products from flowering, non-woody, and nonpersistent plants), botanicals (entire or processed part of a plant, e.g., root, leaves, and bark), essential oils (hydrodistilled extracts of volatile plant compound), and oleoresins (extracts based on nonaqueous solvents) (Windish and Kroismayr 2006) (Fig. 4).

Classification of Phytogenic Based on Their Properties

Antimicrobial, antioxidants and anti-inflammatory, growth promoters, palpability and gut function modulators, and immunomodulators

(I) **Antibacterial Activity of Phytogenic Solutions**

Herbs and spices are well known to exert antimicrobial actions in vitro against important pathogens including fungi (Windisch et al. 2008). A common feature of phytogenic compounds is that they are the very multifaceted mixture if bioactive component. Phytochemicals in phytogenic compounds are well known to have antimicrobial activity (Cowan 1999). Investigations on phytochemicals indicated that phenolic contents like carvacrol, thymol, phenylpropane, limonene, geraniol, and citronellal are the important active

Table 1 Commonly used plants as feed additive in animal healthcare and livestock production

Botanical name	Parts used	Important active constituents	Common uses	Reference
Asparagus racemosus	Root	Shatavarins I–IV, asparagamine	Galactogogue, antistress, immunostimulant	Ananthanarayana et al. (2002), Dahouda et al. (2009)
Acacia catechu	Stem wood extract, fruit	Catechin, quercetin, epicatechin	Antidiarrheal, anti-inflammatory, antioxidant	J.A. Duke (1992), Rastogi and Mehrotra (2005)
Allium sativum	Bulb	Allicin, allin, methyl allyl disulfide	Hypolipidemic, carminative, antiprotozoal, anti-inflammatory	Hussain et al. (1992), Sharma et al. (2000–2005)
Aloe barbadensis	Leaf	Aloin, barbaloin, emodin	Emmenagogue, anti-inflammatory, antibacterial	Blumenthal et al. (1998), Rastogi and Mehrotra (2005)
Balanites roxburghii	Fruit, seed, seed oil	Balanitisins A-E, marmesin, bergapten	Purgative, spasmolytic, anti-colic, anthelmintic	Bilore et al. (2004–2005), Hussain et al. (1992)
Cissus quadrangularis	Steam, root, leaves	Quadrangularins, piceatannol, pallidol	Fracture healing, useful in dyspepsia	Ananthanarayana et al. (2002), Rastogi and Mehrotra (2005)
Curcuma longa	Rhizome	Curcumin, turmerone, desmethoxycurcumin	Anti-inflammatory, carminative, spasmolytic, antioxidant, hepatoprotective	Blumenthal et al. (1998), J.A. Duke (1992), Hussain et al. (1992)
Eucalyptus globulus	Leaves, oils	Cineole, pinene, limonene, eucaglobulin	Anti-inflammatory, carminative, digestive, expectorant, antibacterial	Rastogi and Mehrotra (2005), Blumenthal et al. (1998), Hussain et al. (1992)
Glycyrrhiza glabra	Root	Glycyrrhizin, liquiritin, glabranins	Antihistaminic, expectorant, anti-inflammatory	J.A. Duke (1992), Blumenthal et al. (1998)
Leptadenia reticulata	Root	Hentriacontanol, stigmasterol, rutin	Galactogogue, stimulant, uterine cleanser	F. Mirzaei (2011), Hussain et al. (1992)
Ocimum sanctum	Whole plant, leave, oil	Eugenol, ursolic acid, carvacrol, luteolin, methylchavicol	Immunomodulator, anti-inflammatory, antitussive, antiprotozoal	Sharma et al. (2000–2005), D. Brown (1996), Rastogi and Mehrotra (2005)
Phyllanthus emblica	Fruit, leaves	Ascorbic acid, gallic acid, emblicanins A and B	Antioxidant, hepatoprotective, immunomodulator	Ananthanarayana et al. (2002), Rastogi and Mehrotra (2005)
Solanum nigrum	Whole plant	Solasodine, solasonine, solanine, solamargine	Hepatoprotective, antioxidant, mycotoxin inhibitor, diuretic	J.A. Duke (1992), Hussain et al. (1992)
Swertia chirata	Whole plant	Swertiamarin, swerchirin, gentianine	Hepatoprotective, anti-inflammatory, anthelmintic	Bilore et al. (2004–2005), Hussain et al. (1992)
Withania somnifera	Root	Withaferin-A, withanine, somniferin	Immunomodulator, antistress, antioxidant, adaptogenic	D. Brown (1996), J.A. Duke (1992)

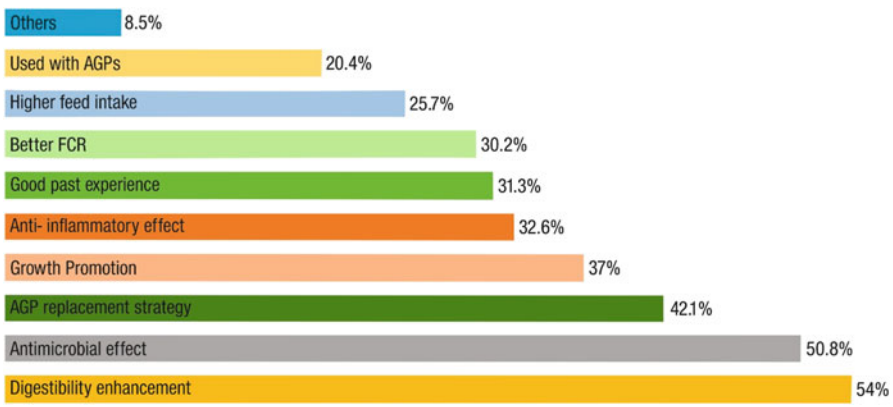

Fig. 4 Top reasons for use of phytogenic feed additives (in %)

compounds that have the antimicrobial function (Gheisar and Kim 2018). Limonene and compounds from *Sanguinaria canadensis* which are non-phenolic also show high antibacterial activity (Newton et al. 2002; Burt 2004). Yang et al. (2015) suggested that the antimicrobial action of PFAs varies by the location of their functional hydroxyl or alkyl groups. Investigations show that the presence of delocalized electrons and the hydroxyl group of phenolic terpenoids are

important elements for antimicrobial action of phytochemicals. Phytochemicals exert their antimicrobials activity through different mechanisms; tannins, for example, act by iron deprivation, hydrogen bonding, or non-specific interactions with vital proteins such as enzymes (Scalbert 1991). Tannic acid inhibits the growth of important intestinal bacteria such as *Bacteroides fragilis*, *Clostridium perfringens*, *E. coli*, and *Enterobacter cloacae* (Chung et al. 1993). Alkaloid is known to be a DNA intercalator and an inhibitor of DNA synthesis through topoisomerase inhibition (Karou et al. 2006). The main mechanism by which saponins display an antimicrobial activity is based on their ability to form a complex with sterols present in the membrane of microorganisms.

Essential oils have long been recognized for their antimicrobial activity (Lee et al. 2004), and they have gained much attention for their potential as an alternative to antibiotics in broiler chickens. Some studies with broiler demonstrated in vitro antimicrobial efficacy of essential oils against *E. coli* and *Clostridium perfringens* (Jamroz et al. 2003; Mistsch et al. 2004). Essential oils act on pathogenic bacteria by blocking quorum sensing (anti-quorum sensing) activity of the pathogenic bacteria. Extracts of plants of different species like *Chamaesyce hypericifolia*, *Conocarpus erectus*, and *Quercus virginiana* show quorum sensing inhibiting property and guard the growth of pathogenic bacteria (Adonizio et al. 2006). Moreover, structural properties such as the presence of functional groups (Farag et al. 1989) and aromaticity (Bowels and Miller 1993) are also responsible for the antibacterial activity of essential oils. It was postulated regarding the terpenoids that terpenoids and phenylpropanoids can penetrate the membrane of the bacteria and reach the inner part of the cell because of their lipophilicity (Helander et al. 1998). The important benefits of antimicrobial action of phytogenic products are that they can improve the microbial hygiene of carcasses. Aksit et al. (2006) illustrate that the addition of essential oil reduces the load of total viable bacteria or pathogens (e.g., *Salmonella*) on broiler carcasses.

(II) Antioxidant and Anti-inflammatory Action

Antioxidant activity is one of the important properties of phytogenic products which contribute to the reason for use as feed additives in humans as well as animals. Their ability to scavenge free radicals may play an important role in preventing some diseases caused by free radicals, such as cancer and heart diseases (Miguel 2010). The previous investigation has suggested that the antioxidant activity is due to their ability to donate hydrogen or an electron to free radicals and also delocalize the unpaired electron within the aromatic structure which are the main mechanisms of protecting other biological molecules against oxidation (Fernandez-Panchon et al. 2008; Giannenas et al. 2013). Brenes and Roura (2010) have reported that a wide range of herbs and their extracts have potential antioxidant functions, especially those products derived from the plant family Labiatae such as rosemary, oregano, and thyme. Blending of the phytogenic products like thyme in the feed of the ducks causes the reduction in thiobarbituric acid reactive substances (TBARS) value of breast meat significantly (Mohammadi et al. 2015a). Cherian et al. (2013) reported that feeding broiler chickens with PFA (*Artemisia annua*) resulted in a significant reduction in TBARS value in breast and thigh meat. The reduction in TBARS value might be due to an individual or shared antioxidant properties of polyphenolic compounds or vitamin E in *Artemisia annua*. The antioxidant activity of the phytogenic products is due to both phenolic and non-phenolic content (Cuppett and Hall 1998). Placha et al. (2014) have demonstrated that supplementing the diet of broiler chickens with thymol can reduce the oxidation of fatty acids indicated by the lower malondialdehyde level in duodenal mucosa. Franz et al. (2010) have advocated that phytobiotics can beneficially affect some antioxidant enzymes such as glutathione peroxidase and superoxide dismutase, consequently affecting lipid metabolism in animals. Other plant species such as coriander, curcuma, ginger, anise, and plants that are rich in flavonoids or anthocyanins also have antioxidant activities (Nakatani 2000; Wei and Shibamoto 2007). The active compounds of phytogenic compounds may have protective roles for feed lipids against oxidative damage, similar to antioxidants such as a-tocopheryl acetate or butylated hydroxytoluene that is usually added to diets (Gheisar and Kim 2018).

Inflammation is the normal protective phenomenon induced due to injury to the tissue or infection to counter invaders in the body (pathogens) and to remove dead or damaged host cells (Stevenson and Hurst 2007). Miguel (2010) stated that some essential oils have the ability to scavenge free radicals. In addition, they can also act as anti-inflammatory agents because one of the inflammatory responses is oxidative burst in diverse cells. Essential oils (eucalyptus, rosemary, lavender, millefolia) and other plants (pine, clove, and myrrh) are also used in mixed formulations as anti-inflammatory agents.

(III) Growth-Promoting Property

Regarding the growth-promoting activity of the phytogenic compounds, lots of investigations have been conducted during the last two decades. The growth-promoting activity of the herbal feed additive has been reported in swine (Wenk 2003; Kim et al. 2010; Mohammadi et al. 2015b). Li et al. (2012) compared the performance of pigs fed with the diets supplemented with essential oils and reported weight gain and digestibility of dry matter, and

crude protein were improved by 10.3%, 2.9%, and 5.9%, respectively. They suggested that improved performance of pigs was the result of improvement of the intestinal morphology and consequently improvement of nutrients digestibility. Yan et al. (2011) have reported that adding an herb extract blend (containing buckwheat, thyme, curcuma, black pepper, and ginger) to the diet of growing pigs resulted in increases in average daily feed intake (ADFI) and final body weight (BW). Feeding broiler chickens with the diet containing 0.075% of a phytogenic blend led to 3.9% and 3.4% improvement in BWG and FCR, respectively (Mohammadi et al. 2015a). According to the researcher proposal, phytogenic compounds act differently to elicit its growth-promoting activity. Improving palatability and flavor of feed, increasing feed intake, stimulating the secretion of digestive enzymes, and increasing antimicrobial activity are some of the main modes of action that might have led to the improved growth performance of animals (Jang et al. 2004; Czech et al. 2009). Different investigations have suggested that removal of in-feed antibiotics has resulted in the significantly negative effect on the performance of pig and poultry. This negative effect can be alleviated by incorporation of phytogenic product as growth promoters in the feed of pig and poultry (Yakhkeshi et al. 2011).

(IV) **Influence on Palatability and Gut Function**

It is claimed that phytogenic products are positively effective on the palatability and flavor of feed, thus promoting feed utilization and enhancing the production performance (Windisch et al. 2008). Some investigators had found a decrease in the feed intake due to incorporation of phytogenic products as growth promoters in feed (Maass et al. 2005; Roth-Maier et al. 2005), while some are claiming phytogenic solutions cause increase in the feed intake and palatability of feed (Kyriakis et al. 1998; Kroismayr et al. 2008). Chrubasik et al. (2005) have reported that a wide range of phytobiotics (including herbal plants and their extracts) are known to have beneficial impacts on the digestive tract (such as laxative and spasmolytic effects). In addition, they can prevent flatulence. Furthermore, Patel and Srinivasan (2004) have suggested that phytogenic substances can stimulate digestive secretions such as saliva and bile. They reported that improving enzyme activity is the main mode of nutritional action of phytogenic feed additive (PFA). Rao et al. (2003) have reported that the in vitro activities of rat pancreatic lipase and amylase are significantly enhanced when they were in contact with various spices and spice extracts. There is increase in enzymatic activities in pancreatic homogenate and pronounced bile acid flow in rats fed with phytogenic feed additive (Patel and Srinivasan 2000). Similar reports of enhancing the activities of digestive enzymes such as pancreatic amylase, trypsin, and maltase by essential oils in the diets of broiler chicken were given by researchers (Lee et al. 2003; Jang et al. 2004, 2007). Jamroz et al. (2006) suggested that feeding broilers with a diet supplemented with PFA resulted in stimulating the secretion of mucus in the intestine of broilers. This effect was assumed to reduce the adhesion of pathogens, thus stabilizing microbial eubiosis in the gut of animals.

(V) **Immunomodulators**

Phytogenic additives are having potential effect on the immune system of living organisms. β-glucans (oligosaccharide) is found in plant components mainly in aleuronic layer of barley and oat bran is an important immunomodulator. Bamboo leaf extract appears a new and promising source of β-glucans. Ohtsuka et al. (2014) evaluated the effect of an extract of β-glucans obtained from bamboo leaves (*Sasa sensanensis*) in cattle and report the increase in the activity of $CD8^{+}$T lymphocytes.

3 Quality Standards for Animal Feed Additive Industry

Faced with the problem of increasing nutritive value of the feed with limited resources of land and capital, soon it was discovered that unwanted chemicals and adulterants were being used in animal feeds and it helped to have a high analytical grading for the feed. So, came in place quality standards which laid down guidelines for the manufacturing to marketing of the animal feed and set up regulations which made it mandatory for feed manufacturers to abide by the set standards.

One of the premier authorities in the world with respect to animal feed industry—the American Feed Industry Association (AFIA)—has defined feed quality-control programs as: "All actions directed towards ensuring the product meets the specifications established by the manufacturer." AFIA is one of the most premier organizations (Maurya 2017). Any standard feed quality-control program must contain four necessary components (Pal and McSpadden Gardener 2006):

- Ingredient quality
- Process control
- Finished feed quality
- Control of toxic substances, including pathogenic microorganisms

3.1 The Importance of Quality Assurance

Quality assurance is one of the most important criteria in maintaining the industry standards and also to apply for various certifications related to product manufacturing

practices and standards. It creates a market value for the product and greater consumer acceptability. It needs to be understood that feed safety is not the only element that determines the safety of food of animal origin but that the use of other products, such as drugs and growth promoters (hormones and beta-agonists), also has an impact.

3.2 Quality Control of Feed

The process of conversion of high-quality ingredients into high-quality feeds involves three important components within the feed mill: personnel, machinery, and procedures. In event of any compromise in any of these three components, the consistent production of high-quality feeds is unlikely.

However, it is equally important to ensure the blending of personnel, machinery, and procedures together toward the common goal of efficient production of high-quality feeds (Jones 2006). Quality control in feed plant is of utmost importance for overall success and profitability of animal enterprises. The most critical factors affecting nutrition and high performance of animals are feed quality control and ration consistency. The degree of quality is the consistency in which feed is formulated, processed, produced, and delivered as compared to what is expected.

Quality has been defined as "Degree to which a set of inherent characteristics fulfills requirements" (Garg et al. 2013). This clearly indicates that achieving quality means fulfilling requirements. The requirements may come from customers and in some cases from regulatory authorities. Usually quality is verified by comparison with a known standard. However, a relative value of quality over time is extremely valuable and useful in many situations.

Animal performance is directly affected by feed quality, and this relationship is important as it not only encompasses the quantitative amounts of all feed components but also the digestibility and metabolism of those components. Thus, the main challenge that lies for animal science researchers as well as for nutritionists and other stakeholders involved in feed production is the consistent monitoring of all the aspects of feed production system and measurement of those variables that are good indicators of quality control.

In some cases, post-marketing quality checks are done to keep a tab on shelf life as well as customer satisfaction as it can have an enormous impact on quality as perceived by them. In view of this, monitoring of quality control at different points has been classified as under:

- Quality control of raw materials and finished products
- Quality control during storage
- Quality control during production

3.3 Necessity for Quality Control

The objective of quality control of animal feed and feed additives is to ensure that consumer obtains feeds that are unadulterated and true to their nature and produce desired results. Quality control is, therefore, defined as the maintenance of quality at levels and tolerances acceptable to the buyer while minimizing the cost of processing.

The Bureau of Indian Standards is the nodal organization responsible for laying down the quality control specifications of various feed ingredients and compound feeds to ensure maintenance of the minimum contract specifications, suitable for inclusion in the compounded feeds, and indicating the maximum proportions of inclusion of feedstuffs (Uppal et al. 2004).

3.4 Evaluation of Feed for Quality

The feeds are usually subject to the following three types of tests: physical, chemical, and biological.

3.4.1 Physical Evaluation

Physical evaluation must be carried out by highly trained personnel to identify the changes in the nature of the raw material/feeds. The main attributes checked in a physical evaluation are color, size, homogeneity, smell, taste, touch, and sound.

Physical Methods to Detect Adulteration or Contamination

The common contaminant or adulterant is husk or sand. The best method to detect husk in the feedstuff is winnowing while sieving is performed for differentiating contaminants based on particle size. Sand is detected in feed using a traditional yet effective method where a weighed quantity of the grain is soaked in water and then by sieving with hand the grains can be separated. The remaining water is decanted, and the settled sand is weighed to assess the level of contamination.

3.4.2 Chemical Evaluation

For chemical evaluation of animal feed, the first and foremost requirement is that of an analytical laboratory for precise estimation of nutrient contents and contaminants. Proximate principles of feed are analyzed using chemical evaluation.

3.4.3 Ingredient Specifications

Ingredient specifications of animal feeds and feed additives are crucial in a feed quality assurance program. Ingredient specifications serve as the basis on which agreements are written, feed/rations are formulated, and ingredient inspections are performed. Description of feed ingredients and general nutritional specifications may be found in BIS

specifications for feeds and feed ingredients in India. It is done both for quantitative and qualitative specifications and standards.

