Preface

Before I introduce *The Handbook of Eating and Drinking: Interdisciplinary Perspectives*, let me explain why we need another book on food and eating. There are already so many books on food, especially cookbooks and travel books. There are also many scientific and technical books on subjects surrounding food, including food science, food technology, biology, physiology, nutrition, dietetics, social sciences, and many others. There are also books on the history of food and philosophical approaches to food and eating including ethics. And there are many books on the issues involved in serving food and on culinary applications.

However, there are fewer books examining the acts of eating and drinking, bringing food and beverage in contact with people, and in context with people. Thus, this Handbook differs from many other books because it is not aimed at eating and drinking in isolation nor at food and drink separate from the people who are consuming them.

In addition to this different perspective on eating and drinking, this Handbook is aimed at combining in *one place* all of the various fields that deal with eating and drinking. This includes technical and scientific subjects such as biology, nutrition, social science, etc. It also includes applied subjects such as food service, culinary arts, and business/marketing. It also includes non-technical subjects like the history and philosophy of eating/drinking.

Why is it important to combine all of these fields into one book? Why has this never been done before? First, it is important because the solutions to most problems of eating and drinking involve many disciplines. We slowly have learned this over the past decades. Dieting for better health involves knowledge of food chemistry, social sciences, nutrition, cultural food choices, food pathologies, and probably others. If we want to address dieting in specific population groups, we might need to get into ethics, culinary approaches, and food service approaches. Providing for undernourished populations in the developing world and undernourished parts of the developed world involves some of these same approaches, as well as others. We cannot solve the varied problems of eating and drinking without understanding the complexity of eating and drinking.

That is another reason why it is important to combine all of the relevant fields of inquiry into one book. People who want an overview of the component fields of eating and drinking need a place to find comprehensive knowledge across these fields. So too, professionals who work in one field need up-to-date reviews of the state of the other fields in eating and drinking. One cannot expect either laypeople or professionals to read individual textbooks in each subject area of interest.

The Handbook of Eating and Drinking: Interdisciplinary Perspectives presents over 70 chapters in 15 areas of eating and drinking. The book begins with an historical perspective and ends with perspectives on what may lie ahead in eating and drinking. The Handbook is not a static view of each field; rather chapters will be updated, replaced online, and then published when new editions are released. Also new topics will be added over time. The goal is to keep the Handbook updated with progress in the fields as they grow. The Handbook will be a living book.

I hope you will benefit from this first-time presentation of this very broad view of eating and drinking, both in your personal approach to eating and drinking and in your professional pursuits as they relate to this important topic.

I am pleased to acknowledge the support of the following individuals:

1. For support in launching the Handbook: Morgan Ryan, Senior Editor, Behavioral Science, New York
2. For continued enthusiasm and advice: Michael Hermann, Executive Editor, Major Reference Works, New York
3. For detail work in completing the chapters involving communication with authors and Editor: Juby George, Editor, Major Reference Works, New Delhi
4. For detail work in editing the chapters with authors: Leo Mosquline, Project Manager, SPi Global – Content Solutions

About the Editor

Dr. Herbert L. Meiselman is an internationally known expert in sensory and consumer research on food, food product development, and food service. He received his training in Psychology and Biology at the University of Chicago, University of Massachusetts, and Cornell University. Dr. Meiselman retired as Senior Research Scientist at Natick Laboratories where he was the highest-ranking Research Psychologist in the United States government. His accomplishments were recognized with a 2005 Award from the President of the United States. Dr. Meiselman has served in Editorial roles for *Food Quality and Preference*, *Journal of Foodservice*, and *Appetite*. His current interests include the effects of context/environment, emotion, wellness, psychographics, and meals and menus. He edited a large volume on *Emotion Measurement* in 2016 (2nd edition expected 2021) and published an edited volume on *Context: The Effects of Environment on Product Design and Evaluation* in 2019. Dr. Meiselman is the author of over 190 research papers and 6 books. Dr. Meiselman has worked in a broad range of fields related to eating and drinking: basic academic research, food product development, institutional food service design and evaluation including hospitals and military, fine dining food service, health and wellness, culinary evaluation, and an historical approach to meals. He has served as President of the Research Committee of the Institut Paul Bocuse, Lyon, France, and also served on the Research Committee for the Culinary Institute of America, Hyde Park, New York, and the food service program at Orebro

University, Sweden. Dr. Meiselman has served as Visiting Professor at Bournemouth University, UK; Reading University, UK; and Orebro University, Sweden; he is currently an Adjunct Visiting Professor at Charles Sturt University, Australia.

H. L. Meiselman (ed.), *Handbook of Eating and Drinking*,
https://doi.org/10.1007/978-3-030-14504-0_161

Abstract

This chapter presents a history of human-centered product research including product design and product evaluation. The chapter begins with the world of food business in the early 1900s and moves through a variety of themes and disciplines, including the period of testing for quality, the reign of the "golden palate," the emergence of descriptive analysis, and the growth of psychophysical thinking. The chapter traces the history of this field up until the growth of modern methods beginning in the 1970s. The chapter shows the approaches, some of the early research pioneers, some of the types of results obtained, an analysis of "whys" behind the themes, and the controversies based on intellectual histories.

Historical Background: The Early Twentieth Century

If one were to look at the way products are developed today, one might think that statistics, modeling, professional expertise, and a strong intellectual heritage have been in play for decades. Most food companies, worldwide, subscribe to the now widely held belief that to design foods requires a knowledge of the consumer, a talent in the creation of tasty mixtures, and a profound understanding of trends, all together collaborating to make today's test products become tomorrow's massive successes. One cannot help but be impressed by the talents involved, whether one refer to expert panels (e.g., Caul 1957), to statistical texts (Box et al. 2005), to consultants specializing in new product design, or to trends monitoring which drive the development of new foods (Costa and Jongen 2006).

This review covers the various *Zeitgeists* (*German term literally meaning "spirit of the time"*), in the history of human-centered research, including both product design and product evaluation, beginning with the "golden palate," and moving to today, with the plethora of product offerings, the paradox of choice, the change in the nature of expertise, and recently the focus on low cost testing.

A Century Ago or Even Earlier: Before Consumers

If one wants to understand how today is so different, then one can go back a century or more, to a time when the packaged goods industry for foods was just developing (► Chap. 57, "Measuring Meaning of Food in Life" by Ruffieux in this volume also discusses this early period). The time was decades just before the turn of the century to some 10 or 15 years after World War I. Those with a penchant for photographic history are treated to the myriad photographs of the stores those days, the corner grocers, often weighing out the product, in a way that can be still seen when one goes to some stores or to farmer's markets. The shopper could buy some packaged goods, but there were few supermarkets, and even fewer, if any, elaborate food halls in the way we now know. Of course, big cities had big food markets even years ago, to entice shoppers and make the effort easy and social. The storekeeper might offer the customer a taste of the product before purchase, a delightful custom which remains today, but today's in-store tastings are now efficient affairs, with companies specializing in in-store demonstrations and tastings.

Nonetheless, in such a world product development proceeded with commercial products like Kellogg's Corn Flakes (started 1906) and Campbell Soup Company (started 1869, condensed soups 1896–1897), along with other iconic companies and brands. The world of iconic brands stretched all over Europe, from Twinings and Cadbury in the UK to Liebig in Germany and so forth. The focus was on the one product to sell, not on the paradox of choice driven by a plethora of products which occupy the shelf in a marketing war, so-called facings, each item being a different size of the basic product, a different flavor, and so forth, all designed to proclaim "Buy Me," and grab the customer's last money.

The Early Days, Product Quality, Statisticians, and Statistical Tests

Quality Control and the Rise of Subjective Testing

In the 1930s and 1940s, product design was just a gleam in the mind of some forward thinkers. The notion that one could formalize product design using subjective perceptions was new and only infrequently recognized, much less implemented. Typically, practitioners used sensory perception to determine whether two products were the same or different (e.g., two batches from the product, two samples from different suppliers). This seemingly simple task laid the groundwork for product design, not so much because difference tests guide design, but because they paved the way to use subjective measures to guide decisions about products, such as accept/reject. What began as new efforts by some bench researchers and developers to understand differences would lay the groundwork for today's product design efforts. The full flower, however, would take years, as well as the entry of many different talents, such as marketers as well as experimental psychologists, especially psychophysicists.

The individuals who were doing tests of acceptance in the late 1930s and early 1940s, worked in companies and, later, in the late 1940s, were at the Food and Container Institute of the Armed Forces operated by the US Army Quartermaster Corps in Chicago. From these professionals and others who attended the yearly conferences of the IFT (Institute of Food Technologists), one got a "picture" of sensory evaluation in the guidance of product design.

Among the biggest contributors to the development of the field of human-centered research on food products were the US Army and its laboratories, first in Chicago, Illinois, and then in Natick, Massachusetts. The Army laboratories in

Chicago and Natick are extensively reviewed by Meiselman and Schutz (2003). The Army's Quartermaster Subsistence Research and Development Laboratory in Chicago established a Food Acceptance Branch in 1944, headed by Franklin Dove. This was followed by a food acceptance conference in December 1945, probably the first food acceptance conference worldwide. Dove published a paper on food acceptability in 1947 which describes the new taste panel booths at the laboratory. In 1949, David Peryam became head of the Food Acceptance Branch. Peryam was a psychologist, marking the introduction of psychologists into the field of food acceptability. Peryam was joined by psychologists Norman Girardot, Howard Schutz, Joseph Kamen, and others. A long line of research psychologists followed Peryam leading up to the current authors of this chapter who joined the Army's laboratory in Natick in 1969.

The work of the Food Acceptance Branch in Chicago focused broadly on food-related behavior, including both acceptance testing of products and studies of food habits. For acceptance testing, the laboratory used both expert and trained panels and consumer panels, usually using a paired preference method (Dove 1947). Studies of food habits were conducted under contract by universities who studied food preferences for a list of foods, along with consumer information on preparing and serving these foods. The studies of food preference continued from the Chicago period to the Natick period.

The most well-known output of the Food Acceptance Branch in Chicago was the development of the nine-point hedonic scale. This project was started by Peryam and Girardot in 1949 (Peryam and Girardot 1952) who were joined by researchers at the University of Chicago in 1951, including L. L. Thurstone, Lyle Jones, and Darrell Bock (Jones et al. 1955). The team conducted many individual studies including testing the semantic meaning of various phrases ("like extremely," etc.), varying the number of categories, scale balance, numbers of positive and negative scale categories, and presence of a neutral category. They found an advantage for longer scales, but no advantage for a neutral point or the same number of positive and negative categories. The nine-point hedonic scale has probably been the most widely used scale of food acceptance in the world, because it is easy for consumers to use. Many people using it do not know the extensive testing that went into its development. Nevertheless, the scale has had problems because of problems with translation into other languages (ref) and because of the lack of equal intervals as should be found on in interval scale (see ► Chap. 12, "Measuring Liking for Food and Drink" by Ares and Vidal in this volume) (Fig. 1).

Both Chicago and Natick Laboratories worked on the relationship of food acceptance to food consumption. Schutz and Kamen found that 50% of the variance in choice or consumption could be accounted for by hedonic mean scores but that up to 75% could be accounted for if one looked at individual food groups rather than food items. Cees de Graaf and colleagues (de Graaf et al. 2005) found significant but moderate correlations using data from Natick field testing of rations,

Like Extremely
Like Very Much
Like Moderately
Like slightly
Neither Like nor Dislike
Dislike Slightly
Dislike Moderately
Dislike Very Much
Dislike Extremely

Nine point hedonic scale: in its pure form the 9 point hedonic scale does not have lines connecting the scale points and does not have numbers associated with each scale point.

Fig. 1 Nine-point hedonic scale

indicating that acceptance is an important factor, but not the only factor contributing to intake.

Statisticians, Difference Tests, and the Emergence of Interest in Design of Experiments (DOE)

The emergence of interest in testing differences naturally involved statisticians, who were the experts regarding inferential statistics. By the period between the late 1930s and the 1950s, the world of food design and development was becoming more professionalized. There was interest in doing the "right test." For the first few years, the focus was on inferential statistics, namely, do two or more products differ from each other? The question of the time was "is there a difference, and is the difference making the product better, or is it making the product worse?" Product designers and developers were not thinking about systematic variation of products, nor about uncovering rules. The times called for the human being simply as a tester, an "assessor," in many of the scientific papers.

Statisticians, however, were moving to modeling, in order to understand the relation between variables. A new culture was beginning to emerge, a culture of systematic variation. Statisticians realized that they could use their armory of tools to understand the relations between variables, specifically those variables under the developer's control, and other variables measured by people, namely, perception. For example, one could learn how the amounts of two ingredients, e.g., sweetener and flavoring, together drive the perception of "perceived strength of flavor" by systematically mixing different levels of sweetener with different levels of flavoring (the ingoing experimental combinations or experimental design) and instructing panelists to rate the flavor intensity as they perceived it. This systematic approach produced a body of useful knowledge for the developer, far deeper than the knowledge that would be obtained by asking why two beverages of the same type differ in their respective "strengths of perceived flavor."

The foregoing, focusing on systematic variation, and the linkage between two variables, an independent variable under control and a dependent variable that is measured, falls into the category of designed experiments, or more typically and formally DOE, Design of Experiments. The application of DOE to the design of food would come later, in the late 1940s, more in the 1950s and 1960s, and flower in the 1970s–1990s. During 1950–1965, there was a growing interest in DOE in the chemical industry, perhaps because it had financial ramifications such as increasing the yield from chemical reactions.

DOE opened the minds of professionals, allowing for more complicated experiments, and thus laid the groundwork for product design. The traditional scientific method postulated how important it was to isolate a variable and study it. The notion that one should look at mixtures, to understand the system, was occasionally thought of, but the lack of fast and easy computation made these multivariate studies more of theory to be studied than a work tool to be used. DOE would become far more important later, when computers enter the science, because DOE PLUS COMPUTERS enabled the statistician, and thus the engineer, and scientist, to study the workings of several variables at once, and even nonlinearities and interactions between variables. All these would become important in the world of food design. Names such as Cochran (1950) and Box et al. (2005) are important, as are Plackett and Burman screening designs (Vanaja and Shobha Rani 2007). These statisticians contributed to this newly emerging field of DOE, which would lead to food design some decades later. The reader is directed toward the later papers cited here, because they put the earlier work into clear focus in terms of the major contributions made in those early methods.

Describing Versus Designing: Structuralist Versus Functionalist Agendas

By Way of Introduction to this Section

Structuralism and functionalism are two early schools of experimental psychology, holding sway from the end of the nineteenth century to the early and middle part of the twentieth century (Benjamin 1988). Their use here is metaphoric. Structuralism asserted that one could “understand” the psychology of perception by understanding the attributes or aspects that people perceived. To researchers in structuralist psychology, the prescribed approach was introspection, to list the different attributes of perception, whether those be the attributes or dimensions of vision, hearing, smelling, tasting, and feeling. One could get a sense of how people organized their perceptions. In contrast, researchers in functionalist psychology asserted that a better approach was to understand how the person behaved and how different aspects or dimensions of perceptions “functioned” to guide behavior.

Structuralism seems always to precede functionalism, going back to Aristotle. Aristotle's science classified to understand how aspects of the natural world distributed themselves. Yet even for a genius such as Aristotle, knowing the aspects of the world, the different features shared or not shared by living organisms, did not tell Aristotle how these organisms functioned. One could only guess about function by knowing structure.

The same distinction between structuralism and functionalism applies to the design of foods, with the structuralist agenda of description virtually always preceding the functionalist agenda of determining relations between variables. As we see below, the world of food design was dominated in the early days by description, holding the belief that if one "knew" the different notes or perceptual characteristics of the product, one might be able to develop better products of its type, or perhaps correct some of the quality errors. In contrast, later scientists and practitioners developed the relations between ingredients/process levels and consumer acceptance, in order to drive better product design.

Contrasting Beliefs and a Detour: What Can Be Judged and by Whom

A sense of what "was" sensory analysis, and what was its focus, comes from the now historic book by Amerine et al. (1965), *Principles of Sensory Evaluation of Food*. The 602-page book was the first book in the set of monographs published by Academic Press. This book, published more than a half century ago in the mid – 1960s, emerged from years of painstaking library research as well as personal experience. The topics in the Amerine et al. book deal less with the design of foods and more to with the study of the assessors. Examples of chapter titles are Factors Influencing Sensory Measurements (Chap. 5), Laboratory Studies: Quantity-Quality Evaluation (Chap. 8), Consumer Studies (Chap. 9), Statistical Procedures (Chap. 10), and Physical and Chemical Tests Related to Sensory Properties of Foods. The Amerine et al. (1965) book helps us understand the background out of which product design emerges. If one were to trace the history of product design back to first-order questions, perhaps the first question would not be about the product itself but rather about the person who is doing the judging. The first question was "who is able to judge the product?" The question about what the product should be hardly emerges in the early days.

The detour in consumer-driven product design comes out of a continuing issue in the evaluation of food, namely, who is competent to judge the aspects of food and thus give direction to design. Some of this focus on the "expert" can be traced to the world of certain kinds of products, such as wine, beer, and perfume. These products came with a mystique, the wine expert, the *beer meister*, and the expert perfumer. There was a sense that only these experts "knew" the product. The patronizing undercurrent was that for the most part, consumers simply did not know good from bad, although of course they knew what they liked and disliked. As of this writing, 2019, the role of "experts" continues to be important, especially in the aforementioned areas of wine, beer, and perfume, where sensory properties can be romanticized in advertising, in turn increasing the value of the brand.

A Land of Plenty: The Rise of Descriptive Analysis (Structuralism) to Guide Product Design

Product design would "somewhat" change in the 1930s, as the world enjoyed the bounty of better food, through advances in food preservation and food transportation. An important step was taken by the Arthur D. Little Company, a technical consulting company in Cambridge, Massachusetts, where Stanley Cairncross and his colleagues developed a system for describing the sensory characteristics of a product (Cairncross and Sjöström 1950). The method was being worked on in the late 1930s and would become a flagship approach in the 1940s. The notion was to help product design by identifying the sensory characteristics, so-called "notes" of a product. It was assumed that the product developer would "know what to do" once the notes were identified in the Flavor Profile. Importantly, the exact linkage between this description and product development could not be specified as a series of specific operations, which converted these "notes" to formulations.

The logic of identifying "notes" or attributes, and assuming that such identification, either by experts or consumers would guide product knowledge and thus product development did not begin with the Arthur D. Little Corporation. As noted above, describing one's sensation appears to be the first step in systematic science, going back to Aristotle's classification of animals, plants, and even constitutions of city states. Then there was Francis Bacon and, in psychology, the emergence of the Structuralist School, which assumed that we would know how perception works if we could only describe the perceptions that we have. The efforts did not end there. It was assumed in wine making, beer brewing, and fragrance development that a description of one's perception would somehow lead the developers to design and develop a better product. Again, as noted above, these descriptions resided in the purview of the expert, whether the business-oriented expert (e.g., perfumer) or the trained expert.

Modern-day efforts for product design using descriptive analysis have focused on training panels, including the Texture Profile (Civille and Szczesniak 1973), the Spectrum™ method (Meilgaard et al. 1999), and Quantitative Descriptive Analysis (QDA®; Stone et al. 1974). There remains little published evidence showing the *precise* steps in the linkage between descriptive analysis and product design. Professionals in the world of sensory analysis have, for the most part, directed their use of expert panels to quality control. The experts, trained in descriptive analysis, can describe two samples, and identify the sensory aspects, the notes which make these samples different from each other. This ability to describe the nature of differences can, of course, be a hint to copy a product by incorporating the "notes," but it's more often used to identify the nature of differences between a "gold standard" product (the "ideal") and a production or storage sample.

Psychophysics (Functionalism) Moves into the Food Industry

In the early 1860s, the German polymath scientist, Gustav Theodor Fechner, hypothesized that one could measure the perceived intensity of a stimulus, doing so by measuring successive difference thresholds (Stevens 1961). That is, one could begin with a sample of salt water and find the concentration of salt water that would be just noticeably different. This magnitude of change was defined as one JND, one just noticeable difference. One could erect a "sensory scale" by cumulating these JNDs and plotting them against the physical level of a test stimulus (e.g., the salt concentration in the water).

The foregoing is an academic treatment of the foundation of psychophysics. It has little or nothing to do with product design, but successors in psychophysics would have a great deal to do with design, and with the success of products. What Fechner suggested is that one could relate the physical intensity of a stimulus (think "ingredient") to the perceived intensity.

It would be about 80 years until a more direct approach would take hold, one which would link practical product design to psychophysics. This more direct approach is called *direct scaling*. The respondent is exposed to an array of test stimuli, one stimulus at a time in irregular order, and assigns a number on an attribute scale to match the perceived magnitude of the stimulus. The attribute could be sensory, such as the saltiness of salt solutions, or hedonic, such as the liking of the salt solution, or even a more cognitively complex phrase such as "perceived healthfulness of the salt solution."

Psychophysics/scaling entered the food industry in a slow but relentless progression. The Army psychologists in Chicago, Peryam, Pilgrim, etc. worked with the scaling expert Thurstone at the University of Chicago to develop the hedonic scale and to test many variations of that scale. At the US Army Chicago laboratory, Pilgrim, Schutz, and Kamen conducted a number of studies in taste and odor psychophysics in the 1950s. They conducted research on difference thresholds for the basic tastes (Schutz and Pilgrim 1957a), as well as on the relative sweetness of a number of natural and synthetic sweeteners using suprathreshold rather than absolute threshold measurements, demonstrating the importance of suprathreshold rather than threshold measures (Schutz and Pilgrim 1957b). The first systematic study of interactions of suprathreshold taste stimuli was conducted, and it was found that in most cases the effects were those of simple enhancement or masking. A one-person olfactorium was constructed, and studies included olfactory adaptation and development of an odor classification system.

When the Chicago laboratory moved to Natick, none of the researchers moved with it, and most of them went into industry and did not publish many research papers (see Meiselman and Schutz 2003). The exception was Howard Schutz. Schutz had received his education in experimental psychology in the 1950s. Schutz was interested in statistical modeling and analysis, rather than in rigorous testing. Schutz's contribution may be to have opened the eyes of the field to the importance of consumers, perhaps because of his tenure at Hunt Wesson Corporation, where he was responsible for running a commercial sensory evaluation laboratory in the 1960s. Schutz moved to UC Davis after Hunt Wesson and spent many summers working at the Natick Laboratory – he was the only Chicago alumnus in sensory and consumer testing who worked at Natick.

Roland Harper was probably the first psychologist in Europe to work on the sensory properties of foods beginning in the 1940s, around the same time as the US Army Chicago group. Harper joined the agricultural laboratory in Shinfield from 1946 to 1950 (where author Meiselman worked in 1990–1991 along with Howard Schutz). There is evidence of Harper's communication with Thurstone in 1948, around the same time that Thurstone was working with the group of Army psychologists in Chicago (Land 1988). In 1961–1962 he spent a sabbatical year in S. S. Stevens' psychophysical laboratory at Harvard University, from which author Moskowitz graduated 8 years later in 1969.

By the late 1950s, another sensory scientist interested in food emerged in Europe, Egon (Ep) Koster in the Netherlands. He also received his degree in sensory psychology, specializing in the sense of olfaction. Later he would apply his sensory and psychology skills to working on food products. Koster contributed important papers in sensory and consumer psychology of food well into the 2000s. Both Harper and Koster were trained in psychology, while another influential early figure was trained in food science.

These later years were the same years that Rose Marie Pangborn was starting her career in the United States. She attended New Mexico University (degree 1953) and then Iowa State University (degree 1955). She began working at the University of California at Davis in 1955, where she worked for 35 years until her death in 2000. UC Davis became a powerhouse in sensory and consumer science during and after her tenure. Her early papers (maiden name Valdes, married name Pangborn) were published in 1956 and 1957.

Drewnowski (1993) reviewed the contributions of Rose Marie Pangborn at the first Pangborn Sensory Science Symposium in 1992. He noted that her work covered sensory evaluation of food and the evaluation of food preferences. Pangborn was one of the first sensory researchers who moved from model systems (sugar in water, salt in water) to real foods, using canned apricots (Valdes and Roessler 1956) and vanilla ice cream (Pangborn et al. 1957). She also studied more complex sensory stimuli, combining several sensory modalities (sweetness, viscosity, texture). Pangborn also was among the first to study individual differences in perception, applying this to product perception and to the relationship to food preference and management of body weight. This interest in individual differences also extended to determinants of food acceptance, and Pangborn included individual attitudes in her research on nutrition. Perhaps the biggest contribution of Rose Marie Pangborn was her pioneering efforts in training 30 years of undergraduate and graduate students to do testing in a logical, scientific, rigorous way and to report the data in the proper format. Pangborn produced a generation of good researchers and teachers.

A Cadre of Chemosensory Psychophysicists Enters the World of Food

The 1960s grew into a fertile period for the growth of interest of psychophysicists in the chemical senses, taste and smell, and in the lower senses, touch. The focus would first be limited to so-called model systems, a focus that would later evolve to real foods and even full meals. The impetus for this was what has been called the "new psychophysics." This new psychophysics attempted to uncover quantitative relations between the physical stimuli and subjective responses, with many of the results suggesting that the relation could be described by a power function of the form: sensory rating = k (physical intensity)^n. It was the exponent which was of interest (Stevens 1975).

Natick Laboratories was opened in 1954 as the Quartermaster Research and Development Center, and the US Army food research program moved from Chicago to Natick in 1963. The nutrition research from Chicago moved to Colorado and eventually to Natick, and the dietetic services moved to Virginia. Between 1963 and 1966, a taste test laboratory with 11 testing booths was constructed in Natick. A joint annotated bibliography on acceptance and preference research was published jointly by Chicago and Natick (Bell et al. 1965). Beginning in 1966, Harry Jacobs began a program in behavioral sciences (psychology and other human sciences) with a strong emphasis on food. Harry Jacobs hired Linda Bartoshuk from Carl Pfaffmann's sensory laboratory at Brown University. Jacobs was interested in basic animal studies of appetite regulation. Bartoshuk was interested in basic human studies of taste processes and taste perception. Shortly after that, Howard Moskowitz and Herbert Meiselman were hired. Both Moskowitz and Meiselman would eventually apply their research to actual foods, with Moskowitz interested in the relation between ingredients and perception and Meiselman interested in meals in real-world settings out of the laboratory. Over time a number of other professionals/psychologists worked at Natick including Richard Bell, Armand Cardello, Barbara Edelman-Lewis, Dianne Engell, Edward Hirsch, F. Matthew Kramer, Owen Maller, and Richard Popper. These professionals were joined by a cadre of technical support people and by a rotating group of Army psychologists assigned to Natick for a two-year period, often bringing with them valuable skills in related disciplines. The military psychologists were especially helpful in conducting large-scale studies of food products and food service with military personnel on military bases and in the field. Finally, the civilian staff and the military staff were joined by a large number of visiting scientists from laboratories all over the world.

The Natick researchers conducted basic psychophysical studies of taste, smell, and texture and their relationship to liking. They applied related methods to study food preferences, food compatibilities, and boredom as applied to menu planning. They extended the study of short-term food preferences to studying long-term preferences. They studied the relationship between data collected in the laboratory and data collected in the field from soldiers and from university students. They extended this work with research on the role of context or environment on ratings of food and beverages. This topic would become a major topic in the field decades later (see Meiselman 2019). Another new approach in sensory and consumer research was the introduction of expectation theory and methods – this topic is covered below.

In both Europe and America, the psychophysicists were just beginning to look at the relation between the physical stimulus and liking, first with model systems as science (e.g., sugar in water), but insensibly moving toward the evaluation of real foods. Their work was primarily academic, but both authors moved inexorably toward the study of actual foods. For example, fairly early in his tenure at the US Army Natick Laboratories, author Meiselman began to measure liking both in the laboratory and in the field (see Meiselman and Schutz 2003). In contrast, during the same period, author Moskowitz began to use psychophysics to study the nature of liking as well as sensory perception as they are driven by the interactions of sweeteners in cola (Moskowitz et al. 1979). In a parallel path, psychophysics was at the ground in one of the first syntheses in behavioral economics, the economics of sweetness scales (Moskowitz and Wehrly 1972). These latter psychophysics studies would remain academic for the early part of the 1980s but then evolve into larger studies, using psychophysical thinking and experimental design. Those will be covered below.

The Zeitgeists of "Disciplines": Psychophysics, Sensory Professionals, and Market Researchers

The German philosopher Hegel postulated the ever-repeating dialectic of thesis, antithesis, and synthesis. Advances in every era bring with them conflicts and then synthesis and advance in the wake of those conflicts. We turn now to the 1970s, when forces would interact with each other in ways that might now have been expected from the decades before but which would prove extraordinarily fruitful as one looks back at these conflicts. The focus of the period was "drivers of liking," or in effect, what makes a product good? We move past the era of difference testing, a worldview which remains with us in full force but generally relegated to quality assurance.

In the 1960s, a new discipline emerged, market (or marketing) research. The focus of this new discipline was the consumer and the market. Most of the efforts focused on the role of consumer responses to product advertising and to product packaging at the point of sale. Market researchers combined scientists and practitioners, with an array of learned journals, such as the *Journal of Market Research*, to memorialize some of the more important efforts of an academic nature. There was also Robert Ferber's book, *The Handbook of Marketing Research* (Ferber 1974) and the comprehensive *Handbook of Marketing Scales* (Bearden et al. 1993).

Market researchers were interested in people, specifically in the response of people to products. It was market researchers who popularized the notion that product acceptance might vary, some of the variance traceable to error inherent in measuring subjective responses, but perhaps also traceable to the fact that people simply had different preferences. Market researchers were able to recognize these differences in their "product tests," evaluations of product samples before the product would be launched, to guard against market failure (so-called disaster checks).

With the introduction of market researchers into the world of product testing, there were three different groups of professionals offering direction and "insight" on the design of products, inputs which were sorely lacking just a decade before:

1. *Sensory psychophysics*: Psychophysicists were entering the business world, choosing to work for manufacturing companies or consulting groups. Often, the psychophysicists would work in the sensory department of a company. Abandoning the traditional academic route, these business-oriented scientists often brought with them the desire to use their psychophysics to drive product creation, rather than to continue the clerical work of difference testing, to which the sensory department had evolved.
2. *Sensory professionals*: The sensory professionals remained bound to their descriptive analysis and graphical representation of the data. They seem not to have been able to show the way that descriptive analysis would drive improved product acceptance. Perhaps their main contribution was to pronounce in their presentations that the product developer would (somehow) recognize certain departures from the standard for current quality control or recognize new notes in products that were to be copied, used as springboards for the company's new and competitive entry.
3. *Market and consumer research*: The discipline of marketing research was growing. The focus, limited as it was on whether a product passed a specific level for acceptance or was better than a comparison product, necessarily had to look at differences among respondents, the individuals who participated in the market research studies. Whereas psychophysicists and sensory professionals focus at the product itself, marketing researchers focused on the consumer and the resulting pattern of acceptance, recognizing that people differed. They did not, however, have the necessary tools to understand what drives liking beyond the so-called cross-tabulation methods, comprising tables of product scores by subgroups of respondents (e.g., frequent vs infrequent users, older vs younger, brand-loyalists vs non-loyalists, and so forth). As part of the contribution of market and consumer research, there would spring up a new form of understanding consumers, so-called psychographic segmentation (Wells 1975). The focus would be on the psychology of the consumer, specifically what type attitudes were possessed by different segments of consumers and what types of behaviors were exhibited. Food was no longer simply the ingredients and taste, but rather the "right message to the right person" and "the right product to the right person."

Zeitgeists of Method in the 1960s, 1970s, and 1980s

The three groups of players in the design of product used different tools. We will look at the research tools and then discuss the underlying rationale of each tool, the role of the relevant group, and finally how each tool helped move forward the capabilities of food design.

Single Test Stimulus and Analysis: Cross Tabulations

The term “cross tabulation” refers to the evaluation of one product (or perhaps two), deconstructed into the ratings by different groups or different test conditions. As strange as that might sound today, as of this writing (2019), when cross tabulations were done for product tests, mainly by market researchers, there was a sense that the “answers were in there, in the cross-tabs.” A good analogy today is “Big Data.” There is no reason to assume that the analysis will produce an answer telling the product design what to do to create a better product, but it is satisfying to the researcher to show an “effect,” e.g., that more frequent users prefer the less sweet product.

Single Test Stimulus: Just About Right (JAR) Scales

The JAR or just about right scale is widely used today to identify what to change. The JAR scale asks the respondent to judge whether a product has too little of an attribute (e.g., sweetness), just the right amount, or too much.

Although there have been many developments using the JAR scale, such as penalty analysis (Narayanan et al. 2014), the origin of the JAR scale as used today may have its origins in a discussion about applying psychophysics to business issues in product design. During the September 1968 meeting with Loren B. Sjostrom and Anne Nielsen of Arthur D. Little, Inc., author Moskowitz suggested that the Flavor Profile could be improved by using psychophysical scales to identify how to change a product. The researcher would instruct the respondent to rate the amount of a sensory attribute and the degree of change to make a better product. The psychophysical scale would then show the sensory level and in turn the physical level to optimize acceptance, in the opinion of the respondent. Four years after that first 1968 meeting, the approach was codified in a peer reviewed paper in the *Journal of Applied Psychology* (Moskowitz 1972), demonstrating the practicality of the approach with Kool-Aid, tuna fish spread, and hamburgers of different grinds, respectively.

The JAR scale was and remains attractive. It was easy to apply, to analyze, and to report to product developers who could understand what the scale meant. What was not so clear was what exactly to do with the results when the data fail to be accompanied by a functional relation between “sensory amount” and “physical level,” i.e., when the psychophysical curve was absent. For example, when the respondents said much too sweet, just what did that mean? And what should one do when people disagree? And what about certain attributes for which one never has enough, such as “natural flavor?” In commercial applications for manufacturers conducted as far back as the 1980s, author Moskowitz discovered that for some attributes such as “real chocolate flavor,” the more chocolate one added to the product, the more bitter the product tasted, and the less natural the product tasted. The same type of finding emerged for flavor. Real flavor did not come from the flavoring but from the “sugar.” It required product development expertise to understand just exactly what the JAR data required in terms of subsequent product design.

Single or Multiple Test Stimuli: The Self-Designed Ideal

Once we admit of the ability of consumers to point to changes in a product, e.g., by the JAR scale, it is not far afield to instruct consumers to describe their ideal product, using the same attributes and the same scale as they used to describe products. One can then compare the magnitude of the ideal product (emerging from the mind of the consumer) to the scores of actual products, tested by these same consumer respondents, at the same time. The products which score closest to the self-designed ideal are presumed to represent target products.

The JAR Scale, the Self-Designed Ideal, and Efforts to Validate Them

The JAR scale and the self-designed ideal instruct consumers to rate products and conceptualize how they would change the product. When it comes to validating the results, how does one then validate the JAR scale and the self-designed ideals, respectively, either analytically or in subsequent direct tests.

Some published literature, primarily in the academic world rather than in the corporate world, has focused on the ability of the JAR scale and the self-designed ideal to guide successful product design. We thus rely on the literature, which presents studies that can be described primarily as methodological. The published studies suggest that the JAR scale and the self-designed ideal do point, albeit in a general way, to a better product (Li et al. 2014).

Finding actual corporate case studies in the literature is difficult to do, but one industry-facing organization, ASTM, the American Society for Testing and Materials (Committee E-18 on Sensory Analysis), has created recommended practices for the JAR scale. That such attention is paid to the topic of standardizing the JAR scale attests to its practical use and importance for product design. The JAR scale is used to guide product redesign, with the directional referring to changes in the sensory attributes of the product being tested. In contrast, there seems to be no clear literature about the practical, industrial use of the self-designed ideal to guide product design, even though the approach has been around for more than 46 years (Drewnowski and Moskowitz 1985; Moskowitz 1972).

Let us assume that we can, in some way, predict the liking of the product which is perfect on the JAR scale, or which "delivers" the sensory profile of the self-designed ideal. Are there data showing that this product expected to perform in an optimal way, if we were able to estimate the liking of this product? Keep in mind that the JAR scale and the self-designed ideal work only with sensory attributes, and do not involve the key evaluative criteria of overall liking, or likelihood to purchase. In a study of pizza, with all ingredients disguised to maintain corporate confidentiality, Moskowitz demonstrated through modeling that one could create a set of equations relating formula variables to liking, to sensory attribute levels, and to JAR scales. Using the model, it was possible to set the JAR scale values all to 0 (no change required) or to set the sensory attributes to the level defined by the self-designed ideal. The results suggested that the products emerging from this exercise were not optimally acceptable, i.e., the formulations expected to generate JAR scale values of 0 (just about right), or to generate the self-designed ideal (Moskowitz 2001).

It may be that the JAR scale and self-designed ideal work for attributes which are not inherently hedonic, such as appearance, texture, and flavor attributes. For those nonjudgmental attributes, respondents have a sense of what they want. For many other attributes, such as salty, fatty, and so forth, the JAR scale and the ideal levels must be interpreted with a note of caution because the respondent often either never gets enough (natural flavor) or always has too much (e.g., fatty for a health-oriented food). Table 1 (section A) shows the results of a commercially funded study with

Table 1 Data from a 1993 commercially funded study on consumer responses to 11 prototypes of frankfurters, prior to the selection of one product to "go to market." No prototype ever scores sufficiently "meaty," whether in terms of the JAR scale or in terms of the self-designed ideal

A – Average JAR (just about right) scale results for 11 frankfurter prototypes					
	JAR	JAR	JAR	JAR	JAR
Code	Dark	Smoky	Meaty	Salty	Greasy
101	6	−1	−8	2	−1
102	7	−4	−10	1	−3
103	−17	−8	−16	2	−1
104	−10	−11	−16	2	1
105	−21	−16	−14	5	−2
106	1	−8	−11	4	5
107	31	−16	−13	−5	2
108	−4	−7	−10	−2	−4
109	−20	−13	−20	−7	−5
110	−29	−14	−17	−4	−1
111	−4	−8	−21	9	1

B – Minimum, Self-Designed Ideal, and Maximum for 11 frankfurter prototypes on nine 'sensory' attributes			
	Min	Ideal	Max
Dark	19	45	67
Long	26	67	74
Processed App	57	30	69
Aroma	41	46	54
Smoke Flavor	31	36	51
Meaty	34	76	55
Salty	30	25	51
Aftertaste	40	32	61
Firm	29	46	60
Juicy	42	57	60
Greasy	21	13	34

"frankfurters," wherein the respondent rated the sensory intensity of attributes, the sensory ideal of the attribute, and the JAR scale for the attribute. We show the results for the 11 products. The important thing to note is that none of the 11 test samples ever scored high enough on the attribute of "meaty." Of course, it might well be that these frankfurter prototypes were simply not sufficiently "meaty," but we find similar types of failure to deliver on other attributes which are "hedonics in disguise," such as "real chocolate flavor, etc."

When we move to the self-designed ideal (Table 1, section B), we see the same type of problem emerging. One attribute, meaty, shows a self-designed idea outside the range of the levels achieved by the 11 prototypes. Again, the problem emerges, namely, "what should the developer do with these results?"

Multiple Test Stimuli: Mapping

Placing points on a geometrical space appeals to researchers. Whether the points define some type of function or the points define the location of an item in space, there is the perennial desire of a research to display data visually. Quite often, such displays reveal patterns that would be otherwise undetected. Mapping began with statisticians, who suggested that factor analysis, which reduces the dimensionality of a set of variables to a simpler set of orthogonal primaries, could be even more valuable when one plotted the stimuli as points in this orthogonal space, as Fig. 2 shows. The size of the letter is proportional to overall liking (LTOT).

When used for product design, maps reveal open areas, opportunities for new products. In today's business parlance (2019), the term is "white space." Author Moskowitz developed methods by which to identify the sensory profile of the products to be fit into this whole, using a method called "sensory-based engineering." The approach used the coordinates of the map as independent variables and each of the sensory attributes and the rating of liking as separate dependent variables. The optimization routine identifies the coordinates in the factor space corresponding to the "best product" and then estimates the likely sensory profile of that best product (Moskowitz 1994).

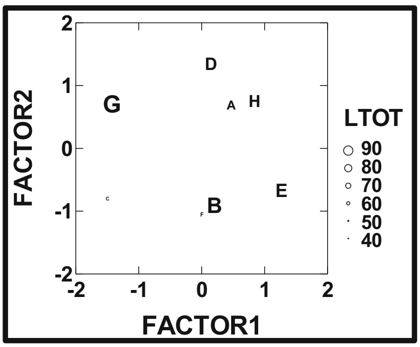

Fig. 2 Example of a map, showing the location of products as letters, with the size of the letter proportion to product acceptance (LTOT = overall liking)

Multiple Test Stimuli: Response-Response Analysis

Regression analysis occupies the honorable position of being perhaps *the* statistical method to uncover so-called drivers of liking. The original use of regression analysis by statisticians involved the analysis of large data sets in order to identify which of the measured factors covary with a key evaluative criterion.

Focusing on food, the application translates into the simple problem of which of a variety of ingredients drives liking or which of a set of sensory attributes drive liking, respectively. The researcher assembles a set of products, either variants of each other in terms of ingredients/processes or of the same general type. The researcher instructs the panelists (consumers, experts) to rate the products on a set of scales (e.g., sensory perception of color, aroma, taste, mouthfeel) and instructs the consumers to rate the products on an evaluative criterion, e.g., "liking" or "purchase intent." The latter evaluative ratings are obtained either from the same panelists providing the sensory ratings or from other panelists representing the ultimate consumer.

When the researcher works with a single set of products, whether or not these products are systematically related to each other by an underlying design, it is straightforward to plot the relation between acceptance (e.g., overall liking) on the ordinate and sensory attribute level on the abscissa. Figure 3 shows the results for the study of the frankfurters, from personal data collected by author Moskowitz in 1993.

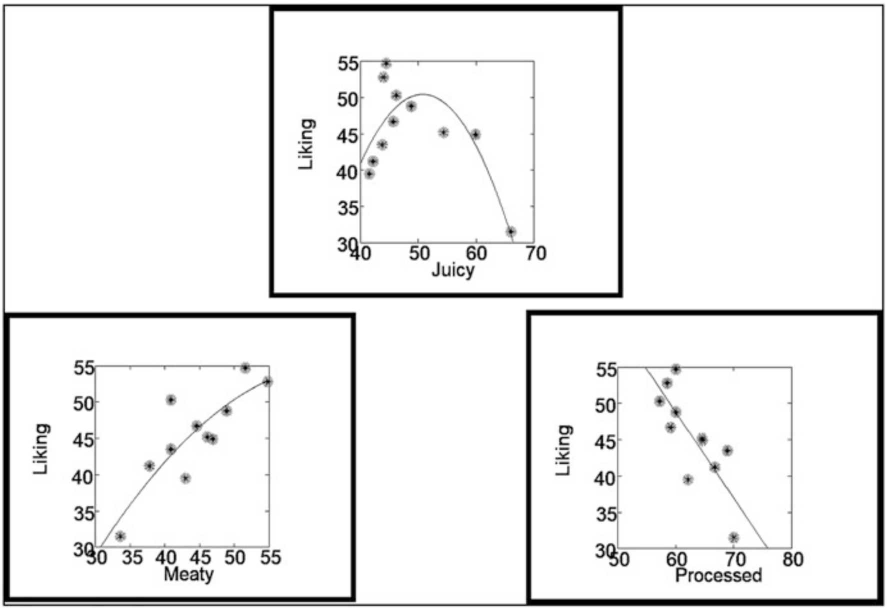

Fig. 3 The scatterplot relation between sensory attribute level and overall liking for the 11 frankfurters introduced in the previous sections. The filled star/circles correspond to the 11 samples. The statistical program (Systat) fits a quadratic function to the scatterplot

The abovementioned approach is called R-R analysis, or response-response analysis. We look for relations between two variables, neither of which is systematically varied. Rather, both variables emerge from the evaluation of the same 11 meat samples. We cannot discover "causality" but simply get a sense of which attribute covaries with liking.

Systematics: Creating and Using Psychophysical Curves

The new psychophysics has had a direct impact on the world of product design, perhaps one that was anticipated. Over the earlier decades of the twentieth century, researchers began to explore the use of people as "measuring instruments." For food, this systematized effort began in earnest with ratings of liking of different products, with such ratings being analyzed for differences (Peryam and Pilgrim 1957). Some researchers realized, however, that they had a tool by which to understand how ingredients drove responses, whether the response is the perceived sensory intensity of the food or beverage (e.g., the sweetness of cola) or the degree of liking. Psychophysicists, specializing in the study of the relations between sensory magnitude and physical intensity, soon began to contribute to this effort, especially with simple systems, such as colas and some foods (Moskowitz et al. 1979). What is important to keep in mind is that these curves provided foundational knowledge. It was quickly discovered that the same percent change in ingredients could very well produce radically different perceived changes. Doubling the concentration of a flavor ingredient, for example, was seen to be less effective than doubling the concentration of sugar for the same food. We will elaborate this type of thinking below, when we deal with stimulus-response analysis and response surface designs.

Stimulus-Response Analysis

Product design becomes far more powerful when we move from testing one product or several unrelated products to a set of prototypes that are systematically varied. The original thinking comes from both statisticians who promoted the idea of DOE (design of experiments) and from psychophysicists who promoted the idea of uncovering lawful relations between physical stimuli and subjective responses.

Beyond the design of experiments, the creation of the systematically varied prototypes lies on an entire body of statistics known as regression analysis or curve fitting. With regression analysis, one discovers how a physical ingredient or set of ingredients drives a response, the most important response being overall liking. Furthermore, with nonlinear regression analysis, it becomes easier to uncover optimal or most highly liked product formulations within the range of prototypes tested, but a formulation not necessarily one of the prototypes created.

Figure 4 shows a schematic example of the approach. The regression modeling typically creates either a linear plot, described by the equation and shown as

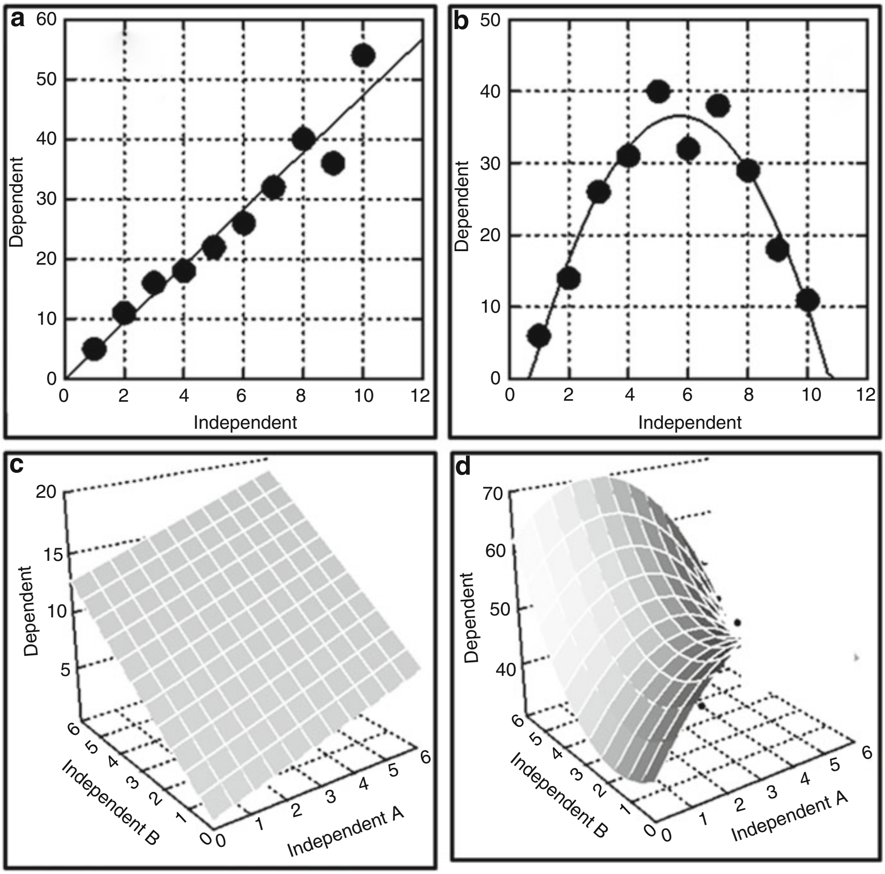

Fig. 4 Schematic example of scatterplots showing the relation between a dependent variable (ordinate) and either one independent variable (panels A and B) or two independent variables (panels C and D). The plots represent the type of relations one might observe when the dependent variable (ordinate) continues to increase linearly with increases in the independent variable (panel A, panel C) or when the dependent maximizes at some intermediate point of one or both independent variables (panel B, panel D)

examples (left panels) or described by a quadratic equation, in Fig. 4 (right panels). The plot can either reflect a one-ingredient system (Panel A, Panel B) or a two-or-more ingredient system (Panel C, Panel D). We present a visual only of the two-ingredient system, but the mathematical modeling can accommodate many more independent variables, even when we cannot easily visualize the model.

Regression modeling plays an important role in product design for at least two reasons.

1. Regression provides insights into what might be important, giving specific, testable direction for product design. The developer creates a quantitative

structure to discover what operationally varied factor might be important, rapidly providing insights that could not be obtained were the effort to be focused on one product.

2. The second, perhaps more important, is that regression analysis forces the necessary shift from focusing on one product to focusing on many products. One soon realizes the futility of efforts to understand the drivers of liking by relating the rating of liking for one product to the rating of sensory attributes for the same product, using as inputs, both the sensory and the liking ratings assigned to a single product by many respondents. The reliance on one product alone produces a fallacious approach, confusing the "noise or variability-based" information in the variation of responses to one product with the "signal-based" information from the variation of responses to many products. As the intellectual development of the field proceeded, this change in focus, from the study of variability to the study of patterns, would inevitably lead to more powerful tools.

Expectations

Another methodological breakthrough in the development of consumer methodology for food and drinks was the application of expectation theory and expectation methods. Perhaps the lead researcher in this area has been Armand Cardello from the US Army Natick Laboratories. Cardello (2007) lays out the history of expectation theory and research. Like some other methods in this chapter, expectation theory and methods developed within psychology in the earlier part of the twentieth century. Broadly speaking, expectations refer to the anticipation that something will occur; when applied to foods and drinks, expectations refer to the anticipation that a product will contain an attribute or result in a consequence. Early discussion of expectations focused in its role in human behavior, especially motivation and cognition. Expectation was applied to consumer research in the 1970s in the context of models of consumer satisfaction and service quality. This satisfaction work led Cardello and colleagues to apply the expectation model to product satisfaction (Cardello et al. 1985; Cardello and Sawyer 1992).

Expectation research uses the model of confirmation/disconfirmation in which a person's expectations are either met (confirmation) or not met (disconfirmation), resulting in a product producing satisfaction or rejection. Research has shown that the acceptance rating of a product often moves in the direction of its expectation, referred to as assimilation. If you expect a product to be good, you will rate it higher than if you expected a lesser rating. This is important for product design, product advertising, and product success, because final acceptance by the consumer is due to the actual product attributes but also to the expectation of those attributes. Product liking is due to more than the physical make-up of the product, as noted above. In addition to the assimilation model of expectations, there are also other models including (1) generalized negativity, (2) contrast, and (3) assimilation-contrast. The contrast model is one that is observed when a product falls much below its expectation, leading to rejection. Setting product expectations too high can lead to product rejection.

Conclusions

As we reach the end of this history, and this writing (2019), we are approaching the greater part of a century since the first efforts at applying knowledge about the human senses have been applied in a significant way to the development of foods. What then have we learned in the past century? What has really transpired, and how have we developed? There are some key trends that we should note.

1. *Descriptive analysis*: Research revealed that for easily understood attributes, the ability of consumers to detect and report the magnitude of changes was equivalent to that of experts, at least for sensory attributes that were obvious, and did not need explanation to be recognized before being evaluated in an experiment (Moskowitz 1997; Ares and Varela 2017). Research has shown that it's not all about experts, with consumers relegated to relatively blunt instruments whose only ability was to respond with "like, neutral, or like." Rather, one should look at experts as trained to recognize notes and to describe whether this description is relevant to product design or simply limited to quality control. It is important, to note, however, that consumers, even untrained consumers, can do a reasonably "good job" evaluating sensory attributes that are easy to understand and with which they have had everyday experience. However, some commercial research heavily depends on trained panels for quality control and other functions.
   In a broader sense, trained panel work has not delivered what people thought it would deliver. There was a sense, perhaps not well stated, that if we understand the sensory properties of the food, we could formulate newer and better products. Unfortunately, the promise of descriptive was never fulfilled in an operationally defined way. That is, there seems to be no simple relation between how a product is described and what the product developer must do to change the product.
2. *Product testing*: Testing products has survived and flourished. Today, more than ever, corporations depend upon the scores in so-called product tests to move forward with a prototype toward market, to modify the prototype, or sometimes to just "kill" the project. Testing, in fact, of all the contributions from human research, has been the most absolutely robust, perhaps because it is structured and well-choreographed, admits to "best practices," and can be supported by numbers, by statistics. All three of these reasons make it easy to adopt testing as a standard procedure in corporate work.
   But a number of things have changed in product testing. The product evaluations are typically done with "target consumers," i.e., with consumers who are representative consumers of the products. They are less frequently done with

convenience panels, i.e., panelists who are company employees and available for testing. For larger companies, product testing is often done in multiple countries, without the assumption that one test in one country guaranties global success. What remains to be done is to better design these cross-cultural tests, which remain a challenge, as discussed at a Pangborn Sensory Science Symposium (Goldman 2006). Another change in product testing is the growth of the field of sensometrics, with much more advanced statistical designs for data collection and analysis. A final change is the growing appreciation of the context in which product tests are conducted, with a growing use of home testing and non-laboratory testing. Of great interest here is the growth of virtual reality as an alternative to changing actual testing locations (Meiselman 2019).

3. *Experimental design*: Experimental design of products has had its ups and downs, due in great measure both to the benefits it provides and to the effort and cost it demands. Experimental design forces the developer to create products, an effort often resisted because it requires time, investment, and effort, all three in a world which seeks success using faster and less expensive methods. Those are the downsides, which stop experimental design in its tracks and limit its true value. We can expect more experimental design work, however, when the methods become less expensive, faster, and obvious, rather than seeming esoteric and unapproachable.
4. *Expanding the field – sensory becomes sensory and consumer*: In the early 1970s, the Institute of Food Technologists formed the Sensory Evaluation Division (SED). At that time, the world of human food research as we think of it comprised the so-called sensory researchers in laboratories. There were some researchers such as author Meiselman who campaigned for the broader study of food habits (Meiselman 1992), but the majority of research facilities and research focus remained steadfastly on what we today would call sensory issues, with foods as the primary focus and the person as a secondary, convenient instrument on par with instruments but of course an instrument which "evaluated" as well (good versus bad, etc.). Over the decades, however, the world of human food research expanded its borders, incorporating market researchers and anthropologists. The IFT later changed its name to the Sensory and Consumer Sciences Division to recognize the importance of consumers.
5. *Data analysis*: The advent of the computer has brought with it many methods. It is hard to know which methods have lasting impact. There are those which appear at one or another conference, and have "staying power" such as temporal dominance as a research tool or conjoint measurement for messages as research and as a development tool. There are also methods that are accepted, but their utility is less clear, such as mean drop analysis, a method of cross tabulation of one product to find out what are the important attributes. We can be reasonably assured that the continually increasing group of young, sophisticated, and motivated researchers will continue to introduce new data analytic methods at today's pace and no doubt increase the pace in the future.

Part II

The History of Eating and Drinking

A Swift Overview of Eating and Drinking Since Antiquity

2

Paul Erdkamp, Wouter Ryckbosch, and Peter Scholliers

Contents

Abstract

This chapter offers a very broad survey of the transformation of diet in past 2500 years. Such an ambitious venture tends to highlight spectacular changes, such as the so-called Columbian exchange of the late sixteenth century. These changes undoubtedly altered the diet radically, but many other, small and less striking developments also played their parts in the long run. This survey focuses on the history of eating and drinking, primarily but not exclusively in the West, and *not* on the history of agriculture, commerce, retailing, or cooking. It emphasizes the quantity and diversity of food, its consumption, food policies, and health implications. Inevitably, all big and small changes in the food chain are reflected in the history of eating and drinking.