3.5 Quality Control Legislations in Indian Feed Industry

In the organized sector, animal feed production is a competitive domain, and feed producers therefore attempt to produce feed of the highest possible quality (Dhobi and Malla 2015). Regular analysis of proximate principles is done for keep a check on the quality of feed. The animal feeds and feed additives are analyzed for amino acids, aflatoxin, ochratoxin, castor, tannins, and urease activity compulsorily among others. Raw materials employed in manufacturing of animal feed and finished products are subjected to microbial examinations such as microbial counts, *Salmonella* and *Escherichia coli* testing and mold count as well. Industry also employs latest technologies and modern equipment such as High-Performance Liquid Chromatography (HPLC) and near-infrared (NIR) analyzers for spectroscopic examination. Current analytical techniques are engaged to estimate vitamins, minerals, and other feed additives. Most of industries are promoting HACCP—Hazard Analysis and Critical Control Points— measures to guarantee safe feeds. Now, India is also following international standards of animal feed industry to upgrade its manufacturing standards and compete with the world market by indigenous manufacturing of animal feed and feed additives to reduce the cost as well.

In India the national quality control standards for manufacture and storage conditions of animal feeds and feed additives are regulated by a statuary body, the Bureau of Indian Standards (BIS). It was established under BIS Act, 1986. Before 1986, Indian standards Institute was regulating the quality control of several feed commodities. The objectives of BIS are as follows:

I. Harmonious development of the activities for standardization of various commodities
II. Marking
III. Quality certification of goods
IV. Attending to the connected methods

The Bureau has set up subcommittees for the standardization of different types of commodities. A subcommittee on animal feeds called Animal Feeds Sectional Committee has been specifically set up to check the quality of animal feeds and feed additives ingredients. The members of Animal Feeds Sectional Committee are a panel of eminent nutritionists and comprise of expert members from the following bodies:

I. Indian Council of Agricultural Research (ICAR) institutes
II. State agricultural universities
III. Feed industry
IV. Government departments having specialization in animal nutrition
V. Feed technologist concerned with animal husbandry activities

The Government of India is empowered with registration act on the Agricultural produce (Grading and Marketing), known as 'AGMARK' standards to fix quality standards and prescribe terms and conditions for using the seal, 'AGMARK'.

Government is also bound to ensure following of control measures by legislation to ensure quality and safe feeds and feed additives at controlled cost. Many regulations have been put forward:

I. The Prevention of Black Marketing and Maintenance of Supplies of Essential Commodities Act, 1980
II. The Standards of Weights and Measures (Packaged Commodities) Rules, 1977
III. The Consumer Protection Act, 1986
IV. Schedule of Tariff Values of the Articles Liable to Cess for 2006–2007
V. Agricultural Produce Cess Act, 1940
VI. Edible Oils Packaging (Regulation) Order, 1998
VII. The Prevention of Food Adulteration Rules, 1955

The latest legislation in this respect is Cattle Feed (Regulation of Manufacture and Sale) Order, 2009. However, in spite of all legal presence of these measures and legislations, feed quality checks in India leaves much to be desired. All said and done, not enough is done to keep a cap on feed quality in this country. This is very much factual for small-scale feed manufacturer, where adulteration is barricade.

The nodal organization involved in India toward developing interlinkages between industry academia and other sectors toward feed manufacturing practices and setting quality norms is the Compound Livestock Feed Manufacturers' Association (CLFMA).

3.6 Latest Developments in Feed Quality Assurance Sector in the World

Safe animal feeds can only be produced with safe ingredients. In order to combine the experience of existing feed ingredient assurance programs into one program that can operate across the world with one set of standards, the International Feed Safety Alliance (IFSA) as a joint project is initiated by the standard owners (IFSA Feed Ingredients Standard 2007).

To comply with the standards of IFSA, the participant countries need to apply the principles of Hazard Analysis and Critical Control Points (HACCP) and Good Manufacturing Practice (GMP). Participants certified will have to demonstrate that there are controls at each step of the supply chain that guarantee the safety of the feed constituents supplied.

3.6.1 GMP: Good Manufacturing/Managing Practice

A key point for attention in the quality control programs for animal husbandry is the safety of animal feed. GMP standard is one of the main elements for any animal feed quality program (Coelho and de Toledo 2017).

3.6.2 Risk Management

Risk assessment forms the basis for determining control measures. Risk assessment is a component of risk management, resulting in:

- Determination of control measures for eliminating or reducing these risks and controlling them at an acceptable level, including tracking and tracing of products
- Determination of product standards and action values for undesirable contaminants in feeds
- Implementation of a measuring strategy (monitoring and verification) for checking whether or not the control measures are effective

In an HACCP methodology, a well-considered and sensible balance has to be established between preventive procedures and monitoring of feed constituents for the presence of risks. Nevertheless, where there are uncertainties about the ability to get a hold on the risks, precautionary measures such as eluding use of a specific product must be taken. Several control measures and product standards have already been combined in legislation, but they are moderately fragmented with many limitations. To address this shortcoming, the GMP+ standard for animal feed offers a coherent framework.

The GMP+ standard currently comprises the following elements:

- General requirements for a company's quality system, comparable with and based on the ISO 9002 standard, in order to render quality assurance demonstrable.
- Criteria for risk assessment based on HACCP principles.
- Several additional sub-codes including generic control measures in the production process allied to the use of additives, drugs, undesirable substances, and hygiene (*Salmonella*). These additional control measures have been specified for the production and supply of compound feedstuffs, premixes, straight feedingstuffs and feed ingredients, and feed fats (in addition to those for feed ingredients), for storage and transshipment of feeds, and for transport.
- Minimum requirements for in-company inspections, such as quality assurance for laboratory analyses, sampling frequency, etc.

A set of product standards, comprising of European Union legal standards, additional national legal standards, and several supra-legal standards settled with the partners in the chain.

3.6.3 Early Warning System

An early warning system (EWS) is intended to be a safety net, as a supplement to quality management systems like GMP, ISO 9002, and HACCP. The goal is to identify, communicate, and eliminate possible or potential hazards which may occur despite all preventive measures taken (Stark and Jones Frank 2009).

No quality system is able to avoid totally all problems which may be caused by incidental factors (human error, natural events) or criminal acts. A proactive approach must be adopted to prevent potential hazards manifesting themselves. Key elements in such a system include speed, care, confidentiality, accountability, and responsibility.

3.6.4 International Legislations Associated with Feed Safety

Food hazards associated with feeds form an important part of public health importance. Hazard is defined as "A biological, chemical or physical agent in, or condition of, food/feed with the potential to cause adverse health effect" (Sareen 2010).

Under WTO, SPS Article 3 which deals with harmonization encourages use of international standards for food safety and animal and plant health, i.e., Codex. Important Codex work on feed safety includes:

- Classification of foods and animal feeds (CAC/Misc 4-93)
- Codex General Standard for Contaminants and Toxins in Foods and Feeds (CODEX STAN 193-1995)
- MRLs for pesticides (CAC/MRL 1-2009), veterinary drug (2-2009), extraneous MRLs (CAC/MRL 3-2001)
- Code of Practice for the Reduction of Dioxin and Dioxin-like PCB Contamination in Foods and Feeds (CAC/RCP 62-2006)
- Code of Practice for the Reduction of Aflatoxin B1 in Raw Materials and Supplemental Feedingstuffs for Milk-Producing Animals (CAC/RCP 45-1997)
- Code of Practice on Good Animal Feeding (CAC/RCP 54-2004)

Other Codex Standards: Applicable to Feeds

Traceability: Principles for traceability/product tracing as a tool within a food inspection and certification system (CAC/GL 60-2006)

Risk Analysis:

- Working principles for risk analysis for application in framework of Codex Alimentarius
- Principles and GL for the conduct of microbiological risk management

Nutraceuticals in Organ- and System-Disorders

Nutraceuticals in Arthritis

Ramesh C. Gupta, Robin B. Doss, Rajiv Lall, Ajay Srivastava, and Anita Sinha

Abstract

Currently, in the United States, every fifth adult dog or horse suffers from arthritis. The two most common types of arthritis are osteoarthritis (OA) and rheumatoid arthritis (RA). OA occurs with greater frequency than RA. OA is an inflammatory heterogeneous chronic degenerative joint disease (DJD) characterized by chronic and progressive degradation of the articular cartilage, osteophyte formation, thickening and sclerosis of the subchondral bone, bone marrow lesions, hypertrophy of bone at the margin, synovitis, synovial fluid effusion, and fibrosis. Common clinical signs and symptoms associated with OA in dogs and horses include limping, immobility, stiffness of joints, crepitus, periarticular swelling, palpable effusion, and pain upon manipulation of the joint and limb. The pathophysiology of OA is very complex because there are multiple etiologies for this disease, and as a result, treatment is complicated. Pain and inflammation associated with OA are often managed by pharmacological suppression or surgery among a few other modalities. NSAIDs are known to have severe side effects, and surgery is very expensive, so the use of nutraceuticals appears to be a viable alternative for prevention and treatment of OA. This chapter describes various nutraceuticals that have the potential to exert antioxidative, anti-inflammatory, antinociceptive, and chondroprotective effects in osteoarthritis.

1 Introduction

Arthritis is a chronic debilitating disease that commonly afflicts a large number of humans and animals around the world. Currently, in the United States, every fifth adult dog or horse suffers from arthritis. The two most common types of arthritis are osteoarthritis (OA) and rheumatoid arthritis (RA). OA is an inflammatory heterogeneous chronic degenerative joint disease (DJD) characterized by chronic and progressive degradation of the articular cartilage, osteophyte formation, thickening and sclerosis of the subchondral bone, bone marrow lesions, hypertrophy of bone at the margin, synovitis, synovial fluid effusion, and fibrosis. Eventually, an animal's quality of life is compromised due to decreased stability, decreased mobility, loading, stiffness of joints, lameness, and pain, and in advanced stages, animals are unable to walk. RA is a chronic disease characterized by inflammation, pain, swelling, and stiffness of multiple joints. Among all animal species, dogs and horses suffer more with arthritis, and OA occurs with a greater frequency. The etiology of OA is multifactorial involving age, injury, lack of exercise/excessive exercise, nutritional deficiency, metabolism, obesity, genetic predisposition, infection, environment, etc. (Van Meurs 2017; Gupta et al. 2019). Although any breed of dog can develop OA, large breed dogs (such as German Shepherds, Labrador Retrievers, Newfoundland, Rottweilers, Siberian Huskies, and others) are genetically predisposed for OA and are >45% more likely to develop this disease. Due to multiple etiologies in OA, its pathophysiology is very complex involving several cellular and biochemical mechanisms and molecular pathways in degradation or loss of cartilage.

Common signs and symptoms associated with OA in dogs and horses include limping, immobility, stiffness of joints, crepitus, periarticular swelling, palpable effusion, pain upon manipulation of the joint, and lameness (Gupta et al. 2009, 2012; Lawley et al. 2013; Fleck et al. 2014; May et al. 2015; Murdock et al. 2016). Nonsteroidal anti-inflammatory drugs

R. C. Gupta et al. (eds.), *Nutraceuticals in Veterinary Medicine*, https://doi.org/10.1007/978-3-030-04624-8_24

(NSAIDs), which are potent cyclooxygenase-2 (COX-2) inhibitors, have been the choice of therapeutic drugs for OA for a long time. Other pharmaceuticals, such as grapiprant, diacerein, and tramadol, are also used to minimize OA-associated pain (Permuy et al. 2015; Rausch-Derra et al. 2016; Guedes et al. 2018). Due to the side effects of NSAIDs on the cardiac, hepatic, renal, and GI systems, they are currently being replaced by nutraceuticals. This chapter describes the pathophysiology of OA, biomarkers of disease detection and progression, and a number of nutraceuticals that are currently used or have a potential to manage the signs and symptoms of OA and to improve the quality of an animal's life.

2 Pathophysiology of OA

OA is a heterogeneous chronic degenerative joint disease (DJD) of the entire joint affecting cartilage, bone, adipose, and skeletal muscle, thereby causing remodeling and failure of the joint (Ramírez-Flores et al. 2017; Gupta 2016; Svala et al. 2017; Gupta et al. 2019). Degradation of cartilage is a primary pathological feature of OA, which occurs in two phases, anabolic and catabolic. In the anabolic phase, the chondrocytes attempt to repair the damaged extracellular matrix (ECM), and in the catabolic phase, enzymes produced by chondrocytes and other cells digest the ECM. In the latter phase, inhibition of ECM synthesis also occurs, leading to accelerated erosion of the cartilage (Castrogiovanni et al. 2016; Svala et al. 2017).

In OA, change in the shape of the joint occurs as a result of a loss of articular cartilage, osteophyte formation, subchondral sclerosis, bone marrow lesions (BMLs), and synovial proliferation, and these alterations subsequently lead to decreased stability, mobility, and loading. The normal joint cartilage consists of 5% chondrocytes and 95% ECM. In OA cartilage, decreases in the number of chondrocytes and in their ability to regenerate the ECM in response to stress have been described (Portal-Núñez et al. 2016). OA chondrocytes show a senescence secretory phenotype (SSP) exhibiting overproduction of cytokines (IL-1 and IL-6), matrix metalloproteinases (e.g., MMP-1, MMP-3, MMP-10, and MMP-13), and growth factors (e.g., epidermal growth factor). During cartilage degeneration, the inflammatory processes cause excess production of ROS, RNS, oxygen, and PGE_2 levels, and as a result, their increased levels are found within the joint (Bakker et al. 2017; Wan and Zhao 2017; Chin and Ima-Nirwana 2018). The release of inflammatory mediators such as PGE_2 and NO triggers chronic inflammation and apoptosis (Amin et al. 1997; Attur et al. 2008). Modulation of *N*-methyl-*D*-aspartate (NMDA) receptors and ATP-citrate lyase is also reported to be involved in chondrocyte metabolism alteration and articular cartilage degeneration (Chen et al. 2018a; Kalev-Zylinska et al. 2018).

In the early stages of OA, progressive depletion of the cartilage proteoglycan leads to a net loss of matrix from the cartilage. OA is characterized by the degradation of cartilage matrix components, including cartilage-specific type II collagen and proteoglycan, ultimately resulting in the loss of cartilage structure and function. Breakdown and deterioration of the cartilage have been correlated with increased activities of certain enzymes, including MMPs. In the early and middle stages of OA, bone attrition (decrease or loss of bone height and contour) is observed. In late-stage OA, thickening of subchondral bone occurs, which is accompanied by decreased mineralization. Subchondral bone attrition is also associated with the severity and loss of cartilage in adjacent regions and areas of BMLs, indicating an increased load on the bone-cartilage biomechanical unit. BMLs are indicators of OA progression and are considered an important risk factor for structural deterioration. Radiographic evidence of OA may show cartilage degeneration, presence of its remnants, and osteophyte formation in the OA joint.

Activity of pro-inflammatory cytokine IL-1β can be detected in synovial fluid from OA joints where it induces gene expression of matrix-degrading enzymes in the chondrocytes. In synovial fluid of OA patients, another pro-inflammatory molecule from natural killer cells is expressed, i.e., protease Granzyme A, which may contribute to chronic articular inflammation. NF-κB appears to be a key transcription factor that drives the expression of OA inducer genes in response to the activation of toll-like receptors and an interleukin receptor by ECM fragments and IL-1β. Pro-inflammatory cytokines, such as IL-1β, are produced in the OA-stimulated mitogen-activated protein kinase (MAPK) pathways through the extracellular signal-regulated kinases (ERK)½, p38 kinase, and c-June N-terminal kinase (JNK). Elevated MAPK phosphorylation results in activation of transcription factors, which in turn upregulates the production of several molecules, such as MMPs and aggrecanases, which are responsible for matrix degradation. In OA, IL-1β induces activation of the NF-κB signaling pathway in human chondrocytes, thereby causing low-grade pain (Wan and Zhao 2017). Sluzalska et al. (2017) demonstrated that NF-κB, p38 MAPK, and JNK signaling pathways are all involved in IL-1β-induced phospholipids (PLs) biosynthesis. Recently, McAllister et al. (2018) demonstrated that the nucleotide-binding and oligomerization domain-like receptor containing protein 3 (NLRP3) inflammasome is implicated in the pathogenesis of OA by producing IL-1β, TNF-α, and MMP-3, which drive cartilage degeneration and synovial inflammation. During OA progression, fibroblast-like synoviocytes undergo alterations in their PL composition to adapt to the new diseased environment (Reviewed in Gupta 2016; Gupta et al. 2019). Additionally, multiple studies have implicated PKCδ as the rate limiting factor in which PKCδ is situated at the convergent point of multiple signaling inputs, including PGF-2, substance P, TNF-α, IL-1, and fibronectin

fragment. PKCδ activation can lead to NFκB activation in addition to MAPK activation, and these pathways work in concert to inhibit anabolic signaling and stimulate ECM degeneration (Lee et al. 2013).

There are some additional signaling pathways involved in OA-related cartilage degradation (Wang et al. 2017; Chen et al. 2018b; Deshmukh et al. 2018). Wnt/β-catenin plays a critical modulatory role in maintaining the bone-cartilage biochemical unit. Increased expression of Wnt-induced signaling protein 1 (WISP-1), Wnt-16, and Wnt-28 have been reported in OA cartilage and may contribute to cartilage degradation by upregulating MMPs and aggrecanases (Blom et al. 2009). Wnt signaling affects the pathogenesis of OA by modulating both the differentiation of osteoblasts and chondrocytes and through the production of catabolic proteases (Deshmukh et al. 2018). A bone-cartilage modulatory pathway, transforming growth factor β (TGFβ), is required for the maintenance of metabolic homeostasis and structural integrity of healthy cartilage. This factor is highly expressed in normal cartilage but nearly absent in OA cartilage. Recently, Wang et al. (2017) described that TGFβ/ALK5 signaling maintains articular cartilage homeostasis, in part, by upregulating proteoglycan 4 (PRG4) expression through the PKA-CREB signaling pathway in articular chondrocytes. Loss/interruption of TGFβ signaling in cartilage results in loss of proteoglycans and cartilage degeneration. Thus, inhibition of endogenous TGFβ leads to increased damage to the cartilage.

Recently, Lu et al. (2014) and Carpio and Westendorf (2016) suggested that the initiation and progression of OA are contributed to expression patterns and enhanced activation of histone deacetylases (HDACs). Overexpression of HDAC4 promotes matrix-degrading enzymes and enhances catabolic activity of chondrocytes in OA cartilage (Lu et al. 2014). Both HDAC1 and HDAC2 suppress the expression of genes encoding ECM genes, such as type II collagen (Cil2a1), aggrecan (ACAN), and cartilage oligomeric protein (COMP). Interestingly, Pujol et al. (2018) reported that the reduction in nerve fiber density in synovia occurs with advanced cartilage degeneration, suggesting that peripheral neuropathy is associated with OA in the horse. Whether this link is associated with neuropathic pain remains to be elucidated. The pathophysiology of OA has been discussed in detail elsewhere (Gupta 2016; Gupta et al. 2019).

3 Diagnosis of OA

In clinical veterinary settings, diagnosis of OA is often based on observational (Gupta et al. 2009, 2012; Fleck et al. 2014; Lawley et al. 2013; Murdock et al. 2016) and radiographic findings (Ramírez-Flores et al. 2017). Dogs, cats, and horses all exhibit OA-associated pain due to inflammation in the joint(s). Biochemical biomarkers have become exceptionally useful in diagnosis and treatment of OA.

3.1 Pain Measurement

On a monthly basis, dogs and horses are evaluated for overall pain, pain upon limb manipulation, and exercise-associated lameness using the Glasgow scoring system for a study period of at least 4–5 months (Gupta et al. 2009, 2012, 2019; May et al. 2015; Murdock et al. 2016). In dogs, overall pain is graded on a scale of 0–10: 0, no pain; 5, moderate pain; and 10, severe and constant pain. Pain upon limb manipulation is evaluated during the extension and flexion of all four limbs for a period of several minutes. Pain level is graded on a scale of 0–4; 0, no pain; 1, mild; 2, moderate; 3, severe; and 4, severe and constant. Pain and lameness are measured after physical exercise and graded on a scale of 0–4: 0, no pain; 1, mild; 2, moderate; 3, severe; and 4, severe and constant. In horses, pain is measured using similar criteria and scales. Additionally, flexibility and range of motion in the affected joints are measured using a goniometer (May et al. 2015).

In dogs, a ground force plate (Kistler Instrument, Amherst, NY, USA) is utilized to quantitatively measure the lameness-associated pain in each leg of every dog (Gupta et al. 2012). The Kistler's ground force plate (GFP) system consists of plates, lasers, and a computer (Fig. 1). The GFP measures two major parameters: (1) peak vertical force or g force (Newton/kg body weight) and (2) impulse area (Newton sec/kg body weight).

3.2 Observation of Ortolani and Cranial Tibial Drawer Examination

Ortolani and cranial tibial drawer examination is performed to evaluate pain, gait, and lameness in dogs. The Ortolani Maneuver is a common test performed on canines that are predisposed to hip dysplasia such as German Shepherds or larger breed canines. The Ortolani is performed on the hip joint by flexing the knee and hip to 90 degrees, placing the index finger on the greater trochanters and abducting the hip (Ortolani's sign 2007; Fleck et al. 2014). As the hip is abducted, or moved away from the body, a positive Ortolani will present with a "clunk" sound or feeling as the femoral head relocates anteriorly to the acetabulum, or hip socket. In moderate arthritis, dogs may exhibit a negative Ortolani sign (Fleck et al. 2014; Gupta et al. 2019). Cranial tibial drawer is another test that can be performed upon physical examination to indicate arthritic changes and to diagnose the rupture of the cranial cruciate ligament (CCL). A positive tibial drawer is elicited with the ability to move the tibia cranially or forward

Fig. 1 Pain evaluation using ground force plate

in respect to the fixed femur. For a detailed procedure, refer to Devine (1993) and Gupta et al. (2019).

3.3 Biochemical Biomarkers

There are several biochemical biomarkers related to inflammation and pain (cytokines, PGE_2, c-reactive protein, TNF-α, TSG-6, etc.) and cartilage damage and loss (COMP, MMPs, fractalkine, type II cartilage fragments, bone sialoprotein, c-telopeptide of type I collagen, hyaluronan, aggrecan, ghrelin, lubricin, follistatin-like protein 1, etc.). Some of these biomarkers can be measured in synovial fluid (Trumble et al. 2004; Venable et al. 2008; Kamm et al. 2010; de Bakker et al. 2017; Heikkilä et al. 2017; Shahid et al. 2018), while others are measured in blood or urine (Bay-Jensen et al. 2016; Singh et al. 2015; Gupta et al. 2019). PGE_2 is produced by the action of COX enzymes in various cells, and its increased concentration in synovial fluid correlates positively with OA pain in dogs (Trumble 2005) and horses (Van Loon et al. 2010). It has also been reported that substance P enhances the release of PGE_2 from chondrocytes, and the concentrations of substance P and PGE_2 correlate with each other in the synovial fluid of OA horses (Kirker-Head et al. 2000). Recently, microRNAs (miRNAs) that are more sensitive and specific to OA have been identified in circulation, and they aid in early disease diagnosis and progression. Some of these have potential for therapy. For details on biomarkers of OA, see recent publications (Gupta 2016; Gupta et al. 2019).

4 Nutraceuticals in the Management of OA

There are a number of nutraceuticals that are currently used or have potential to manage the signs and symptoms of OA in dogs and horses (Gupta et al. 2009, 2012; Gupta 2016; Comblain et al. 2015; Bhathal et al. 2017). Furthermore, multicomponent nutraceuticals are popular for treatment or adjunctive therapies in veterinary medicine despite the lack of evidence of efficacy for many products (Martinez et al. 2015). The objectives in managing OA include minimizing joint pain by reducing the inflammation and slowing the progression of the cartilage damage, thereby increasing joint flexibility and quality of life. Some of the nutraceuticals are discussed here in brief.

4.1 Glucosamine and Chondroitin

Glucosamine (glucosamine sulfate, *GS*, or glucosamine hydrochloride, *GH*) and chondroitin sulfate (CS) are components of the ECM of articular cartilage. The structural formulas of glucosamine and chondroitin are shown in Fig. 2. Glucosamine (2-amino-2-deoxy-*D*-glucose) is a constituent of glycosaminoglycan, which plays a role in the normal growth and repair of articular cartilage. It is commonly considered a building block of cartilage.

Glucosamine is commonly obtained from crab, lobster, and shrimp shells. After oral administration of glucosamine (GS or GH), 90% of GS is absorbed from the small intestine. Due to an extensive first-pass metabolism, its bioavailability is only 25% (Sentikar and Rovati 2001). Adebowale et al. (2002) reported the bioavailability of GH at 12%. Excretion of glucosamine is mainly through the kidneys with only a trace amount of unmodified glucosamine eliminated through the stool (Persiani et al. 2005; Block et al. 2010). CS is a sulfated glycosaminoglycan (GAG) composed of a chain of alternating sugars, *N*-acetyl-*D*-galactosamine and *D*-glucuronic acid. CS is also a normal constituent of articular cartilage, and it is usually obtained from animal cartilage (such as the trachea and shark cartilage).

Approximately 30% of CS is absorbed, with a 12–13% bioavailability (Deal and Moskowitz 1999). Adebowale et al. (2002) found the bioavailability of CS to be 4.8–5.0%. For detailed pharmacokinetics of CS, readers are referred to Adebowale et al. (2002), Jackson et al. (2010), and Jerosch

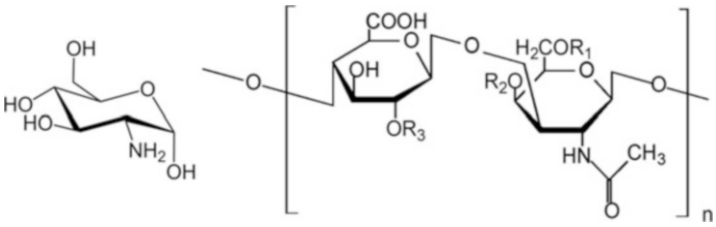

Fig. 2 Structural formula of glucosamine (left) and chondroitin (right)

(2011). Comblain et al. (2015) reported that the oral bioavailability and pharmacokinetics of GS and CS play an important role in optimizing OA management.

Glucosamine and chondroitin provide anti-inflammatory, anti-arthritic, and cartilage repair effects by multiple mechanisms. Some of these mechanisms include (1) reduced expression of MMPs (MMP-1, MMP-3, and MMP-13) and inhibited c-jun amino-terminal kinase and p38 phosphorylation and consequently c-jun binding activity (D'Abusco et al. 2007), (2) enhanced proteoglycan synthesis (Hooper 2001), and (3) suppression of IL-1-induced gene expression of iNOS, COX-2, mPGEs, and NF-κB in cartilage explants. CS also inhibits NF-κB nuclear translocation and phosphorylation of p38 MAPK, ERK½, and JNK (Jomphe et al. 2008; Stabler et al. 2017). As a result, reduced production of NO and PGE_2, two mediators responsible for the cell death of chondrocytes and inflammatory reactions, may occur (Chan et al. 2005).

Frech and Clegg (2007) and Hochberg et al. (2008) reported that CS exerts its anti-OA effects by producing hydration that helps create osmotic pressure within the ECM to maintain the compressive resistance of cartilage and improves function/mobility of the joint. CS stimulates chondrocyte metabolism, leading to the synthesis of collagen and proteoglycan (Jerosch 2011). It may also protect existing cartilage from premature breakdown. CS may reduce inflammation, inhibit synthesis of MMPs, increase synthesis of ECM constituents, and reduce apoptosis of articular chondrocytes (Monfort et al. 2008; Vangness et al. 2009). Glucosamine and chondroitin, when given in combination, offer synergistic effects, such as anti-inflammatory, antioxidative, and chondroprotective (Dechant et al. 2005; Neil et al. 2005; Trumble 2005; Valvason et al. 2008; Gupta 2016).

The doses, route, and duration of glucosamine and chondroitin treatment in dogs and horses are summarized in Table 1. In a double-blind study, McCarthy et al. (2007) evaluated the efficacy of Synoquin SA, a product of Vets Plus Inc. (475 mg GH and 350 mg CS per 1 g), in OA dogs for a period of 70 days. Dogs received Synoquin SA according to their body weight (1 g for 5–19.9 kg; 1.5 g for 20–40 kg; and 2 g for >40 kg) twice daily for 42 days. After 42 days, the daily dose of GH/CS was reduced by one-third for the subsequent 28 days. The treatment significantly ameliorated the signs and symptoms of OA in the study dogs. In a number of studies, GH and CS produced no side effects and were found to be well tolerated (Gupta et al. 2009, 2012). However, in few studies, glucosamine was found to be unsafe at higher doses (Giaccari et al. 1995; Breese McCoy and Bryson 2003; Lafontaine-Lacasse et al. (2011).

4.2 Hyaluronan

Hyaluronic acid (HA), commonly called hyaluronate or hyaluronan, is a nonsulfated glycosaminoglycan (GAG), produced by chondrocytes and synovial fibroblasts. HA is an important component of articular cartilage ECM that coats each chondrocyte. It is also present in synovial fluid. Its chemical formula is shown in Fig. 3. Within the joint cavity, HA molecules are predominately synthesized by type B synoviocytes. HA (a polymer of disaccharides) can be 25,000 disaccharide repeats in length, with a molecular weight (Mol Wt) of 5000–20,000,000 Da. HA is synthesized by hyaluronan synthases (HAS), of which vertebrates have three types (HAS1, HAS2, and HAS3). These enzymes lengthen HA by repeatedly adding glucuronic acid and *N*-acetylglucosamine to the nascent polysaccharide. HA is catabolized by hyaluronidases, and the MW of HA in cartilage decreases with age, but the amount increases (Holmes et al. 1988; Gupta 2016).

Intra-articular (IA) treatment with HA has been investigated in a number of studies, and it has been used for decades as OA therapy in dogs and horses (Armstrong et al. 1994; Kuroki et al. 2002; Frisbie et al. 2009; Jerosch 2011; Carapeba et al. 2016). In a recent study, HA was also administered intravenously in horses (Frisbie et al. 2016). There is controversy over the efficacy of orally administered HA. Pharmacokinetic data revealed that orally administered high-molecular weight HA also reached the joint (Balogh et al. 2008), which provides a rationale for the oral supplementation of HA. In addition to its contribution to the structural properties of the ECM, HA may have a role in regulating the synthesis of proteoglycans during maturation of articular cartilage and in repair processes (Kuroki et al. 2002).

Philip (1989) and Jerosch (2011) reported that HAs of higher MW were more effective than those of lower MW. Ghosh and Guidolin (2002) demonstrated that HAs within the Mol Wt range of 0.5×10^6–1.0×10^6 Da partially restored synovial fluid rheological properties and synovial

Table 1 Nutraceuticals in osteoarthritis

Nutraceuticals	Dog	Horse	References
Glucosamine + chondroitin	2 g glucosamine HCl + 1.6 g chondroitin sulfate, daily	5.4 g glucosamine HCl + 1.8 g chondroitin sulfate, twice daily for the first month, and once daily thereafter	D'Altilio et al. (2007), Gupta et al. (2009, 2012)
	1 g Synoquin SA (475 mg GH: 350 mg CS) for 5–19.9 kg; 1.5 g for 20–40 kg; and 2 g for >40 kg) b.i.d for 42 days. The daily dose was reduced by one-third for the subsequent 28 days. For details, see text	–	McCarthy et al. (2007)
Hyaluronic acid (HA)	5 mg for ≤10 kg; and 10 mg for ≥11 kg, IA	40 mg, IA	Auer et al. (1980), Carapeba et al. (2016)
Curcumin	4 mg/kg, twice daily for 20 days	–	Colitti et al. (2012)
Omega-3 fatty acids	69 mg EPA + DHA/kg/day for 84 days	15 g EPA + 19.8 g DHA/day for 90 days	Manhart et al. (2009), Mehler et al. (2016)
Vitamin E	400 IU/dog, once a day	–	Rhouma et al. (2013)
Shilajit (purified)	500 mg twice daily for 5 months	–	Lawley et al. (2013)
Type II collagen (active)	10 mg daily	160 mg daily	DeParle et al. (2005), D'Altilio et al. (2007), Peal et al. (2007), Gupta et al. (2009, 2012)
Bioactive collagen peptide (BCP) (Petagile®)		25 g or 50 g/day for 12 weeks	Dobenecker et al. (2017)
Avocado/soybean unsaponifiables (ASU)	10 mg/kg/day for 8 weeks or 300 mg every 3 day for 15 weeks	Avocado/soybean (1:2 ratio) unsaponifiable oil in 6 mL molasses/day for 70 days	Kawcak et al. (2007), Boileau et al. (2009), Altinel et al. (2011)
Green-lipped mussel (GLM) (*Perna canaliculus*)	GLM 0.3% of dry food diet or Lyproflex®	25 mg/kg body wt/day, po for 56 days	Bui and Bierer (2003), Cayzer et al. (2012), Rialland et al. (2013), Hielm-Björkman et al. (2009)
	450 mg GLM for <25 kg; 750 mg for 25–34 kg; and 1 g GLM for >34 kg/day	–	Bierer and Bui (2002)
Crominex® -3+	25 mg Crominex® -3+ (500 μg trivalent chromium; 7.5 mg amla extract; and 7.5 mg purified shilajit), twice daily	500 mg Crominex® -3+ (10 mg trivalent chromium; 150 mg amla extract; and 150 mg purified shilajit), twice daily	Fleck et al. (2014), May et al. (2015)
Boswellia serrata extract (acetyl-keto-beta-boswellic acid, AKBA)	150 mg daily	–	No publication available
Terminalia chebula extract (TCE)	500 mg TCE, twice daily	–	Murdock et al. (2016)

IA intra-articularly

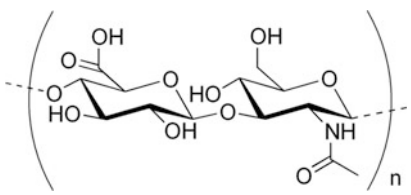

Fig. 3 Structural formula of hyaluronic acid (HA)

fibroblast metabolism in animal models. These authors also described the interaction of HA with pain receptors and analgesic effects. HA exerts pharmacological actions by mitigating the activities of pro-inflammatory mediators and pain-producing neuropeptides released by activated synovial cells (Kuroki et al. 2002; Gupta 2016). Moreland (2003) reported that HA can reduce nerve impulses and nerve sensitivity associated with the pain of OA. HA can also reduce OA-associated pain by decreasing PGE_2 and bradykinin synthesis, as well as substance P (Reviewed in Gupta 2016).

In regard to cartilage repair, Kuroki et al. (2002) suggested that intra-articular administration of HA has a direct effect on chondrocytes or synoviocytes and the production of transforming growth factor (TGF)-β, basic fibroblast-derived growth factor (FGF), and insulin-like growth factor (IGF)-1. Histological evidence suggests that HA prevents the degradation of cartilage and may promote its regeneration. Ghosh and Guidolin (2002) also provided evidence that HA treatment mitigated synovial hypertrophy and increased the

numbers of synovial fibroblast-like cells while decreasing macrophages, lymphocytes, mast cells, and adipocytes. HA appears to provide cartilage protection by the downregulation of cytokine; free radicals, such as NO; and proteolytic activities in the synovial fluid.

Like glucosamine and CS, HA is a slow-acting anti-OA agent that may be used prophylactically or therapeutically as an anti-inflammatory disease-modifying agent in OA (Kuroki et al. 2002; Venable et al. 2008; Aubry-Rozier 2012; Carapeba et al. 2016). Marshall et al. (2000) reported that a series of three weekly injections of 0.5 ml (4 mg) of Ha (Mol Wt, 6×10^6 Da) ameliorated the severity of OA in dogs. The use of intra-articular (IA) HA has been prescribed for synovitis or OA in the horse since 1975. HA is commonly used in the treatment of articular disorders (carpal and fetlock joints) in horses, especially those involved in racing competition and heavy work. HA can be injected directly into an affected joint. Auer et al. (1980) reported that in naturally occurring and experimentally induced OA in horses, IA injection of HA (40 mg) significantly reduced lameness and increased weight bearing on the treated limb, measured using the ground force plate. HA is especially indicated for mild to moderate levels of synovitis associated with equine OA. However, it has a limitation in treating severe synovitis or OA.

During the last decade, the use of intravenous HA has become common, especially for less localized disorders. However, there is only one licensed product made by Bayer (Legend® in the United States, Hyonate® elsewhere). It has been suggested that when used in combination, HA not only provides improved beneficial effects of corticosteroids but it can placate the side effects of certain corticosteroids. According to Canadian regulations, HA in HY-5- preparation should not be administered to horses that are to be slaughtered for meat. However, in Europe the same preparation is not considered to have any such effect. HA is known to produce some side effects, such as muscle pain, cramping, pain in the injected knee, and swelling in the arms and legs making movement difficult (Rutjes et al. 2012).

4.3 Curcumin

Curcumin is an active ingredient of the yellow Indian spice turmeric, which is obtained from the roots of *Curcuma longa*. The nutraceutical value of curcumin has been recognized in a number of diseases (Javeri and Chand 2016; Shome et al. 2016; Du et al. 2017: Kurien et al. 2017; Shen et al. 2017), including OA (Henroitin et al. 2014; Comblain et al. 2015; Zhang et al. 2016) and cancer (Jayakumar et al. 2017). In in vitro studies, curcumin has been shown to decrease the synthesis of iNOS, NO, PGE_2, Il-6, IL-9, COX-2, MMP-3, and MMP-9 by inhibiting NF-κB translocation and TNF-α signaling pathways in the chondrocytes, thereby providing a chondroprotective effect (reviewed in Comblain et al. 2015). In a mouse model of OA, Zhang et al. (2016) reported that both curcumin and the nanoparticles encapsulating curcumin suppressed mRNA expression of pro-inflammatory mediators IL-1β and TNF-α; MMPs 1, 3, and 13; and aggrecanase ADAMTS5 and upregulated the chondroprotective transcriptional regulator CITED2 in primary cultured chondrocytes in the absence or presence of IL-1β. Oral administration of curcumin significantly reduced OA disease progression but showed no significant effect on OA pain relief.

Colitti et al. (2012) treated dogs with curcumin (4 mg/kg, bid) for 20 days and found that curcumin targets I-κB upregulation in the TNRF1 signaling pathway and IL-18 downregulation in the role of cytokines in mediating communication between immune cells. Curcumin was also found to inhibit macrophage proliferation by downregulating TNF-α and activating fibrinolysis. In essence, curcumin exerts antioxidative, anti-inflammatory, and chondroprotective activities. Additionally, curcumin increases synthesis of type II collagen. Following its oral administration, the bioavailability of curcumin is poor as is its effectiveness against OA. For that reason, intense research efforts are underway to enhance its bioavailability by using various formulations (including bioenhancers) and delivery systems. Recent studies suggest that by conjugating curcumin to metal oxide nanoparticles or encapsulating it in lipid nanoparticles, dendrimers, nanogels, and polymeric nanoparticles, the water solubility and bioavailability of curcumin can be improved and thus increase its pharmacological effectiveness (Shome et al. 2016).