Dietary transformations · World history · Long-term food history · Nutritional transition

Introduction

Writing a survey of about 2500 years of eating and drinking throughout the world cannot but be unsatisfactory and incomplete. Authors or editors who have ventured to do this used hundreds of pages or several volumes, unless they considered one specific foodstuff. All of these studies emphasize the crucial role of food in great transformations such as urbanization or migration, as well as in everyday processes such as identity construction or social differentiation. By asserting a central role of eating and drinking in social relations, economics, policy, language, medicine, gender, fears and dreams, or any other domain, this survey aims to do no less.

Rather than proposing a chronological ordering, a thematic structure is chosen with topics that have recently attracted great interest in historical studies. This yielded eight chapters. The daily diet is connected to malnutrition and health, which links up with dietary insights and advice; the latter connects to food beliefs, policies, and rituals; all is situated within the exchanges of ideas, people, and products. Geographically, this survey at first concentrates on Ancient Greece and Rome, as the world of classical antiquity shows that developments did not take a linear course, and at the same time often offered the origin and inspiration of later ideas. Our survey takes a more global view from the late Middle Ages onwards. Because the emphasis is on eating and drinking, this essay only marginally addresses the history of agriculture, retailing, or cooking. Some aspects are, inevitably, also largely ignored, such as time spent on eating or its material culture.

Daily Diets

For long, the basic foodstuffs consisted of vegetables that provided the necessary carbohydrates. Grain continued to be the staple source of life across Europe, rice performed a similar role in East Asia, and maize allowed for the Inca, Maya, and Aztec civilizations to prosper. The importance of complimentary foodstuffs – dairy products, fish, meat, and legumes – varied according to place and time, but the tyranny of the starchy crops was most prominent when necessity forced people to choose for the cheapest sources of energy (Braudel 1992). Caloric intake was near the subsistence limit for most people living before the industrial era, averaging approximately 2,400 kcal per adult per day (Pomeranz 2005). Nevertheless, huge chronological, geographic, and social variations existed.

The diet in Classical Antiquity it is often observed was dominated by the so-called Mediterranean triad consisting of cereals, olive oil, and wine. Although not entirely untrue, this view needs nuance and clarification (Garnsey 1999; Wilkins and Hill 2006; Wilkins and Nadeau 2015). First, there was no common diet in Antiquity, as it varied according to geographical, rural/urban, and socioeconomic background. Moreover, the general term "cereals" encompasses a wide variety of crops, including various species of wheat and barley, each with different properties and eaten in different forms. On the Greek mainland and islands, species of barley remained important, as they were better suited to the dry climate, while the Romans preferred wheat. There is a general trend over time from hulled wheats (such as emmer wheat) to naked wheats, in particular hard wheat, which were easier to process and transport, and therefore better suited to provisioning the cities (Heinrich and Hansen 2018a, b).

Literary sources show a clear cultural preference for consumption in the form of leavened bread, made out of hard wheat, although other forms of (un)leavened bread were eaten too. Cereals were also eaten in the form of porridge. Various kinds of cereals offered the largest part of calories, mostly so in cities, as the people in the countryside had access to a wider variety of foodstuffs. Yet, consumption of pulses, such as lentils, chickpeas, and faba beans, should not be underestimated. Cereals and pulses were often eaten in combination. Olive oil was a staple in Mediterranean lands, while lard or butter took its role in Central and Western Europe. Wine mixed with water was common, but the poor generally drank sour wine (*posca*) mixed with water, or the last dregs of pressed grapes. In the countryside, the milk of cows or goats was drunk, but cheese was a more common way of consuming milk (Broekaert 2018).

Rich Greeks and Romans basically ate the same foodstuffs, but in more luxurious forms – white bread rather than porridge – and in different proportions, with more meat, sea-fish, richer wine, and fruits. Poor people, in particular in the countryside, often had to rely on food that well-to-do Romans saw as fodder, such as barley and other "inferior" cereals, while some country-dwellers had to make do with acorns and chestnuts during part of the year.

Not only the number of calories matters, but also the variety of caloric sources. Pulses and legumes were a vital source of proteins, which was all the more important as the consumption of animal proteins was probably limited for most people, not only in Antiquity, but also in later centuries. In the Greek world, many people probably consumed meat of cattle, pigs, or sheep mainly in a sacrificial context (Ekroth 2007). In Roman times, access to meat seems to have increased (MacKinnon 2004, 2018; Chandezon 2015). Fish was consumed fresh, salted, or otherwise processed for long-term storage (such as the famous fish-sauce *garum*), but consumption of seafood was limited away from the sea-coast (Mylona 2015; Marzano 2018).

The extent to which Europeans in medieval and early modern times were more carnivorous than Asians, Africans, or Americans has been an important topic of debate among historians (Braudel 1992). When European travelers, diplomats, or merchants in the seventeenth and eighteenth centuries wrote about the diet of the Chinese, Turks, or Japanese, they often remarked how rarely meat was eaten, although later estimates have placed the aggregate protein consumption in the seventeenth century in China on par with that in England (Pomeranz 2005). Perhaps differences were clearer in earlier times, since it is commonly held that in the two centuries following the Black Death (ca. 1348), meat consumption in Europe was more common than it had been before or would be again until modern times (Abel 1937; Teuteberg 1986). The idea was that the decline in population numbers and the redistribution of resources and economic bargaining power following the demographic crisis of the Black Death allowed for a richer diet for the remaining population. More recent research has called into question this straightforward relation between meat consumption and demography, and in particular the rise of meat consumption in the post-Plague period (Thoen and Soens 2010). However, it is clear that after 1550, when the population began to exceed pre-Plague levels again, regularly eating meat became a prerogative of the rich, or at least confined to a more limited number of days per week or per year. Declining numbers of butchers, decreasing revenues from excises on slaughtered animals, and the dwindling share of meat in hospital budgets all suggest that the carnivorous consumption of Europeans had finally reached the lowest point of its long decline since the Middle Ages.

Everywhere across the world before the eighteenth century, most of the food and drink was locally produced. Cities procured their food provisions as much as possible from their immediate surroundings (a distance of some 25 kms), and the local prevalence of meat, fish, and specific vegetables largely determined the daily diet of consumers. Transport costs and the hazards of long-distance trade loomed too large to allow for most – but not all – bulk consumables to be transported. However, exceptions existed, and these became more prevalent over time. Some densely populated places did import their basic necessities from much further away. Imperial Rome depended on grain from Egypt and modern Tunisia, while Constantinople, capital of the Byzantine Empire, received grain from the lands surrounding the Black Sea and the Aegean. Florence relied on Sicilian grain since at least the thirteenth century, regions such as Picardy exported large quantities of grain to Paris and Flanders since the late middle ages, and in early modern times the urban population of Holland relied on the regular shipping of grain from the Baltic Sea (Braudel 1992).

However significant such reliance on trade trade, these quantities and regions were exceptional, as the vast majority of food and drink was consumed in the immediate vicinity of where it was produced. This reliance on local produce does not imply that monotony was the rule. Even for those who could not rely on the import of foodstuffs from farther away, there was often a great variety of food types available in medieval and early modern times. Forests, rivers, and wild places abounded with wild birds, fish, mushrooms, herbs, berries, roots, nuts, fruits, and edible plants that either disappeared over time or were in later times no longer deemed sufficiently edible (Albala 2003).

By the late eighteenth century and worldwide, the so-called industrial revolution had affected the daily life of ten-thousands of people in a negative way: many men and women lost their job, called upon charity, moved to overcrowded towns and became fully market-dependent. Only few people gained from the process of industrialization thanks to high returns or well-paid jobs in new trades. As a consequence, social and spatial inequality grew, with direct effects on the daily diet. It took several decades before the majority of the people, aided by rising purchasing power, benefited from improvements in agriculture, transport, manufacturing and distribution, which coincided with big geographical disparities.

Data of the *Food and Agricultural Organization*, starting in 1961, allow to assess the nutritional transition in the world since 1800 by adding estimates on caloric intake per head in the nineteenth and first half of the twentieth centuries (FAOSTAT 2018; Allen et al. 2005). Around 1800, parts of Asia, Europe, and North America had a similar supply of about 2,300 kcal per head per day, but different protein intake due to higher consumption of meat and dairy products in Europe and North America. Other parts of the world had much less food available. The average caloric supply in Western Europe rose slowly until the late 1850s, albeit with huge fluctuations and geographical variations, to grow almost linearly up to the 1910s (3,200 kcal), which, for the first time in history, assured food security for most of the West-Europeans. Then, calorie supply declined until the 1960s (3,050 kcal), to increase again since then (3,350 kcal).

In general, most parts of the globe lagged behind this West-European pattern to various degrees. Changes of the human height (in which food plays a crucial role, next to diseases, hygiene and preadult labor) allow us to assess nutritional standards in the past. The average stature of men in northern Europe gradually declined from the late middle ages until the early nineteenth century, when it started to grow irregularly (Baten and Blum 2014; Steckel 2005). In Latin and North America, height stagnated in the nineteenth century and grew afterwards, especially in Canada and the United States; in Asia it dropped until 1880 and, again, in 1910 to only increase after 1950; height fluctuated heavily in Sub-Saharan Africa in the nineteenth century, to stagnate in the twentieth century; finally, height oscillated in North Africa and the Middle East until the 1910s, to increase from then onwards. After 1960, the world's average caloric supply grew to 2,880 kcal per head per day (in 1961: 2,200). This caloric intake fulfills energetic needs and brings about a fast-growing group of people with overweight in many countries. Yet, health concerns gradually influence the wealthier people's food consumption in well-off countries, who lower their consumption of, for example, sugar and alcohol.

As mentioned above, up to the 1900s most people ate and drank what was locally produced. Only small, elite groups regularly consumed food and drinks that came from remote shores, for example, cocoa, wine, or spices. Yet, radical changes occurred with the coming of new foodstuffs that, gradually, were locally grown (see below, the Columbian exchange). For instance, the diffusion of potatoes in Europe or of cassava in Africa and South-East Asia transformed the staple food in the first half of the nineteenth century. However, as the international trade intensified after 1850 (among other things, caused by expanding colonialism), the daily diet transformed once and for all. Worldwide, a pattern has developed in which the rising purchasing power of the masses determined the pace of changes. At first, more of the staple food is consumed, then, little by little, more expensive food (meat, fats, sugar, dairy products) drives back the importance of staple foods, and finally, a diverse diet emerges with a high share of animal foodstuffs (Grigg 1999). This global process involves the expanding consumption of manufactured food, the lengthening of the food chain, the fading away of seasonal foods, the appearance of "food niches" (aimed at particular groups such as youngsters, sportsmen or young mothers), and the idea of food security and of individual choice regarding eating and drinking (Scholliers 2007). This transformation can be summarized by the concept of nutritional transition, or the move from almost constant undernourishment to enough and even too much food (Popkin 2011).

From Malnutrition to Obesity

The cereal-dominated diet of the premodern world has often been regarded as poor in nutrients, but this is a misconception that takes insufficiently into account that other elements of the diet (though often contributing little in calories) offered various nutrients (Heinrich and Hansen 2018a). While two decades ago it was generally assumed that dietary deficiencies were widespread among the population of ancient Greece and Rome (Garnsey 1999), recent studies are less pessimistic about health and living standards (Waldron 2006; Killgrove 2018). Medical literature indicates the presence of diseases, like scurvy, that are the result of an unbalanced diet, but does not indicate how many individuals were affected. Osteological analysis of skeletons offers insight into the health of individuals. Porotic hyperostosis, for example, a condition that leads to porous bone tissue in the cranial vault, has been interpreted as an indicator of widespread iron deficiency, but was in most cases probably caused by red blood cell shortage, parasites or lead poisoning. Recent studies find relatively few indications that individuals had suffered from chronic dietary deficiencies. On average, yet, people in Roman times were shorter compared to earlier and later periods. However, this is largely the result of the lesser intake of animal proteins, as the skeletons were predominantly taken from urban graveyards. Most osteological studies do not point to a clear difference between men and women, although, in view of male dominance within the households, it is reasonable to assume that under stressed circumstances, women and children were more vulnerable than adult men.

Chronic under- and malnutrition were common experiences in the medieval and early modern world as well – but again this should not be generalized. The spread of diseases related to overly monotonous diets also points to the role of malnutrition – especially in the centuries leading up to the industrial revolution. *Scurvy*, caused by lack of vitamin C, is well known for its prevalence among sea-farers. More common was *pellagra*, also caused by vitamin deficiency, which was widespread in eighteenth-century Italy as a result of an overreliance on maize (the daily diet of the poor). In Asia it was *beriberi* that was caused by poor diets with a lack of variety and vitamin content. Health implications, caused by deficient nutrition, endured in the nineteenth and twentieth century, but diminished unevenly and gradually according to dietary improvements in specific parts of the world. The nutritional transition initiated different health issues.

Overweight people have always existed, but they constituted a small minority in most parts of the world during most of the time. In Europe and the United States, corpulent men and women often were a sign of well-being, but very obese men and women were a curiosity at fairs (Oddy et al. 2009). Only after the transition from insufficient to rich diets, fat people were perceived as an issue. In the United States, a "creeping" obesity crisis occurred. It appeared in the 1910s, when health concerns about overweight people mixed with notions of the ideal body, which led to innumerable dieting schemes, but burst after the Second World War.

With regard to both under- and overconsumption of food, debate exists about responsibility: the individual or "society"? For a long time, the former received the most attention, but more recently the latter gained more support – referring to the global escalation of convenience foods, fast expanding eating out, and the role of advertisements.

Famine

The harvest of staple foods was vulnerable to adverse weather, but also to man-made disruption, such as plundering soldiers. Growing barley or other so-called inferior cereals, which had short growing cycles and were less vulnerable to drought, alleviated but did not solve the threat of harvest failure. During Antiquity, general mentions of the fear of shortage and famine are numerous, but it is difficult to establish how frequent and serious food crises were. Literary sources on the ancient world pay most attention to political centers like Athens, Rome, or Constantinople, but precisely their political status ensured them a stronger entitlement to food. High food prices probably caused increased mortality among the urban poor and certainly caused increased inequality. If literary or epigraphic sources mention food shortages, it generally is to emphasize the measures taken by rulers, benefactors or – in the Later Roman Empire – the Christian church, but the gravity of the crisis is hidden from our view. Widespread drought or back-to-back harvest failures depleted reserves, leading to famines characterized by increased mortality. The few famines that are narrated in detail show that, just as in later times, they caused high mortality due to epidemics rather than starvation. Reliable figures are rare in sources on the ancient world, but occasional claims of hundreds of thousands of victims (e.g., 800,000 in Numidia in 125/124 BCE according to Orosius 5.11.1) are not to be rejected out of hand (Erdkamp 2018).

In the medieval and early modern world too, famines were a recurrent phenomenon, given the persistently low surplus produced in premodern agriculture. Almost everywhere famines were frequent: at least once every generation in premodern times a wide-spread famine struck most places in Europe, leading to anxiety and insecurity (Ó Gráda 2010). Unlike modern famines, medieval and early modern food shortages were usually caused by back-to-back harvest failures, often the result of too little or too much rain. They could be influenced by natural disasters such as long-term climatic shifts or volcanic eruptions (for instance, the Famine of One Rabbit of 1454).

However, the risk of famine was not equally spread across premodern societies, and man-made factors could severely exacerbate the destructive forces of nature. Warfare increased the chance that bad harvests would result in famine, as when the notoriously wet springs of 1315 and 1316 combined with warfare, caused a three-year-long famine across much of Northern and Central Europe. The unevenness across time and space with which famines struck the preindustrial world also suggests that risks could be mitigated even before modern times. Harvest shocks could be better absorbed where yields were higher, where transport networks were developed more fully, and where agricultural surplus in good years allowed for coping mechanisms to be better developed. A wide range of precautionary measures were practiced throughout premodern Europe. In times of scarcity, marriages were postponed, with a reduction in births as a result. Public granaries could allow the storage capacity to overcome temporary adversities, and trade or exchange arrangements could similarly help to overcome setbacks. If dearth struck nevertheless, poorer consumers tried to safeguard their caloric needs by "trading down" to inferior substitutes for wheat, such as oats or barley.

As a telling sign of the early improvement in the English economy, the size and duration of food crises declined gradually over time, to such extent that it was spared major peace-time famines since the 1620s. In Japan famines occurred less regularly in the seventeenth and eighteenth centuries than before. In Germany famines also became rarer in the eighteenth century, but in most parts of Eastern Europe the threat of famine lingered on until at least the end of the eighteenth century (Ó Gráda 2010).

In the nineteenth century, the general improvement of food supply and the growing buying power ended periods of starvation, except for specific episodes linked to war. Yet, also plant illness, weather conditions, ruinous policy, and speculation caused starvation. Some of these factors were increasingly under control in more and more parts of the world since the 1950s, although there remain "problem areas" while new risk areas emerged (Messer 2013). Estimations of the number of deaths due to famine reveal huge fluctuations between 1870 and 1920 (3.1–16 million deaths per decade), a disastrous increase between 1920 and 1970 (9.8–16.6 million), and an impressive fall since 1980 (0.9–1.3 million) (De Waal 2018). Mass starvation occurred in India under colonial rule in the 1870s, in Ukraine in 1932–1934, in large parts of the world as a consequence of the Second World War, and in China during the Great leap forward of 1958–1962. Since the 1960s, the Horn of Africa is permanently imperiled by hunger, which international aid campaigns only partly remedied.

Globalization and Intercultural Exchange

Throughout Antiquity crops and animals were spread from East to West, including such seemingly ordinary foodstuffs as peaches, wine, and chicken (Garnsey 1999). The consumption of wine, which was imported into Gaul by Greek traders, was adopted by Celtic leaders as a means to emphasize status. The increasing communication and trade across long distances under Roman rule stimulated the process of the diffusion of new crops and animals even more. Roman soldiers and civilians in central and northern Europe held on to their culturally accustomed foodstuffs, and in the early empire olive oil, wine, and fish sauce were transported from the Mediterranean to the northern provinces. Wine cultivation spread northwards too, first in southern Gaul, later also further north. Olives only grow in a limited range along the Mediterranean coasts and hence olive oil disappeared in central and northern Europe when the ethnic composition and dietary preferences of the Roman army changed.

Among the plants spread northwards were several Mediterranean herbs like coriander, poppy seed, dill, and mustard. Commerce along trade routes towards the East, reaching India and even beyond, ensured a steady supply of black pepper and other spices (Sidebotham 2011). The price of pepper was not excessive, and it was within reach of large segments of society. With the decline of the Roman Empire in the West, many imported foodstuffs disappeared, though some plants became permanent features of central and northern European garden plots (Cool 2006).

From the late middle ages onwards, the search for profitable spices spurred European overseas expansion and the desire for more reliable and abundant supplies of exotic cash-crops lay at the heart of the slave-based plantation system that was set up across the world (Curtin 2002). A desire for exotic foods and drinks was not the only factor in these developments: so, too, were intra-European warfare and imperial competition, the search for precious metals, and nonfood consumer goods. Nevertheless, food did play an important role. Exotic condiments had been known in Europe since Antiquity, and with the growth of international commerce in the later middle ages, they regained their place in the European imagination, if not perhaps in most kitchens. Spices such as pepper, cinnamon, cloves, or nutmeg travelled from East Asia to Venice, and then further across Europe (Freedman 2008). Since quantities were low and prices high, the incentive to find new routes was huge. By the end of the fifteenth century, Portuguese and Spanish seafaring had resulted in the establishment of a direct sea route around the African continent to the Indian Ocean, and in the opening of the American continent to European exploration, conquest, and commerce.

The spectacular strengthening of global commercial ties as a result of the new sea routes pioneered by Vasco da Gama and Christopher Columbus brought about major shifts in eating and drinking practices across the world. The variety of edible crops expanded everywhere. Europeans, for instance, discovered sweet potatoes, maize, chili peppers, and tobacco in the Americas. Over the following centuries they would also become familiar with tomatoes, green beans, turkeys, cacao, and squash. Meanwhile, wheat, horses, and livestock travelled in the other direction. This so-called Columbian exchange did not leave untouched the world outside of the Atlantic. Maize, cassava, and groundnuts were introduced from America to Africa, while tomatoes, sweet potatoes, and chili peppers influenced Asian eating practices (Albala 2003). Other things being equal, these exchanges themselves reduced global vulnerability to famine (Ó Gráda 2010).

From the sixteenth century onwards, the grip of European trading companies on the global production sites of exotic comestibles was gradually strengthened. In the most extreme cases, this resulted in colonial exploitation, with slave-based plantations for the production of sugar, nutmeg, coffee, or tobacco as sad examples. In other cases, such as those of tea or pepper, no unfree labor was involved until the nineteenth century, yet the quantities produced, shipped, and consumed globally still expanded to unprecedented levels. Already before modern times this implied that global consumer goods could become within reach of average – and even poor – households in Europe (O'Rourke and Williamson 2009). However, it is a telling irony of the early modern age that even though globalization in theory brought more potential variety in eating and drinking habits, in practice it was for many a period of increasing monotony. Sugar and pepper became more widely consumed than ever before, but at the same time a range of other spices almost entirely disappeared from European kitchens after the sixteenth century. Potatoes and maize could offer more – and cheaper – calories per hectare, as a result of which some European regions gradually became overly reliant on a monoculture of those crops, leading, for example, to the Irish Great Famine of the 1840s.

The Colombian exchange not only affected the types of food and drink consumed worldwide but also sorted cultural effects. From at least the sixteenth century onwards, eating and drinking rituals, their meanings, and their connotations travelled the world. They influenced the performances of eating and drinking themselves, as in the case of smoking or the drinking of hot beverages, which were unknown in Europe before the introduction of tobacco, coffee, and tea in the seventeenth century, but also the meanings of food and drinks: their perceived medical effects, or the degree to which they could function as social markers. This globalization of foods and drinks thus brought with it a complex history of cultural and scientific exchange, in which the perceptions, uses, and qualities of foodstuffs became appropriated differently in new contexts. Chocolate, for instance, was first introduced in Spain from Meso-America as a spicy rather than as a sweet drink, yet between the seventeenth and early nineteenth centuries it was gradually transformed into a sweet beverage with aristocratic connotations (Norton 2008).

International food trade grew swiftly from 1815 to 1914, then weakened up to 1940, but skyrocketed after 1950 (Federico and Tena-Junguito 2016). The colonial system until the 1960s and, then, free trade enabled this growth. Foods such as cocoa, life cattle, alcoholic beverages, and, increasingly, grain represented the bulk of the overall trade until the First World War. The share of fresh food diminished as manufactured foodstuffs, such as canned food, biscuits, dried pasta or soft drinks, grew in the 1920s. New modes of transport and preservation, particularly cooling – also in private homes, first in the West, then globally – revitalized international trade in fresh food such as herbs and dairy products since the 1960s, which contributed to the idea of ever-expanding choice, although it furthered global homogenization.

Availability of food from far remote shores changed the diet radically. The mass import of American wheat into Europe from the late 1870s onwards, for example, caused the fall of bread prices, which was *the* condition to revolutionize the overall spending pattern. The share of bread in the total budget of an average West-European household plunged from about 40% in the first half of the nineteenth century to 15% in the 1920s and to 3% today, gradually initiating the so-called consumer society.

Exchange of goods came along with the exchange of money, people, and ideas. Migrants took with them not only their language and religion, but more tenacious, also their foodways (Gabaccia 2017). The flow of migrants rose impressively throughout the nineteenth and twentieth centuries, with millions of people moving from Europe to the Americas, from Africa and Asia to the Americas and Europe, and within each continent. They all opened their own shops and eating places, often confronted with prejudices and xenophobia, although, inevitably, mixed diets emerged to various degrees, such as fusion (i.e., combination of existing foodways) or creolization (i.e., creation of new forms). This led to paradoxes to which testifies the fact that chicken tikka masala was labeled the English national dish in 2011. Culinary writers and performers (chefs, travelers, bloggers, . . .) contributed to the wide diffusion of both indigenous ("authentic" or "traditional") and creolized dishes in an ever-growing flow of culinary books, exhibitions, articles, and radio- and TV-shows.

Governing Eating and Drinking

All over the world and throughout time, governments interfered with eating and drinking, and in some periods most people actually depended entirely on help to survive. Starvation, however, was not the only reason to develop specific policies. Political and economic structures and strategies were aimed at securing the food supply of the urban populace in Ancient Greece and the Roman Empire. Most towns and cities relied largely on their hinterland, and taxes and rents ensured a large percentage of the harvest. When local harvests failed, imports were required. However, high transportation costs over land and limitations of communication, commercial networks, and buying power restricted access to outside resources for much of the people. Apart from the most powerful ones, towns and cities did not control outside resources and were therefore limited to measures intended to attract traders to supply the urban market. Guided by the notion of a "just price," close supervision and regulation of the city's food market aimed at keeping prices low and avoiding speculative behavior. However, authorities did not have the means to prevent high prices when the supply failed. Members of the urban elites frequently stepped in by selling food at prices that were below current market level (Erdkamp 2005). Only with the rise of Christianity in the Later Roman Empire did measures emerge specifically aimed at the poor and destitute (Garnsey 1999).

Food riots did not occur in classical Athens, as the democratic institutions gave the citizens sufficient means to put pressure on authorities. Urban food riots did occur in Roman times, though, and not only in Rome. Riots were seen as the expected consequence of price rises, which indicates that they were relatively common (Erdkamp 2002). The political status of Rome and, later, Constantinople ensured a stable supply. The well-known distribution in Rome of free grain (later, bread) to adult male citizens was instigated in 123 BCE as a measure to stabilize the food market. From Augustus onwards, roughly about one third of the population of Rome ate grain or bread provided through this scheme, but also the remainder largely went through state-controlled supply channels known as the *Annona* (Erdkamp 2005).

In classical Athens, public largesse was a civic duty of the rich; in imperial Rome it was a monopoly of the emperor. Outside Rome the local elites demonstrated and legitimized their social and political position by benefactions that included public banquets, which reflected the social hierarchy of the communities: the higher the status of the recipient in the community, the better treatment in terms of food and wine that he could expect during the banquet. Sumptuary laws issued by Roman statesmen and emperors ostentatiously aimed at limiting excessive spending on luxuries, but the frequency with which these were issued shows that they had little impact on reality, beyond emphasizing the virtues of the lawgiver.

Medieval and early modern governments were most clearly concerned with regulating access to foods and drinks, rather than with eating and drinking itself. Market regulation attempted to guarantee the fairness of the prices for basic foodstuffs (the aforementioned notion of a "just price" lingered on until today), as well as the quality and safety of foods that spoiled quickly, or of which the quality could not be visibly or tacitly gauged. Eating and drinking itself was much more rarely the subject of governance intervention, unlike the abundant sumptuary legislation that attempted to regulate the wearing of clothes by limiting specific clothing types to specific social groups or occasions. In some cases, such legislation was also imposed on eating and drinking habits, for instance by imposing limits on the lavish spending on wedding and funeral banquets. It is unclear if such regulation sorted much effect (Hunt 1996).

Today, food supply still worries authorities because lack of food often causes social outbursts (e.g., Egypt's bread riots in 2017). In the nineteenth century, securing sufficient food came along with quality concerns about food. The former intensified throughout the world because of the growing dependency of the market and the need to feeding the wage workers at low cost, but the latter – food safety – was mostly new (Bruegel 2012; Joseph and Nestle 2012).

To secure sufficient and cheap food when domestic output coped with difficulties, national authorities lowered taxes, subsidized producers and retailers, established control systems with maximum prices, put up storehouses, and organized food distributions. In many countries after 1950 food crises vanished, and only tariff policy remained. Yet, many people hold authorities responsible for taking care of the food supply. In other countries, however, diverse food policies continued to be applied according to food availability. Local initiatives influenced eating in a very direct way: public and private charity distributed staple foods on a daily basis, as was the case in Europe in the 1840s, 1850s, and during both world wars. This still is the case in many countries around the world until today, including rich Western countries.

Other interference with food related to alcohol consumption (Phillips 2014). For long, too much alcohol drinking was seen as lack of self-control. Although it was tolerated, public drunkenness was rebuked and penalized, lest it was totally prohibited for religious reasons. In Western countries in the nineteenth century, however, drinking was medicalized and conceived as a social problem, labeled alcoholism. It was central to the authorities' so-called social question that included immorality, delinquency, disease, prostitution, socialism, and other calamities. Consumption of strong drinks would lead to unemployment, poverty, misery and, inevitably, ruin the body and the family. Antialcohol campaigns emerged in the 1810s and intensified in the 1840s and, again, 1880s, which brought about successful temperance movements all over the world. In turn, since 1900 this led to temporarily or partly prohibition of producing, selling, or consuming alcohol in many countries across the world, such as Australia (1910–1928), some states in India (after independence), Norway (1916–1927), Russia (1914–1923), the USA (1920–1933), and Yemen (1962–1990).