In several studies, curcumin has been investigated in combination with other nutraceuticals, such as boswellic acid, type II collagen, green tea, resveratrol, and others to achieve greater anti-OA effects than curcumin alone (reviewed in Comblain et al. 2015; Haroyan et al. 2018; Zhang et al. 2016). For further details on curcumin, readers are referred to Chap. 1 in this book.

4.4 Methylsulfonylmethane

Methylsulfonylmethane (MSM), also known as dimethyl sulfone (Fig. 4), is a naturally occurring organosulfur compound present in some plants. MSM supplements, available in both tablet and liquid form, are marketed with a variety of claims. MSM is often given in combination with glucosamine and/or chondroitin to prevent or treat OA.

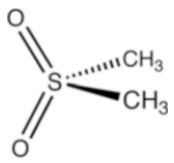

Fig. 4 Structural formula of methylsulfonylmethane (MSM)

MSM, by having high sulfur content, is used by the body to maintain normal connective tissue. It may provide anti-arthritic effects via its antioxidative, anti-inflammatory, and analgesic activities (Kim et al. 2006; also reviewed in Gupta 2016). In OA, MSM serves the same purpose as the NSAIDs, but MSM has none of the negative outcomes that are associated with NSAIDs.

In a clinical trial, Kim et al. (2006) found that compared to placebo, 3 g of MSM twice a day (6 g/day total) for 12 weeks produced significant decreases in WOMAC pain and physical function impairment. MSM ameliorated symptoms of pain and improved physical function during the intervention without major adverse events. In another clinical trial, Debbi et al. (2011) reported that patients with OA of the knee taking MSM 3 × daily (1.125 g) for 12 weeks showed a decrease in pain and improvement in physical function. Usha and Naidu (2004) treated patients with knee OA with either 1.5 g MSM (500 mg tid), 1.5 g glucosamine sulfate (GS), or MSM plus GS, or placebo for 12 weeks. Significant decreases in the Lequesne Index were reported with MSM, GS, and their combination ($P < 0.05$). The authors reported a 33% decrease in pain in the MSM group, joint mobility, swelling, and global evaluation, and walking time was also improved.

The recommended dose of MSM in dogs is 250–500 mg/day, and in horses it is 10–15 g/day. Dogs receiving MSM should be checked regularly for liver and kidney functions, and the lens in their eyes for opacity. Some dogs may show mild GI upset with vomiting and diarrhea, while others may show allergic reactions such as rash, hives, and difficulty breathing. MSM is not recommended for use in pregnant animals and those that are allergic to MSM or have urinary tract or bladder cancer.

4.5 Collagen

Type II collagen is the main collagen component of the hyaline cartilage, which is destroyed in OA by MMP 13 (Xu et al. 2007). Glycosylated undenatured type II collagen (hereafter referred to as type II collagen) has been shown to be effective in ameliorating pain associated with arthritis in humans (Trentham et al. 1993; Crowley et al. 2009), dogs (Gupta et al. 2012), and horses (Gupta et al. 2009). In clinical trials conducted on moderately arthritic dogs, type II collagen at 10 mg daily for a period of 120–150 days significantly reduced pain associated with OA (DeParle et al. 2005; D'Altilio et al. 2007; Peal et al. 2007; Gupta et al. 2012). In horses also, daily administration of type II collagen (160 mg) was found to be effective in reducing OA pain (Gupta et al. 2009). These supplements were well tolerated as no side effects were observed. For details on mechanism of action and safety of type II collagen, readers are referred to Marone et al. (2010) and Gupta (2016).

Collagen peptides are reported to stimulate the biosynthesis of extracellular matrix molecules in cartilage tissue and diminish degenerative processes by modulating the expression of collagenases and proteoglycanases (Schunck et al. 2007a, b, 2017). In a clinical trial, Dobenecker et al. (2017) supplemented OA horses with 25 g or 50 g bioactive collagen peptides (BCP, PETAGILE®) for 12 weeks. An orthopedic examination revealed that in a dose-dependent manner, BCP provided significant improvement in OA-associated lameness and pain in horses.

4.6 Avocado/Soybean Unsaponifiables

Avocado and soybean unsaponifiables (ASU) have been used in the treatment of OA for decades. The active ingredients of this extract are a sterol-rich hydrolyzed lipid fraction (Castrogiovanni et al. 2016) and synergism between the avocado and soya components. Their relative ratios (one-third avocado oil and two-third soybean oil) also appear to be important (Reviewed in Gupta 2016). ASU appears to stimulate ECM synthesis. Boumediene et al. (1999) and Altinel et al. (2007) also reported that ASU can stimulate the expression of TGF-β1 and TGF-β2 genes in cultured bovine chondrocytes and in canine joint fluid. Furthermore, Altinel et al. (2011) demonstrated that dogs treated with ASU (300 mg every 3 days) for 15 weeks showed significantly more collagen and chondral tissue content by increasing TGF-β in the tissues. Synthesis of plasminogen activator inhibitor 1 (PAI-1) at both the mRNA and protein levels has been an additional contributing factor. Henrotin et al. (1998) demonstrated that ASU can inhibit the action of IL-1β on MMP 3, IL-6, IL-8, and PGE_2 production and IL-1-β-stimulated collagenase synthesis by articular chondrocytes.

In another study, Boileau et al. (2009) demonstrated that treatment with ASU (10 mg/kg/day) could reduce the development of early OA cartilage and subchondral bone lesions in the anterior cruciate ligament of dogs. This effect appears to be mediated through the inhibition of iNOS and MMP-13, which are key mediators of the structural changes that take place in OA. In essence, ASU can be useful in preventing or blocking erosion of the tissue in OA and slow down joint space narrowing and repair of cartilage (Maheu et al. 1995, 1998; Lequesne et al. 2002). ASU extract did not decrease clinical signs of pain in horses with experimentally induced OA and there did appear to be a disease-modifying effect of treatment compared to placebo.

4.7 The New Zealand Green-Lipped Mussel

Perna canaliculus (green-lipped mussel, GLM) is a rich source of glycosaminoglycans (GAGs), omega-3 fatty acids, and eicosatetraenoic acid (ETA). GAGs exert anti-inflammatory activity and lubricate joints in OA patients. ETA appears to act as a dual inhibitor of arachidonic acid oxygenation by both the cyclooxygenase (COX) and lipoxygenase pathways. Unlike many NSAIDs, GLM is gastroprotective and does not affect platelet aggregation, suggesting that ETA may selectively block the pro-inflammatory COX-2 pathway rather than the physiologically important COX-1 pathway (Rainsford and Whitehouse 1980; Bierer and Bui 2002).

Bui and Bierer (2003) evaluated the efficacy of GLM powder (0.3% of a dry diet) for alleviating clinical signs of OA in dogs. Joints were evaluated for degree of pain, swelling, crepitus, and reduction in range of motion. By the end of 6 weeks, GLM-treated dogs showed significant improvement in arthritic score, joint pain, and swelling, without significant improvement in crepitus and range of joint movement. In another study, these investigators (Bierer and Bui 2002) treated OA dogs with GLM-containing PEDIGREE® JointCare™ Treats (450 mg for <25 kg, 1 Treat; 750 mg for 25–34 kg, 1.5 Treat; and 1 g for >34 kg, 2 Treats) for 8 weeks. The findings revealed reduction in lameness and pain associated with OA in dogs. Rialland et al. (2013) evaluated the effect of a GLM-supplemented diet on pain behavior and functioning in dogs. These investigators observed that dogs receiving a GLM-rich diet showed an increase in concentrations of plasma omega-3 fatty acids (EPA and DHA), improvement of peak vertical force using ground force plate, and reduced OA signs. In a double-blind clinical trial, Hielm-Björkman et al. (2009) evaluated efficacy of freeze-dried green-lipped mussel preparation (LYPROFLEX®) in OA dogs for a period of 8 weeks. The findings revealed that GLM was more effective than placebo and less effective than the positive control dogs receiving carprofen, without any side effects. The standard dose of GLM is 77 mg/kg/day in OA dogs.

Lyophilized products from green-lipped mussel are also used to treat horses with OA (Cayzer et al. 2012). In a randomized, double-blind, placebo-controlled study, horses were dosed orally with 25 mg/kg body wt/day for 56 days. The findings revealed that the treatment significantly alleviated the severity of lameness and joint pain and improved response to joint flexion in horses with lameness attributed to OA in the fetlock (Cayzer et al. 2012).

4.8 Naturally Preferred Holistic Frozen Dog Treats

Broderick et al. (2013) conducted a clinical trial on client-owned moderately arthritic dogs to evaluate Naturally Preferred Holistic Frozen Dog Treats (a product of Henry Schein Animal Health) for anti-arthritic efficacy, safety, and tolerability. In Group-I (<50 pounds each), each dog received a half treat, while those in Group-II (>50 pounds each) received a full treat daily for a period of 4 weeks. At weekly intervals, dogs were evaluated for OA-associated pain (overall pain, pain upon limb manipulation, and pain after physical exertion) and physical parameters (body weight, heart rate, and body temperature), serum analysis for hepatic (bilirubin, ALT, and AST), renal (BUN and creatinine), heart and skeletal muscle (creatine kinase) biomarkers, and hematological parameters. Marked reduction in arthritic pain was noted in dogs of both groups within a week with significant and maximum effects after 4 weeks. The product, Naturally Preferred Holistic Frozen Dog Treats, provided amazing results in reducing OA-associated pain and was found to be safe and well tolerated. All ingredients of this product are natural, and the mechanism of action for anti-arthritic effects remains proprietarily confidential at this time. For further details, refer to Broderick et al. (2013).

4.9 Omega-3 Fatty Acids

Omega-3 fatty acids (also called ω-3 fatty acids or *n*-3 fatty acids) are polyunsaturated fatty acids (PUFAs). The three types of omega-3 fatty acids involved in mammalian systems are α-linolenic acid (ALA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA), and they are commonly found in walnuts, flaxseed, fish oils, etc. *n*-3 fatty acids act via reducing IL-1β, PGE_2, ADAMTS-4, COX-2, IL-1α, iNOS, and TNF-α, MMP-3, and MMP-13 (Kremer et al. 1987; Zainal et al. 2009; Adler et al. 2018), aggrecanase and collagenase activities, and increasing collagen synthesis (Kremer et al. 1987). EPA is the most effective, followed by DHA, and ALA. PUFAs can modulate mammalian targets of rapamycin (mTOR) signaling, leading to a protective activation of autophagy in the chondrocytes (Villalvilla et al. 2013).

In several studies, it has been shown that dietary supplementation with marine *n*-3 fatty acids is beneficial for the treatment of canine OA (Fritsch et al. 2010; Roush et al. 2010a, b; Moreau et al. 2013; Mehler et al. 2016). In dogs, cats, and horses with naturally occurring OA, omega-3 fatty

acids supplemented diets could improve mobility and activity (Moreau et al. 2013; Corbee et al. 2012; Gupta 2016). In a 12-week clinical study, Fritsch et al. (2010) found that the required dose of carprofen to improve lameness decreased significantly faster in dogs supplemented with omega-3 fatty acids compared to control (3.5% and 0.1%, respectively). Findings of Roush et al. (2010a, b) suggested that ingestion of fish oil omega-3 fatty acids (3.5% in food) for 90 days increased the EPA concentration in serum 15-fold and improved clinical signs in dogs with OA based on orthopedic evaluations and force plate analysis. In a recent study, Mehler et al. (2016) determined the effects of EPA + DHA (69 mg/kg/day for 84 days) on the clinical signs and erythrocyte PUFA concentrations in OA dogs. The findings revealed that dogs receiving EPA + DHA showed a significant decrease in arachidonic acid (17%) and an increase in EPA (13.3-fold) and DHA (3.3-fold) in the blood, which correlated well with improvement in OA signs, without any major side effect. Horses supplemented with omega-3 fatty acids (EPA, 15 g/day; and DHA, 19.8 g/day) for 90 days showed significant decreases in plasma concentrations of PGE_2 and synovial fluid white blood cell counts, but force plate analysis indicated no significant change. For details on omega-3 fatty acids, readers are referred to a chapter on omega fatty acids in this book.

4.10 *Boswellia serrata* Extract

The beneficial health effects of *B. serrata* (often called Indian Frankincense, a plant native to India) extract are attributed to boswellic acids (alpha-boswellic acid and beta-boswellic acid). The other chemical constituents include volatile oil, terpinols, arabinose, xylose, uronic acid, β-sitosterol, and phlobaphenes (Goyal et al. 2011; Patel et al. 2013). Both boswellic acids have a hydroxyl group, and they differ only in their triterpene structure. The chemical structure of alpha-boswellic acid is shown in Fig. 5. One of the six boswellic acids, acetyl-keto-beta-boswellic acid (AKBA) is present at 2–3% of the total extract and is the most important for anti-OA effects. Acetyl-boswellic acids exhibit anti-inflammatory and anti-arthritic properties by inhibiting leukotriene synthesis (Ammon et al. 1993; Upaganlawar and Ghule 2009).

5-Loxin® (a patent product of PLT Health Solutions, Inc.), having 30% AKBA, provides improvement in joint mobility and comfort within a week. It inhibits 5-lipoxygenase, NF-κB, and MMP-3. 5-Loxin® positively impacts biomarkers of inflammation and arthritis, such as TNFα, CRP, and IL-6. Currently, the product Nutraquin+ is also on the market for OA in dogs, cats, and horses.

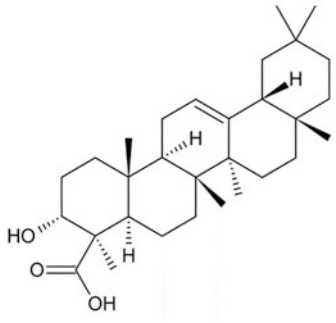

Fig. 5 Structural formula of alpha-boswellic acid

4.11 Shilajit

Shilajit is a blackish-brown exudate from the sedimentary rocks of the Himalayan Mountains, which contains many herbo-mineral constituents, primarily dibenzo-α-pyrones (DBPs), DBP-chromoproteins, and fulvic acids with a DBP core. Purified shilajit is prepared from this exudate by a proprietary extraction process (Natreon Inc., New Brunswick, NJ). Shilajit is known to exert several biological and pharmacological actions, including antioxidative, anti-inflammatory, anti-arthritic, immunomodulatory, and energetic properties (Lawley et al. 2013; Gupta 2016). In a 5-month clinical trial, administration (bid) of purified shilajit alone (500 mg) or shilajit (7.5 mg) in combination with trivalent chromium (500 μg) and *Phyllanthus emblica* (amla) extract (7.5 mg) significantly reduced arthritic pain in dogs (Lawley et al. 2013; Fleck et al. 2014). It seems that shilajit alone or in combination with chromium and amla extract attenuated arthritic pain by antioxidative, anti-inflammatory, and immunomodulatory mechanisms. Shilajit has been reported to be safe in long-term studies (Lawley et al. 2013; Fleck et al. 2014; Stoh 2014; Gupta 2016; Velmurugan et al. 2012).

4.12 Devil's Claw

Devil's claw (*Harpagophytum procumbens* and *Harpagophytum zeyheri*) is a small desert plant native to Southern Africa. It is also known as the wood spider or grapple plant. The plant/root extract has iridoid glycosides, such as harpagoside, harpagide, and β-sitosterol, which are active ingredients (Georgiev et al. 2013). Harpagogenin has also been suggested as an active principle of these plants. The structural formula of harpagoside and harpagide is shown in Fig. 6. The plant extract or its active ingredient(s) are

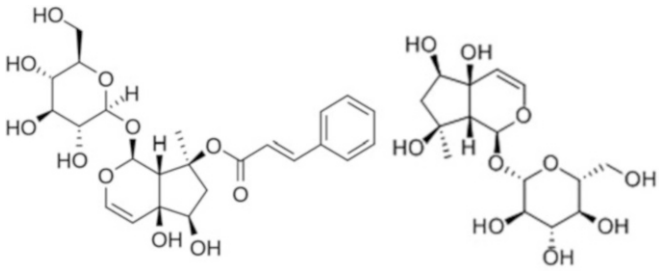

Fig. 6 Structural formula of harpagoside (left) and harpagide (right)

commonly used to treat pain and inflammation in joints associated with OA in humans, dogs, and horses, thereby improving their flexibility and mobility. The plant/root extract is available in powder or liquid form. In humans, Devil's claw extract has been found as effective as NSAIDs or diacerhein in reducing back pain or OA pain (Leblan et al. 2000; Wegener and Lupke 2003; Oltean et al. 2006). Lim et al. (2014) reported that harpagides can reduce the production of inflammatory cytokines (IL-1β, IL-6, and TNF-α) in macrophage cells. In another study, this plant extract has been shown to reduce inflammation by suppressing the inflammatory gene expression pathway by blocking a transcription factor activation protein-1 (AP-1) (Fiebich et al. 2012). In addition, harpagoside inhibits COX-I, COX-II, iNOS, and NF-κB activities (Huang et al. 2006).

In humans, a dose of 500 mg two to four times daily has been shown to exert anti-inflammatory, analgesic, and anti-arthritic effects. The recommended dose for standard Devil's claw extract is 250 mg capsule (small), 500 mg (medium), and 1 g for a large dog for the treatment of OA. The extract is also recommended for horses and ponies (0.5–10 mg/kg body wt/day) that suffer from OA and other joint-related illnesses. Devil's claw extract can be given for a long period of time without producing side effects. It is not recommended in pregnant animals.

4.13 Sauchinone

Sauchinone is one of the lignans isolated from *Saururus chinensis*, which has antioxidative, anti-inflammatory, hepatoprotective, and anti-osteoarthritic properties. Recently, Gao et al. (2017) investigated the anti-inflammatory effects of sauchinone in IL-1β-stimulated chondrocytes. Results revealed that sauchinone significantly attenuated activation of NF-κB, production of NO and PGE_2, as well as inhibited MMP-3 and MMP-13 release in human OA chondrocytes, most likely by inhibiting the activation of NF-κB signaling pathway. Gao et al. (2017) suggested that sauchinone may be a potential agent in the treatment of OA.

5 Novel Nutraceuticals

5.1 C-Phycocyanin

In an in vitro model of canine OA, Martinez et al. (2015) evaluated a commercially available c-phycocyanin-based nutraceutical (PHYCOX, which contains the active ingredient blue-green algae extract, a product of Dechra Pharmaceuticals, Northwich, UK) and some other selected ingredients (glucosamine hydrochloride, methylsulfonylmethane, turmeric, eicosapentaenoic acid, docosahexaenoic acid, vit C, vit E, selenium, etc.) for antioxidative, anti-inflammatory, and chondroprotective activities. Biomarkers for inflammation and catabolism of the ECM included PGE_2, TNF-α, IL-6, MMP-3, NO, and sulfated glycosaminoglycans. The antioxidant capacity and inhibitory activities of nutraceuticals on COX-1, COX-2, and lipoxygenase (LOX) were also evaluated. The findings revealed that PHYCOX and select ingredients mediate antioxidative, anti-inflammatory, and chondroprotective activities and may be useful in OA management in dogs and other animals after in vivo investigations and clinical trials.

5.2 Resveratrol

Resveratrol (trans-3,4′,5-trihydroxystilbene) is a natural polyphenol compound present in the skin of red grapes, cranberries, and peanuts. The compound is proven to exert antioxidative, anti-inflammatory, cardioprotective, and antitumor properties. In a number of in vitro and animal studies, resveratrol provided significant protective effects against articular cartilage degradation (Elmali et al. 2005; Lee et al. 2013). In human chondrocytes, Csaki et al. (2008) and Shakibaei et al. (2008) demonstrated that both

anti-apoptotic and anti-inflammatory regulatory mechanisms are mediated by resveratrol (reviewed in Lee et al. 2013). Recently, resveratrol has also been found to alleviate RA by inhibiting ROS, inflammation, MAPK signaling pathways, and angiogenesis (Yang et al. 2018). Based on these findings, resveratrol appears to be a novel nutraceutical that should be evaluated for anti-arthritic properties and safety in dogs, cats, and horses.