Wine and spirits were often adulterated. Food fraud was not new, it came under many forms and related to many foodstuffs. However, the nineteenth century, again, led to new challenges (Atkins 2013). These were due to big transformations (industrialization, urbanization, individualization, . . .), as well as to the lengthening of the food chain, which included a growing number of actors who saw profit opportunities. Water was added to milk, chalk and field beans to flour, which was illegal but did not threaten health; copper sulfate, coloring agents, alum, and all sorts of stuffs were added to flour, which also was illegal but, moreover, could harm health. Until the 1860s, authorities focused on honest food trade, but since then also health concerns were part of regulations. Detecting food adulteration was done by chemists, physicians, and charlatans, but increasingly so by recognized chemical laboratories, serving the authorities, merchants, and consumers. These could easily discover falsifications by 1900 but had difficulties with the emerging sophisticated production processes (chemical flavor improvers, emulsifiers, color agents, sweeteners, . . .), of which the general public became aware in the 1970s.

National and, later, international institutions fixed norms for quality so as to guarantee generally accepted quality norms and, hence, trust in food. Influential was the 1905 French legislation on appellations of origin pertaining to wine, mustard, cheese, cider, and other foods, primarily intended for economic reasons, but with an effect on quality and health. In 1963, the World Health Organization started establishing international food standards (the Codex Alimentarius). Recurring food scandals, however, led to genuine food panics, as for instance in Scotland in 1964 (corned-beef typhoid outbreak) or Japan in 2008 (poisoned dumplings), which backs Ulrich Beck's notion of "risk society" (Ferrières 2006).

Optimal Diet

Philosophy and medicine in classical antiquity are intricately linked, and both can be seen as characterized by a system of contrasts. First, the contrast in Greek and Roman perception between the cooked and uncooked, cultivated and wild, civilized and barbaric, which reflected the dichotomy between "us" and "the other." Barbarians ate uncooked food and products of the wild, unlike civilized people who ate the produce of cultivated fields and domesticated animals. Whether Scythians, Huns or Homer's cyclops, they were characterized in Greek writing as not belonging to the realm of civilization by their food and drink. Another contrast was that between excess and moderation, the first also a mark of the uncivilized. In Plato's view of the soul and body, intellect is located in the head, emotions in the heart, while the lower belly is linked to the lesser needs of humankind. Giving in to the needs of the body is a sign of moral weakness, to which not only barbarians, but also slaves and women were thought easily to succumb. Restraint in the face of luxury and pleasure is a common ideal in Graeco-Roman philosophy, most explicitly in that of the stoics (Wilkins and Hill 2006).

Medical thinking was based on the principle of the four humors (or temperaments), propagated by the writings of the second-century physician Aelius Galenus (or Galen). According to this theory, the balance of bodily fluids in the body determined one's health. The four humors were either hot or cold, dry or moist. Food and drink were not only characterized by both contrasts, but they also contributed to the balance of the body. Hence, food played a large role in medicine, as ailments were thought to be caused by an imbalance that could be cured by a particular diet. Women differed from men, being moist and cold, and therefore required a different diet from men (Wilkins and Hill 2006).

These lines of thinking largely prevailed in the early modern period. As is fitting for a world in which medicine enjoyed only few successes, and the little effect it sorted was more obviously noticeable in preventing rather than in remedying illness, knowledge about the dos and don'ts in eating and drinking was considered crucial for good health. More so than in modern medical or dietetic sciences, mental and physical well-being were thought to be very directly linked to what one ate and drank. Medical thinking on the subject in the medieval and early modern era still relied mostly on the synthesis made by Galen, whose ideas were re-introduced in the European middle ages by Arab translators. This theory provided the framework from which arose a range of theories that would dominate discussion about the optimal diet up to the 1910s.

Since each individual had his/her own humoral composition, and all organic matters were composed of elements with specific humoral properties, there existed no universal optimal diet. Rather, the specific humoral properties of each individual at a given moment determined what the optimal diet was. Age, gender, weather, illness, occupation, and activities all played a role in determining the suitable diet. The main object of discussion was then how to reliably determine which humoral properties a given condiment possessed. For this one could rely on the knowledge inherited from antiquity, on appearance and taste, or on similarity in provenance and type to other foods whose properties were known.

This is not to say that medical thinking on diets did not change between the high middle ages and the end of the eighteenth century: sixteenth-century humanists such as Andreas Vesalius turned their attention to the original Greek texts of Galen, instead of relying on older translations from Arab, and as a result of the studies of humanist scholars, the texts of Hippocrates were re-discovered as one of the original sources that had influenced Galen. However, by and large such changes in medical knowledge required only minor adjustments and corrections to dietetic knowledge but did not fundamentally alter the way of thinking about the relation between food and health. Deeper shifts in medical thinking about the optimal diet emerged only in the seventeenth and eighteenth centuries, when different schools of medical thinking emerged, such as the iatrochemical school of Paracelcus, and the Leiden school of Hermann Boerhaave. However, the effect of these new modes of thinking on dietetics was in most cases superficial and slow to spread. Until the early nineteenth century most prevailing ideas about diets derived from older, humoral, ways of thinking about the human body, even if they were no longer explicitly motivated in those terms (Albala 2003).

For the majority of the world population before the nineteenth century the choice of food and drink was overwhelmingly dictated by local availability. Nevertheless, for better-off households there was room for fashion and taste. In sixteenth-century Europe, Italy was the culinary fashion-maker, the place from which shifting tastes gradually spread around. The most influential exponent of Italy's role was Bartolomeo Scappi, whose *Opera* of 1570 provided an exceptionally thorough illustrated guide to Italian gastronomy in his time. In the early seventeenth century, Spain would become the new gastronomic center, before moving to France. Although the limited availability of imported foods and drinks compared to today might make the impact of fashion less obvious, there are clear examples of changing tastes over time in the early modern period. The separation of savory from sweet courses (deserts) in the different courses of a meal is an invention of seventeenth-century French gastronomy that became so self-evident that for many modern observers it is hard to perceive that it is not a universal preference of humans, but a taste that was only developed very recently in the history of humankind.

The importance and success of culinary fashions in early modern Europe was greatly helped by the invention of the printing press in the fifteenth century. Although recipe books in scriptural form were frequently copied and enjoyed some popularity already in the late medieval period, the sheer number of recipe books printed from the sixteenth century onwards indicates a change in scale that is unlikely to have occurred without the printing press.

Throughout the nineteenth and twentieth centuries, nutritional insights renewed drastically, which directly affected the way people conceived of *good* eating (Carpenter 2003). Around 1800, centuries-old concepts about the diet still prevailed, although gradually new insights had emerged in the eighteenth century linked to the so-called chemical revolution in Western Europe. Despite this, very old concepts related to the four bodily humors left traces up to the 1960s. Three big innovations may be detected in nutritional sciences in the nineteenth and twentieth centuries: the application of the concept of calorie (1880s), the discovery of vitamins (1920s), and the full awareness of dangers of overeating (1950s). Of course, dietitians dealt with food-related illnesses (beriberi, scurvy, pellagra, etc.), but particularly the three innovations inspired food recommendations to which the general public mostly reacted ambiguously: some recommendations were totally ignored, while others were eagerly applied.

Prior to the "calorie-era," food advice and eating rules aimed at well-balanced diets. This consisted of the staple food that should be complemented by protein-rich foodstuffs, some variation in the menu, and suggestions regarding a peaceful eating atmosphere. These, and other eating rules, appeared in household education for young girls in several parts of the world after 1870, aimed at cooking well at low cost and creating a joyful home for husband and children. After 1900, the general public started to learn about the notion that all food and drinks consist of carbohydrate, protein, and fat that provide energy, which is quantifiable by calories. Bodily requirements were established too (3,000 kcal per day for an adult man). Hence, it became easy to compute exactly the necessary daily intake of food. Moreover, the kilocalorie "equalized" all foodstuffs, and therefore energy-rich food, such as peas and sugar, was highly promoted, while even alcohol was seen as energy provider. It took several decades to realize that sugar was not harmless, while the antialcohol lobby immediately reacted against the preeminence of the calorie (Scrinis 2013).

The coining of the vitamin in the 1910s, previously the "unknown substances essential to life," had immediate impact on food advice and manufacturers, to which testify the many advertisements in popular newspapers throughout the world in the 1920s and 1930s. Moreover, the insight that heating fresh food may partly eliminate the effect of vitamins led to the reappreciation of raw foodstuffs. Whole meal bread contains more vitamins than white bread. This led dieticians to promote the former type, which the (European) consumer rejected until the 1990s. After 1950, food supplements with all sorts of vitamins became increasingly popular.

Finally, the insight of the dangers of overeating concurred with the expanding availability of food in most parts of the world after 1980 since it may lead to heart diseases, diabetes or some cancers. So far, the avalanche of food advice and a never-ending stream of dieting gurus cannot end the recent "obesity crisis."

Restrictions

Unlike Jewish religion, which imposed strict dietary laws about what and with whom one could eat, Greek and Roman beliefs were not linked to strong ideas concerning impure foods. This is not to say that there were no cultural boundaries, for example, concerning the animals to eat. Eating wild animals, apart from wild boars, deer, or hares, was frowned upon, but also domesticated animals, like dogs or horses, were not normally eaten. Cannibalism, which is sometimes mentioned in the context of severe famines, was obviously a strong taboo. Vegetarianism was rare in Antiquity, although it existed among certain groups. Pythagoras believed in the reincarnation of human souls, be it in humans or animals. Hence, he and his followers regarded the eating of animals as a form of cannibalism. Also, the Neoplatonist Porphyry rejected eating meat. In general, he advocated an ascetic table, but realized that only philosophers could pursue this.

Paradoxically, food and eating were *and* were not important to most mainstream communities of Christianity, as it spread into Graeco-Roman society. Commensality, the act of eating together, was at the heart of Christian rituals. At the same time, these same communities chose not to adhere to Jewish dietary laws, thereby allowing Christians to remain part of wider, predominantly pagan communities. In its late first-century formulation, the Gospel says that purity was a matter of belief, not of food (Mark 7, 14–19; cf. Luke 11, 37–42). However, against the background of philosophical approaches to the relationship between body and soul, Christian writers developed a Christian discourse on food, which was mainly aimed at reaching higher forms of Christian religiosity by negating the demands of the temporary, worldly domain. Christian asceticism, which became strongly developed in the fourth century, aimed at fighting the body by depriving it from its sustenance and by condemning pleasure that could be arrived from the act of eating. Asceticism became a predominant feature of monastic life in Late Antiquity. However, outside monasteries there remained a tension between the emphasis on asceticism in Christian thinking and reality, as banquets and self-indulgence remained important elements of Christian ways of life among the elites (MacGowan 1999; Smith 2003).

Medieval and early-modern medical thinking about the optimal diet provided a few guidelines in making dietary choices, but before the nineteenth century it imposed little in terms of general rules or restrictions. If medicine offered few universal recommendations for restraint, religion did. In late medieval Christian Europe, there were an estimated 150 fasting days spread over the year, during which all healthy individuals were expected to abstain from consuming animal products – not only the flesh, but also derivatives such as butter or milk. Some of those fasting days were strict, others – such as the weekly fasting on Friday – were "minor" and allowed for some flexibility. After the Reformation, thinking about restraint in eating and drinking diverged across Europe. Lutherans did not adhere as strictly and as often to fasting as Catholics did, while Calvinists tended to favor a more austere living style in general, but not necessarily according to the rhythm of feasting and fasting imposed by the Catholic calendar (Albala 2003).

Regardless of the specific religious confession one belonged to, it was widely held throughout medieval and early modern Europe that the ability to refrain from eating and drinking could be a powerful marker of spiritual achievement. Mystic women, ascetic movements among the clerical orders, and heretics demonstrated their exceptionality by imposing specific restrictions in eating and drinking (Bynum 1988). This phenomenon lingered on, or re-emerged, in the eighteenth and nineteenth centuries, when the temperance movement allied religious ideas with restraint in eating and (especially) drinking habits.

Religion was not alone in imposing restrictions on eating and drinking. Starting from the Renaissance, a growing concern for more restrained and civil table manners gradually spread across Europe. Communal dishes made way for individual plates, table cloths, and napkins presumably improved table hygiene, and as the fork was gradually introduced from Italy to the rest of Europe, eating with bare hands became less accepted. Historians and sociologists have debated whether this concern for civility spread across early modern Europe as a result of the influence of courts, urbanization, rising living standards, changing social inequalities, or shifts in moral thought (Sarti 2004). Yet, between medieval and modern times there was much less change in *what* was eaten, than in *how* it was eaten.

In the nineteenth and twentieth centuries too, food restrictions come under many forms. Religious prescriptions continue to form the basis of food and drink regulations and avoidances, thus constituting clear and strong identifying boundaries. Yet, regulations were followed to different degrees throughout space and time. For example, alcohol consumption in countries with a Muslim majority fluctuated under the influence of the intensity of faith, legal prohibition, social pressure, international exchanges, or identification with peers (such as youngsters). Still, century-old food restrictions remain important as part of traditions that recently obtained new interest in some parts of the world. In Europe, however, the impact of the Church diminished after the Second World War, which clearly shows in the declining fasting observance and the vanishing of fish-days on Wednesdays and Fridays.

New food restrictions surfaced. Deliberate refusal of meat eating existed since classical Antiquity, while meatless days were part of religious rules, and some doctors advised to moderate meat consumption for health reasons. However, in Western countries, by the end of the nineteenth century, vegetarianism was institutionalized when various associations with a slowly growing number of (middle-class) members appeared. Sign of its success was, for example, the opening of a vegetarian restaurant at the 1910 World Exhibition in Brussels (Belgium). Motives for refusing to eat meat included animal welfare, economic concerns, health, philosophical objections, or expression of solidarity and empathy with other people, which all persuaded a growing number of people throughout the world in the late twentieth century. Nonetheless, vegetarianism (and its variants such as veganism or *flexiterianism*) remains a marginal phenomenon worldwide (Ankeny 2017).

Deliberately restricting eating and drinking occurred also within the frame of slimming. Dieting was not new, but with the increased attention to the (Western) beauty ideal of the body, more and more men and women paid attention to food intake. Long-established food avoidance may vanish. The recent case of eating insects (entomophagy) in Western countries exemplifies this. After being qualified for centuries as inedible food that arouse disgust, insects for human food are now praised for its high protein supply, sustainable production, and low cost.

Transgressions of food avoidances and taboos occur for various reasons and are accepted momentarily. For example, unrestrained eating may be stimulated at particular occasions such as Christmas eve, when even children may be allowed to drink some alcohol.

Commensality and Celebrations

The Greeks and Romans preferred to eat three meals a day, with the evening meal as the main one. This structure persisted in many parts of the world until today. In Antiquity, breakfast and lunch were usually light, with some bread, possibly dipped in olive oil, cheese or eggs, and meat for the prosperous. The famous poem *Moretum* depicts a farmer getting up in the morning and eating freshly baked bread with a mix of cheese, vegetables, herbs, and salt before he sets out to work. The evening meal could either be eaten in the domestic sphere or in a more public setting. In Greece, women may not have joined their husbands during the evening meal. Homer depicts aristocratic women as being present at banquets and busy with textile work, while the men enjoyed their meal. In classical Athens, aristocratic men reclined during dinner at home, while their wives sat beside them. Roman custom, however, was for men and women to have their meals together. During more formal meals, children sat at a separate table (Dunbabin 2003; Wecowski 2014).

In cities many kinds of cold and warm food and drink were available in the inns and taverns and from street vendors, which may be related to the generally limited living space of the common people and requirements of work. For the same reason, for more festive meals many common people relied on celebratory meetings of the *collegia* (associations of different kind combining religious and professional functions), which were often sponsored by rich patrons. In Roman times, women were present at such meetings, as were slaves.

Festive meals of all classes were meant to express one's social standing. While the aristocracy in Homer sits during banquets, from the archaic onwards until the end of Antiquity, the well-to-do recline during their dinner, while being served by servants. Even Jesus is depicted in the Gospel as reclining during the Last Supper. The symposium in classical Greece was solely a meeting of men of the upper classes. Social equality was limited to the guests present. The etiquette and conversation during the symposium ruled out the participation of the uneducated. The only women present were servants and fluteplayers. The ideals of the Roman banquet centered on simplicity, friendship, and social equality, in other words, the pleasant gathering of likeminded people who enjoyed a good meal. Reality was different, though, as social hierarchy was expressed in the arrangement of guests and even quality of food and wine served. Writers like Martial and Juvenal complained about the haughtiness of their patrons at dinners, while conspicuous spending could lead to excess, as famously parodied in the Banquet of Trimalchio scene in Petronius' *Satyricon* (Wilkins and Hill 2006).

Social hierarchy was not limited to the upper classes, as is revealed by the regulations of the *collegia* dinners. Patrons celebrated their own birthdays and those of family members by paying for these festive meals, but distinction was also made among the *collegia* members between the well-to-do "middle class," who contributed wine and food, and the common members. Seating arrangements expressed this hierarchy, while rules applied against rowdy behavior.

In many respects, the role of eating and drinking in celebration during the medieval and early modern period formed a logical counterpoint to the importance of fasting in the Christian calendar. The indulgence in food (meat) and drink during Carnival stood in contrast to the period of fasting that followed it. Some religious celebrations were linked to specific foods or drinks, such as the symbolic importance of eating lambs and eggs at Easter. However, more so than religious meaning, feasting was infused with social significance. Communal eating and drinking cemented social ties, both horizontal and vertical ones. The community and cohesion of a family was tellingly symbolized by the sharing of "bed and table," while confraternities, guilds, civic militias, and voluntary associations rarely spared expenses for the organization of their guild meals. Drinking also played an important role in social life, in particular alcoholic consumption. The consumption of intoxicant drinks probably increased during the early modern period and forms an intriguing contrast to the growing importance contemporaries placed on civil table manners during this same period.

In the modern period and until today, food and drinks continue to be used to show rough and subtle differences between countries, regions, towns and countryside, men and women, and especially, rich and poor. Celebrating was one of the most evident occasions to clearly mark these differences, but in the course of the nineteenth century new occasions appeared on the individual and collective level.

The process of individualization comprised the celebration of one's career moves, birthdays, or anniversaries, which all led to special dining. This was mainly limited to well-off people: poor people celebrated collective events (e.g., the end of the harvest) by having loads of their habitual fare. However, in the twentieth century, a birthday or school success was increasingly celebrated among the middle and working classes too. Moreover, people tended to visit friends and relatives much more than ever before, to share a meal. In general, dinners of the rich were to some extent imitated by poorer people, and according to the increase of the purchasing power of the masses, more or less luxurious food and drinks were consumed, which became particularly apparent in the 1980s. The case of (sparkling) wine illustrates this well. This imitation led to the search of new forms of distinction by the rich who eagerly use haute cuisine and its continuous innovations.

Collective eating and drinking have existed since long, but the nineteenth century, again, brought about new features: throughout the world, big banquets were organized to celebrate the nation, the monarch, an institution (e.g., parliament, a trading board, or a workers' union), an international exhibition, the visit of a diplomat, or an aristocratic marriage. On a more modest level, collective meals were organized by a literary society, savings association, sports club, or any cultural group. The aim was to create and strengthen solidarity and identity.

A new possibility to draw clear lines of distinction was offered by the modern Parisian-style restaurant. Fancy eating out in public places existed in earlier centuries, for example, in China in the seventh century, but the nineteenth-century restaurant had more influence in that it appeared throughout Europe and its colonies, North and South America, Australia, and parts of Asia. Worldwide, eating out was common for travelers who could visit locales of very different kind, but where, in general, choice of food was limited. The Parisian restaurant appeared somewhere in the 1780s as a public place catering for richer patrons with specific characteristics: individual tables, menu cards, prices, stylish décor, and waiters and, above all, the possibility to choose among a wide selection of food and wine. The bourgeois clientele, men and women, visited these places to see and be seen, meet with people, and enjoy food. Culinary journalists and writers of traveler guides commented upon this new cultural locus of the rich, thus establishing, destroying and diffusing cooks' reputations (Shore 2007).

The middle and lower classes ate out for reasons linked to work: they purchased soup, bread, cold meats, and the like, often sold by street vendors. In big cities in the last quarter of the nineteenth century, new forms of popular eating out appeared, such as the snack-bar or the automat, which were the precursors of today's (transnational) fast food eating places. By 1900 more and more people dined for pleasure in restaurants of various status (brasseries, bistrots, cafés, inns, . . .), offering local specialties, and increasingly, foreign cuisines. The latter's success is connected to movements of migrants and tourists, particularly after 1950.

Conclusion

Most people for most of the time and in most places ate very monotonously, had barely enough and risked starvation frequently. Only a small group enjoyed food security and diversity, using it as a sign of status. Despite the many innovations of the Columbian exchange, the diet of the masses started to change definitely with the growth of agricultural output, international trade, and transportation facilities around 1800. The disparate evolution of purchasing power, however, led to very uneven nutritional changes throughout the world.

Perhaps the most telling transformation in the world's food history is the changing significance of food. For centuries, food was a bare necessity for most people, and although it obviously still has this function, more and more people see and use food in a different way: a means of individual and group expression, element of pleasure, and idea of choice. This is the move from the "taste of necessity" to the "taste of freedom" or even "of luxury." A clear chronology is lacking, although worldwide the 1980s seem to have played a decisive role because of striking changes in world trade, demography, purchasing power, politics, consumption, and perhaps decisively, meaning of food.

History of Eating and Drinking in the Ottoman Empire and Modern Turkey

3

Özge Samancı

Contents

Abstract

This chapter offers a broad survey of the history of food and drinking culture in the Ottoman Empire and Modern Turkey covering a time period of more than 700 years. This study aims to present changes and continuities that occurred in the Ottoman culinary culture in more than 600 years. Considering the vast territories of the Ottoman Empire encompassing modern Turkey, most of Southeastern Europe including present day Balkan region, Greece, parts of Ukraine, Middle east, North Africa as far as Algeria, and large part of Arabian Peninsula, it is not easy to make a comprehensive portrait of the food culture in all of the Ottoman territories. Istanbul, the capital city of the Empire as well as the Ottoman palace that represents a model for the rest of the empire, constitutes the subject matter of

the chapter. Ottoman palace culinary culture, courtly banquets versus daily food and drinking habits of the common people, food culture in religious communities, and traditional and new table manners are the thematic topics in the chapter. Eating and drinking habits in modern Turkey reflecting a direct continuation from the Ottoman past constitutes another subject.

Introduction

Ottoman Empire was founded in Anatolia (Asia Minor) at the end of the thirteenth century by the Turkish tribes who originated from Central Asia. This Empire grew to be one of the most powerful states in the world during the sixteenth century. The Ottoman period covered more than 600 years and came to an end in 1923 when it was replaced by the Turkish Republic and by the various successor states in southeastern Europe and the Middle East. Considering the long-shared history across the vast territories of the Ottoman Empire, the formation of food cultures in the Middle East, Anatolia, and the Balkans reflects a synthesis of multiple culinary heritages in which migrations, wars, political domination, trade, and religions played an important role. The culinary heritages on these geographies have been formed over the centuries as a result of culinary amalgamation of ancient Anatolian and Mediterranean civilizations, nomadic Turkish, medieval Arab-Persian, Byzantine, and Ottoman cultures. Among these ancient culinary heritages, the last is Ottoman. For centuries, Ottoman territory had been a house for different cultural groups, where Sunni and Alevi Muslims, Orthodox Christians, Catholics and Jews mingled and co-habited. The interaction between these cultural groups had an impact on the formation of a hybrid and rich cuisine over time. Istanbul, the capital city of the Empire since 1453, became the house of the Ottoman elites where a refined culinary culture flourished over hundreds of years. Although the culinary habits and traditions were noticeably changed, enriched, or renovated in the Ottoman territories since the end of the thirteenth century to the last days of the Ottoman Empire in the 1920s, a coherent gastronomic language with some distinctions was formed in the vast territories of the empire (Samancı 2019).

Ottoman Palace Cuisine

The Ottoman palace cuisine had the characteristics of an “haute cuisine” that differed from the cuisine of the common people by the quality, abundance, and diversity of the foodstuffs used in the preparation of the dishes as well as by the number of its kitchen staff, the quality of the food, the tableware used at table, and the codes of good manners at the table (Samancı 2015a). The food and drinking habits of the Ottoman ruling elites in different part of the Empire reflected also the qualities of the imperial cuisine.

The Topkapı Palace built by Sultan Mehmet II after the conquest of Istanbul in the fifteenth century remained the center of refinement and elaboration of Ottoman haute cuisine until the nineteenth century. The kitchens of the Topkapı palace, which are extended along the right side of the second court, were designed as a huge complex for different functions. They were divided into nine units catering to different groups of the palace hierarchy (Necipoğlu 1991). They had a separate confectionery and an outer commissariat each with its own staff and equipment. The confectionery was used to prepare fruit conserves, syrups, desserts, pickles, and medicinal preparations as sweet pastes. Apart from the nine imperial kitchens and the confectionary, which were located in the second courtyard of the Palace, a special kitchen located in the Harem was only reserved for the Sultan. The organization of the kitchen staff in the palace was similar to that of the army. Under the supervision of the chief imperial cellar, the head chef directed the kitchen staff. Under the chief cook and the secretaries of the storeroom, the cooks worked with apprentices and helpers recruited from young boys conscripted for the janissaries. Tasters supervised the preparation of the dishes. The waiters were responsible for importing food to the different rooms in the palace (Bilgin 2008). The kitchens of Beşiktaş Palace (or the former Çırağan Palace), Dolmabahçe Palace, which later replaced the Beşiktaş Palace, and finally Yıldız Palace, the imperial residences during the nineteenth century, resemble Topkapı Palace in terms of kitchen structure and organization (Samancı 2008).

The royal kitchens were the heart of the palace serving food to its thousands of inhabitants. At the beginning of the sixteenth century, the Topkapı palace kitchens were serving food per day to more than 4000 people. Apart from its practical significance, the huge complex of the kitchens played a central role in the palace ceremonies. The kitchens symbolized the generosity of the sultan who distributed food to his inner household, the resident staff, his slave soldiers, and the imperial council officials and also to official guests visiting the palace (Necipoğlu 1991; İnalcık 1991). Apart from these, during the imperial festivals, the kitchens worked with a high capacity serving food to more than 5000 people.

The palace was the residence for both the Sultan and for members of the dynasty as well as the center for the administrative mechanism; therefore, due to its function, a special attention was given to the provisioning of the palace. The imperial kitchens had the privilege of providing the best qualities of food products from different parts of the empire in Istanbul. A department reserved for purchases and expenses for the palace kitchen was established at the end of the fifteenth century. The network of provisioning of foodstuff to the palace was founded, supervised, and maintained regularly by the palace officials (Bilgin 2008). Provisions for the palace were supplied by Istanbul markets and from the countryside. All perishable food items and most of the other food products were purchased from Istanbul markets. The areas from where provisions were supplied to the palace were dispersed over large and geographically diverse lands of the Empire such as southern and northern parts of Marmara, Eastern Anatolia, the Aegean Islands, Balkans, Wallachia and Moldavia, Egypt, Cyprus and Crimea (Bilgin 2008).

Food and Beverages in the Ottoman Palace

The basic consumption food items in the Ottoman palace were meat, rice, flour, butter, and sugar. Sheep meat was the most favored one, along with lamb, kid, and poultry. Beef was used to make pastrami in the imperial kitchens. Offal, that is the head, the tripe, the feet, and the intestines of the sheep, were also used in cooking in the imperial kitchens. Fowl such as pigeon, partridge, pheasant, duck, and goose were the delicacies served to the table of Sultan and high dignitaries in the palace. Compared to meat and poultry, the supply of fish to the imperial kitchens was very limited until the nineteenth century. Seafood such as oysters, shrimps, fish roe, and caviar were generally absent in the palace cuisine; except in the fifteenth century where these food items were supplied to the kitchen of the Ottoman Sultan Mehmet II. During the nineteenth century, the consumption of fish increased in the Ottoman palace. Salted bonito, caviar, bottarga along with fresh fish from the Bosporus were served to the table of Ottoman Sultans (Samancı 2015b).

Dairy products such as milk, butter, cheese, milk cream, and yogurt were the staple foods in the Ottoman cuisine, both for the elites and the common people. Clarified butter was the favorite one among the other types of fats and oils such as tail fat, olive oil, and sesame oil. The use of olive oil was restricted in the Ottoman palace cuisine. During the nineteenth century, the consumption of olive oil was relatively increased in the Ottoman palace (Samancı 2015b). Wheat flour was the major ingredient used in the preparation of different types of bread (with yeast or without yeast), sweet, and savory pastries. Different types of bread were prepared in the imperial bakeries according to the hierarchy of palace residents. Rice was a luxury cereal devoted to the table of Ottoman elites, while cracked wheat (called *bulgur*) was the staple in the daily diet in rural areas. Lentil, chickpea, and broad bean were the types of legumes consumed in the Ottoman Empire until the late eighteenth century. Common beans and green beans, originated from the Americas, were introduced into the Ottoman cuisine during the nineteenth century.

The consumption of desserts as well as sweet drinks was a privilege devoted to the elites. Thus honey and sugar were used extensively in the preparation of different types of desserts, sorbets, compotes, and jams in the Ottoman palace. Treacle of grape (called *pekmez*) was another sweetener used in the kitchen. Spices were expensive but indispensable ingredients in the palace cuisine. Saffron, mastic (the resin obtained from *Pistacia lentiscus* tree), cinnamon, ginger, cumin, lemon pepper, cardamom, cloves, musk, and black pepper were the major types of spices used in cuisine. Allspice, paprika, red pepper, and vanilla (both originated from South America) enriched the spice repertoire of the Ottoman elite cuisine in the nineteenth century (Samancı 2015b). Seeds such as sesame, nigella seeds, and poppy seeds were used mainly in the preparation of savory pastry products. Apart from a wide range of spices condiments such as verjuice (juice of unripe grapes), rose water and orange blossom water were used regularly in the preparation of dishes in Ottoman elite cuisine. The use of spices was important also from the dietetic point of view. They were also used in the preparation of therapeutic products such as pastes and elixirs.

Apart from the high consumption of meat in the Ottoman kitchen, the various kinds of vegetables were the main ingredients used in making dishes. Eggplant, spinach, gourd, leek, cabbage, turnip, chard, fresh broad-bean, carrot, okra, artichoke, and cucumber were the vegetables used in the preparation of dishes in the palace kitchen until the nineteenth century. Onion was the basic ingredient of many kinds of dishes. Parsley, dill, mint, and garlic were used to give a flavor to the dishes. In addition to the list given above, celery, lettuce, vine leaves were other vegetables mentioned in the imperial kitchen records. New vegetables, native of Americas, such as tomato, corn, potato, green bean, zucchini, Jerusalem artichoke, green, and red peppers were introduced into the Ottoman territories since the eighteenth century, but they began to be used in the kitchens of the Ottoman palace during the nineteenth century (Samancı 2006).

Both fresh and dried fruits were commonly consumed and used in cooking in the palace cuisine. Plum, quince, apricot, sultanas, and sour cherries are examples of fruits used in the preparation of meat stews. Apple, pear, sour, and sweet pomegranate, various kinds of grape, watermelon, melon, date, fig, plum, peach, apricot, cherry, lemon, bitter orange, wild apricot were the fruits mentioned in the kitchen account registers of the palace. Chestnut, almond, hazelnut, walnut, and dried fruits such as prunes, dried apricots were present also in daily diet of the palace inhabitants.

Apart from water, beverages consumed in the palace consisted of fruit compote (*hoşaf*), sherbet (şerbet), a cereal-based fermented beverage (*boza*), and coffee. *Hoşaf* was a kind of sweet soup made of pieces of fresh or dried fruits, water, and sugar. It was served in big bowls and consumed with spoons during the meals. Sherbets made of fruit juice, flower's essence, or dried fruits were served during the day (Samancı and Croxford 2007). Sherbets prepared with rose, violet, tamarind, narcissus, quince, sour cherry, and flavored with expensive spices like musk, ambergris in the palace cuisine symbolized the refinement of the Ottoman elite culinary culture. Some of the sherbets were brought to the palace from the provinces of the empire such as citron sherbet (*hummaz*) from Egypt, rhubarb sherbet from Damascus. Palace residents had the privilege of using ice and snow in their beverages to keep them cool. During warm summer days, snow gathered at snow deposits in Istanbul and snows brought from the peak of Uludağ mountain (in the province of Bursa) were used in drinks as coolers. *Boza* was a fermented beverage made of wheat, rice, or barley, and it was prepared and consumed in large quantities in the Ottoman palace during the sixteenth and seventeenth centuries. Coffee had been known and consumed in Istanbul since the sixteenth century. Since the first half of the seventeenth century, coffee was listed among the ingredients supplied to imperial kitchens (Bilgin 2008).

Banquets and Daily Meals in the Ottoman Palace

Food had symbolic meanings in Ottoman court ceremonies, with the Ottoman Sultan displaying his munificence and his splendor to his people through feasts. By feasting and entertaining his subjects, the Sultan received their homage, while the subjects enjoyed themselves while participating in the festival. The consumption of plentiful food and the various impressive spectacles during the imperial festivals symbolized the splendor of the Ottoman palace for the populace's benefit. The quality and the quantity of the dishes served during the banquets organized in order to celebrate the circumcision of an Ottoman prince or the wedding ceremony of an Ottoman princess was impressive in the Ottoman palace. Different types of dishes were served to different groups of guests according to their rank. For example, in 1539, during the imperial Ottoman festival organized to celebrate the circumcision of two Ottoman princes, Bayezid and Cihangir, a series of banquets were prepared for a large number of guests, which included the public, on the order of Ottoman Sultan Suleiman the Magnificent. In addition to the public feast where 5000 bowls of food were prepared and served – rice pilaf (*dane*), rice pudding with saffron (*zerde*), 600 boiled sheep, 40 roasted beef cattle and a 1000 savory pastries ç*örek*) – on each day a banquet was arranged for a special group of guests such as officials, clerics, ambassadors, and janissaries. Six hundred tables were prepared for these military and religious men. The menu was the same for each banquet and comprised nine dishes: rice pilaf (*dane*), rice pudding made with saffron (*zerde)*, chicken soup, three sorts of sweetmeat, roasted chicken, as well as roasted lamb and sheep. Another banquet was organized for the pashas and Ottoman notables. This menu of 12 dishes was richer than that for the janissaries (infantry units) and clerics (Kut 1987). Each banquet menu was arranged according to the social rank of the guests, with the most delicate and appetizing dishes prepared for the Sultan's table and the high Ottoman dignitaries. The menu for this banquet consisted of 41 dishes. The different sorts of pilaf were the most interesting part of the feast, as apart from ordinary rice pilaf, colored varieties of pilaf created a visual spectacle. Four soups and five sweetmeats were offered with different kebabs and stews. Alongside lamb, chicken, and mutton, duck, goose, partridge and peacock were among the delicacies presented at the table. During the henna night, the night before the wedding ceremony, in addition to the above-mentioned dishes, stuffed gourd, stuffed eggplant, quail kebab and 53 desserts including halva, fruit jams, candied fruits, fruit pastes together with different sweet pastries were served to the guests (Tezcan 1998). As portrayed in several miniatures illustrating the banquets given during the Ottoman imperial festivals, the dishes were served one by one in Chinaware or in copper plates on low tables. The food might be served also in one time, as in French service style during the feasts organized on military expedition or during the feasts offered to a large group of people (Figs. 1 and 2).

Compared to the menus served during the banquets, everyday meal served to the palace residents was modest. For example, an everyday meal for the viziers, served after a council session in the Topkapı palace during the seventeenth century, consisted of six dishes and included items such as rice pilaf, chicken soup layered pastry stuffed gourde, and meat kebab (Reindl-Kiel 2003). Kebab, rice pilaf, soup, savory pastry, vegetable stews, or stuffed vegetables, desert, and fruit compote continued to be basic types of dishes served to the residents in the Ottoman palace during the nineteenth century. Chicken dishes, fish, and offal were types of dishes served occasionally (Samancı 2015b).

Fig. 1 Banquets given to the Ottoman religious men during the imperial festival in 1720, *Surname-i Vehbi*, Topkapı Palace Museum Library, (Bilgin and Samancı 2008)

Feasting was a key element in the Ottoman palace ceremonies with respect to receiving foreign envoys. Numerous travelers' accounts from the fifteenth to the early decades of the nineteenth centuries depicting the reception of foreign envoys in the Ottoman palace imply that offering food to foreign guests was a constant and permanent part of the court ceremonies. Generally a very rich menu consisting of traditional Ottoman dishes was served to the guests. Special servants called "tablakar" carried the tray of dishes from the kitchens to the rooms where the dinner would be served. The dishes are served one by one on low table. The banquets were in fact political occasions during which two parties fraternized and exchanged ideas. The host of these feasts was the Ottoman sultan, who demanded the allegiance of his guests in return for his generosity (Samancı 1998).

Food and Beverage Habits in Istanbul

As the capital of the Ottoman Empire, Istanbul had the privilege of sourcing the best and most varied ingredients from each of its regions. Beyond the food items and products of its immediate territorial limits, the kitchens of Istanbul also used foodstuffs from distant geographical regions of the Empire. The production and provision of foodstuffs in Istanbul have always been under the control of the Ottoman state. The food supply of the capital was one of the priorities of the state. State authority manifested over the economy in many ways: regulation of production, fixing of prices, requisitioning of labor, merchandise and even capital, export prohibitions. These measures were taken in order to ensure the supply of the capital city. Products such as cereals, animals, dairy products, coffee, olive oil, butter, vegetables, fruit, and spices arrived at the ports of Istanbul from the different regions of the Empire. Larders such as Unkapanı, Balkapanı, Odun İskelesi, and Yemiş İskelesi along the Golden Horn were the places of distribution of these commodities. Most of the vegetables and fruits consumed in Istanbul were grown in the city. Istanbul vegetable gardens, vineries, and gardens supplied the markets of the city. Milk, yoghourt, and dairy products were supplied from the small dairy farms in Istanbul. All food merchants were attached to guilds such as bakers, butchers, confectioners, grocers, fishers, kebab makers, halva sellers, vegetable and fruit sellers, poultry dealers, etc. People could buy food as well as ready prepared meals (such as kebabs, halva, tripe soup) in the shops of these merchants. Street vendors also sold all types of food while traveling through the city or neighborhoods (Samancı 2015b).

The price lists of the foodstuffs sold in the market provide a detail picture of the food items available in the capital. The Ottoman cookbooks show that the food ingredients used in the Ottoman palaces and in elite households were very similar. The key items were: mutton and lamb, poultry and game, fish, cereals, milk and dairy products, dry pulses, animal fat and vegetable oils, sugar and honey, spices, fresh and dry fruits, and vegetables. One of the main differences between the ingredients available in Istanbul's markets and in the imperial cellars was the variety of fish and shellfish. Different kinds of fish and shellfish caught from the Bosphorus were remarkable. The markets of Istanbul offered a great variety of fish such as the goby, the eel, the sea bass, the mullet, the red pageot, the swordfish, red gurnard, scorpion fish, the mackerel, the saurel, the common mendole, bluefish, and the bonito. Lobster, oyster, crab, scallop, shrimp, and mussels were sold also in the markets. Shellfish and fishes constituted the main food items of the Christian population – both Armenians and Greeks – during Lent (Yerasimos 2008). During the nineteenth century, the consumption of fish and shellfish increased among the Muslim population as the Ottoman cookbooks witness.

The most popular hot beverage consumed in the Ottoman Empire was coffee. Coffee had been known and consumed in Ottoman society since the sixteenth century. Tea was not a common beverage in nineteenth-century Istanbul until the twentieth century, when it outpaced coffee. Another hot beverage that was common in nineteenth century's Istanbul was *salep,* which was a hot beverage of milk, thickened with salep powder (flour made from the tubers of the orchid) and sugar. The three main types of fruit juices consumed were compote, sherbet, and cordials (Samancı 2018a). Although the consumption of alcohol was forbidden in Ottoman society by Islamic religion, accounts of travelers and memoirs written in the nineteenth century show that Istanbul inhabitants, both Muslim and non-Muslim, drank wine and *raki* in the city's taverns (Georgeon 2002). These alcoholic beverages were served with appetizers called *meze* such as salads, nuts, fruits, and seafood.

Food Culture in Ottoman Religious Communities

For centuries, Ottoman territories had been a house for all religions where Muslims, Christians, and Jewish mingled and co-habited. The interaction between different cultural groups had an impact on the formation of a hybrid and rich cuisine in time. The cuisine of the different communities in the empire (Muslim, Jewish, Christian) shared the characteristics of the same regional cuisine, dictated mainly by geography. However, the normative rules of each religion constituted the barriers between the culinary cultures of each community. Pork was illicit food for Muslims and Jews, but allowed for Christians. Seafood and fish were widely consumed by Christians, especially during Lenten days. The Jewish community, whose religion did not allow the use of meat and butter in the same dish, favored the use of vegetable oil. Consumption of alcoholic beverages was forbidden for the Muslims but allowed for the rest of the society. Cookbooks published in Turkish using the Arab and Armenian script during the second half of the nineteenth century exemplified the existence of a cuisine shared by both Ottoman Muslim and Armenian communities in Istanbul (Samancı 2015b).

Food and Medicine

Ottoman medicine and Islamic medicine were based on Greco-Roman medicinal traditions, which relied mainly on Hippocrates and Galen. Dietetics was, along with surgery and pharmacology, one of the three basic branches of ancient medicine. The principles of healthy and balanced nutrition in Ottoman medicine are based on the theories of “humors” (Sarı 2008). According to this theory, the macrocosm consists of four elements: air, fire, earth, and water, whose qualities are wet, hot, dry, and cold. To the four elements corresponded the four humors of the human body: the yellow bile, the atrium, the blood, and the phlegm, that is to say respectively the hot dry, the cold dry, the hot wet, and the wet cold. Dietetics was one of the major methods of treatment of health. Each food having qualities associated with the four humors (hot, cold, dry, and wet), the doctors recommended to their patients a specific diet corresponding to their temperament. It should be noted that there is a direct relationship between cooking and medicine in Ottoman culinary culture until the nineteenth century. Recipes written by Shirvani in the fifteenth century and Ottoman medicinal manuscripts from the fourteenth to the seventeenth centuries reflect all the dietary concerns in Ottoman cuisine. Dietary rules based on the theory of humors have played a decisive role in the formation of taste preferences in the Ottoman culture, because they determined the combination of ingredients used in the preparation of dishes (Samancı 2015b).

Ottoman Cookbooks

An Ottoman physician, Shirvani in the fifteenth century, wrote the earliest cooking manuscript known in the Ottoman world. Originally, this manuscript was the translation of a medieval Arab cookbook written in the thirteenth century by

Muhammad Ibn al-Kareem al-Baghdadi; however, the Ottoman author, Shirvani, added 80 recipes that were not in the Arabic version (Argunşah and Çakır 2005). This manuscript highlights the culinary exchange between Ottoman haute cuisine and medieval Arab cuisine. It also indicates the relation of food and traditional medicine in the Ottoman culture. In the manuscript, Shirvani, who was a doctor, explained each dish according to its medicinal quality. Two Ottoman cooking manuscripts were written in the eighteenth century. These manuscripts constitute the basic sources for cookbooks that would be published during the nineteenth century (Samancı 2015b).

Between 1844 and 1900, a series of Ottoman cookbooks published in Istanbul illustrate the colorful richness of the Ottoman cuisine. The first cookbook, entitled *Melceü't-Tabbahin* [The Refuge of Cooks], was published in 1844. After its initial publication in 1844, *The Refuge of Cooks* became so popular that it was reprinted nine times in the following years until 1889. The author, Mehmed Kamil, a professor at the Ottoman medical school in Istanbul, wrote in the introduction of the book that he decided to write it in an attempt to revive old recipes that were forgotten or practiced incorrectly by the cooks of Istanbul. The two main sources used by Mehmed Kamil were the eighteenth century Ottoman cooking manuscripts. The book included 273 recipes. An Ottoman gentleman Türabi Efendi translated *The Refuge of Cooks* into English in London in 1864.The *Refuge of Cooks* became a reference for other cookbooks published in Istanbul such as *Yeni Yemek Kitabı* (The New Cookbook) of 1880, *Ev Kadını* [The Housewife] of 1882, and *Aşcı Başı* [The Chef] of 1900 (Kut 1990). Between 1871 and 1926, seven cookbooks in Armenian script were also published in Istanbul. The recipes in two Armenian cookbooks published in Istanbul, *Keys of Cooks* (1876) and *New Cookbook* (1889), have similarities with the above-mentioned Ottoman cookbooks published during the nineteenth century. Another Ottoman cookbook, which reflects Istanbul style cuisine, was published in 1870 in Bulgarian. Titled *Every Type of Dishes Prepared in Istanbul (Tsarigrad) Style*, this book reflected the interest of Bulgarian elites in Istanbul cuisine (Detchev 2018).

According to the cookbooks, the types of the dishes known and prepared in Ottoman cuisine can be categorized as soups (ç*orba*), kebabs-stews-grills (*kebab-yahni-külbastı*) prepared with mutton, lamb, poultry, and fish, meatballs (*köfte*), vegetable stews flavored with meat (such as *bastı, kalye, türlü*), vegetables stuffed with minced meat or with spiced rice (*dolma)*, vegetables cooked in olive oil (*zeytinyağlı*), pickles (*turşu*), salads (*salata*), egg dishes (*yumurtalı yemekler*), pilafs (*pilav*), savory pastries (*börek*), sweet pastries (such as *baklava, kadayıf*), *helva*, milk puddings, fruit desserts, jams (*reçel*), compotes (*hoşaf*), sherbets (*şerbet*), and cordials (*şurup*).

The broth of meat and of chicken was used generally in preparing the soups. Flour, almond, or vermicelli was used to thicken it. Lemon juice, unripe grape, or bitter orange juice provided the sour flavors. The use of parsley and of mint was widespread. Kebab can be defined as a dry-cooking method. Spit roasting in front of hot fire (called ç*evirme*), grilled meat on skewers, roasted meat in oven constitutes some of the examples of kebab. Following kebab, stewing (*yahni)* was the second common method of cooking meat or poultry in the Ottoman cuisine. Apart from onions, dried fruits were also used in preparing meat stews. Honey, vinegar, molasses of grape, prunes, apricots, and almonds were also used in meat stews (Yerasimos 2005). The meatballs called *köfte* were prepared with minced mutton meat, grated onion, and spices. The *köfte* were roasted, griddled, fried, or braised. Fish and mussel stews cooked in olive oil were named *pilaki*. *Pilaki*s prepared with mussels, fish, or oysters were delicacies in the cuisine of the Christian communities of Istanbul. Like the stuffed vegetables cooked in olive oil (*yalancı dolma*) and seafood dishes, *pilaki* was among the special dishes Christians prepared in Istanbul especially during their fasting periods (Matthaiou 1997).

Savory pastries and sweet pastries were essential dishes in the Ottoman cuisine. Dough made with flour, water, and salt formed the basis of the thin sheets of *yufka* used in the preparation of savory pastries. Rice pilaf was one of the dishes served to the table of the elites during every meal in Ottoman society. Pilaf was mostly eaten at the end of the course and was accompanied by fruit compote. The pilaf made of cracked wheat was regarded as an inferior dish and not a part of the elite's culinary culture. *Pilaf*s were also prepared with pieces of lamb, chicken, bluefish mussels, or with vegetables such as eggplant and tomatoes. Pasta called "*makaronya*" was a new dish that was introduced into Istanbul's cuisine around the 1850s (Samancı 2015b).

The Ottoman recipes of the nineteenth century include a large range of vegetable dishes. Vegetables were braised in clarified butter with pieces of mutton, onions, and with the addition of a little water. Stuffing vegetables, leaves, and even some fruits with minced meat and braising them was another frequent method used for cooking vegetables. Vegetables such as zucchinis, gourd, okra, eggplants, or fresh beans were stewed with pieces of mutton and onions in butter. Verjuice or lemon juice was used to give such dishes a sour flavor. Cinnamon, fresh mint, garlic, and sometimes sugar were other condiments used in braising vegetables. Recipes after the 1880s also include tomato juice as a condiment used in braising vegetables (Samancı 2018a).

Stuffed vegetables called *dolma* were prepared in two ways, with minced meat and with spiced rice. Eggplants, zucchinis, cucumbers, turnips, vine leaves, and green tomatoes would be stuffed with a mixture of chopped meat, rice, salt, pepper, and onion. Vine leaves, hazelnut leaves, quince leaves, spinach, or mallows were wrapped around a small amount of minced meat. Stuffed melon and pumpkin were two varieties of savory-style dolma with a sweet flavor. Another kind of stuffed dish was prepared with rice mixed with onion, salt, cinnamon, pepper, pine nut, raisin, allspice, and fresh herbs. These *dolma*s were called "fake *dolma*s" because they did not include any meat. Olive oil was used in braising these "counterfeit" stuffed vegetables in a small amount of water with, lemon, sour plums, or sour cherries.

Salads, pickles, spiced meats, and seafood are just some of the appetizers described in the Ottoman cookbooks of the nineteenth century. Salads were simple, prepared with just one or two different herbs or vegetables. Another salad dressing used was *tarator*, a purée made of nuts, olive oil, lemon juice, salt, garlic, and bread crumbs. Desserts had a very special place in the Ottoman culinary culture. They were served during celebrations of circumcisions, weddings, and religious feasts as a symbol of joy. Desserts such as halva were also served during funerals in order to offer comfort against the pain of the loss of a loved one. The various kinds of desserts described in the cookbooks of the time can be grouped as follows: sweet pastries soaked in sugar syrup (*baklava, kadayıf*), halva, puddings, fruit jellies, fruit desserts, cookies, jams, and candies. Fruit juices made of dried or fresh fruits such as compotes, sherbets, and syrups are also included as varieties of desserts (Samancı 2018a).

Food and Drinking Habits in the Ottoman Territories

The border of the Ottoman Empire stretched from the Northern Carpathians and Southwest Ukraine and the Caucasus to Southern Arabia, Upper Egypt, and along the coast of North Africa to Tunisia and Algeria in the 1600s. The Black Sea coast, the steppes of Anatolia and Syria, a large part of the Mediterranean Sea, and the deserts of Arabia and North Africa were part of this huge empire that ruled on three continents. Considering the long-shared history across the vast territories of the Ottoman Empire, the formation of food cultures in the Middle East, Anatolia, and the Balkans reflects a synthesis of multiple culinary heritages in which migrations, wars, political domination, trade, and religions played an important role (Fragner 1994). Despite the geographical diversity in the Ottoman Empire between different regions, today it is discernable to notice a kind of a common gastronomic language in old Ottoman territories. The Balkans, Greece, Anatolia, and the Middle East share today a common culinary culture, with regional differences. The diffusion of a common gastronomic language that covers comparable culinary techniques and dishes in Ottoman territories is not easy to explain. The long historical background, in which migration, trade, and population exchanges played a role in the mutual dissemination of cultural practices including the culinary one should be considered. The Ottoman Empire has ruled the Balkans and Middle East throughout the centuries and thus deeply affected these territories in various areas such as politics, economy, culture, religion, society, etc. These effects have inevitably turned into legacies on various levels and in various fields including culinary legacies. The presence of Ottoman governmental officers in the Ottoman provinces from the very beginning of the empire contributed to the transmission of Ottoman elite food culture to the remote reaches of the Empire (Samancı 2019). Ottoman public kitchens (*imarets*) opened in Ottoman cities where free meals distributed on behalf of Ottoman palace also signaled the Ottoman presence throughout the empire (Fig. 3).

Based on the information gathered from the notes in travelers' accounts as well as the account registers of Ottoman hostelries founded in Ottoman cities, it will be possible to give a general but incomplete picture of food and drinking habits in the territories of the Ottoman Empire. The everyday food in the modest houses in cities or in rural areas differed from the Ottoman haute cuisine by the simplicity and monotony of the foodstuffs. Local food products dictated most of the time the food habits of the Ottoman peasants, as in rural regions in the Balkans (Samancı 2018b).

Bread was the main foodstuff in Ottoman geography. Bread in Anatolia was made mostly of wheat flour. Barley bread was also consumed especially during food scarcities. In his travel book, Evliya Çelebi (seventeenth century) describes the

Fig. 3 "Dinner at Crisso" (Dodwell 1819)

local types of breads made in Anatolian cities. The bread was baked in the oven, in a tandoor, or on a hot plate. Apart from bread, different types of savory pastries were available in the food system. Rice consumed in Ottoman palace cuisine was a luxury for ordinary people in Anatolia and Balkans. Rice cultivation was limited in Anatolia and the Balkans. Apart from special occasions, the public was only able to taste the rice soup and rice pilaf served in the Ottoman hostelries. Compared to rice, bulgur is an easily accessible food item in Anatolia. Lentils, broad beans, black-eyed peas, chickpeas, and mung bean are the legumes known in the Ottoman geography. Dried beans were introduced into the Ottoman geography during the nineteenth century (Yerasimos 2011).

The most preferred type of meat, the prestigious food in the Ottoman geography, was sheep and lamb. Veal, beef, and goat meat consumption also existed. The meat was consumed by the Ottoman elites in their daily life, but common people might consume it only during special times like weddings, Eid al-Adha, and other special occasions. Pork, which was forbidden for Muslims in the Ottoman world, was consumed by Christian communities, especially in the European provinces (Blaszczyk and Rohdewald 2018). Poultry, which was consumed widely among the Ottoman elite, considered to be easy to digest and more nutritious than red meat, was consumed occasionally by the rest of the society. Turkey, known as Egyptian chicken, was known in Ottoman territories since sixteenth and seventeenth centuries. Partridge, quail, snipe, pheasant were types of fowl hunted in some of the regions in the empire. The diversity of fish and seafood offered by the sea and rivers in the

Ottoman geography was quite high. The consumption of fish and shellfish depended on their availability. As mentioned earlier, the consumption of fish, shellfish was more popular among the Christian communities during Lent period.

Butter, clarified butter, animal fat like tail fat, olive oil, and sesame oils constituted to be the types of fat and oils consumed in the Ottoman Empire. Clarified butter with fat obtained from the tail of sheep were the main kinds of fat. The consumption of vegetable oil was popular among the Jews, who did not consume meat and dairy products at the same time. Vegetable oils became also important among the Christians during their abstinence periods when they could not consume animal based food items. Olive oil production was limited in the Ottoman Mediterranean world including the Aegean cost in Anatolia, Greece, south of Anatolia, and north of Africa. Sesame oil constituted the basic kind of vegetable oil in Anatolia. Cheese and yogurt were the basic dairy products produced and consumed by the Ottoman population. Sugar was a luxury food item in the daily food habits of the common people; thus honey and treacle of grape were used in the preparation of desserts and sweet beverages. Spices and dried herbs used for medicinal purposes were also important ingredients used in cooking in Ottoman cuisine. Vegetables and herbs offering a rich variety in different regions of the Empire constitute also important ingredients used in cooking. In the eighteenth century, corn, green tomato, and fresh peppers, and in the nineteenth century red tomatoes, beans, and potatoes entered the Ottoman cuisine. Different kinds of fruits cultivated in Ottoman geography constituted also important food items in Ottoman diet (Samancı 2016a).

New Table Manners and New Food Habits in the Nineteenth Century

The eating habits of Ottoman society remained largely unchanged up until the nineteenth century. The meal was eaten around a low table (*sofra-sini*). People sat cross-legged on cushions and ate from the same plate. Spoons and fingers were the only eating utensils used. Knives and forks were unknown. Meals were not served in a special dining room, but people of all classes chose to eat wherever they wanted and a table was brought to them. Generally speaking people ate twice a day. They had a morning meal around 10 o'clock in the winter and around 11 o'clock in the summer and the evening meal before sunset.

During the nineteenth century, European lifestyle as well as culinary habits became sources of inspiration for those among the Ottoman elites who supported reform. During the second half of the century, a new style of eating called *alafranga* (alla franca, in the European style) became fashionable within Ottoman elite circles. European-style table manners, having meals on a high dining table, sitting on a chair and using individual knives, forks, spoons, glasses, as well as European porcelain tableware were increasingly in use among Ottoman elites. Having three meals per day as breakfast, lunch, and dinner would become also a norm in urban culture toward the end of the nineteenth century (Fig. 4).