5.3 Bovine Lactoferricin

Bovine lactoferricin is a 25-amino acid cationic peptide with an amphipathic, anti-parallel β-sheet structure that is obtained by acid-pepsin hydrolysis of the N-terminal region of lactoferrin found in cow's milk (Lee et al. 2013). In addition to antiviral, antibacterial, and anticancer properties, this peptide exerts antioxidative, anti-inflammatory, and anti-pain activities (Guillen et al. 2000; Hayashida et al. 2004). Lee et al. (2013) also reported that bovine lactoferricin reverses the catabolic effects of PGE_2 and IL-1 on matrix-degrading enzyme production, proteoglycan accumulation, and expression of factors associated with oxidative stress and inflammation. By exhibiting these properties, lactoferricin seems to be a promising nutraceutical for the treatment of OA in animals.

5.4 Botulinum Toxin

Botulinum toxin A (BoNT A, IA) has been shown to reduce joint pain in OA dogs. In a recent investigation, Heikkilä et al. (2017) injected BoNT A intra-articularly (30 IU, IA) in the OA joint of dogs. The findings revealed that synovial fluid PGE_2, but not serum PGE_2, could be a biomarker for chronic OA and pain in dogs. However, substance P in neither synovial fluid nor in serum seems to be a good biomarker of OA pain in dogs. For detailed biology, pharmacology, toxicology, and safety of BoNTs, see recent publications elsewhere (Pirazzini et al. 2017; Cope 2018).

5.5 Eggshell Membrane

Eggshell membrane, which contains glucosamine, chondroitin, collagen, and hyaluronic acid, has been indicated in the treatment of OA (Ruff et al. 2009). The product NEM® (natural eggshell membrane; ESM Technologies, LLC, Carthage, MO, USA) contains glucosamine, 1%; chondroitin sulfate, 1%; hyaluronic acid, 2%; and collagen type I, 5% (Ruff and DeVore 2014). In a series of in vitro and in vivo studies in rats, Ruff et al. (2009) and Ruff and DeVore (2014) found that NEM® can influence early phase pro-inflammatory cytokines such as IL-1β and TNF-α. This product can also influence later-phase pro-inflammatory cytokines like monocyte chemotactic protein 1 (MCP-1), macrophage inflammatory proteins (MIP-1α and MIP-1β), regulated upon activation of normal T-cell expressed and secreted (RANTES), and vascular endothelial growth factor (VEGF). Another product Movoflex™ Soft Chew (Virbac Corp., Fort Worth, TX, USA), which contains eggshell membrane, is also on the market for OA in dogs, although no published data are available.

5.6 microRNAs (miRNAs)

The importance of miRNAs has recently been recognized in veterinary medicine (Hollis and Starkey 2018). The "Omics" technology has helped in identifying miRNAs that not only serve as novel biomarkers to predict the early onset of OA and its progression but they also have potential for new modalities in OA treatment. In a number of investigations, miRNAs have been shown to be involved in the pathogenesis of OA and degradation of the ECM and cartilage (iNOS expression, inflammation, autophagy, apoptosis, chondrocyte metabolism, differentiation, and homeostasis) (reviewed in Gupta et al. 2019). In an OA rat model, Wang et al. (2016) demonstrated that miRNA-98 expression is reduced in the cartilage cells by apoptosis, and the overexpression of miRNA-98 inhibits cartilage cell apoptosis. In a similar investigation, miRNA-140 levels were significantly reduced in human OA cartilage-derived chondrocytes and synovial fluid compared with normal chondrocytes and synovial fluid. Overexpression of miRNA-140 in primary human chondrocytes promoted collagen II synthesis and inhibited MMP-13 and ADAMST-5 expression (Si et al. 2017). These investigators demonstrated that intra-articular (IA) injection of miRNA-140 can alleviate OA progression by modulating ECM homeostasis in rat and may have potential as a new therapy for OA in dogs, horses, and humans. Currently, a large number of miRNAs are under investigation to identify their roles in pathogenesis, diagnosis, and treatment of OA (Gupta et al. 2019).

5.7 Spermidine

Spermidine, a natural polyamine involved in a wide range of cellular processes, is widely recognized to induce autophagy and to reduce oxidative stress. Silvestri et al. (2018) evaluated the ability of spermidine to protect cultured articular chondrocytes against hydrogen peroxide (H_2O_2)-induced oxidative stress by modulating the autophagic process. The findings revealed that autophagy promotion participates in the protection afforded by spermidine against oxidative stress. Jeong et al. (2018) demonstrated that spermidine

significantly inhibited the production of pro-inflammatory mediators such as NO and PGE_2 and cytokines including TNF-α and IL-1β in RAW 264.7 macrophages without any significant cytotoxicity. Spermidine significantly decreased the elevation of NO and ROS levels in an LPS-stimulated zebra fish model and reduced the inflammation-associated migration of immune cells such as neutrophils and macrophages. Spermidine, via autophagy, antioxidative, and anti-inflammatory properties, appears to be a promising candidate as a new treatment for OA. In addition, spermidine has emerged with antiaging properties, such as reducing the age-related oxidative protein damage, free radical-scavenging activities, and the overproduction of ROS (Reviewed in Jeong et al. 2018).

6 Concluding Remarks and Future Directions

Osteoarthritis (OA) is a chronic degenerative joint disease (DJD) that commonly afflicts dogs and horses due to many predisposing factors. The pathophysiology of OA is very complex because of multiple etiologies and underlying mechanisms. Biomarkers of early disease detection and progression and disease reversal during treatment are well defined, and many of them are validated. Inflammation and pain associated with OA are major complaints. Signs and symptoms are often managed by using NSAIDs, therapeutic drugs, and sometimes surgery. Currently, nutraceuticals have replaced other treatment modalities because of their efficacy and safety. This chapter describes etiologies and pathophysiologies of OA and a number of nutraceuticals that are commonly used to prevent or ameliorate OA in dogs and horses. Also described are some nutraceuticals that have the potential for treating OA in animals.

Nutraceuticals for Antiaging

Bhanushree Gupta, Bhupesh Kumar, Anshuman Sharma, Deeksha Sori, Rahul Sharma, and Saumya Mehta

Abstract

Aging is a complex biological phenomenon in which structural and functional changes take place over time in a living organism. The relationship between diet and aging is quite interesting. Antioxidants and decrease in caloric intake help in slowing the aging phenomenon. Oxygen plays many significant roles in the body. First and foremost it is required to sustain life. However, oxygen also produces reactive oxygen species (ROS) which is injurious to health and one of the major factors responsible for aging. Healthy food and lifestyle, in addition to dietary antioxidants, are required to increase quality of life and slow the aging process. Dietary antioxidants (adaptogens, coenzyme Q10, isoflavones, anthocyanins, probiotics, vitamin A, vitamin C, vitamin D, and vitamin E) and microelements such as manganese, zinc, selenium, and iron help in slowing the aging process because of their ability to reduce the amount of ROS in cells, which ultimately results in an increase in life span of organisms. The objective of this chapter is to highlight the importance of antiaging nutraceuticals and to discuss modern theories of aging. Further, the role of antiaging nutraceuticals as antioxidants is described along with mechanisms to increase lifespan.

Keywords

Aging · Antioxidants · Quality of life · Lifespan · Nutraceuticals

1 Introduction

Aging is a complex biological and unavoidable phenomenon which is characterized by physiological changes in cells and tissues that results in increased risk of disease and death. It also means to grow and become mature along with these physiological changes (Lee et al. 2006). Aging depends on both internal and external factors. Internal factors are normal naturally occurring processes which take place within the cell. External factors include nutritional deficiencies, hormonal imbalances, ultraviolet irradiation, chronic sun exposure, and other factors such as smoking and pollution. Skin aging can be diminished by proper preventive measures including skin care, a balanced diet, and antioxidant-enriched supplements. With these methods, harmful effects of free radicals can be reduced (Schagen et al. 2012).

The effect of nutrition on the aging process has long been a matter of interest not only in animal research but in humans as well. An element of nutrition can be provided through nutraceuticals. As the name suggests, "nutra" means food and "ceutical" refers to the medicinal product properties. According to the 1996 definition by the Foundation for Innovation in Medicine (FIM), nutraceuticals are "food or food ingredients providing medical and health benefits, including prevention and/or treatment of diseases (Vranešić-Bender 2010)". Such products include isolated nutrients, dietary supplements, genetically engineered "designer" foods, functional foods, and herbal extracts (Kwak and Jukes 2001). According to the above statement, nutraceuticals are distinct in that they add up to long-term health benefits with additional consumption in the form of supplements.

Scientific data suggest that antioxidants show favorable effects in many chronic and age-related diseases like cancer and neurodegenerative diseases. A large number of substances, such as vitamins, carotenoids, and flavonoids, show antioxidant properties in that they show significant benefit for prevention or treatment of chronic diseases, ultimately resulting in a healthy and increased life span. The antioxidant substances derived from foods are currently a large area of research, especially coenzyme Q10, phytoestrogens, probiotics, and omega-3 fatty acids. These substances antagonize inflammatory and degenerative processes in the body and provide favorable effects in the digestive and immune systems, thereby increasing quality of life (Patel and Singh 2014).

2 Signs of Aging

Wrinkles around the eyes, brows, and regions of the neck are clear signs of aging. The hair becomes gray, maximal heart rate declines due to a decrease in oxygen use capacity, approximately 10,000 neurons of the brain become dysfunctional, vision becomes less clear, and the maximal capacity of the kidney and liver to filter waste material decreases (Patel and Singh 2014).

2.1 Theories of Aging

Based on common assumptions, the following theories have been postulated to describe the phenomenon of aging:

2.1.1 Free Radical Theory

Free radicals are highly reactive, short-lived uncharged species having an unpaired valence electron. These free radicals are needed in various metabolic processes, including protection of the body from infection, in the synthesis of hormones, and for production of energy released from food. In all these conditions, free radicals are required in specific amounts. Excessive production of free radicals is responsible for specific damage to the body including DNA, elastin, and collagen (Agarwal 2013). Damage occurs when a free radical takes or pulls an electron from any molecule, most likely from a neighboring molecule, to pair its unpaired electron and convert the molecule to a free radical.

Oxidative damage to macromolecules like DNA and proteins is accumulated but is not single handedly significant enough to cause aging. Oxygen has many important roles in the body. Not only is it required for life, but it is also involved in the production of many potentially injurious compounds. Some reactive oxygen species (ROS) are given in Table 1.

When attacked by free radicals results, the DNA molecule undergoes genetic mutations which cause synthesis of dysfunctional protein. This mutation may be corrected by DNA-repairing enzymes. Free radicals are generated during energy production, i.e., ATP. During the aging process, mitochondria lose their efficiency for ATP production. There are several scientific studies (Agarwal 2013) which prove that mitochondrial DNA is more prone to mutation than core DNA.

Table 1 Reactive oxygen species

Superoxide anion radical	$(O_2)^-$
Hydroperoxyl radical	HO_2
Hydrogen peroxide	H_2O_2
Hydroxyl radical	OH^-
Peroxide radical (R=lipid)	ROO^-
Singlet oxygen	$^1O_2$

A decreased intake of calories aids in slowing the aging phenomenon and promotes life span in rats, spiders, flies, fish, etc. (Vranešić-Bender 2010). Older rodents are generally involved in these kinds of studies in which they are given a special diet full of vitamins and minerals (Wickens 2001; Cui et al. 2011).

Mechanism of Action

The imbalance between free radicals and prooxidants is defined as oxidative stress. Severe oxidative stress causes cell dysfunction. Oxidative stress occurs because of a disturbance in the amount of prooxidants and antioxidants. Humans have built-in antioxidative systems that help present free radical damage. Prevention is only possible with the intake of enough antioxidants included in the food. In stress conditions, there are increased amounts of free radicals. Free radicals take an electron from the neighboring stable molecule along with concomitant generation of free radicals. Increased electron transfer may cause damage to the membrane and repress the cell's defense system. It is the structure of the antioxidant which enables it to donate electrons for a free radical, resulting in stabilization of the molecule.

There is a shortening of telomeric sequences in DNA with cell replication and aging. Biological aging can be indicated by telomeric length. Recently, it has been shown that an increased uptake of multivitamins has a great impact on telomeric length because this modulates oxidative stress and the proteins involved in inflammation. Studies have shown that women with a higher intake of multivitamins have 5.1% longer telomeres as compared to women with a lower intake of multivitamins (George and Ritter 1996; Xu et al. 2009).

There are many compounds with antioxidative properties. Dietary antioxidants help in increased regulation of ROS, which aids in improved physiological functions in the human body (Lueckenotte 2000; Rath and Shinde 2012).

Figure 1 shows the potential of antioxidants in a hierarchical manner. Catalases and peroxidases are the most active

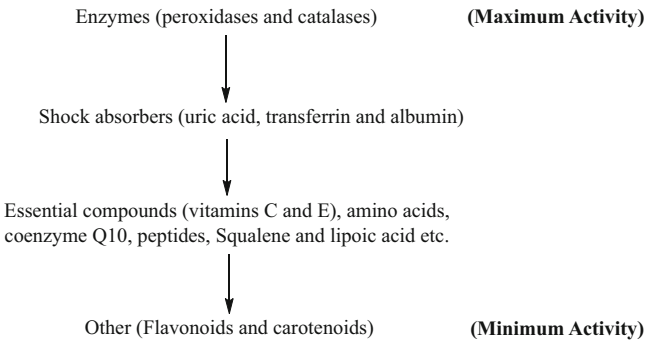

Fig. 1 Antioxidant hierarchy

antioxidants. The second class consists of shock absorbers, and the third is represented by essential antioxidants like vitamins, amino acids, and some complex macromolecules like coenzyme Q10. The last class is the largest consisting of natural compounds like flavonoids and carotenoids (Lueckenotte 2000).

Catalases and peroxidases are the most active antioxidants which play a vital role in antioxidant defense. The enzymes reduce the excess amount of free radicals and are commonly found in the subcellular organelles (Tabassum and Rasool 2012). These enzymes can perform their function properly only with the adequate supply of elements including zinc, selenium, manganese, copper, and iron.

2.1.2 Stochastic Theory

The stochastic theory is also called the wear and tear theory and was proposed by August Weismann (Peng et al. 2014). According to Weisman an excess of fat, certain injuries and infections, and excessive irradiation with UV light are the main causes of aging. This theory was later modified by Hart and Setlow (1974) who proposed that aging is due to DNA damage and mutation in proteins. According to their research, there is a positive correlation between DNA and life span.

2.1.3 Mitochondrial Decline Theory

According to this theory, cytochrome c oxidase, an enzyme which plays a vital role in the mitochondrial electron transport chain (ETC), continuously declines over time in both vertebrates and invertebrates (Benzi et al. 1992; Schwarze et al. 1998). Due to a deficiency in the activity of cytochrome c oxidase, activity of the electron transport chain is reduced. Therefore, there are close connections between MDTA and FRTA. Improving the antioxidant defense system also enhances the functional decline of mitochondria along with the decreasing amount of free radicals.

2.1.4 Theory of Ubiquitin Proteasomal System Decline

According to this theory, misfolding and aggregation of proteins are the reasons behind aging. 26S proteasome is responsible for degradation of the misfolded protein. It is a complex consisting of 20S core chamber and two 19S caps attached to it from each end (Thrower et al. 2000; Verma et al. 2001). It is reported that the activity of 26S proteasome declines over time, hence its capacity to degrade protein decreases with time. This causes an accumulation of misfolded proteins leading to the development of several neurodegenerative diseases such as Alzheimer's and Parkinson's.

2.1.5 Immunologic Theory

The immunologic theory states that a decline in activity of the immune system is the main force behind aging. A wide range of foreign molecules are detected and destroyed by the immune system to preserve the healthy cells. It is reported that a characteristic of the immune system to resist infectious diseases reduces over time, therefore increasing the risk of death in the elderly (Lueckenotte 2000).

In Vivo Model of Aging

Scientific research shows that sanitation and food intake increase the human life span, but an increasing life span does not mean that an individual remains in good health, i.e., living longer does not mean increased quality of life. A healthy diet and lifestyle improve the health condition, and in such cases nutraceuticals play a vital role in reducing aging. Before the divergence of species, the various orthologs of ancestral genes provide information regarding the similarities and differences in the species. Through this information, one can understand how a species can be useful as a model. Two often used biological models, rats and mice, possess 85% of human genes and are therefore widely used for various studies.

Caenorhabditis elegans as in vivo model:

Caenorhabditis elegans is a round worm which is distantly related to humans and provides many physiological similarities, such as the nervous and digestive systems (Barnett et al. 2016; Fitsanakis et al. 2019). *C. elegans* is an invertebrate, and its in vivo model is very closely related to previously mentioned vertebrate models. Between 40% and 80% of human genes have orthologs in *C. elegans* (Brenner 1974; Lai et al. 2000; Shaye and Greenwald 2011). This model was proposed in 1970 by scientist Sydney Brenner (1974) and is widely used in research. With the help of genetic tools like green fluorescent protein (GFP), the effect of nutraceuticals on the life span of worm can be measured. This extension of life span indicates the beneficial effects of nutraceuticals. Due to

similarities in genes of worms and humans, it has been expected that these nutraceuticals have beneficial effects on humans by inhibiting one or more aging condition.

3 Antiaging Nutraceuticals and Functional Foods

3.1 Adaptogens

Adaptogens are used in the stabilization of physiological processes and for maintaining homeostasis. They are used in herbal medicine. These compounds increase the body's ability to resist the damage from risk factors and decreases cellular sensitivity to stress. Adaptogens lead to protection from stress increasing the resistance to stress and also promoting or restoring normal physiological function.

Some of the most popular adaptogens include:

1. Brahmi (*Bacopa monnieri*)
2. Ginkgo (*Ginkgo biloba*)
3. Amla (*Emblica officinalis*)
4. Curcumin (*Curcuma longa*)
5. Liquorice (*Glycyrrhiza glabra*)
6. Ginseng (*Panax ginseng*)

3.1.1 Brahmi (*Bacopa monnieri*)

Brahmi is a perennial herb. It has purple flowers and small oblong leaves. The bacosides are the most valuable nootropic phytochemicals found in *Bacopa monnieri*. Its main function is to protect the brain from free radicals and to stimulate learning and cognitive functioning. Brahmi contains two important phytochemicals, herpestine (Fig. 2) and brahmine. Regular use of Brahmi oil prevents several diseases, such as amnesia and Alzheimer's disease (Talokar et al. 2017).

3.1.2 Ginkgo (*Ginkgo biloba*)

Ginkgo biloba is the scientific name of Ginkgo. The main function of this plant is to enhance the amount of oxygen availability to the tissues. The leaves of ginkgo help in maintaining glucose level in the brain and also aid in blood flow to the brain. It also improves mental functioning in human beings. Generally, 24% flavone glycosides are present in ginkgo leaf extract along with flavone glycosides, isorhamnetin (Fig. 3) lactone derivatives (ginkgolides), ascorbic acid, catechin, and shikimic acid. The components of ginkgo are active scavengers of free radicals which cause the death of premature cells (Talokar et al. 2017). For further details on *G. biloba*, readers are referred to Dziwenka and Coppock (2016).

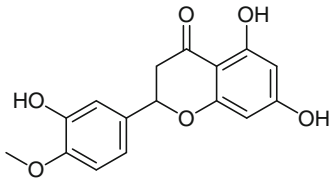

Fig. 2 Herpestine

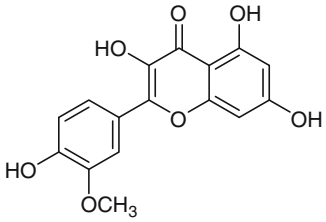

Fig. 3 Isorhamnetin

3.1.3 Amla (*Emblica officinalis*)

Emblica officinalis is commonly known as amla and belongs to the family Phyllanthaceae. The amla churn possesses memory enhancing activity due to its cholesterol reducing properties in the brain along with total cholesterol in the body, which has proven helpful in the treatment of Alzheimer's disease (Talokar et al. 2017).

3.1.4 Curcumin (*Curcuma longa*)

Curcumin is derived from turmeric which is a spice of the ginger family. It has yellow pigment, and it has many biological roles such as antioxidant, anticarcinogenic, and anti-inflammatory (Krausz et al. 2014; Pal et al. 2016). Due to these properties, curcumin is known as a potential drug for the treatment of cancer (Perrone et al. 2015). Curcumin has the capacity to suppress pro-inflammatory cytokines and prostaglandin E_2 (PGE_2), tumor necrosis factor-α (TNF-α), and cyclooxygenase-2 (COX-2). This suppressing activity shows anti-inflammatory properties of curcumin (Krausz et al. 2014; Perrone et al. 2015). Furthermore, curcumin fills in as an antioxidant agent by diminishing ROS production, hindering lipid peroxidation, and scavenging free oxygen radicals (Krausz et al. 2014; Perrone et al. 2015). Oral ingestion of curcumin in rodents showed amelioration of cystic fibrosis imperfections and hindrance of tumor expansion, yet human studies are lacking (Egan et al. 2004; Kunnumakkara et al. 2008; Draelos 2010).

3.1.5 Liquorice (*Glycyrrhiza glabra*)

The root of *Glycyrrhiza glabra* is liquorice, which belongs to the Fabaceae family. The roots and rhizomes of the plant act

as a brain tonic which helps to maintain blood sugar levels in the body. Glycyrrhizin is the main constituent of liquorice having antioxidant properties which help to increase memory, protect the brain from damage, and maintain neuronal function (Talokar et al. 2017).

3.1.6 Ginseng (*Panax ginseng*)

The roots of Ginseng plants are used for many medical purposes. The roots of this plant contain ginsenosides. Ginsenosides modulate the immune function which enhances the body's resistance against stress, trauma, anxiety, and fatigue. It helps in improving memory and learning performance and has anti-stress properties (Talokar et al. 2017).

3.2 Probiotics and Prebiotics

Probiotics are fermented products which change the diversity and activity of microorganism flora present in the gastrointestinal tract for the benefit of the individual. It improves the immune status of the person and makes up for malnutrition in aged people. Some of the probiotic microorganisms are *Lactobacillus rhamnosus* GG and *Lactobacillus reuteri* (Patel and Singh 2014).

Prebiotics are ingredients which cannot be digested but when taken in significant amounts can stimulate the activity of the friendly flora in the colon and improve health conditions.

3.3 Coenzyme Q10

Coenzyme Q10 (CoQ10) or ubiquinone is a fat-soluble benzoquinone compound with antioxidant properties. It aids in production of other antioxidants like α-tocopherol. It protects from UV radiation damages, serves as a cofactor in the production of ATP, and also works as membrane stabilizer. As the synthesis of CoQ10 reduces with aging, a regular dose of 60 mg/day helps to decrease wrinkles (Vranešić-Bender 2010; Talokar et al. 2017; Uekaji and Terao 2017).

3.4 Polyphenols

Polyphenols are present in plants as secondary metabolites and are mainly found in cereals, vegetables, fruits, and beverages. Polyphenols are attracting the attention of antiaging researchers due to their anti-inflammatory, antioxidant, and anticarcinogenic properties. These properties allow polyphenols to be able to prevent numerous health issues including asthma, cancer, diabetes, infection, and cardiovascular disease (Manach et al. 2004). Polyphenols are divided into various functional groups like flavonoids, lignans, phenolic acid, and stilbenes (Manach et al. 2004). Lab investigations of various polyphenols, such as grape seed proanthocyanidins, genistein, green tea polyphenols, silymarin, and resveratrol, led in small animal models of UV-prompted skin irritation, oxidative stress, and DNA damage. It is proposed that these polyphenols, joined with sunscreen protection, can shield skin from the adverse impacts of UV radiation, including the risk of skin cancers (Nichols and Katiyar 2010). Some flavonoids, polyphenols, and botanical antioxidants and their properties are described below.

3.4.1 Flavonoids (Phlorizin)

Phlorizin is a type of flavonoids that occurs naturally in a few plants. For more than 150 years, it has been widely utilized in the pharmaceutical industry and serves as a platform for physiological examination. An investigation to study the effect of phlorizin on life expectancy of the yeast *Saccharomyces cerevisiae* demonstrated a change in the reasonability of the yeast. Numerous other botanical extracts have been portrayed to have intense antioxidant properties. For example, apigenin (Sim et al. 2007), genistein, and silymarin have been shown to have beneficial effects on skin aging parameters (Katiyar 2002; Moore et al. 2006).

3.4.2 Resveratrol (Stilbenes)

Resveratrol is a natural polyphenol found in the skin of grapes and peanuts that exhibits antioxidant properties. It has been the subject of extraordinary studies over the last two decades because of its antiaging properties. Resveratrol works both as a chelating agent and as a radical scavenger, and moreover it exerts anti-inflammatory activity. It is also beneficial in cardiovascular, Alzheimer, and many other diseases (Di Franco et al. 2012; Risuleo 2016).

3.4.3 Apple Polyphenol

The apple contains many phytochemicals, mainly polyphenols which have antioxidant properties. Polyphenols, including chlorogenic acid, phloretin, proanthocyanidin B2, epicatechin, catechin, and rutin, are those most commonly found in the apple. Consumption of an apple is responsible for lowering the risk of cardiovascular disease and hypercholesterolemia. Several studies show that consumption of an apple reduces the risk of various cancers, especially lung cancer, and it is found more effective in women than in men (Feskanich et al. 2000; Marchand et al. 2000; Arts et al. 2001; Sesso et al. 2003).

3.4.4 Blueberry Extract

Blueberries are rich in polyphenols and also have higher antioxidant properties as compared to other fruits and vegetables. The natural compounds present in blueberries can reduce age-related losses (Joseph et al. 2005). It has been reported that daily consumption of blueberries can

improve memory function in adults. However, but this research is constrained due to a low number of samples and data (Krikorian et al. 2010).

3.4.5 Tea Catechins and Theaflavins

Tea is one of the most popular beverages, and it is consumed by a majority of the population. Tea leaves contain catechins and theaflavins, which are responsible for various health benefits. Several scientific studies showed that DNA oxidation reduces through consumption of black or green tea (Meng et al. 2001; Rietveld and Wiseman 2003). In vivo studies showed that catechins and theaflavins increased average life span of *Drosophila* (Bauer et al. 2004; Li et al. 2008).

3.4.6 Black Rice Anthocyanins

Black rice is rich in dietary antioxidants, and its supplementation has various beneficial effects, such as anticancer, anti-Alzheimer's, and anti-inflammatory. Black rice has an antioxidant property due to its abundant content of anthocyanins such as cyanidin-3-*o*-glucoside and peonidin-3-glucoside (Chiang et al. 2006).

3.5 Vitamins

3.5.1 Vitamin C

Vitamin C, a highly water-soluble vitamin (Fig. 4) also known as ascorbic acid, is a white colorless crystalline compound having strong reducing properties which make it a good antioxidant in a hydrophilic environment. It is photosensitive in nature (Schagen et al. 2012; Souyoul et al. 2018). Humans are unable to synthesize ascorbic acid naturally in their bodies and attempt to fulfill their requirements for vitamin C via ascorbic acid-enriched sources like green peppers, kiwifruit, oranges, grapefruit, brussel sprouts, strawberries, citrus fruit, and broccoli (Talokar et al. 2017). Vitamin C is oxidized into dehydroxy ascorbic acid, which enters the cells and is then converted back to ascorbic acid via the reduction process (Subramani et al. 2014). It is important to the human body for preventing disease related to connective tissue and for improvements in immune and cardiovascular cell function (Talokar et al. 2017). Deficiency of vitamin C causes a disease known as scurvy with clinical signs of fragility, gum bleeding, petechiae, and slow wound healing (Boyera et al. 1998). Vitamin C is a strong antioxidant and free radical scavenger that prevents damage to cell membranes, tissues, and DNA from free radicals (oxidation), and it is also important in collagen hydroxylation and beneficial in the maturation process of extracellular and intracellular collagen (Wu et al. 2017).

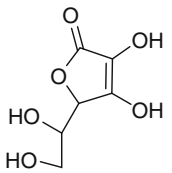

Fig. 4 Vitamin C

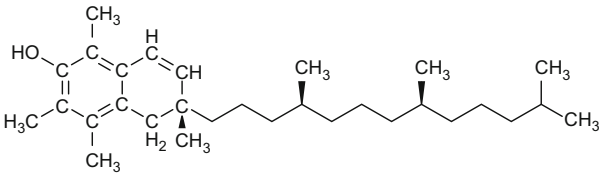

Fig. 5 Vitamin E

3.5.2 Vitamin E

Vitamin E (Fig. 5) is a group of fat-soluble vitamins collectively called "tocopherols." It is a membrane-bound antioxidant along with a free radical scavenger. Tocopherol is similar to vitamin C in that it is a nonenzymatic antioxidant (Lyons and O'Brien 2002; Ristow and Schmeisser 2011). It is present in vegetables, safflower oil, wheat germ oil, sunflower oil and seeds, almonds, peanuts, soy, corn, and meat (Stahl et al. 2006; Suganuma et al. 2010). Deficiency of vitamin E manifests in edema with seborrhiec changes or papular erythema, dryness, and depigmentation in prematurely born babies (Passi et al. 1991). Intake of vitamin E helps against collagen cross-connecting and lipid peroxidation, both of which are connected to maturation of the skin (Schagen et al. 2012).

Vitamin E and vitamin C are synergistic in nature. When UV-activated particles oxidize cell components, a chain reaction of lipid peroxidation in the membranes, which is rich in polyunsaturated fatty acids, is induced. In this reaction, the antioxidant agent D-α-tocopherol is oxidized and converted into the tocopheroxyl radical and then further recovered by ascorbic acid (Chan et al. 1991; Fryer 1993). Through this process, the cell membrane is stabilized by preventing the oxidation of polyunsaturated fatty acids. Vitamin E has been observed to inhibit erythema and endless UVB-initiated skin damage and reduce sunburned cells and photocarcinogenic effects (McVean and Liebler 1999; Makrantonaki and Zouboulis 2008).

3.5.3 Vitamin D

Vitamin D is a fat-soluble vitamin synthesized by the human body during exposure to sunlight. It also acts as a

prohormone. Small amounts of vitamins D2 and D3 (Fig. 6) originate from the dietary intake of animal-based foods, such as egg yolk or fish. Some products, like cereals, margarine, and milk, can be enriched with vitamin D (Schagen et al. 2012). The skin is a significant site for vitamin D3 UVB intervention. Vitamin D is stored in the lipid parts of the body, and an overabundance of this vitamin can have unwanted effects like weakness, poor appetite, weight loss, and vomiting. Vitamin D serves an important role in bone integrity and calcium homeostasis. It is also important for various physiological functions including release of inflammatory cytokines, regulation of growth, and immune response (Reichrath et al. 2007). It shields human skin cells from UV-incited cell passage and apoptosis and restrains the initiation of stress-actuated protein kinase (De Haes et al. 2003, 2005). Many studies show that oral vitamin D treatment prevents skin cancer, which is connected with antiaging effects (Lehmann 2009). Production of vitamin D3 decreases with advancing age. Several factors such as malnutrition, infrequent sun exposure, and behavioral effects can be responsible for vitamin D deficiency. Therefore, supplementation of vitamin D and calcium is essential for humans and animals (Makrantonaki and Zouboulis 2008).

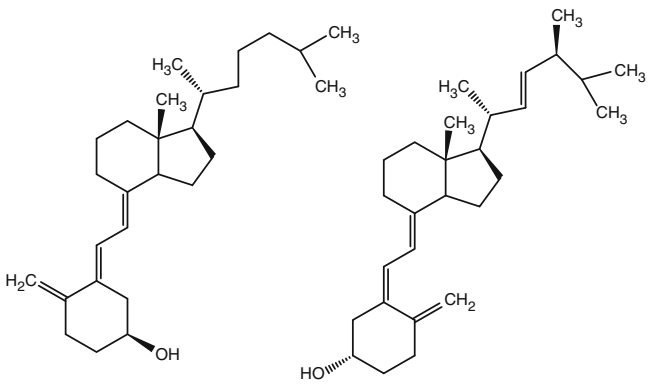

Fig. 6 Vitamin D2 (left) and D3 (right)

3.6 Carotenoids

Carotenoids are derivatives of vitamin A such as astaxanthin, β-carotene, retinol, and lycopene, which are generally exceedingly viable antioxidants and have been recorded to be photoprotective. Human skin is moderately enhanced by lycopene and β-carotene, contrasted with lutein and zeaxanthin, conceivably reflecting a particular function of hydrocarbon carotenoids in human skin photoprotection (Scarmo et al. 2010).

β-Carotene (Fig. 7) is the most important member of the carotenoids (Britton et al. 2008). It is found in the human diet in sweet potatoes, carrots, pumpkin, papaya, and mangos. An important role of β-carotene is to exert pro-vitamin-A activity. β-Carotene can be separated into two molecules of tansretinol by the BCMO1 enzyme. β-Carotene can also go about as a lipid radical scavenger and as a single oxygen quencher (Grune et al. 2010). On the basis of dissemination of BCMO1 in tissues, β-carotene digestion occurs in a number of organs, including the skin (Lindqvist and Andersson 2004). β-Carotene is an efficient photoprotector, and it prevents UV-prompted erythema (Sies and Stahl 2004).

Astaxanthin (Fig. 8) is found in algae, yeast, shrimp, salmon, crustacea, trout, crawfish, and krill. Astaxanthin has impressive potential and promising applications in human well-being and nutrition (Hussein et al. 2006). It has an exceptional potential for ensuring protector life form against a number of diseases (Higuera-Ciapara et al. 2006). The UV defensive impact of algal extract is due to 14% of astaxanthin compared to engineered astaxanthin.

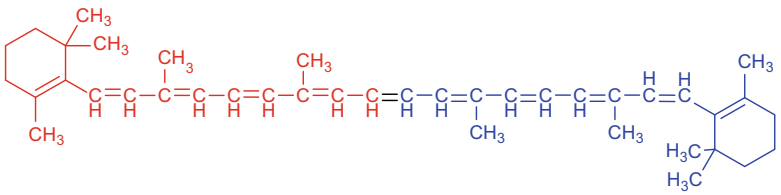

Fig. 7 β-Carotene

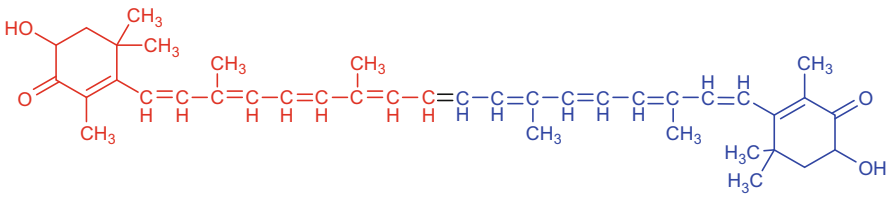

Fig. 8 Astaxanthin

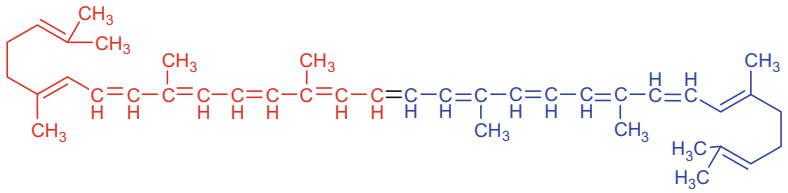

Fig. 9 Lycopene

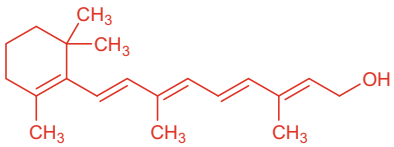

Fig. 10 Retinol

Preincubation with engineered astaxanthin or an algal extract could forestall UVA-induced changes in cell superoxide dismutase action and decline in cell glutathione content (Lyons and O'Brien 2002). Suganuma et al. (2010) showed that results of UVA radiation, such as skin wrinkling, can be prevented and minimized by topical or oral uses of astaxanthin.

Lycopene (Fig. 9) is a red carotene, carotenoid, and phytochemical present in red fruits and vegetables, tomatoes, and other red products such as papayas, red carrots, and watermelons (Schagen et al. 2012). In spite of the fact that lycopene is synthetically a carotene, lycopene has no vitamin A activity. It does however show strong tendencies as a single oxygen quencher (Evans and Johnson 2010). Some results indicate that lycopene and β-carotene protect the skin against sunburn by expanding the basal guard against UV light-intervened damage and their products are also known to be effective against cancer and in decreasing the activity of MMP-1, an enzyme that is responsible for the breakdown of collagen (Pohar et al. 2003; Etminan et al. 2004; Stahl et al. 2006; Stahl and Sies 2012).

Retinol (Fig. 10) is a fat-soluble vitamin consisting of isoprene units. Since it cannot be synthesized by the human body, it is necessary to fulfill the requirement of this vitamin by external sources (diet) such as with fatty fish, cheese, milk, egg yolks, etc. Its two derivatives, retinoic acid and retinaldehyde, are important for growth, helpful in reproduction, and responsible for epithelial tissues maintenance (Zouboulis et al. 2008). Retinaldehyde is also very important for vision and is produced in a reversible process by the oxidation of retinol.

Vitamin A applied topically has been shown to possess various counter actions against irregular pigmentation of skin aging and skin wrinkling. The effects of vitamin A and acid derivatives on bleaching agents and chemical peeling have been evaluated. The MMP-mediated and UV-induced collagen breakdown have been reduced by the treatment of topically applied retinoid (Fisher et al. 1997, 2000; Lee et al. 2012).

4 Concluding Remarks and Future Directions

Aging is a process that depends on many internal and external factors. Aging theories have linked aging with an excess of free radicals, an imbalance in diet and biological mutations. Nutraceuticals have been assumed to be a critical part of enhancing life span and helping the endogenous antioxidant framework, with antioxidant-containing items that are regularly present in the skin. A steady diet of antioxidant-rich products (vegetables, fruit, and wheat grains) has certain health properties, which can delay aging. The nutraceuticals lead to very few irrelevant symptoms in contrast with its significant impact on cell digestion. Nutraceuticals seem to hold a great promise to delay or combat aging process.