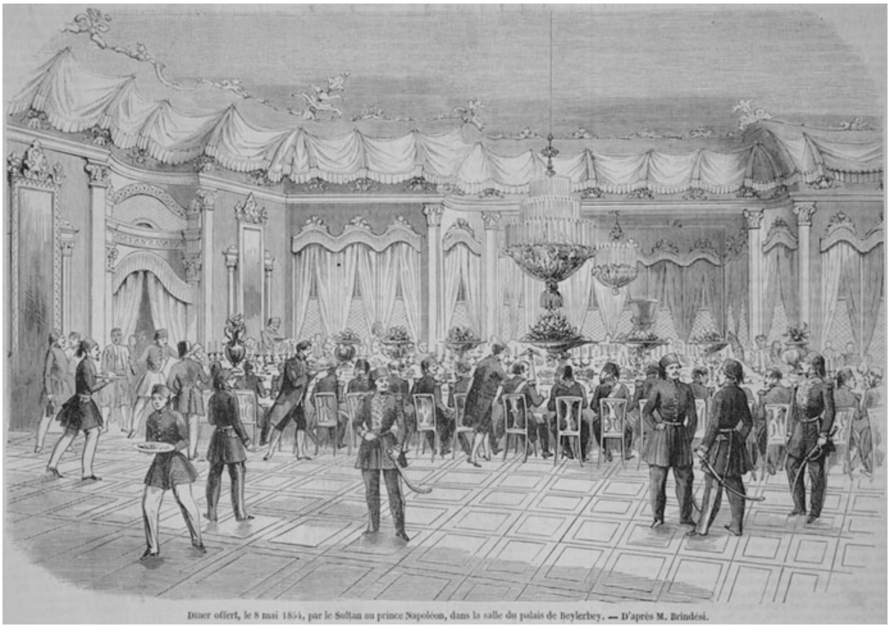

Fig. 4 Dinner given for the honor of Prince Napoléon by Sultan on 8 May 1854, Beylerbeyi Palace, Istanbul (L'Illustration: Journal universel, Tome: XXIII, Paris 1854)

Parallel to the novelties adopted into the Ottoman culinary etiquette, European cuisine, especially French, started to influence the cuisine of Istanbul's elite during the second half of the century (Samancı 2003). Starting since 1830s, the Ottoman palace adopted also the European style of banqueting for receiving its honorable guests. During Sultan Abdülmecid's reign (1839–1861), these banquets also started to reflect European tastes, in contrast to the typical meals served to the residents of the Ottoman Palace. Dishes served during these official banquets included both Ottoman and French-inspired dishes. The French influence, which was gradually introduced to the Ottoman palace and related circles through official dinners and feasts, soon trickled down to the Istanbul elites, leading to the adoption of new tastes outside the imperial cuisine. These new dishes were also promoted in European-style restaurants, cafés, and patisseries, which opened in the districts of Pera and Galata in Istanbul after the 1850s (Samancı 2015b) (Fig. 5).

Ottoman cookbooks published since the 1870s, such as *The New Cookbook* (1880) and *The Housewife* (1882), included new recipes inspired from French and European cuisines. The foreign dishes in these late nineteenth-century cookbooks included new soups such as vegetable soup, Hungarian soup, pea soup, oyster soup, prawn soup, pastes, broths, sauces, pates, some meat dishes as roast beef, grilled cutlet, beef steak, and *ragout* as well as garnishes, pasta, and canned food. The recipes stated as sauces were egg sauce, lobster sauce, mussel sauce, spiced sauce, or tomato sauce. Mushrooms, tomatoes, potato, glazed onions, bread, spinach, sorrel,

peas, asparagus, chicory, and French peas were some of the garnishes mentioned in the cookbooks. Different types of paste, which were essentially paste made of game, poultry, and fish, were also among the French dishes that entered the Ottoman cuisine. Crèmes (*krema*), cakes (*pasta*), biscuits (*bisküvi* or *gevrek*), cakes such as savarin, and a new type of ice cream (*kalıp dondurmaları*) were some of the European desserts mentioned in these cookbooks (Samancı 2018). Apart from wine and rakı, during the nineteenth century, new alcoholic beverages enriched also the drinking habits of urban elites: beer, champagne, and spirits imported from Europe.

Eating and Drinking Habits in Modern Turkey

In republican Turkey (since 1923), founded on the remains of the Ottoman Empire, the culinary tradition has continued to represent both traditional and new "modern" features both in urban centers and rural areas. The different regions, which make up Turkey each offer their culinary individuality linked to their ecological heritage and the various influences these receive or have received in the past. The cuisine of Istanbul continued to serve as the urban model par excellence (Sauner 2008).

The dichotomy of traditional (*alaturka*) and modern (*alafranga*) cuisines, which emerged since the second half of the nineteenth century in Ottoman culture, became evident in the urban centers during the first decades of Republican era. The cookbooks published since 1930s clearly demonstrate this dilemma. While eating and drinking habits in urban areas adopted new modern table manners and some of the new culinary techniques, food culture including table manners in rural areas remained for a long time traditional. Modern table manners as well as new dishes inspired from European cuisine have become widespread in society through the educational institutions such as girls' schools and institutes (Samancı 2016b).

During the Republican period, the culture of eating out in the cities has been developed. European-style restaurants, which started to be opened in Istanbul since the second half of the nineteenth century, became widespread during the Republican period. As a result, the culture of restaurants in the European style has been recognized along with the traditional ones such as eatery shops called "*esnaf lokantasi*" and street food sellers. The migration movement from rural areas to cities accelerating since the 1950s has brought new tastes to the culinary culture in the cities; examples of South-east Anatolian cuisines such as spicy kebabs, kibbeh, or *lahmacun* (a kind of flatbread topped with minced meat mixture made of parsley, onions, red peppers, tomatoes) became widespread then in Istanbul.

The food industry, which was developed during the Republican era, influenced the dietary habits of the Turkish population. New consumer goods such as tomato paste with the development of the canning industry, margarine with the development of the oil industry, and sparkling and noncarbonated drinks with the development of the beverage industry entered into the daily life of Turkish people. Generally speaking, the change in eating habits reflects the opening up of the country, and its growing industrialization. Eating habits have undergone a certain number of changes since the 1960s. The development of transport and the increasing importance of the urban model have led to the arrival of fruit and fresh vegetables in regions which previously did not eat them (Sauner 2008). These changes have introduced a greater diversity in the diet, which was previously based on local products and linked very strongly to family economics. Vegetable oil (sunflower or maize oil) or margarine have almost entirely replaced traditional tail fat and butter, while the habit of drinking tea all day long has become established over the last 40 years (Sauner 2008).

The period since the 1980s constitutes a decisive era where changes in eating and drinking habits became more evident in Turkey. This period corresponds notably with a big opening towards the exterior, the generalization of the market economy, the concrete implications of massive urban migration, and the participation of women in the business sector and the large-scale development of the media. Global food chains as well as restaurants serving international cuisine started to be opened in cities. The urban population, which represents 70% of the population, started to buy the basic ingredients, which would previously have been home made. On the other hand, regional cuisines have gradually integrated also the variety of ingredients available in the city. Numerous dishes prepared in Anatolia were little known in Istanbul until recently. The opposition between an urban diet and a rural one continues to represent an important factor of social difference. The urban centers continue to attract rural populations affected by the economic crisis. Even though emigrants preserve their main food habits in their new home, they also quickly adopt some aspects of urban food culture (Sauner 2008). Food publications and media programs, which have been increasing since the 1990s, have brought urban and rural culinary cultures closer to each other and led to the emergence of a more homogenized culinary culture in the country. After 1990, the traditional food production and culinary practices were subjected to a rapid change in both rural and urban areas in Turkey with the impact of globalization, urbanization, and a decrease in agricultural production.

Today's regional cuisines in Turkey are defined as the Black Sea (iconic foods are anchovies, maize and kale), Mediterranean (represented by citrus fruits, tahini and pomegranate), south-east Anatolian (famous for kebabs and *lahmacun* and baklava), Aegean (renowned for fish, shellfish dishes, olive oil and wild herbs), central Anatolian (homeland of wheat, bulgur and a savory pastry called *börek*), eastern Anatolian (land of butter, meat and wheat), and Marmara cuisines (representing the Ottoman culinary heritage). These regional cuisines tend to accentuate their differences in tastes and culinary practices from the national Turkish cuisine represented in Istanbul (Samancı 2019).

Conclusion

Food and drinking habits in Turkey as well as in Balkans, Greece, and Middle East reflect still today an Ottoman culinary heritage. Despite the changes that occurred in food production and consumption patterns in Turkey because of various factors such as industrialization, population growth, and migration from rural to urban areas and globalization, traditional food habits in terms of food preparation techniques still continue. The basic types of dishes prepared in today's Turkish cuisine such as kebab, stews, *köfte*, pilaf, halva, baklava, savory pastries, stuffed vegetables, and various desserts have existed since the Ottoman era. New culinary techniques adopted from European cuisine since the nineteenth century such as sauce, garnish, French fries, cake, creamy pastries like profiterole became acculturated today in Turkish cuisine. Regional differences in Turkish cuisine in terms of use of ingredients, food rituals, and culinary techniques continue to exist, but each day food culture in Turkey becomes more homogenized representing a national cuisine.

History of Spices

4

Paul Freedman

Contents

Abstract

Spices had an important place in ancient and medieval cooking. Medical theories about diet and health overlapped with taste preferences. The recipes of classical Greece and Rome favor sharp flavors, while those of the Middle Ages result in dishes that are sweeter and more perfumed. Spanish and Portuguese colonization of the Americas circulated the chili pepper whose acceptance was considerably greater in Asia and Africa than in Europe. The origins of modern European cuisine can be identified in changes led by France during the seventeenth century. Among the key shifts was the displacement of spices in sauces and their general decline in all manner of recipes. Britain and North America retained a certain affection for spices through the cuisine of foreigners – Indian and Mexican restaurants, for example. Some of this love of the piquant has now spread through culinary globalization.

Introduction

This essay looks at the history of spices, particularly in Europe and North America. Most of the spices used in cooking come from tropical countries that have extensive and complex culinary cultures. From the ancient and medieval European perspective, the places that supplied precious and expensive spices were distant and exotic, even magical. India was the most important of the Asian lands where spices were reputed to be abundant. This version of India combined real and imagined attributes, rivers of jewels, hot climate, naked wise men, and proximity to the Garden of Eden, but also cobras and semi-human people, some with dog heads, others with no head at all but faces in their chests. A venerable legend, going back to the seventh-century AD, has it that there are vast pepper forests in India infested with poisonous snakes. The only way to obtain the pepper is to burn the trees, driving out the snakes. This explains why pepper is black and shriveled and why it is costly, because in order to have another harvest, a completely new set of trees has to mature (Freedman 2008, pp. 133–134). The coexistence of attractive and disturbing exoticism is typical of the image of Asia in European eyes and the allure of its precious aromatic products.

European attempts to discover where spices came from constituted a long research campaign that would transform the world, beginning in the sixteenth century. European colonization of the Americas resulted in some incremental additions to the list of spices, most importantly the many kinds of chili peppers. These would have a greater impact on India, Indochina, and Africa than on Europe where by the eighteenth century, the use of all spices in cooking was declining because of changes in gastronomic taste and the image of spices as luxuries.

The Repertoire of Spices

Spices have historically been distinguished from herbs. While employed in similar ways as spices, herbs are domestic European products. Gathered from gardens, forests, and hedgerows, herbs fetched modest prices. Spices, however, were once valuable mainstays of international trade. In the medieval era, they were sold in small amounts at high prices by apothecaries rather than alongside routine cabbages or fish in food markets. Indeed, their value was so great as to stimulate extremely risky expeditions to find their native habitat.

Spices were imported aromatics derived from roots, resins, fruit, or bark. Because of the distance they had to traverse, they had to be nonperishable, at least in the short to medium term. Some spices such as nutmeg or black pepper release their flavor when ground so that they will keep a long time until they are pulverized. A pharmaceutical text of the eleventh century known as Circa *instans* and its later French version, the *Livre des simples médecines*, states that nutmeg will last for 7 years and peppercorns for 40 (Freedman 2008, p. 123). In other cases, such as ginger, the spice must have arrived in Europe dried up and deteriorated in comparison with its condition when it was harvested. Saffron was exceptional as it was among the most valuable and durable spices but could be grown in Europe. In the Middle Ages, when the use of saffron was all the rage, the major saffron suppliers were Catalonia and Tuscany.

If we look at products the term “spices” covered, we find that many are not the familiar edible substances we would expect but any relatively nonperishable commodity valuable enough that was profitable to transport even small amounts over long distances. Thus, what appear as spices in merchant manuals might include medicinal substances, perfumes, and even materials used for dyeing textiles. *La pratica della mercatura,* a medieval handbook of commerce composed around 1340, lists 288 so-called spices, classifying, for example, 14 kinds of alum, an inedible mineral used as dye fixative. The Florentine Baldassare Pegolotti, author of this manual, mentions some now mysterious spices such as *vescovo* (literally “bishop”) (Lopez and Raymond 1955, pp. 109–114). Marvelous drugs include “mummy” (*mumia*), a solidified secretion of embalmed corpses, considered a sovereign remedy for dysentery and bleeding, especially useful for treating wounds (Camille 1999, pp. 297–318). This too was a nonperishable import, usually but not exclusively from Egypt. Anything valuable in small quantities from far away might qualify as a spice, but here, since the discussion is about food and drink, we will limit ourselves to edible products.

Gastronomy

Classical literature has many descriptions of feasts, but only one complete cookbook survives, that attributed to Apicius, a first-century Roman gastronome of whom Pliny the Elder said: “Apicius, the most gluttonous gorger of all spendthrifts, established the view that the flamingo’s tongue has a particularly fine flavor” (Pliny 1983, p. 133). The book, known as *Apicius de re coquinaria*, may have been put together around a core of recipes going back to the era of Apicius, but he seems to have been famous as an aficionado rather than as an author of recipes. The Latin style of the book indicates a considerably later compositions, probably at the end of the fourth or the early fifth century (Wilkins and Hill 2006, pp. 208–209). From the Greeks, there are no complete cookbooks, but information can be reconstructed from the discourses about food composed by Athenaeus of Naucratis who wrote in Greek and flourished around 200 AD. His *Deipnosophistae* (*The Learned Banqueters*) is an immensely long series of witty conversations about food, purportedly during a single banquet, the apotheosis of the sometimes-annoying habit of talking about other meals and food while dining. Athenaeus’ opinionated gentlemen recite snatches of poetic and philosophical texts that have allowed later scholars to put together pieces of otherwise lost works of Greek literature. For example, Athenaeus includes 62 excerpts from the lost cookbook of Archestratus, *The Life of Luxury* (Archestratus 2011).

Classical connoisseurs favored sharp, pungent herbs such as rue, thyme, and myrtle. Their favorite spices were pepper and silphium, a latter a plant that grew in what is now Libya. Silphium was a wild shrub, never domesticated, whose extinction by the first-century AD was due partly to bringing land under cultivation and partly to its excessive popularity. Its taste appears to have been strong, sharp, and sour as can be deduced from its replacement by the Indian spice asafetida, which Roman gourmands considered an adequate if imperfect substitute (Dalby 2000, pp. 17–19).

If silphium was the great exotic spice of ancient Greece and Republican Rome, pepper was the most sought-after spice of the Roman Empire. Archaeological exploration of sites along the Egyptian Red Sea coast has revealed extensive pepper importation from western India and aided by the predictable monsoon winds of the Indian Ocean. This trade was sometimes seen as disadvantageous to Rome, and critics bemoaned the love of luxury that induced the Empire to part with its treasure for gourmet frivolities. Pliny, again in the role of advocate for culinary simplicity, asked, "Who was the first to try it (pepper) with food? Who was so anxious to develop an appetite that hunger did not suffice?" Pepper (he continues) is neither sweet nor beautiful, merely pungent; nevertheless, men travel to India and spend gold and silver to acquire it (Pliny 1968, pp. 28–29). Goods from India were sold in Rome at 100 times their original value, Pliny estimated (Pliny 1947, p. 101).

The *De re coquinaria* mentions a large number of Mediterranean herbs along with imported spices such as ginger, peppers, coriander, and cumin. The recipes are exotic, even for their time, including unusual ingredients like flamingos, parrots, and sea urchins. There are six recipes for sow's womb. The various sauces usually include herbs as well as pepper. A wine sauce to serve with truffles consists of pepper, lovage, coriander, rue, and honey along with the wine (Apicius 1936, p. 56).

Medieval culinary taste in comparison to that of the ancient world was for sweet rather than sharp spices. The medieval spice dossier was larger than that of the Roman Empire and included cinnamon, nutmeg, cloves, and sugar. Although not aromatic, sugar functioned as a spice because it was expensive, imported, and credited with medicinal as well as gastronomic uses. Information about these new spices as well as their supply was obtained via the Islamic world, which by 900 controlled North Africa, the Middle East, and the former Persian Empire and would soon incorporate much of India. Islamic traders handled the spice trade from Indonesia and South Asia as far as the Mediterranean.

Spices were not the only luxuries picked up by elites in Christian Europe from their perceived religious enemy. Silk clothing, inlaid metalwork (e.g., "damascened" steel), and perfume substances such as musk and ambergris were brought from Islamic civilization by Crusaders, Venetians, and other intermediaries to become items of high fashion. The use of spices as well as dried fruit, rosewater, almonds, and sugared sweets such as nougat suggests Islamic origin. There are very few actual correspondences between Arabic cookbooks and those of the medieval West, however. Wine and pork, forbidden to Muslims, were basic to Christian European cuisine. Even when the name of a dish was adopted, the European version often differed radically. North African *ma'mūniyya* was boiled rice with chicken and sugar, sometimes scented with camphor or musk. Across the Mediterranean, *mawmeny* or *mamonia* was a cold pudding made with almond milk and wine that contained raisins, spices, sugar, and ground chicken or mutton (Laurioux 2005, pp. 313–316).

Considerable Islamic influence seems, nevertheless, undeniable. Medieval cuisine tends to be more fragrant than that of the classical period and more oriented toward meat. Fish remained important in Catholic Europe because fasting regulations forbade meat during a considerable part of the year, almost half of the days according to some scrupulous observations, but meat was preferred. The prestige accorded in the Middle Ages to lamprey, which tastes like beef but qualified as a fish for fasting purposes, suggests how much esteem meat received (Freedman 2020).

Medieval cuisine depended on aromatic ingredients now almost unknown in Europe and North America such as Indian long pepper or African malagueta (a peppery spice more often known as "grains of paradise") or spices such as galangal, familiar today through Thai or other East Asian food. In Geoffrey Chaucer's *The Canterbury Tales* (written shortly before 1400), the cook, one of the pilgrims, is said to be expert in the use of galangal as well as a spice mixture called *poudre marchant*:

> A Cook they hadde with hem for the nones,
> To boil the chiknes with the marybones,
> And powdre-marchant tart and galingale.
> Wel coude he knowe a draughte of London ale.
> He coulde roste, and seethe, and broille, and frye,
> Maken mortreux, and wel bake a pie. (Chaucer 1962, p. 423)

The tart *poudre marchant* is mysterious because it does not appear anywhere in medieval cookbooks.

The fourteenth-century *Le Viandier*, the most widely circulated medieval cookbook, lists what a chef should to have on hand by way of spices: long pepper, ginger, grains of paradise, mastic, saffron, "round" (i.e., black) pepper, cinnamon, cloves, cassia, and nutmeg. Individual recipes in the *Le Viandier* employ other spices such as cubeb, cardamom, and zedoary (Laurioux 1989, p. 40).

Pepper, ginger, sugar, and cinnamon were the most common imported spices during the Middle Ages, making up over 90% of those brought to Venice between 1394 and 1405, for example (Wake 1979, p. 396). What distinguished the truly wealthy from the merely comfortable classes was consumption of the most expensive spices such as cloves, saffron, nutmegs, and grains of paradise.

As is the case today in most countries whose cuisine includes a range of spices, mixtures were made up by spice merchants and used in recipes. Various combinations such as *garam masala* in modern India or *ras-el-hanout* (literally "the best of the shop") in Morocco include certain defined ingredients, but each person's blend is different. The skill of the cook is measured by expertise in mixing spices and timing their use while cooking. Although Chaucer's *poudre marchant* is otherwise unattested, there were a number of widely recognized standard mixtures. *Poudre blanche* blended cinnamon, nutmeg, and ginger; *poudre fort* involved black pepper or even more pungent long pepper in combination with sweet spices such as cinnamon and ginger; and *poudre de duc* (supposedly named after the Doge of Venice) used sugar in the same way as pepper in *poudre fort*, as a medium to be mixed with sweet spices, especially cinnamon (Scully 1988, p. 357; van Winter 2007, p. 384).

Medieval culinary preferences included combining sweet and sour ingredients, paying attention to color and employing sugar to flavor entrées. Recipes make considerable use of such products as almond milk while ignoring butter and present a repertoire of sauces that were primary vehicles for the use of spices.

There is some debate as to the quantities of spices used as the recipes are not specific. The immense amounts of spices bought for state occasions do not mean they were all to be applied to preparing dishes – many were given away as presents – yet the numbers are nonetheless impressive. For the marriage in 1475 of George, Duke of Bavaria-Landshut (known to contemporaries as "George the Rich"), 386 pounds of pepper were ordered, along with 286 lbs. ginger, 207 lbs. saffron, 205 lbs. cinnamon, 105 lbs. cloves, and 85 lbs. nutmeg (Freedman 2008, p. 6).

A household advice book of the late-fourteenth century known as the *Ménagier de Paris* is an unusual source of culinary information because the author was a member of the upper bourgeoisie, not a man of the highest rank, while most other medieval cookbooks are by court chefs. The author of the *Ménagier* wrote a private compendium intended for his young wife's instruction rather than a work of public circulation designed to impress others. What is striking about the over 400 recipes in the *Ménagier* is not so much the quantity of spices as their ubiquity. Spices now relegated to dessert in European cuisine (cinnamon, cloves, and nutmeg) appear in meat, fowl, and fish recipes. The author of the *Ménagier* is by no means recklessly extravagant. He recommends making *sauce moutarde* with spices that have already been used to flavor wine, aspic, or other sauces, showing thrift as well as enthusiasm for spices (Brereton and Ferrier 1994, p. 748).

A Catalan cookbook written shortly before 1500 by Mestre Robert, chef to the king of Naples, gives about 200 recipes of which 154 contain sugar, 125 cinnamon, 76 ginger, 54 saffron, and 48 pepper (Mestre Robert 1977). The presence of these ingredients in non-dessert dishes contrasts greatly with what would become the norm for European cuisines after about 1700 at the latest. Clearly, spices were consumed by the higher ranks of medieval society in great quantities, variety, and in all manner of preparations.

Medicine and Cooking

Although the focus of this article is the use of spices in gastronomy, something should be said about the overlapping considerations of health in relation to diet. In the ancient Mediterranean and in medieval Europe as well, spices, diet, and health were closely linked. The greatest classical authority on medicine, Galen (129–ca. 200 AD), was the author of *On the Powers of Food*. He distinguishes himself from mere cooks in that his primary aim as a physician is health and not pleasure. Many delicious things are bad for you, but Galen acknowledges that in order to induce people to follow a healthful dietary regimen, what doctors recommend must be at least moderately appealing (Wilkins and Hill 2006, pp. 10–11).

The distinction between cookery and medicaments remained uncertain, and it is sometimes hard to decide whether we are dealing with medical or culinary recipes. The *Opusculum de saporibus* of Maino de Maineri, dating from between 1330 and 1340, provides recipes for all manner of highly spiced sauces for meat, but it is what we would consider a medical handbook with warnings against excessive use of sauces by healthy people who really do not need them (Thorndike 1934, p. 186; Scully 1985). The author admits, however, that sauces were invented by those more interested in pleasure than health, so that although there is a border between medicine and cuisine, it is constantly being crossed.

The intersection of cuisine and health considerations is evident in the prevailing medieval theory of humors, the four fundamental bodily fluids that corresponded, it was thought, to the four basic elements (earth, water, fire, and air) and the four physical qualities, hot, cold, moist, and dry. The four humors were blood, yellow bile (also known simply as bile), black bile, and phlegm. Blood is linked to air and has warm and moist qualities. Yellow bile's element is fire and it is hot and dry. Phlegm is cold and moist, just as water is. Black is cold and dry and corresponds to earth. Individuals must balance these, although no one is perfect. Everyone has a particular temperament favoring one of the four humors, but too much imbalance results in disease as well as distortions of personality (Scully 1995a, pp. 41–51).

Foods themselves possessed humoral properties, and so diet was supposed to be adjusted to the individual temperament. Some spices such as pepper were regarded as extremely hot, while others such as cinnamon were only moderately so. Spices were for the most part considered medically hot and dry, countering the excessive moisture and coldness inherent in many meats and fish and tempering other ingredients.

A person of melancholic humor should consume more hot and dry spices than one of bilious temperament who must avoid too much spice because he is already sufficiently or even excessively hot and dry. As already mentioned, lamprey, a migratory eel-like creature, was classified as a fish. As with eels (to which in modern scientific taxonomy it is not, in fact related), lamprey was supposed to be dangerous as well as delicious. Cold and moist in the fourth degree, lamprey needed to be cooked in such a way as to neutralize its perilous humoral properties. Black pepper sauce was recommended because pepper was hot and dry in the fourth degree (Flandrin 1999, pp. 320–327).

In the *Opusculum de saporibus*, there are classic culinary preparations such as green sauce (parsley, rosemary, breadcrumbs, white ginger, cloves, and vinegar) useful on boiled mutton, kid or veal, and black pepper sauce, which includes verjuice, pureed liver, toast, and, of course, pepper, appropriate for roast geese and aquatic fowl. The definition of "appropriate" for sauces involved both complementary taste and humoral balance.

In order for the tempering process to achieve equilibrium, the ingredients had to blend (Scully 1995b). Meat was better complemented by sauces when minced or ground up, one reason for the highly processed nature of medieval food preparation. Recipes seldom involve simple treatment but rather call for many steps that often render the ingredients unrecognizable. Typical of complex poultry dishes is a recipe from a fifteenth-century English cookbook for *blaunche de sorre*, which involves blanching and grinding almonds and combining them with sweet broth into which is put ground cooked capon. This mixture is then boiled in milk, sugar, and sweet wine (Hieatt 1988, p. 58).

Spices such as nutmeg or cinnamon that we associate with cooking were also key ingredients in medicines and preventives (Matthews 1980; Whittet 1968). The word "recipe" was applied to pharmaceutical as well as culinary preparations, and in most European languages other than English, the word for "prescription" and "recipe" is the same. Medieval pharmaceutical manuals offer directions for filling pomanders, portable openwork metal balls that carried aromatic products in order to counteract bad odors that were not only unpleasant but also thought to carry disease. Edible spices like nutmeg and cinnamon were included along with perfume ingredients. On the other hand, substances we think of as medicinal or cosmetic – ambergris, musk, camphor, or sandalwood – were added to food in imitation of Arab, Persian, and Indian practice. As late as the English Restoration era, eggs with ambergris were a luxurious and (supposedly) healthful favorite (Macaulay 1849, p. 442).

A longer-lasting aspect of the dual role of spices as both food and medicine is in the origins of candy. Like cordials (flavored alcohol distillations), candies began as digestive aids to be consumed after a meal. Sharp medicinal herbs could be rendered pleasant when made into a kind of brandy, as with some of the modern descendants of monastic concoctions such as Chartreuse or Bénédictine. Similarly, sugared spices, known as comfits, originated as ways of consuming spices directly, rather than as sauces to accompany food. Pharmacists made up medicines with sugar paste called electuaries, and one finds these being eaten as what might be considered after-dinner wellness treats. In Chrétien de Troyes' twelfth-century romance *Perceval*, the hero arrives at the mysterious Grail Castle where a meal whose main course is peppered venison is followed by candied fruit, nutmegs, cloves, gingerbread, and electuaries. An example from real life, just before retiring into a conclave to elect a new pope, the cardinals at Avignon in 1371 ate 12 pounds of candied spices (Chrétien de Troyes 1991, pp. 421–422; Aliquot 1984, pp. 132–133).

Spices and Modern Cuisine

Modern European cuisine differs from that of the Middle Ages, rejecting the spectrum of complex and piquant flavors in favor of intensity and simplicity. Many Asian spices such as zedoary, long pepper, and galangal, all familiar to medieval cooks, were discarded. Modern cuisine and its turn away from spices began in seventeenth-century France with the development of what would become classic haute cuisine that was based on new principles. In particular, sauces were now rich, buttery meat reductions flavored with shallots, herbs, and truffles rather than the thin, sweet and sour spiced sauces of the Middle Ages. France, the trendsetter, became by the middle of the eighteenth century the undisputed guardian of culinary orthodoxy, a position it held until the end of the twentieth century. An important aspect of what has rightly been called a culinary "revolution" was to devalue spices.

Seventy percent of the English medieval recipes collected in a modern adaptation entitled *Pleyn Delit* call for some sort of spice, usually in combinations, and 27% of its recipes specifically require cinnamon. Compare this with François Massialot's *Cuisinier roial et bourgeois*, published in 1691, which has cinnamon in only 8% of its recipes and is altogether lacking in such medieval requisites as saffron or grains of paradise (Hieatt et al. 1996; Flandrin 1992, pp. 177–192; Peterson 1994, pp. 195–196).

Sugar was segregated into a dessert course, but it would break out of the confines of conventional cooking and dining, accompanying chocolate, coffee, and tea, all unknown to the Middle Ages. No other edible commodity would have such a cataclysmic effect on world history as sugar. Insatiable European demand fueled the first great trans-Atlantic slave trade and made New World colonization tremendously profitable (Mintz 1985).

Black pepper also was an exception to the eclipse of spices, retaining some modest importance in French cuisine for savory dishes. Saffron shows up in a few Spanish preparations, in *risotto alla Milanese* and in the French monkfish recipe *lotte au safran*. Nutmeg is still used in Italian sauces. Modern European cuisine, however, relies on culinary effects that have nothing to do with spices.

The reformed French cuisine of the seventeenth century stressed harmony and smooth combinations of natural flavors. Simplicity, authenticity, intensity, and vividness were placed above what was seen as an unpleasant medieval fondness for the exotic, unusual, and complicated. In the cookbooks published by François Pierre La Varenne (*Le cuisinier françois*, 1651) and Nicolas de Bonnefons (*Les délices de la campagne*, 1656), "delicate" and "natural" cooking meant, in the first place, simplicity that depended not on spices or other distractions but on the actual quality of primary ingredients. This might include vegetables, which had been largely despised or ignored by medieval chefs. Typically, the new French simplicity was rather expensive and elaborate. The garden expert Jean-Baptiste de La Quintinie identified 47 varieties of pears that, with the aid of hothouses and strategically positioned garden beds, could produce fruit every week between July and February. Bonnefons in *Le Jardinier françois* shows how to have cabbages ready to pick during 10 months of the year (Pinkard 2009, pp. 67–78).

Amidst all this attention to primary constituents of cooking, spices were attacked as covering up natural tastes, as childish, and even as "Arab." The first criticism is part of a consistent oscillation in Western gastronomic history between nature and artifice, between simplifying in order to experience the beauty of fine ingredients and innovation in order to create never-before experienced taste sensations. Each in turn produces a counterreaction, rediscovering basic products or putting together daring and novel concepts.

The seventeenth century saw a turn toward natural flavor. In another treatise by Bonnefons, meaningfully entitled *Les délices de la campagne* ("The Delights of the Countryside"), the author instructs his reader: "Each food in its natural taste is more agreeable." Thus, "A cabbage soup should taste entirely of cabbage, a leek soup of leeks. . .." (Pinkard 2009, p. 120).

"Childish" meant use of sugar in meat or other courses where it was now deemed inappropriate. Medieval taste had mingled sweet and savory flavors and spices in a way that resembles current Middle Eastern or North African cuisines. In seventeenth-century Europe, as has been mentioned, sugar was separated from savory courses, while spices considered sweet, such as cinnamon, cloves, and nutmeg, were likewise restricted to desserts.

Finally the supposedly "Arab" aesthetic reflects the degree to which medieval cookery had been influenced by the complex, perfumed, high-end cuisine of the Caliphate and its successors, but now this was a source of contempt for the reformers. The cookbook author known to posterity only by the initials L. S. R. in his *L'art de bien traiter* of 1674 criticized his predecessors for mixing fruit, meat, and spices (e.g., turkey with raspberries, frog legs with saffron). His withering judgment was that "[these] would be more willingly tolerated among the Arabs. . .than in a refined atmosphere such as ours, one of propriety, delicacy and good taste" (Wheaton 1983, pp. 150–151). The implications of this condemnation go beyond the historical connection between prestige cuisines during the Middle Ages to an identification of Europe and modernity itself with a virtuous yet elegant culinary aesthetic.

The modern sauces of seventeenth-century France were thickened with roux, egg yolks, and butter. Glossy and rich, they were not spicy and so differed in texture and flavor from the thin, grainy aromatic medieval sauces that used breadcrumbs as thickener. French sauces now incorporated juices produced by principal ingredients, supplemented by liquids such as bouillon, wine, cream, and they were flavored with herbs. Textured, silky, satiny, and velvety, these sauces were voluptuous because they included a lot of fat which magnifies flavor so that peas or asparagus in French sauces could still be said to taste of peas and asparagus. Rather than a humoral corrective as was the medieval practice, sauce here is supposed to enhance and intensify.

The triumph of French cuisine was not immediate, and much of the rest of Europe clung to the medieval and Renaissance practice of using spices extensively. In the second half of the seventeenth century, the French expressed contempt for other countries' old-fashioned culinary customs. Criticism centered on excessive or inappropriate use of spices and sugar. Gaspard d'Hauteville resided for several years in Poland in the mid-seventeenth century, but never got used to its exotic and archaic food replete with saffron, sugar, cinnamon, and nutmeg. French cookbooks sometimes described chicken with saffron as prepared "in the Polish style" (Pinkard 2009, p. 125). Italy and Provence too were suspect for their spicy and sweet sauces, and the Spanish, according the Countess of

Aulnoy writing in 1691, were hopelessly addicted to perfumed food and saffron (Gillet 1985, pp. 159–167).

There are a number of possible reasons for this French revolt against more than a millennium of spiced foods and particularly spiced sauces, but no single cause is in itself convincing. Disenchantment with spices may have something to do with the arrival of new beverages coffee and tea from Asia and Africa, and chocolate from the New World. Unlike spices, these produced psychological effects through caffeine. Tobacco, not an edible but certainly a psychoactive New World product, might also have cut into the appeal of spices as a rather different aromatic delivery system. This would not, however, explain the continued attachment to spices outside of France, in places such as England whose aristocracy adopted most French innovations enthusiastically. The real counterexamples are the Ottoman Empire and the Islamic world generally where coffee had been known for centuries, and tobacco was rapturously welcomed, yet in these lands spices remained vital culinary ingredients.

New World Chilies and Their Diffusion

Western European disillusion with spices coincided with the worldwide influence of the major New World contribution to the world of spices, the variety of flavors from chili peppers. The European explorers were disappointed not to have found in the Americas the Asian spices like nutmeg and black pepper that they had set out for, and indeed, the new colonies were relatively poor when it came to aromatic products in comparison with Asia. Allspice is one of the few New World spices commonly sold in Europe and America. Others, like achiote or epazote, have not travelled.

Chili peppers, varieties of the *Capiscum* genus, were first domesticated 7000 or 8000 years ago, probably in central Mexico. The extent and history of their diffusion in pre-Conquest America is unclear, but they were an important flavoring and nutrient and a food associated with religious rituals among many people and nations (Kraft et al. 2014). A physician on Columbus' second voyage, Diego Álvarez Chanca, observed the significance of chilies in the diet of the "Indians," commenting also on the versatility of chili pepper and its many varieties (Olson and Bourne 1906, pp. 311–312).

The chili pepper has influenced only a few aspects of European cuisine. Smoked paprika is a specialty of the Estremadura region of Spain. Although most Italian food eschews piquant flavors, Calabria makes extensive use of dried red pepper, including even in *grappa*. Hungary developed a range of paprikas from mild to hot, and this variety of *Capiscum*, dried and ground into powder, has become the prime symbol of Hungarian cuisine. The use of paprika was extended with the development of mild varieties in the nineteenth and early twentieth (Anderson 2016, pp. 46–55). Apart from these exceptions, however, highly spiced cuisine remains alien to Europeans or has only recently been introduced through global trends such as Thai or Mexican food.

Chili peppers were spread by the Spanish and Portuguese expeditions and conquests. Peppers were adopted not only in places actually colonized by the Iberian powers, but through intermediaries, so that, for example, the presence of hot peppers in China results from diffusion via Portuguese Macao or perhaps India. No area was as quick to adjust its cuisine to the new ingredient as India, almost all of whose cooking styles now employ chilies. Within 50 years of Vasco da Gama's arrival on the west coast of India in 1498, chilies were so familiar that many authorities came to believe they were indigenous (Collingham 2006, p. 11).

Chilies were made into various spice combinations, sauces, and relishes from the piri piri of Portuguese Africa to harissa in North Africa to sambals in Indonesia. The use of chili pepper is not uniform: in China, only in Hunan and Sichuan is it essential to cooking. In Thailand and Indochina, many dishes are infused with pepper, and sauces such as Sriracha give added hot flavor. In Indonesia, hot spices are more often an external relish rather than integral to food preparation.

All of this culinary transfer and activity left the arbiters of European cuisine almost unaffected by chilies save for the above-noted exceptions. During the eighteenth century, French cuisine took over as the international standard of sophisticated food consumed by the wealthy and the aspiring classes.

Spices were largely anathema to the French authorities, but other countries reached compromises with tradition. Margaretta Acworth's manuscript cookbook, dating from the mid-eighteenth century, reflects the tastes of the English lesser aristocracy, the sort of people described in Jane Austen's novels. Acworth offers a recipe for spiced beef in red wine, flavored with pepper, mace, and nutmeg, which maintains a connection to medieval antecedents (Acworth 1987, p. 66). The persistence of spices is visible in puddings, pies, and other desserts. In France, even desserts include spices as only a light flavoring, but the medieval complex of spices, sugar, and dried fruit is characteristic of beloved, if now slightly archaic, English sweets like plum pudding and fruitcake. Gingerbread remains popular in northern Europe while it has disappeared from France and the Mediterranean. Italy is an exception as *panforte*, a flat, fruitcake-like specialty of Siena, reflects a medieval heritage. Christmas treats in particular retain an earlier era's idea of appropriate spices: *Pfeffernüsse* (sweet spiced biscuits) in Germany, *Lussekatter* (saffron-covered buns) in Sweden, and plum pudding in Britain are Christmastime requisites. In the United States, the Thanksgiving holiday menus offer some of the same comforting archaism with highly spiced pumpkin and mince pies. The current American fad for "pumpkin spice" led by such companies as Starbucks and Trader Joe's indicates the persistence and reworking of essentially medieval tastes.

All this notwithstanding, the story of spices in Europe and America in the nineteenth and twentieth centuries was one of decline, in contrast to most of the rest of the world. The hostility toward "Arab" spices expressed by the seventeenth-century French reformers became a broad mistrust of Asian, African, and Latin-American cuisines that were perceived as excessively spicy. In the first place, such use of spices was deemed unpalatable, but it was also believed that spices covered up the use of deteriorating primary ingredients. This partly explains the durability of the false but to this day widespread impression that medieval taste favored spices because of the poor quality of the meat or fish.

In the late-nineteenth-century United States, nutritionists, social workers, and home economists tried to “reform” the food habits of the working classes and to Americanize immigrants from Southern and Eastern Europe. They extolled a simple diet based on meat, dairy products, refined sugar, and modern processed foods and viewed spices as distractions from nutrition. Worse, spices, pickles, and other sharp flavors were thought to lead to indigestion and increase susceptibility to alcoholism (Biltekoff 2013, pp. 24–36; Elias 2017, pp. 32–42).

In addition to suffering from a poor international culinary reputation, Britain and America had a contradictory attitude toward spices. As seen in any number of cookbooks, Anglo-American food was bland, a tendency accentuated by the early embrace of industrially produced bread, canned and later frozen vegetables, and the like. Processing offers convenience, but at some sacrifice of natural flavor. The tasteless primary ingredient encouraged using spices to make things more interesting. Condiments such as Tabasco and A1 Sauce in the United States or Worcestershire sauce and HP Sauce in Britain routinely accompanied all manner of dishes. Barbecue sauce, a combination of sweet and hot tastes, is widely used in the United States, and barbecue flavor was one of the first variations on the standard potato chip, followed by jalapeño, Cajun, and other spice options. Tandoori crisps remain popular in Britain. Until recently, such peculiar tastes were unknown to Continental Europe.

Some of this latent Anglo-American predilection for spiciness comes from colonial or neocolonial empires. Curry was an English adaptation of Indian cuisine widely disseminated as far back as the eighteenth century. In the early nineteenth century, the curries served at the Oriental and East India clubs in London were famous for their fiery flavor (Forrest 1968, p. 53; Prasch 2008, pp. 597–598). By a process that would be repeated with other imported cuisines, curry became progressively milder as every club and hotel dining room in Britain came to offer it. Until the 1960s, English curry was a creamy and only lightly spiced stew, but the pendulum swung back again toward a formula in which chili pepper was predominant and tough guys held “vindaloo” contests to see who could eat the hottest curry. In Martin Amis’ 1989 novel *London Fields*, a small-time criminal patronizes a restaurant called “The Indian Mutiny” where he challenges the waiters to make a mutton vindaloo that is too hot for him (with “napalm sauce”). This insular, xenophobic character considers eating curry as typically British, like playing darts in a pub (Buettner 2008, pp. 881–885). Spicy immigrant restaurant food might be regarded with affection by the nonimmigrant population, but the people who run the restaurants and members of their ethnic group can simultaneously be regarded with contempt, even fear, as is the case with Mexican restaurants and Mexican immigrants in the United States.

In recent decades, the taste for spices has returned to Europe and North America. This is only partly due to immigration and the proliferation of international restaurants. Thai and Tex-Mex food, which are all the rage in Germany and Scandinavia, have little relation to emigration to those countries and more with global popular culture. Restaurants opened by immigrants are, of course, popular in the United States, but the passion for spicy dishes such as Buffalo chicken wings, Nashville hot chicken, or blackened redfish results from the popularization of domestic local specialties.

The change toward a greater appreciation of spice in Western cuisines is furthered by the globalization of taste, a complementary phenomenon to the spread of Western fast foods. Globalization has both homogenizing effects (the same KFC formula in Beijing and Buenos Aires) and eclecticism – the availability of dozens of international cuisines. Fondness for safe versions of unfamiliar cuisine, once a peculiarity of the United States and Britain, has now spread everywhere. Spices remain both cherished ingredients in local products and universal flavorings for an indistinct global assortment of tacos, pizza, and sushi.

5 Simplicity and Performance in Roman Agrarian Foods

Charles Feldman and Prudence Jones

Contents

Abstract

In this chapter, traditional, local, and simply prepared Roman agrarian foods are discussed. While these rustic comestibles were revered by some elites for their symbolically embodied history and cultural capital, they were in stark contrast to the more ostentatious fare dressing other aristocratic tables. The degree of respect for agrarian fare was contingent on the social philosophy of the consumer. For the poor and destitute the food choice was easy, they ate almost anything. For the elite ancient Roman conservative who espoused values from a heroic past, rustic foods offered a venue for political gain. Though, this noble may not have been as principled when eating in private. An aristocratic debate, sometimes against consuming whole animals, sometimes against eating parts of animals, sometimes

against the whole and the part, seemed representative of deeper social issues. The confluence of local and foreign ideology had its effect on consumer preferences and culinary fashion. As long as an ancient Roman food remained intact, recognizable, or natural, it could summon rustic history. When comestibles were masticated or transformed their symbolic meanings moved outside the context of local simplicity, into novelties ascribed to foreign influence. While rustic foods in themselves did not necessarily represent luxury, the local comestible could be manipulated through the artifice of culinary preparation. It was these manipulated foods in particular that evoked mixed messages: traditional by nature, novel through preparation, local yet foreign. The end result, however, would obfuscate historic meanings and, as such, a clear sense of Roman aristocratic identity.

Introduction

> *In earlier times the inhabitants of Italy, said Posidonius, even those who were very well off, used to train their sons to mostly drink, and eat whatever they happened to have. He tells us a father and a mother often would ask a son whether he preferred to have pears or nuts for his dinner. After eating some of these the son was contented and went to bed* (Ath. VI.274).

Posidonius' commentary as relayed through Athenaeus in the third century implied that some ancient Roman foods were imbued with integrity by way of their simple wholesomeness. These rustic foods (*agrestes*) could have been farinaceous products, locally grown fruits, legumes, nuts, or vegetables, or they could have been produced from animals that were hunted or domesticated. On the compendium of processed foods, these foods were simple in that they lay closest to their natural state, requiring a minimum of preparation. Rustic foods could be consumed whole or in part, without any necessary additions, grinding or mixing. These were not the complicated transformed dishes, the stews and the sauces seen among the surviving Roman recipe treatise *De re Coquinaria*.

The context of social conflict in ancient Rome is particularly relevant to understanding these rustic simple foods during the later Republican and earlier Imperial periods (generally the second century BC to second century AD – the era when the textual data on food is most evident). Unequal access to resources precluded choice for many Romans, making consumption of simple foods a matter of necessity for those who were barely surviving, living on whatever they could find. One should assume, for example, that Ovid's fictive peasant couple, Philemon and Baucis, consumed radishes, cream cheese, eggs, nuts, berries, and eggs, because they could not afford to do differently (*Met.*VIII.665–685). At the other extreme, a rustic meal afforded a moral dimension for Roman aristocrats that worked well with the ancient Stoic principles of frugality and self-control (Garnsey 1999). Where an ancient Roman stood regarding social issues was often manifested in the foods he or she chose to eat, report on, or complain about. Roman moralists filtered the values of tradition and national pride through simple foods as an expression of conservatism. To the elite moralist, the idealized Roman past was unified, simple, and uncorrupt, and so was the food. These values were affronted by foreign influence, the influx of riches and ideas from the acquired colonies and its attendant corruptions. Exotic food ingredients and complex, masticated culinary products were topics for many a tirade.

Rustic foods offered the aristocrat a sense of elation that exceeded the food's intrinsic properties. Pliny the Younger, for example, attached to the unpretentious beet, gourd, and shallot the values of, "*unrestrained cheerfulness, simplicity and freedom*" (*Ep*. I.15.2; cf Mart. V.78). These foods were most appropriately served on earthen vessels. Tablecloths, couches on which to recline, or slaves to serve them were not necessary (Mart.V.78; Dion. of Hal. II.23; Hor. *Sat.* I.7.115–18). This lack of pretension was in contrast to an opulent culinary experience, which was a more intense performative occasion. From an alimentary perspective, simple eating was sometimes connected to fitness and well-being (Horace *Sat.* II.2.70–4). Celsus, for example, writing in the early part of the first century AD, dedicated an entire treatise to simple alimentary remedies (*Med.* II.31; cf Orib., V.1, VIII.1–5; Anthim.).

Ingredients of Public Banquets

Although the evidence is limited, historical data attest that the foods served at larger feasts were simple, perhaps as a matter of efficiency. It certainly is difficult to envision ancient Roman chefs creating, opulent stews and sauces in the field for thousands of congregants. Though, some extravagant banquets reportedly included elaborate servings of fish and fowl (Plut. *Caes.* 55.2; Pliny *HN* IX.44; Donahue 1996). In his study of second- and third-century funerary inscriptions, J.F. Donahue (1996) uncovered engravings mentioning the service of mostly simple and local foods at public and private festivals. An extant list of dishes served at a first-century BC priestly inauguration listed only a few imported dishes, with no rare ingredients and while the comestibles were not necessarily simple, there were no overly extravagant preparations. The banquet included sea urchins, raw oysters, scallops, mussels, and cockles, an assortment of meats, fish, fattened fowl, game, hare, and Picentine bread (Macrob. *Sat.*III. 13.12–13; cf Suet. *Iul*. XXXVII.9; Cic. *Phil.* II.116; Pliny *HN* IX.17.1.; Friedlander 1908). Another occasion of record was Julius Caesar's celebration in 46 BC to mark his military triumphs. On this occasion, 6,000 eels (*murena*) were reported to have been served, along with fine Falarian and Chian wines (Pliny *HN* IX.81; cf Varro *Rust*. III.17.3; Cic. *Phil.* II.116; Dio. LXXIII.13.1; Suet. *Iul.*XXXVIII.1, 2; Plut. *Caes.* 55.4). However, the logistics of thousands of fresh fish, from sea to plate, without refrigeration, would have been staggering. Therefore, the reckoning of this event might have been propaganda, to be considered with a measure of skepticism.

Of the other public feasts of which we know, cake and honey wine (*crustulum* and *muslum*), bread and wine (*panis* and *vinum*), and handouts of meat (*viserationes*) were the bill of fare. Dionysius recorded a solemn celebration in which each family contributed a honey cake (II.23). For a feast in the Amphitheater during the Saturnalia (the festival in honor of the god Saturn), Domitian provided sweet meats, plums, figs, pastries, fruit, and must-cakes (a cake made from wine sediment and fillings – Stat. *Silv.* I.6.43; Mart. VIII.78; Donahue 1996; Killeen 1959). A notable exception to banquet simplicity was a feast given for emperor Vitellius to honor his return to Rome in 69 AD. Vitellius reportedly had his captains bring food from the extremes of the empire including 2,000-choice fish and 7,000 birds. In addition, a platter of enormous size that Vitellius called the Shield of Minerva contained a blended mixture of pike liver, peacock and pheasant brains, the tongues of flamingoes, and the milt of lampreys (Suet. *Vit.* XIII.2; Tac. *Hist.* II.62). Again, we should tread lightly in the assessment of these events, which may have been more boastful than real (Corbier 1989).

The elite Roman endorsement of simple foods may have been a devious plan of social stratification and domination. Pierre Bourdieu's high-low argument provides a contemporary understanding of this stratagem. Bourdieu suggested that elites generally design covert plans to maintain class boundaries. In our example, entry to the ranks of the elite would have included an appropriate style of eating. At face value, an elite penchant for rustic foods represented a simple morality, but underneath these foods marked an aristocratic border that excluded foreigners and elite pretenders by rejecting their broader culinary ideas (Edmunds 1980; Bourdieu 1984). That is, certain Roman aristocrats supported their social position through a contrived association with simple living. It was pretense after all, these were nobles of great wealth and influence. To some Romans, consumption of these rustic foods afforded a simple dignity and a connection with the past. Other Romans employed these foods to express prestige and power. From this standpoint, moderation and refinement were held in a precarious balance.

A theme of moral decline over time was a common one in the ancient literature going all the way back to Hesiod in the eighth century BC (*Op.* 109–201). This theme carried over to Imperial Rome when pundits increasingly decried a contemporary decay of virtue and decency. The honor of an elite Roman agriculturist was enhanced by a venerated image of an agrarian past along with spiritual associations. Among the many examples, Romulus, founder of Rome, was portrayed as a rustic. His hut on the Palatine (*Casa Romuli*) was a tourist attraction of the time (Dion. Hal. *Ant. Rom*. I.79). Augustus wore homespun clothes, in deference to a rustic tradition (Suet. *Aug.* 71). The first-century writer Vergil mourned the passing of the idealized rustic life of the small farmer (*Ecl.* 1; 9), while his contemporary Ovid provided a mnemonic description of idealized ancient Roman history when foreign influence and fashion had yet to take its grip (*Fast.* VI.169–82).

Rustic food prescriptions were indemnified in the second century BC agricultural manual of Cato the Elder, *De re Rustica*. They had the virtuous overtones of a pious, self-sufficient Republic that smacked of local agricultural integrity. For example, among Cato's treatise is a recipe for porridge, another for olives and vinegar (*Rust.* LXXXV; CXIX) and his recipe for honey cake made out of cheese and groats (*placenta* – LXXVI) was redolent of a sacrificial cake (cf Hor. *Epist.* I.10.10; Varro *Rust* I.2.28). Two centuries later Athenaeus explained the connection of simple local foods to religious piety, by contrasting the absurdity of indulging of foreign extravagance (IV.274), a theme that had been laced through the ancient Roman literature. The Imperial Roman satirists symbolically contrasted simple agrarian foods with more decadent behaviors in their social commentaries. Persius, writing in the first century, emphasized this point by juxtaposing of simple nettle and pig's cheek to the more opulent goose's liver in a tirade over profligate behaviors (VI.67–74).

Roman writers often portrayed antiquarians as mostly vegetarians who preferred simple meals. For instance, Plautus had his Greek characters call the early Romans *fodder-eaters* (*Pseud.*810; cf Juv. XIV.170–171). Varro told us that the most ancient of Romans meals consisted of grains (*Ling.* V.105). Vergil idealized the Corycian gardener for his traditional self-sufficiency by loading his dinner-table with home-grown delicacies (*G*. IV.116–148). Pliny informed us that the Roman meal *pulmentaria* was so-called, because since the earliest of times Romans lived only on porridge (*puls* – Pliny *HN* XVIII.84; Garnsey 1999; Wyetzner 1995), and Cincinnatus was romanticized for forsaking his toga when plowing his fields (Livy III.26). While beans were sometimes held in high sanctified stature (they held the souls of the dead – Pliny *HN* XVIII.119; cf Ath. II.65c), at other times, they were ascribed to a lowly station, reserved for simple service in clay vessels (Mart. XIII.7, V.78; Hor. *Sat* I.6.116–20, II.6.59; Gell. *NA* IV.11). In a further affront to beans lowly status, the Latin word *fava* was used to signify both the broad bean and the worker (Corbier 1999).

A pantry containing grains, fowl, fish, and pork provided a basic inventory for rustic comestibles (Cic. *Fin.* II.8.23; Varro *Rust.* III.3.4; D'Arms 1999). Cicero mentions fruit and omelets (*Fam.* IX.20). Pliny wrote about a gruel made of pounded emmer wheat (*alicae* – *HN* III.6). Horace employed vegetables, grapes, vetch, long oats, dried raisins, and bits of bacon in developing a heroic context (*Sat*. II.2; II.4.85). His protagonist Ofellus personified this rustic virtue, as he dined on greens, smoked ham shank, chicken, or kid, followed by a dessert of raisins, nuts, and figs (*Sat.* II.2.116–125). Martial, in his Epigrams, provided a fairly complete list of local *agrestes*: cauliflower, chestnuts, pulses, fruit, tunny-fish, sliced eggs, broccoli, sausage, and pease-pudding (V.78) and herbs, squat lettuce, tender young sprouts, leek, mint, and rocket. Add to the preceding a chicken and a ham that has already survived three dinners (X.48). The *De re Coquinaria* provides a number of simple, rustic preparations such as artichokes and eggs (III.19.I) and lentils and chestnuts (V.2.2). Inclusion of agrarian foods in this treatise attests to the versatility of these comestibles within a high-status context.

Honor of Agriculture

The agricultural pursuit to the ancient Romans was more of a sacred art than a job, as the landed gentry did not work. Farming was one of the most dignified Roman professions (Pliny *HN* XVIII.1.5; Sen. *Prov.* III.6). Not only did generals pursue this art, but so did at least four kings of classical antiquity (Pliny *HN* XVIII.4.19–20). Cultivated vegetables were so highly honored that families of the highest rank such as the Lactucinos (of the lettuce) adopted their names (XIX.19.59). The third-century

B.C. senators Curius (Juv. XI.78) and Fabricius were generally known and admired for cooking vegetables gathered in their gardens (Sen. *Prov.* III.6; Dion. Hal. *Ant. Rom*. II.23). This appreciation of rustic identity served as a mark of refinement and a vehicle of performed status for the landed gentry. For example, the elite fashion of "refined starvation" (*famem mundam*) had the haughty crowd hauling vegetables, eggs, fruit, and cheeses to their adorned villas (Mart. III.58.43). Horace provided simple how-to instructions (*Sat.* II) in what appears to be guide for aristocrats returning to their roots:

> *Serve eggs of an long shape, they are sweeter than the round* (19–20) . . .*You will be wise to plunge a tough fowl into diluted wine: this will make it tender* (24–26). . . *Mushrooms from the pastures are best* (20). . . *After dinner, eat the blackest mulberries* (30–32)

Descriptions like these belied a feigned appreciation of rusticity, a message that rings loud and clear in a confession by Juvenal "*I am secretly at heart a glutton: I openly announce to my slave to bring me porridge, while I whisper to him, 'bring me cheesecakes'*" (XI. 60–62). Horace would be unhappy in either direction, for he found extremes of both frugality and gluttony to be distasteful (II.2.65).