Nutraceuticals for Cognitive Dysfunction

Ramesh C. Gupta, Robin B. Doss, Ajay Srivastava, Rajiv Lall, and Anita Sinha

Abstract

With increasing age, humans and animals suffer from partial or complete loss of cognition and memory. As a result, quality of life declines significantly. Among many underlying mechanisms, a significant decline in the neurotransmitter acetylcholine (ACh), an increase in *N*-methyl-*D*-aspartate (NMDA), and oxidative stress are the most recognized events involved in cognition impairment, especially memory and learning. Like chronic neurodegenerative Alzheimer's disease (AD) in humans, canines and felines suffer from memory loss as they become older. Currently, for AD treatment in humans, an NMDA receptor antagonist memantine in combination with the acetylcholinesterase (AChE) inhibitor donepezil, rivastigmine, or galantamine appears to be the best option. A number of therapeutic drugs (selegiline, gabapentin, buspirone, memantine, etc.) are also available for treatment of canine cognition dysfunction (CCD)/cognitive dysfunction syndrome (CDS). A large number of plant extracts, their ingredients, and bioactive compounds of animal origin have been investigated for anticholinesterase (anti-ChE), antioxidative, anti-inflammatory, and immunomodulatory activities, as well as anti-Aβ aggregation and deposition in the brain. Some of these substances have also been shown to normalize the blood-brain barrier permeability and integrity, while others have been demonstrated to restore mitochondrial function. A small number of plant extracts have also shown MAO-B inhibitory property. Currently, demented dogs and cats are given nutraceuticals and/or a therapeutic diet to improve their cognition and memory. This chapter describes various nutraceuticals and substances that have potential to improve cognition and memory in senior dogs and cats.

Canine cognition dysfunction · Memory loss · Acetylcholine · Acetylcholinesterase · Butyrylcholinesterase · Anticholinesterase · Plant alkaloids · NMDA receptor antagonist · Oxidative stress

1 Introduction

Presently, like humans, dogs are also living longer because of better nutrition, environment, and veterinary care. As a result, a large population of dogs, often regarded as senior dogs, suffer from cognitive dysfunction and memory loss (Bain et al. 2001). Prevalence of cognitive dysfunction syndrome (CDS) is extremely high. According to a study of the University of California Davis, 28% of dogs aged 11–12 years and 68% of dogs aged 15–16 years showed one or more signs of cognitive impairment (Neilsen et al. 2001). The prevalence of CDS in cats was found to be 36% in a population of 11–21-year-old cats (Moffat and Landsberg 2003). CDS is underdiagnosed because caregivers may assume behavior changes are a result of normal aging, and veterinarians may not recognize the signs (Salvin et al. 2010). The brain is the most complex organ in the body, and as it ages, certain changes occur, such as (1) oxidative/nitrosative stress, (2) neuroinflammation, (3) decline in acetylcholine (ACh) level, (4) decrease in acetylcholinesterase (AChE) activity and increase in butyrylcholinesterase (BuChE) activity, (5) decrease in choline acetyltransferase (ChAT), (6) increase in *N*-methyl-*D*-aspartate (NMDA) receptors, and (7) microvascular changes (reviewed in Gupta and Dekundy 2005; Sadhukhan et al. 2018; Sen and Hongpaisan 2018; Seo et al. 2018). Although, neurodegenerative changes occur in many regions of the brain, in the context of memory, the

cerebral cortex and hippocampus are of particular importance. Accumulation of a neurotoxic $A\beta_{1-42}$ peptide and hyperphosphorylation of tau, leading to the formation of senile plaques and neurofibrillary tangles in the cortex and hippocampus, are the two pathological hallmarks of AD in humans and CDS in canines and felines.

Plant extracts have been known for a long time to contain a cholinesterase (ChE) inhibiting property. Physostigmine from *Physostigma venenosum* (Calabar bean) and galantamine from *Galanthus nivalis* (snowdrop) are the two most common examples of such plants. Essential oil-rich plants, which are also known to possess an anti-ChE property, have traditionally been used for memory enhancement in humans, and they can also be used for CDS in canines and felines (Orhan et al. 2009). In addition to anti-AChE, antioxidative, anti-inflammatory, and neuroprotective properties (Table 1), some plants have monoamine oxidase (MAO) inhibitory property (Mazzio et al. 2013). Nutraceuticals, such as cinnamon, curcumin, and berberine, can also attenuate β-amyloid and tau levels in brain regions. Recently, Marcelli et al. (2018) proposed an interesting intracellular molecular mechanism implied in AD pathophysiology called SUMOylation. Since there are no pharmacological treatments known to normalize SUMOylation/deSUMOylation equilibrium, some natural compounds are suggested for future convincing therapies. Extracts of many plants or their ingredients offer hope for prevention and/or treatment of cognition decline (Cicero et al. 2018; Momtaz et al. 2018).

Cognition impairment has also been improved by nutraceuticals of non-plant sources. For example, anchovy (*Coilia mystus*) has been shown to contain a peptide, anchovy protein hydrolysate (AHP), which can regulate AChE activity and can also exert antioxidative and neuroprotective properties (Zhao et al. 2017b). Major royal jelly protein 1 is reported to prevent cognition impairment (Chen et al. 2017; Lin et al. 2018). Melatonin from pineal gland appears to offer positive effect on cognitive decline and related anxiety and sleep-cycle disorders in senior dogs.

This chapter describes various options, such as plant extracts, bioactive compounds from invertebrates and vertebrates, and many other nutraceuticals for prevention and treatment of CDS in elderly canines and felines.

2 Canine Cognitive Dysfunction

Senior dogs, aged more than 8 years, can spontaneously develop neurodegenerative cerebral changes and associated impairment of cognitive function (Schütt et al. 2015). Canine cognitive dysfunction (CCD), or cognitive dysfunction syndrome (CDS) in dogs and cats (Landsberg et al. 2012; Vite and Head 2014) appears to be canine/feline counterpart of senile dementia of the Alzheimer's type (Rofina et al. 2006). Schütt et al. (2015) stated that the prevalence of CCD ranges from 14 to 35% in companion dogs more than 8 years of age, and the risk of developing CDS increases exponentially with increasing age (Azkona et al. 2009; Osella et al. 2007; Neilsen et al. 2001: Salvin et al. 2010, 2011). Changes in behavior and daily routines are considered the most important clinical markers of cognitive dysfunction in aged dogs and cats.

3 Pathophysiology

The cellular and molecular biology of memory is very complex (Kandel 2012). The brains of older dogs and cats may show several anatomic and physiologic changes (Vite and Head 2014; Seibert 2017). These changes may include a reduction in overall brain mass (including atrophy of cerebral cortex and basal ganglia), a reduction in the number of neurons, generalized gliosis, degeneration of white matter, demyelination, neuroaxonal degeneration, increase in ventricular size, meningeal fibrosis and calcification, and the presence of β-amyloid (Aβ) plaques. Functional changes occur, such as depletion of neurotransmitters (norepinephrine, serotonin, and dopamine), a decline in the cholinergic system, an increase in monoamine oxidase B activity, and a reduction of endogenous antioxidants (Landsberg and Araujo 2005; D'Amilio et al. 2018). Sechi et al. (2015) also observed a decrease in brain-derived neurotrophic factor (BDNF) in serum correlates with cognitive decline and deficits in LTP and memory. Other etiopathologic factor in cognitive decline is reported to be neuroinflammation through overactivation of microglia (Balducci and Forloni 2018).

3.1 Cholinergic System and Cognition

The cholinergic neurotransmission in the central nervous system (CNS) plays an important role in modulating cognitive processes, such as learning, memory, arousal and deep sleep as well as in modulating locomotor activity (Terry and Buccafusco 2006; Wevers 2011). In neurodegenerative disease, such as CDS or AD, a deficit of ACh and an increase in NMDA receptors and free radicals (oxidative stress) are major underlying modulations (Zhao and Zhao 2013).

3.2 Oxidative Stress, Neuroinflammation, and Neurodegeneration

The brain is very vulnerable to oxidative stress because of (1) high oxygen consumption (>20% of body's total oxygen), (2) high percentage of PUFAs, and (3) low antioxidant

capacity. In the aged brain, excess generation of free radicals activates glia/astrocytes and leads to neuroinflammation (Seo et al. 2018). Oxidative stress has also been implicated in Aβ- or tau-induced neurotoxicity. In addition, evidence suggests that oxidative stress may augment the production and aggregation of Aβ and facilitate the phosphorylation and polymerization of tau, thus forming a vicious cycle that promotes the initiation and progression of neurodegeneration and AD (Zhao and Zhao 2013).

3.3 Pathological Changes

Recently, Schmidt et al. (2015) described that the aged brain develops an abnormal Aβ deposition in brain parenchyma and the walls of the cerebral blood vessels. The prefrontal cortex is the first area affected, followed by the temporal cortex, the hippocampus, and the occipital cortex. These investigators further emphasized that regardless of position, the amount and extent of Aβ deposits correlates with the severity of cognitive impairment.

4 Diagnosis of Cognition Dysfunction

Changes in behavior and daily routines are considered the most important clinical markers of cognitive dysfunction in aged dogs (Schütt et al. 2015). These investigators measured the plasma concentration of both $A\beta_{1–40}$ and $A\beta_{1–42}$ and noted highest levels of $A\beta_{1–42}$ in canine cognition decline (CCD). Concentrations of plasma $A\beta_{1–40}$ and $A\beta_{1–42}$ and the $A\beta_{1–42}/A\beta_{1–40}$ ratio can be used as biomarkers of CCD. Interestingly, Schütt et al. (2015) stated that dogs with CCD are not as cognitively impaired as people with Alzheimer's disease (AD) and thus may correspond to early AD or the mild cognitive impairment (MCI) phase. Dogs with CCD commonly display specific clinical signs, such as aimless wandering, staring blankly into space, avoiding being petted, and difficulty with finding dropped food.

Veterinarians often make a diagnosis of CCD/CDS based on the acronym DISHA (*D*isorientation, *I*nteraction changes, *S*leep/wake cycle, *H*ouse soiling, *A*ctivity level changes) (Landsberg et al. 2003; Landsberg 2005). In brief, DISHA can be described as:

- *D*isorientation—changes in spatial awareness, loss of ability to navigate around familiar obstacles, and wandering behavior
- *I*nteraction changes—decreased interest in social interactions, petting, greetings, dependent or "clingy" behaviors
- *S*leep/wake cycle changes—restlessness or frequent walking during the night, increased sleep during daytime hours
- *H*ouse soiling—no longer lets owner know when it needs to go outside, indoor elimination, incontinence
- *A*ctivity level changes—decreased exploration and response to things, people, and sounds around the house, decreased grooming, decreased appetite, increased anxiety, including restlessness, agitation, and/or separation distress

In addition to clinical signs, veterinarians should examine dogs using the Canine Dementia Scale (CADES). CADES is a statistically validated, highly sensitive rating scale for canine CDS. The scale contains 17 nonredundant items, distributed across 4 relevant domains: (1) spatial orientation, (2) social interactions, (3) sleep-wake cycles, and (4) house soiling. Recently, Madaria et al. (2015) reported that dogs with mild cognitive impairment frequently had impaired social interactions, while dogs with moderate cognitive dysfunction had abnormal social interactions and sleep/wake cycles. Dogs with severe cognitive dysfunction exhibited impairment in all four domains. It is noteworthy that no dog with CCD may show all of these signs. For further details, readers are referred to Landsberg et al. (2012).

Recently, Hampel et al. (2018) described that a comprehensive "omics"-based biomarker may guide the exploration of spatiotemporal systems-wide morpho-functional shifts along the continuum of AD or CDS pathophysiology, from adaptation to irreversible failure. Biomarkers of AD in humans and CCD in dogs have been described in detail elsewhere (Galasko 2006; Schütt et al. 2015; Pitt and Leung 2018).

5 Prevention and Treatment of Cognitive Dysfunction

5.1 Plants Extracts and Their Ingredients

A large number of plants and their ingredients have been found to possess AChE and/or BuChE inhibitory properties to treat AD in humans (Trevisan et al. 2003) and CDS in animals (unpublished). Many plants, in addition to ChE inhibitory property, have antioxidative, anti-inflammatory, immunomodulatory, anti-β amyloid deposition, and many other properties, thereby normalizing neurotransmitter levels and improving cognition and learning memory in canines and felines. Some important plants are discussed here in brief and along with these, the rest are listed in Table 1.

5.1.1 *Polygonum hydropiper L.*

Ayaz et al. (2015) analyzed the essential oils of flowers and leaves of *Polygonum hydropiper* L. and found caryophyllene as the major component in flowers and

Table 1 Plant extracts/nutraceuticals with potential for directly or indirectly improving cognition and memory

Plant extract/nutraceutical	Pharmacological/ biological constituents	Biological/pharmacological activities	References
Angelica archangelica	Imperatorin and xanthotoxin	AChE inhibitory	Sigurdsson and Gudbjarnason (2007)

Aristotelia chilensis	F5	AChE, BuChE, and tyrosinase inhibitory	Cespedes et al. (2017)
Artemisia dracunculus (essential oil)	Estragole	AChE inhibitory	Dohi et al. (2009)
Ascorbic acid	Ascorbic acid	Antioxidative, anti-proteolytic, and anti-apoptotic	Olajide et al. (2017)
Asparagus cochinchinensis	Flavonoids, phenols, saponins, and protodioscin	Antioxidative, increased release of nerve growth factor, AChE inhibitory, and decreased $A\beta_{1\text{-}42}$ peptide production and deposition	Lee et al. (2018)
Bacopa Monnieri (Brahmi)	Bacopasides	AChE inhibitory, antioxidative, neuroprotective	Das et al. (2002) and Zhang et al. (2009)
Berberine (*Berberis vulgaris*, *B. aristata*, *B. aquifolium*, *Coptis chinensis*, *Hydrastis canadensis*) Protoberberine (*Stephania venosa*)	Berberine and berberine metabolites (thalifendine, berberrubine, and jatrorrhizine), protoberberines (stepharanine, cyclanoline, and *N*-methyl stepholidine)	AChE inhibitory, antioxidative, anti-inflammatory, immunomodulatory, neuroprotective, analgesic, Aβ42 inhibitor, and improved cognition and memory	Ingkaninan et al. (2006), Zhu and Qian (2006), Kulkarni and Dhir (2008, 2010), Asai et al. (2007), Kumar et al. (2015), Cai et al. (2016), and Hussein et al. (2018)
Cannabis sativa (hemp seed)	Lignanamides (cannabisin M, cannabisin N, cannabisin O, and 3,3-dimethyl-heliotropamide)	AChE inhibitory and antioxidative	Yan et al. (2015) and Hartsel et al. (2016)
Cashew nut shell liquid (*Anacardium occidentale*)	Anacardic acids	Anti-Alzheimer's disease	Filho et al. (2018)
Cinnamomum verum, C. tamale	Polyphenols, cinnamaldehyde	Anti-tau protein and Aβ aggregation, anti-Alzheimer's disease, and antidiabetes	Momtaz et al. (2018)
Curcumin/turmeric (*Curcuma longa*)	Curcumin, demethoxycurcumin, and bisdemethoxycurcumin	Anti-inflammatory, anti-neuroinflammatory, antioxidative, cytoprotective, prevents Aβ aggregation, and prevents memory impairment	Maheshwari et al. (2006), Chen (2006), Javeri and Chand (2016), Risuleo (2016), Sadhukhan et al. (2018), and Sorrenti et al. (2018)
Cyclotrichium niveum (essential oil)	Isomenthone and pulegone	AChE inhibitory and antioxidative	Orhan et al. (2009)
Elatostema papillosum	Phenolics and flavonoids	AChE and BuChE inhibitory, free radical scavenging, and antioxidative	Reza et al. (2018)
Eugenia dysenterica (cagaita)	Not yet identified	AChE inhibitory	Gasca et al. (2017)
Garcinia madruno	Morelloflavone, volkensiflavone, fukugiside, and amentoflavone	Reduced Aβ peptides deposition in the brain and improved learning	Sabogal-Guaqueta et al. (2018)
Ginkgo biloba	Ginkgolide A, B, and C, bilobalide, ginkgolic acid, and flavonoids (quercetin)	Inhibits Aβ-induced apoptosis in the hippocampus via upregulation of BDNF, neuroprotective, AChE inhibitory, enhances mitochondrial metabolism and ATP production, anti-platelet-activating factor, and cognition and memory enhancement	Das et al. (2002), Dugoua et al. (2006), Reichling et al. (2006), Nagahara et al. (2009), Xiao et al. (2010), Ihl et al. (2011), Islam et al. (2013), Mohanta et al. (2014) and Dziwenka, and Coppock (2016)
Ginseng	Ginsenosides	Decreasing oxidative stress, upregulating plasticity-related proteins in the hippocampus, anti-inflammatory, immunomodulatory, neuroprotective, and improve cognition and memory	Zhao et al. (2009), Li et al. (2015), and Peng et al. (2018)

(continued)

Table 1 (continued)

Plant extract/nutraceutical	Pharmacological/ biological constituents	Biological/pharmacological activities	References
Green tea (*Camellia sinensis*)	(−)-epigallocatechin-3-gallate	Prevents spatial learning and memory impairment by decreasing Aβ1-42 oligomers and upregulating synaptic plasticity proteins in the hippocampus	Li et al. (2009) and Coppock and Dziwenka (2016)
Highbush blueberry (*Vaccinium corymbosum* L.)	Flavonoids	Activation of BDNF/CREB/AKT signaling	Hong et al. (2017)
Inula graveolens (Essential oil)	Bornyl acetate and borneol	AChE inhibitory	Dohi et al. (2009)
Monsonia angustifolia	Justicidin A	Decreased Aβ formation, neuroprotective, and anti-autophagy	Gu et al. (2016) and Chun et al. (2017)
Mutellina purpurea	Pteryxin	BuChE inhibitory	Orhan et al. (2017)
Norea micrantha	Not yet identified	AChE and BuChE inhibitory and antioxidative	Imran et al. (2017)
Polygonum hydropiper L. (essential oil)	Caryophyllene oxide and decahydronaphthalene	AChE and BuChE inhibitory and antioxidative	Ayaz et al. (2015)
Piper hispidinervum (essential oil)	Asaricin	AChE inhibitory	Xiang et al. (2017)
N-3 PUFA	N-3 PUFA	Prevents Aβ-induced depression	Morgese et al. (2018)
Quercetin	Quercetin	Antioxidative, anti-inflammatory, AChE inhibitory, neuroprotective, mitoprotective, reduced Aβ peptide in the brain, and improves cognition and memory	Ay et al. (2016), Dziwenka and Coppock (2016), Islam et al. (2013), Sabogal-Guaqueta et al. (2015), and Teodoro et al. (2016)
Resveratrol	Resveratrol	Antioxidative, anti-inflammatory, increases mitochondrial function, neuroprotective, and prevents memory loss	Marambaud et al. (2005), Porquet et al. (2014), Risuleo (2016), Teodoro et al. (2016), and Sadhukhan et al. (2018)
Rosmarinic acid	Rosmarinic acid	Antioxidative, anti-β-amyloid, neuroprotective, and anti-Alzheimer's disease	Zhang et al. (2016) and Rong et al. (2018)
Safflower seed oil cake (*Carthamus tinctorius* L.)	(+/−)-carthatins A-F (1-6, respectively)	AChE inhibitory	Peng et al. (2017)
Saffron (*Crocus sativus*)	Picrocrocin, crocin, crocetin, dimethylcrocetin, and safranal	AChE inhibitory, antinociceptive, antidepressant, anxiolytic, anti-inflammatory, antioxidative, anti-amyloidogenic, and prevention of cognition and memory impairment	Ghadrdoost et al. (2011), Geromichalos et al. (2012), Ghaffari et al. (2015) and Adalier, and Parker (2016)
Salvia lavandulaefolia	1,8-cineol, and α-pinene	AChE inhibitory	Perry et al. (2000, 2003)
Senna multijuga	7′-Multijuguinone and 12′-hydroxy-7′-multijuguinone	AChE inhibitory	Serrano et al. (2010)
Soybean (*Glycine max* L.)	Di- and tripeptides, isoflavone, genistein	Increased neurotrophic factors (BDNF), normetanephrine, and noradrenaline and prevented cognitive impairment. Genistein alleviates Aβ-induced inflammation through toll-like receptor 4/NF-κB	Ding et al. (2013), Maebuchi et al. (2013), Katayama et al. (2014), Ma et al. (2015), and Imai et al. (2017)
Taurine	Taurine	Improves learning and retention	El Idrissi (2008)
Withania somnifera	Sitoindosides VII-X, withanolides, glycowithanolides, withanoside I, withanolide sulfoxide	Antioxidative, anti-inflammatory, immunomodulatory, antiaging, AChE inhibitory	Bhattacharya et al. (1995, 1997), Schliebs et al. (1997), Choudhary et al. (2004), Kuboyama et al. (2006), and Bharti et al. (2016)
Zephyranthes carinata	3-Epimacronine and lycoramine	AChE inhibitory	Cortes et al. (2015)

Abbreviations: *AChE* acetylcholinesterase, *BuChE* butyrylcholinesterase, *BDNF* brain-derived neurotrophic factor

decahydronaphthalene in leaves. In an in vitro study, these compounds exhibited dose-dependent ChE inhibitory and antioxidant activities, with these being higher in leaves than in flowers (Ayaz et al. 2015). IC_{50} values for AChE inhibition by essential oils from leaves and flowers were reported to be 120 and 220 μg/mL, respectively; and for BuChE inhibition were 130 and 225 μg/mL, respectively.

5.1.2 Piper Species

The essential oils derived from certain piper species (*Piper austrosinense*, *P. puberulum*, *P. flaviflorum*, *P. betle*, and *P. hispidinervum*) showed strong AChE inhibitory activity with IC_{50} values in the range of 1.51–13.9 mg/mL. The most active essential oil from *P. hispidinervum* contained a potent bioactive compound, asaricin, with an IC_{50} value of 0.44±0.02 mg/mL against AChE, comparable to galantamine with an IC_{50} 0.15±0.01 mg/mL (Xiang et al. 2017). The study suggested that the piper essential oils may be a good natural product source for compounds with therapeutic potential for AD or other CNS diseases. The possibility also exists that the oil can be used against CCD/CDS.

5.1.3 *Angelica archangelica* and *Geranium sylvaticum*

Sigurdsson and Gudbjarnason (2007) screened several Icelandic medicinal plants for AChE-inhibiting property. Ethanolic extracts of *Angelica archangelica* seeds and the aerial parts of *Geranium sylvaticum* proved to be effective with IC_{50} values of 2.2 mg/mL and 3.56 mg/mL, respectively. Analysis of *A. archangelica* extract revealed the presence of two major active principles (imperatorin and xanthotoxin), with xanthotoxin being more potent than imperatorin, with IC_{50} value of 155 μg/mL (0.72 mM) and 274 μg/mL (1.01 mM), respectively. Interestingly, Sigurdsson and Gudbjarnason (2007) found a synergistic interaction between the extract of *A. archangelica* and *G. sylvaticum* for anticholinesterase activity.

5.1.4 *Bacopa monnieri*

Bacopa monnieri, often called "Brahmi" meaning Creator, is a small creeping herb commonly found in marshy areas throughout India. The major active ingredients in Brahmi are steroidal saponins called bacopasides. In humans, they are used for many CNS disorders, such as cognitive dysfunction, epilepsy, seizures, anxiety, and depression. In humans, Brahmi has been found to improve the speed of visual information processing and spatial working memory accuracy, as well as reducing subjective anxiety levels (Stough et al. 2001; Morgan and Stevens 2010). It has been mentioned that bacopasides cross the BBB via lipid-mediated free diffusion due to their hydrophobic nature and effects on brain health and function; however there is no definitive evidence to support this fact (Pitt and Leung 2016). In in vitro and experimental studies, Brahmi has been reported to improve cognition by multiple mechanisms, such as its antioxidative, anti-lipid peroxidation, and neuroprotective properties, and by prevention of cell death (Limpeanchob et al. 2008; Hosmani 2009; Saini et al. 2012; Velaga et al. 2014; Le et al. 2015). In addition, Brahmi has been reported to provide neuroprotective and memory-restoring effects due to the ability of bacopasides to alter Ca^{2+} dynamics in smooth muscle cells inducing vasodilation (Kamkaew et al. 2011), thereby providing more oxygen and glucose (reviewed in Pitt and Leung 2016). Furthermore, the levels of neurotransmitters (serotonin, ACh, GABA, and glutamate) are reported to be elevated in the hippocampus of rats fed Brahmi, which appears to facilitate neuronal activity and synaptic signaling (Ranjan et al. 2011). In an in vitro study, Das et al. (2002) also demonstrated that *B. monnieri* extract exerted anti-ChE activity in mice.

In an experimental study, Piyabhan et al. (2016) demonstrated that treatment with Brahmi prior to phencyclidine (PCP, 2 mg/kg, ip, twice a day) prevented cognitive impairment by elevating vesicular glutamate transporter 3 (VGLUT3) in the prefrontal cortex (PFC), striatum, and hippocampus (CA1-3 sectors) of rats. Rats receiving Brahmi after PCP treatment restored cognitive deficit by increasing VGLUT3 in the PFC and striatum. Findings of this study and others suggest that Brahmi could be a new frontier of prevention and restoration of cognitive deficit associated with AD, PD, or schizophrenia.

The recommended dose of *B. monnieri* extract in dogs and cats is 250 mg and 100 mg/day, respectively.

5.1.5 *Curcuma longa* (Turmeric/Curcumin)

The root of *Curcuma longa* contains turmeric, which is composed of a number of compounds called curcuminoids. The main curcuminoids are curcumin, demethoxycurcumin, and bisdemethoxycurcumin. Turmeric has been used for thousands of years to heal humans and animals from a number of illnesses. Currently, curcumin is commonly used to prevent or treat diseases, such as pain, cancer, stroke, AD, epilepsy, depression, obesity, diabetes, and metabolic disorders (Javeri and Chand 2016). Many studies evidenced curcumin's anti-inflammatory action exerted via the activation of transcription factors such as NF-κB and AP-1, and its antioxidative as well as cytoprotective properties (Chen et al. 2006; Maheshwari et al. 2006; Risuleo 2016).

It is documented that low-dose (~50 mg/day) long-term use of curcumin may delay or halt the onset of cognitive impairment in the early stages of AD (Chandra et al. 2001; Hamaguchi et al. 2010). Lim et al. (2001) reported that low-dose curcumin feeding (160 ppm in feed) for 6 months in aged transgenic AD mice was found to reduce astrocytic marker glial fibrillary acidic protein (GAFP), insoluble Aβ, and soluble Aβ, with a 43–50% decrease in plaque level.

Curcumin has also been shown to bind to Aβ and increase brain clearance of Aβ in mouse models of AD and disaggregated fibrillary $A\beta_{40}$ in in vitro studies (Lim et al. 2001; Garcia-Alloza et al. 2007). In in vivo studies, aged transgenic 2576 mice with advanced amyloid accumulation fed curcumin (500 ppm in feed) for 5 months reduced the levels of amyloid and plaques. Findings of these studies and others demonstrated that curcumin crosses the BBB despite the low dose and poor bioavailability (reviewed in Javeri and Chand 2016; Sorrenti et al. 2018).

In experimental studies, high doses of systemically injected lipopolysaccharide (5–10 mg/kg) have been extensively used to study the interaction between peripheral inflammation and neurodegenerative disorders. Peripheral LPS induces synthesis of proinflammatory mediators in the brain, resulting in a variety of central effects, including synaptic dysfunction, neuronal cell degeneration, and cognitive impairment (Qin et al. 2007, 2013). Recently, Sorrenti et al. (2018) demonstrated that curcumin (50 mg/kg) administered orally for two consecutive days prior to a single ip injection of a high dose of LPS (5 mg/kg) in young adult mice prevented the immune response, neuroinflammation, and memory impairment. Additionally, short-term treatment with curcumin, administered at the time of LPS challenge, anticipated the recovery from memory impairments observed 1 month after the inflammatory stimulus, when mice had completely recovered from the acute neuroinflammation. Findings of this investigation suggested that the preventive effect of curcumin in inhibiting the acute effects of neuroinflammation could be of value in reducing the long-term consequences of brain inflammation, cognitive deficits, and memory dysfunction.

Curcumin appears to be a highly promising nutraceutical for prevention and treatment of cognition impairment in canines and felines.

5.1.6 Ginseng

Ginseng is the root of plants (genus *Panax*), including Chinese ginseng (*P. notoginseng*), Japanese ginseng (*P. japonica*), Korean ginseng (*P. ginseng*), Vietnamese ginseng (*P. vietnamensis*), and American ginseng (*P. quinquefolius*). Ginseng is cultivated or grown in mountainous regions (wild) and mainly produced in China, South Korea, the United States, and Canada. The root extract contains many active ingredients, called ginsenosides (ginseng saponins). The content of ginsenosides differs in the different species of ginseng as well as in the different parts of the plant. The total amount of dammarane-type saponins in *P. notoginseng* is reported to be greater than in *P. ginseng* or *P. quinquefolius* (Peng et al. 2018). Dammarane-type saponins can be divided into two groups: protopanaxadiol and protopanaxatriol. A large number of ginsenosides have been identified in *P. ginseng* (Choi 2008; Yang and Wu 2016) and in *P. notoginseng* (Peng et al. 2018). The efficacy of *P. ginseng* on the brain and nervous system has been investigated in several studies (reviewed in Yang and Wu 2016). Ginsenosides do not readily cross the BBB, and only trace amounts can be detected in the brain after oral administration. However, metabolites of ginsenosides cross the BBB and produce direct effects on neuronal cells (reviewed in Pitt and Leung 2016).

In general, *P. ginseng* is considered to be a stimulant to cognition. Xing et al. (2008) reviewed animal study data and reported that ginsenosides Rb1, Rc, Rg1, Rg2, and Rg3 had effects on the CNS. Both ginsenosides Rg1 and Rb1 enhanced activities of the CNS, whereas ginsenoside Rb1 had a much weaker potency. The improvement of cognition was attributed to the higher ratio of ginsenoside Rg1/Rb1 (Chen et al. 2008). Liu et al. (2011) found that ginsenoside Rb1 improved cognitive function and the survival of newborn hippocampal neurons in adult rats due to its anti-stress effects. Ginsenosides Rg1 and Rb1 also helped to facilitate acquisition and retrieval of memory (Wee et al. 2011). Furthermore, ginsenoside Rg1, Rg3, and Re were found to reduce β-amyloid peptide in animal brains following a single dose (Chen et al. 2006).

Ginsenoside-Rh1has been reported to activate estrogen receptor (ER)-dependent gene expression (Lee et al. 2003), and ER activity is correlated with memory function. At the cellular level, ER activity promotes many memory-associated changes, including increases in dendritic spine density, NMDA receptor expression, and long-term potentiation (LTP) magnitude (Smith and McMahon 2005). Many clinical trials have been conducted in healthy as well as in cognitively impaired patients. In some studies, ginseng was found to provide improvements in cognition and memory, while in other studies, very little or no effect (Attele et al. 1999; Kennedy et al. 2001; Scholey and Kennedy 2002; Xing et al. 2008; Kim et al. 2015; Asian ginseng 2016). Ginseng has been used in pets for a number of years to treat several diseases (Addison's disease, congestive heart failure, diabetes mellitus, chronic low-grade hepatitis) and improve cognition and memory, but no controlled clinical trials are reported in canines or felines.

5.1.7 *Ginkgo biloba*

The *Ginkgo biloba* is believed to be the world's oldest living tree, dating back to more than 250 million years ago. It grows in many countries, including Asia, North America, Europe, New Zealand, and Argentina. *G. biloba* is one of the most popular nutraceuticals used in the United States and Europe. Its extract or its active ingredient(s) has been used for thousands of years in a number of diseases. *G. biloba* leaf extract consists of terpene trilactones (ginkgolides A, B, and C and bilobalide), ginkgolic acid, and flavonoid glycosides (quercetin, kaempferol, and isorhamnetin) (Wang et al. 2014).

Gurley et al. (2012) described its therapeutic use for insufficient blood flow, memory deficits, cognitive disorders, AD, depression, vertigo, tinnitus, and intermittent claudication. In humans, *G. biloba* has been indicated for memory enhancement (Dugoua et al. 2006). The WHO has accepted the standardized extracts such as EGb 761 and Li 1370 as anti-dementia drugs based on the in vitro and in vivo pharmacological studies and the numerous clinical studies supporting the efficacy of EGb 761 in the CNS when taking a 240-mg daily dose.

Pharmacological and pharmacokinetic studies suggest that the target of EGb 761 is the CNS (Ude et al. 2013). It can improve cerebral blood flow by 50–100%, increase glucose uptake and utilization, reduce corticosteroid production, and improve mitochondrial metabolism and ATP production, as well as affect intracellular and extracellular ionic gradients (reviewed in Dziwenka and Coppock 2016). EGb 761 has also been shown to reduce cognitive dysfunction in a model of vascular dysfunction in gerbils. The study showed a significant recovery of spatial memory with regular postischemic treatment (Mohanta et al. 2014).

In a number of clinical trials, EGb proved to improve cognition and memory (Lebars et al. 1997; Ihl et al. 2011; Garvilova et al. 2014). In a double-blinded clinical study, mild to moderate AD patients received EGb 761 (240 mg) or placebo daily for 24 weeks. EGb 761-treated patients improved significantly when evaluated on the Short Cognitive Performance Test (Syndrome Kurz Test, SKT) and the Neuropsychiatric Inventory (NPI) test (Ihl et al. 2011). In a similar study, Garvilova et al. (2014) reported that EGb 761 improved neuropsychiatric symptoms and cognitive performance with mild cognitive impairment (MCI). However, in some clinical trials, no difference was found between *G. biloba* and placebo groups.

G. biloba can protect neuronal damage by its direct action on neurons or indirectly by increasing blood flow and antioxidant action (Chan et al. 2007). DeFeudis and Drieu (2000) demonstrated that the high concentrations of EG 761enhanced the uptake of radiolabeled norepinephrine, dopamine, and 5-HT into the synaptosomes of the rat brain. EGb 761 influences the neuromodulation of adrenergic neurotransmission, and this could explain the positive effect on cognition seen in mice and humans. In vivo studies in mice revealed that in EGb 761 extract, terpenoids act by decreasing the generation of free radicals, and flavonoids act by scavenging the free radicals (DeFeudis and Drieu 2000). In addition to anti-apoptotic effect, ginkgolides and bilobalide in EGb 761 protect mitochondria from age-related damage and to improve mitochondrial function and energy metabolism (reviewed in Dziwenka and Coppock 2016). The two proposed mechanisms for mitochondrial protection are (1) inhibition of platelet-activating factor (PAF) at the PAF receptor and (2) blockage of glycine-activated chloride channels in glycine receptors in hippocampal neurons (Ude et al. 2013). Ginkgolide B is proven to be the most potent mitochondrial protectant. In an in vitro study, *G. biloba* extract also exerted anticholinesterase activity in mice (Das et al. 2002).

In canines, *G. biloba* products are indicated in health conditions, such as cognition/memory impairment, depression, anxiety, and tinnitus. In an open clinical trial, Ginkgo leaf extract was administered to 42 elderly dogs at a daily dose of 40 mg/10 kg body wt for 8 weeks (Reichling et al. 2006). The findings revealed that the Ginkgo leaf extract appears to be an efficacious agent that provides a safe dietary supplement for the elderly dogs with age-related behavioral disturbances. *G. biloba* has been included in Senilife®, which is indicated for canines with cognitive dysfunction, but due to limited evidence, it offers weak anti-dementic effect. Senilife® also contains resveratrol, which lacks scientific evidence to support that it improves cognition or memory.

5.1.8 *Crocus sativus* L. (Saffron)

Saffron, commonly referred to as "Red Gold," frequently used spice, has been identified as a memory-enhancing agent (Adalier and Parker 2016). Saffron possesses bioactive compounds (crocin, crocetin, dimethylcrocetin, and safranal), which may exert antioxidative, anti-inflammatory, antinociceptive, anti-ChE, and anti-amyloidogenic activities. Geromichalos et al. (2012) reported the AChE inhibitory activities of crocetin, dimethylcrocetin, and safranal with IC_{50} values of 96.33, 107.1, and 21.09 μM, respectively. Kinetic analysis showed that safranal interacts only with the binding site of AChE, but crocetin and dimethylcrocetin bind simultaneously to the catalytic and peripheral anionic sites. Papandreou et al. (2006) unraveled the underlying mechanism of saffron in AD as antioxidative and the inhibitory activity on Aβ aggregation. *Trans*-crocin-4 (the digentibiosyl ester of crocetin) was found to be the most potent compared to other constituents in saffron. Due to these properties, saffron has been found to be very effective in cognitive impairment and AD (Ghadrdoost et al. 2011; Geromichalos et al. 2012; Ghaffari et al. 2015). In a clinical study, patients receiving 15 mg saffron extract twice daily for 22 weeks had a better outcome on cognitive functions than the placebo group (Akhondzadeh et al. 2010). In another clinical trial, saffron was found to be as effective as donepezil in treatment of mild to moderate AD patients (reviewed in Adalier and Parker 2016). No clinical trials have been reported on saffron in CCD/CDS.

5.1.9 *Monsonia angustifolia*

Monsonia angustifolia is an indigenous vegetable to Tanzania, and it has several bioactive compounds, such as justicidin A, 5-methoxyjusticidin A, chinensinaphthol, retrochinensinaphthol methyl ether, and suchilactone. Among these compounds, justicidin A has been found to possess a neuroprotective property. Gu et al. (2016) reported

that justicidin A protects SH-SY5Y cells from $A\beta_{25–35}$-induced neuronal cell death through inhibition of hyperphosphorylation of tau and induction of autophagy via regulation of the activity of GSK-3β and AMPK and also provided some insights into the relationship between tau protein hyperphosphorylation and autophagy. Chun et al. (2017) investigated the effect of ethanol extract of *M. angustifolia* on Aβ production and spatial learning ability as protection against AD. In an in vitro study, the formation of Aβ peptides was significantly reduced in HeLa cells. In an in vivo study, Tg2576 mice were treated with *M. angustifolia* extract for 6 months and then subjected to a Morris water maze and a novel object recognition test. Findings revealed that the treated mice showed ameliorated behavioral deficits of the AD transgenic mice and reduced levels of insoluble Aβ42 in the cerebral cortex and hippocampus. Justicidin A significantly decreased the formation of Aβ in APPsw-transfected cells. These studies suggest that *M. angustifolia* extract or justicidin A have the potential to be developed as a treatment of AD in humans and CDS in canines and felines.

5.1.10 Berberine-Containing Plants

Berberine (BBR), a nonbasic, quaternary benzylisoquinoline alkaloid, can be obtained from a number of plants (*Berberis vulgaris*, *B. aristata*, *B. aquifolium*, *Hydrastis canadensis*, *Coptis chinensis*, *Argemone mexicana*, and others). Currently, BBR is also available in the synthesized form (BBR chloride and BBR sulfate). BBR derived from plants is found to be of high potency and safer than the synthesized form. For thousands of years, BBR-containing plant extracts have been used in many health conditions, including diabetes, hyperlipidemia, hypertension, ischemic stroke, microbial diarrhea, cancer, etc. In a number of reports, the BBR alkaloid has been indicated in neurological diseases, such as AD, PD, anxiety, depression, and epilepsy (Peng et al. 2004; Yoo et al. 2006; Zhu and Qian 2006; Peng et al. 2007; Kulkarni and Dhir 2008, 2010; Ye et al. 2009; Kumar et al. 2015).