Suggesting that a Roman aristocrat ate frugally is perhaps a misconception that attests to the political exploitation of rustic foods (Friedlander 1908). The food that a noble reportedly ate or served reinforced his or her worldview, an image that was often controlled. For example, particular aristocrats were depicted as eating frugal regimes at least on occasion, though it is clear that nothing, certainly not economics, compelled them to do so. Julius Caesar, it was said, made a suckling pig or a hare last for three days and he was content to dine on cabbages and beans without meat (S.H. A. *Did. Iul.* 3.8). Augustus liked light meals of dates and bread or bread and raisins (Suet. *Aug.* LXXVI.3). Seneca ate figs as an accompaniment to some bread, or figs alone serving as bread if the latter were lacking, and Vespasian ate with an air of frugality that was clearly contrived to be in marked contrast with his gourmandizing predecessor Nero (Tac. *Ann.* III.55; Cass. *Dio.* LXV.10.3). As reported, the third-century emperor Tacitus served only country produce and sacrificial meats at his daily table, while the service of a single bird, pig's jowls, and eggs for were restrained to festive occasions (S.H.A. *Tac*. XI.5).

In ancient Rome, an impassioned call for simplicity was often heard when gluttons were blamed for an economic imbalance. A few Romans like Pliny suggested that the purchase of vast quantities of foreign goods was leading directly to the insolvency of Italy (*HN* XII.41; cf Tac. *Ann.* III.53; Sen. *Prov.* III.6; Cato in Ath. 274–5). Reactionary distaste for foreign products made for good rhetoric, but many a tirade was skewed by ethnocentrism. By harnessing the social capital of cultivated ingredients, the Imperial Roman aristocrat began to assert an element of control over foreign and ethnic intrusion. The Roman idea of rustic agriculture was a mixed bag of ideas that worked well symbolically with a unified Roman image. Society once had been self-sufficient, devoid of foreign products, when loyalties were due first to country. Horace and Juvenal used the city of Rome itself as a symbol of societal corruption. Its diversity not only tainted Rome's purity, but also sapped its strength. Juvenal complained about the hoards that had poured into the city of Rome from the likes of Rhodes, Sybaris, and Miletus (Juv. III. 312–114, VI.298; cf III.305; Braund 1989). Horaces's city-country tale metaphorically described the travails of two mice in an urban-rural antithesis (*Sat*. II.6.77–118). As the tale goes, a country and city mouse were eating the leftovers of an opulent feast (ostensibly in the city of Rome) when they were accosted by two dogs. The country mouse then retreated to his home, to the comfort of simple food and the distance from extravagance.

The topic of virility certainly came to play among the juxtaposition of the noble Roman agriculturist to the more urbane city dweller. The former was a warrior, a true man who embraced the land at its natural bounty. His face, which emboldened many ancient coins and sculptures, was weathered, beaten, and hardened. In contrast, the urbane dweller, we are led to believe, was more effeminate in his profession and lifestyle (Grant 1987; Gruen 1992).

The depreciating value of Roman virility was also linked to changing elite food preferences, an idea remorsefully put forth by Persius: "*When this fake philosophy entered the city along with dates and pepper, our farmers have ruined their porridge with gross oils*!" (*Sat.* VI.40–41). The agrarian, removed somewhat from the urban morass, was left to uphold the standard of *Romanus*, its honor, strength, and integrity. The Roman country gentlemen was expected to eschew the most lavish of comestibles in favor of the manlier fare, such as that of a soldier (cf Sen. *Ep.* XCV.27).

Simplicity as Source of Strength

The traditional connection of simple Roman eating and strength can be explained through an analogy about Rome before the travail brought forth by the general Marcellus. The general's sack of Syracuse in 211 B.C. was a major turning point in Roman attitudes, behavior, and diet. Up until this point, Romans had been accustomed to only war and agriculture; a reliance on simplicity had always assured them victory. Then Marcellus carted back to Rome a trove of luxurious objects and ideas from foreign lands that presumably set Rome on a path of degradation (Polyb. IX.10; Plut. *Marc.*XXI.4–5). The sources make it clear: Rome would have been stronger had it not been introduced to foreign art, attitudes, and, as a point of our concern, exotic food (Gruen 1992). Although we cannot be certain, archeological evidence seems to support that the Roman warrior, whether soldier or noble, ate simply. This harked back to the ideal Roman of the Republic who was a citizen, a soldier, and a farmer (Livy III.26–29).

Literary sources lead us to believe that the Roman warrior would not have been satisfied with anything but simple food. In addition, the logistics required to make refined culinary products for soldiers in the field may have hampered their use. A study of remains discovered at ancient Roman military sites in Britain and Germany uncovered a number of rustic food products, including deer, ox, poultry, hare, and especially beans and lentils (Davies 1971). The ancient tablets found at Vindolanda provide a record of military provisions that support this evidence (Vind. Inv. 88.839). One of the lengthiest existing accounts, a several-day record of an officer's provisions, lists mostly barley and Celtic beer. Although on one exceptional occasion, the officer obtained a bottle of fine imported wine (Bowman 1994). At least when on campaign, the noble would be expected to eat at a common table with the troops. Vitellius was an exception who was roundly despised for gourmandizing in the field (Suet. *Vit.* XIII.2; Tac. *Hist.* II.95). Seneca rhetorically asked if the Roman general Fabricius "*would have been more content if he stuffed himself with fish from a distant shore and with birds from foreign lands?*" (*Prov.* III.6). The implied answer was no.

At times the Roman aristocrat preferred foods that were produced locally, which could also garner desirability and ideological worth. Juvenal's account of a meal he served to Persius provided a lesson in the economics of local food value. He promised that the meal would please, consisting only of courses supplied by Juvenal's farm at Tivoli (XI.64–5). As in the "*old days*," peasants produced bacon at home instead of buying it in the market, we are told by Varro, and they fared well without products sent from town (*Rust.* II.43; Horace *Sat.* II.2.118–125).

The question of whether to serve simple versus elaborate foods was symbolic of the societal tensions developing in the late republic: the idealistic connection to Rome's origins (e.g., the hardy roman farmer) versus the desire for status symbols as increasing wealth flowed into Rome from the provinces (Horace *Ep.* II.1.156–157). The establishment of value among a local foreign dyad rested not only on an aristocrat's politics, but also on his or her keen sense of taste and distinction (Varro *Rust.* I.2.6–7; I.2.43; Horace *Sat.* II.2. 118–125). It was likely that many aristocrats had to tread a fine line between fashion and politics. Petronius provided a complex and comical version of the interplay of these values in his imaginary portrayal of a banquet given by the crude freedman Trimalchio. Everything was grown locally on my estates, Trimalchio boasted, "*I don't buy my wine. My wine and everything else that makes your mouth salivate grow on an estate of mine*" (*Sat.* XLVIII.2). Though, Trimalchio was not above serving exotica such live birds buried inside a pig or sealed inside fake eggs. This confusion must have seemed perplexing yet familiar to Petronious' contemporaries (Schmeling 1970).

Foods Embodying Conflicting Values

The Roman agrarian classified animals in terms of wild, domesticated, or half-wild attributes. Wild foods (foraged grains and undomesticated animals) epitomized the prestige of the hunt, a reminder of a simpler, more heroic past. Though these commodities were not universally appreciated. For example, Galen the late second-century physician denigrated these foods in the following passage:

> [Wild] *foods possess little that is nutritious, are full of bad juices, are bad for the stomach, and are unpleasant to taste, since they are food rather for pigs – wild pigs that is, which live in the mountains, because only wild pigs derive any nourishment from these . . .* (*Alim. Fac.*, trans. Grant 2000)

Strabo, the first-century historian and geographer, used the metaphor of wild pigs to demonstrate the incivility of the tribal Gauls: "*Most of them sleep on the ground and eat their meals seated on hay . . . 'Their swine run wild'*" (IV.4.3, C.197). From Strabo's view, wild pigs seem to go with wild people. Human civility, in part, was marked by the level of their consumption of trained animals. Strabo's perspective holds suit with other Roman aristocrats who saw life as an ordered affair. Pliny, for example, believed that natural divisions of civility demarcate both the animal and human kingdoms:

> *Not only in pigs but in all animals as well, when there is a tame variety there is also a wild one of the same species. This is also true for man, as an equal number of savage races can be predicted to exist*. (Pliny *HN* VIII.79)

As Pliny expanded his analogy from pigs to people, we see an affirmation that aristocratic Romans viewed life as a conflict between domesticated and denatured and virile, wild elements. Ultimately, the domesticated animal, the one that subsumed, was most demonstrative of an owner's prestige. Eating a wild animal was sometimes all right and even esteemed, but eating a "tamed" edible was more refined. It was more efficient to produce a domestically raised animal product as it herded and directed to slaughter with certain efficiency. One could say that domestic food production was generally a more ordered, controlled, civil affair, than the hunt.

The wild animal was strong, free, and heroic, but it made a more or less crude rustic product that, at least to some, was barbaric. A farm-raised, or domesticated, animal embodied a traditional rustic value, and by exercising control over this animal, a Roman could attach to it a modicum of civility. Then again, certain farm-raised products (e.g., farm-raised fish) symbolized corruption and gluttony. Romans considered this the realm of the "half-wild," the midpoint between wild and domestic animals. The *glis,* or dormouse, fell under this category (Pliny *HN* VIII.57). It was not especially wild (specimens were raised in captivity), but it was not tamed or domesticated either. Varro tells us the dormouse could easily be raised in jars inside a villa (*Rust.* III.XV). While the dormouse lacked the prestige of foreignness or rarity, it had an esteemed value that may have rested in its novelty and its perceived ability to transverse wild and tame attributes (Mart. XIII.59; *De re Coq.* IX.396; Pliny *HN* VIII.57). Food of this sort was inconsistently symbolic of both local rustic and opulent hospitality (Hor. *Sat.* II.6.77–118; Petron. *Sat.* XXXI) and at times was a bridge between the two extremes.

Animals: Whole and More than Whole

Chicken and eggs were often eaten in concordance with a rustic morality, offering the tradition of a simple, local, and wholesome meal. The mother of the Roman egg, of course, was the chicken (cf Plut. *Quaest. conv.* 636a). Its egg was round and white, whole and uniform and it had strong symbolic value. The center of the egg was bright yellow, an attribute of the sun (cf Cic. *Nat. D.* II.24) or the stars (Ath. II.58c) and the symbol of fertility (cf Plut. *Quaest. conv.* 636e; Hor. *Sat.* II.4.17–20; Ath.

II.57c). Although Horace tells us that "*cheap eggs*" still had a place in the feast of kings (II.2.45), this had little relation to the pretensions of elite culinary extravagance. While the *De re Coquinaria* has three simple recipes for eggs listed in an opulent banquet (VII.19.1,2,3), the mixed victual and foreign edible garnered the most prestige. Chicken and eggs were most appropriately served at a modest dinner, perhaps with a roast kid and wild asparagus (Juv. XI.65–75; cf Hor. *Sat.* II.4.17–29) or a locally caught *lupus* (Mart. X.48).

There were attempts to appreciate rustic food values by, in effect, increasing their size. The use of fattened fowl in public festivals seems to attest to an elite Roman preference for engorged poultry over natural, free-range, or wild varieties. The aristocrat was generally more appreciative of the flavor attributes of fat, which was often more present in farm-raised animal varieties, as Seneca described:

> *After much feeding and being fattened by force these edibles barely retain their own lard and nearly melt... The delicate flavor of these dishes is what you like.* (*Ep.* CX.11; cf Mart. XI.52)

Fattened fowl were reputedly served at the pontifical banquet given by Metellus and at the feasts given by Caesar (Macrob. *Sat.* III.13.12). Cato provided detailed instructions for engorging or "cramming" of poultry that underscored how this science necessitated a precise knowledge:

> *Cram into the [chicken's] mouth wheat or barley meal soaked in water* (Rust. LXXXIX). *For squabs, blow beans that have been boiled and toasted from your mouth into its mouth.* (XC)

Two centuries later, Pliny shared some of his tips on fattening:

> *Feeding poultry with food soaked in milk makes them much more acceptable* (*HN* X.71). *Castrating roosters makes fattening them easier* (X.25.). *When the liver has been taken [from a goose], it grows larger after being soaked in honeyed milk.* (X.27)

Fattening was not limited to poultry (Pliny *HN* X.23; Macrob. *Sat.*13.13). Slaves at neighborhood shrines routinely sacrificed engorged pigs. A method for their fattening with dried figs and mead was attributed to Apicius (*HN* VIII.209). Dormice were fattened on nuts, acorns, and chestnuts in the darkness of a barrel (Varro *Rust.* III.15.2; Pliny *HN* VIII.82). Hares were taken from the preserves, placed in hutches and fattened (Varro *Rust.* III.14; Macrob. *Sat.* III.13.13). Snails were crammed with must or spelt (Macrob. *Sat.* 13.13) or slime (Sen. *Ep.* XCV.25), and fish were bred to large size (Varro *Rust*. III.1–10; Macrob. *Sat.* III.15.7).

Cattle ate in the fields and fell under a different category from the fattened animals, who were fed in the farmstead (*villaticum*-Varro. *Rust.* III, 2.13). Cattle "*who enhance cultivation as a result of their labor*," Varro instructed, fell under the dominion of the farmer. Cattle not utilized for cultivation came under the auspice of the herdsman (*Rust.* I.2.20–21). The divide between herdsman (*armentarius*) and farmer (*arator*) was more than technical. Since early antiquity, agriculturists tried to distance themselves from pastoral meat eaters, so it is not surprising that there was a hint of disparagement when Varro, the consummate agriculturist, remarked that "*cattle that graze do not produce what grows, they rip it off with their teeth*" (II.4–6); these beasts did not know how to act properly. Pliny in a sardonic moment compared cattle to the lower classes (*HN* XIX.19.51–60). In sum, we can deduce that some Roman cattle worked in the farmstead in accordance to the life and honor of the farmer and that other types were associated with the uncivilized pastoral existence of the herdsman (Daubeny 1857).

By shifting of emphasis from a sacrificial to a performative celebration of meat, the Roman aristocrat was exercising his or her control over this commodity. The demonstrative prestigious consumption of meat affirmed that it was not readily available for popular use. As such, beef from cattle was distributed in a number of Roman grand celebrations. For example, we are told that 120 oxen were sacrificed in the triumph of Aemilius Paullus in 168 BC (Plut. *Aem*. 33.2), and an "enormous quantity" of beef was sacrificed in Judea for the victory of Titus in 71 AD (Joseph. *BJ* VII.16; Corbier 1989). However, the literary accounts of private opulence rarely mention beef. Why, we might ask, was meat from pig (*porcinus*) extensively mentioned in the primary classic literature but meat from cattle (*bubula*) hardly mentioned at all? The explanation according to Ovid was that the ox was spared because it was man's companion in labor (*Fast.* I. 360; 380).

The wild boar and its tame cousin the pig were other animals whose consumption was associated with mixed meanings. The symbolic association of pork products with simplicity and wholesomeness is clear and can be seen throughout ancient literature (Varro *Rust.* II.4.10). The connection of pork products to religion and sacrifice cannot be understated. Varro tells us that the Greek name for the pig was ὕς, from the Greek verb θῦειν, that is, "to sacrifice." It seems as Varro advised, since the origin of sacrificial ties, the victim almost always came the swine family (*Rust.* II.4.9). The boar was a product of a rural and religious simplicity that at times was manifest in the shared meal, but the boar was also representative of luxury (Ath. III.76b) and social differentiation (Juv. V). It is mentioned in connection to a number of performative presentations set in opulent surrounds (Mart. VII.78; Petron. *Sat.* XLI; Macr. *Sat.* III.13.10). The boar became the comestible *par excellence* of a meal, so integrally related to celebration, Martial tells us that one did not dine or entertain without it (VII.59).

The impact of cooked boar's presentation may have been enhanced by its traditional use. It had the virtuous overtones of the hunt and celebratory meal of Rome's good old days (Hudson 1989; *De re Coq.* VIII.1). The sources sometimes connected the opulent service of a boar to mythology as a meal worthy of epic heroes. In Petronius' satire, we find a burly man in hunter's garb cutting open the side of a whole boar (41). Live thrush flew out of the boar, in a meal later described by Macrobius as *Porcus Troianus* (*Sat*. III.13.13), a clear reference to the Trojan Horse (Courtney 2001). A number of mythological references in the literature connected the *Aetolian Boar* to food opulence. Ancient legend has it that Meleager killed this wild beast in a famed hunt (*Hom.* II.9.567). Martial mentioned the *Aetolian Boar* a number of times (VII.27.1–2; XIII.41; XIII.93; Coleman 1990), and Juvenal describes a "*steaming hot boar, worthy of the steel blond Meleager*," in association with the tyrannical station of his fictive patron Virro. The boar was served among the finest of edibles: fattened fowl, truffles, and goose liver (V.114–6).

Fish

The metaphoric conflict and mixed messages inherent to the Roman societal struggle were symbolically mentioned in the ancient discourse about fish. Representative of poverty and simplicity, fish became one of the most prestigious symbols of ostentation. Pliny recalled the name of three dishes used to denote the most luxurious possible banquet: the lamprey, the pike and a mixture of fish (*HN* XXXV.46). As far as traditional capital was concerned, the fish products Athenaeus reported exceeded the qualities of meat eaten by Hercules and the figs eaten by Plato. That is why the term *opsum* (fine relish) was used to connote fish (Ath. VII.276).

At the other extreme, fishing stood akin to gathering and hunting in that it was a trade for peasants. This is because fishing did not require ownership or extensive resource management. Roman prestige emanated primarily from the land, produce and, to a lesser extent, the products of domesticated animals (Purcell 1995). It was relatively easy for Romans to subjugate and control those things. The sea, however, was a different world that was wild, hostile, and uncontrollable. In addition, the sea was considered poor, so poor that only in times of famine or extreme poverty did Romans turn to fishing for survival (Str. VI.2.252; Just. *Epit*. XL.43.5; Purcell 1995).

The image of a Roman selling fresh fish in the market was an anomaly. Lacking effective transportation and refrigeration facilities, it was nearly impossible to import fresh fish from afar, relegating trade to local seaport markets. Thus, Rome's inland location made fish an exceptional part of the local diet and a symbol for extreme ostentation (Lucil. *fr.* IV.2; Juv. IV; Mart. XIV.97; Evans 1890). It was said that the reputed chef Apicius, for example, skillfully packaged fresh oysters to be sent to Trajan while he was in Parthia (Ath. I.7d). We are told that Elagabalus commanded respect by his ability to eat fish regularly, no matter where he was located (S.H.A. *Heliogab.* XXXVII.3). Though even royalty learned to live without fish, as Athenaeus reports in a parable about Nicomedes, the king of Bithynia. So great was his desire for fish, and so lacking was this commodity that the king dispatched a cook to make an imitation of out of a turnip (Ath. I.7e). Consequent to the relative rarity and perishable properties of fish, most ancient Roman trade involving fish was related to its packaging and preservation. Salted and fermented fish products lasted longer and could be imported or distributed over great distances.

The apposition of farm-raised and wild caught fish in the culinary repertoire resulted in abstract meanings, dependent on the worldview of the ancient source. For example, Columella described the tension of both domestication and wildness inherent to fish in ponds when he recommended placing seaweed-covered rocks in the water. "*Though they are prisoners*," he wrote, "*fish should feel their captivity as little as possible"* (*Rust.* VIII.17.6). Farm-raised fish were culinary prizes that commanded astonishingly high prices (Pavlovskis 1973). However, the lamprey was a paradox. It was a locally spawned fish that was not rare, but it had attributed culinary value. Apparently, depending on who was reporting, the lamprey evoked luxury, modest, or rustic value, or no value at all. Lucilius, through Macrobius, mentioned a local variety, *Lupus Tiberinus*, appearing at banquets as early as the late third century B.C. (Macrob. *Sat.* III.16.17; cf Lucil. *fr.* IV.5; Evans 1890). Martial described a meal where an imported Spanish lamprey is served within the modest proximity of beans (*Ep.* VII.78; cf Pliny *HN* XXXII.53), and, in another modest dinner of his recollection, a nondescript variety of lamprey was served together with the rusticity of chicken and eggs (*Ep.* X.48).

Farm-raised and imported varieties of lamprey were held in the highest esteem (Macrob. *Sat*. III.15.9). A particularly fine variety of lamprey from the Sicilian narrows was served to Juvenal's literary patron Virro. The Sicilian lamprey was easily caught, Macrobius recalled, for it was fat and floated to the top. This kind of lamprey was so highly valued that it was imported to the fish ponds of Rome (*Sat.* III.15.7). The variety that Lucilius mentioned, *Lupus Tibernius*, grew locally. He called it the licker of excrement (*catillo* – Macrob. *Sat.* III.16.17). Pliny confirmed that the best lamprey were in fact found between the two bridges, the *Pons Senatorius* and the *Pons Sublicius* of the Tiber River (*HN* IX.79; cf Gal. *Nat. Fac.* VI.714; Colum. *Rust.* VIII.16.2–4; Varro *Rust.* III.3.9–10). This was the most polluted part of the river where the sewers emptied (Evans 1890). It is probably safe to assume that a lamprey caught in sewage was not an appealing edible to most ancient Romans. Though, in the literature the lamprey was sometimes used symbolize how low gluttons would go for their pleasures (Macrob. *Sat.* II.2.31; III.16.11). For Juvenal, the *Lupus Tibernius* was as revolting as it was undignified (V.103–104; cf Gal. *Nat. Fac.* III.30). Because the lamprey lived on sewage (*pinguis torrente cloaca* – 105), Juvenal was able to use it as a metaphor for oppression. This was not just a disgust of taste, but also a disgust of Roman elite degradation.

Then, why did the lamprey achieve such high esteem and be served at the elite table? It would seem that a local, common, and disgusting food product would have been exclusively associated with the lower quarters of Roman society. Like the dormouse, the value of the lamprey may have lied in its ambiguity or its ability to traverse two environments. In its natural environs, the lamprey was an estuarial fish, as it swam from salt to fresh water (Varro *Rust.* III.3.9). Thus, the lamprey, as it was able to thrive in both environments, may have accrued prestige. So, the opportunity to control, domesticate, or improve on this product may have contributed to its value. As a disgusting food product, the local lamprey was unconventional. It would have taken the most adventurous gourmand to overlook its revolting qualities. Though, its repulsive attributes may have contributed to its quality as exotica, garnering this fish prestige for its "funkiness." The explicit contrast between the *lupus*' offensiveness and its social impressiveness, both of which appear in the sources, implies that its image was subject to those who wanted to exploit it for social gain and those who wanted to prevent this. This social imbroglio could be seen with in the symbolic context of conflict surrounding other local varieties of food. One could suggest that to some ancient Romans, even the most disgusting local product was more esteemed than a foreign counterpart. Nevertheless, the paradox of the lamprey, the ambiguity of its prestige and disgust, seems to have contributed to its value.

A discussion on fish would be incomplete without mentioning the sturgeon, the mullet, and the turbot. The display of these fish ushered an aura of extravagance to a meal that was fundamentally based on their relative rarity and size. The overall opulent imagery at a banquet was in direct opposition to a traditional spartan meal of fish. The defining comments about a sturgeon's value came from Cicero (*Fat.* IV) and Macrobius, reporting four centuries later who reminded that "*sturgeon is a meal for the very few*" (*Sat.* XVI.4). The tradition of pomp and honor given to the sturgeon was attested by its service to Publius Scipio, the victor of Africa and Numantia (Cic. *Fat.* IV; cf Pliny *HN* IX.27; Mart. XIII.91; Macrob. *Sat.* III.16.1). A spirit of Roman nobility radiated from this fish that transcended the mundane. Macrobius, for example, observed a crowned sturgeon brought to the table by servants to the accompaniment of music: "*An entry that suggesting the worship of a god rather than the debut of a tasty dish*" (*Sat.* III.16.7). The sturgeon's spiritual value was so high, Cicero informs, that it had the ability to lift one's spirits in times of grief (*Tusc.* III.43).

Aristocratic power and prestige was also expressed through the size of the fish served. Only a powerful ancient Roman noble could command the resources needed to obtain a very large fish. Reluctance to providing a very large fish to the emperor was practically treasonous. Seneca conveys this point in an anecdote about a huge mullet, purchased for an outrageously high amount by the culinarian Octavius for delivery to emperor Tiberius, a gift of which he thought only a Caesar worthy (Sen. *Ep*. XCV.42). To Juvenal, the turbot also was fish too big for the private kitchen. As such, it was a symbol of power. Juvenal devoted his fourth satire to turbot as a symbol of tyranny (IV.65). However, the size of a fish had nothing to do with its taste. Horace makes this clear when he sarcastically chastises those who prefer the larger varieties: "*You praise a three-pound mullet, but it needs to be cut up into smaller portions*" (*Sat.* II.2.35). It would be hard to imagine the pomposity of a Roman fish if it had been cut into pieces. For a grand appearance, an intact large fish was best, a point emphasized by both Horace and Martial, as follows:

> *I'd love to see a big fish on a huge dish* (Horace *Sat*. II.2.39).
>
> *Huge Mullets of cover your dishes of yellow inlaid gold... Do not insult the large gold dishes with a small mullet; it should at least weigh two pounds* (Mart. II.43; XIV.97).

This idea of an ancient Roman "whole" food product is in direct opposition to an edible that in some way had been cut, separated, or disemboweled, in effect losing its natural recognizable integrity.

Whole, Part, Disemboweled, or Cut Up

Ancient Roman aristocratic consumption of certain integral foods, as we have seen, conjured the traditional symbolism of earlier times. As long as a food remained intact and natural, it could summon rustic history. For example, the image of a whole boar roasting on a spit or a fish served whole embodied a sense of Roman times gone by. By being able to recognize its features, one knew that this animal had once been alive and had been involved in a fundamental struggle for survival. Traditional values, however, became mired and complicated when these foods were cut up or, at the furthest extreme, masticated so finely that they lost all of their natural form. No longer looking like it once had been, the food's signifying meaning became abstract, the relationship to the idealized past not as apparent.

While preferences for the specialized part of animal: the gland, the viscera, was an exclusive expression of status, unusual preferences of this sort did not define the eating habits of early antiquity, as Athenaeus reported (III.101a). Rather, it was a rising passion of later Imperial decadence. Value was accrued by the very nature of conspicuous waste of food in a society marked by disparity. It took a very rich noble to afford the purchase of an animal merely for the consumption of a small part. A cooked whole animal generally implied the tradition of the shared meal. The consumption of a particular part of an animal eliminated sharing, for there is not enough to go around. By limiting the amount available to be served, a food product gained exclusivity and, hence, value. In addition, an appreciation of a particular animal part required a refinement of taste: One needed to know which parts were the best. To slaughter an animal for the purpose of consuming a small part of it was a clear act of ancient avarice. The more wasteful the behaviors, the more utility the squandered comestible had in influencing cultural capital, status and prestige. A case in point was Cleopatra's consumption of a valuable pearl at a banquet. By extension, this act not only demonstrated her nonchalance over this wastefulness, but her vast wealth, power, and control over Antony (Jones 2010).

When whole-cooked products no longer differentiated the elite, Seneca recalled, they turned to flamingo tongues and similar absurdities (*Ep. CX* 12–13). Among the many examples are the teats, a glandule, a rib, the tongue, and the spleen from a boar (Ath. III.96; Mart. II.37), and the testicles of capon and preparations for wombs, trotters, livers, and udders (*De re Coq*. IV.3.3; VII.1.1–6; VII.2.1–3; VII.3.1–2). Horace's character Fundanius described a large platter that contained limbs of crane, liver of a white goose, pigeons without rumps, and hares with limbs torn off (*Sat.* II.8). We are also told that Elagabalus, in imitation of Apicius, had a preference for camel-heels, cock-combs taken from living birds, tongues of peacocks and nightingales, visera of mullets, flamingo and thrush brains, and the heads of parrots, pheasants, and peacocks (S.H.A. *Heliogab*. XXX.6). Aristocratic debate continued from the late republic onward over whether or not eating a small part of an animal's body was preferred or suspect. The outcry, sometimes against the whole, sometimes against the part, sometimes against the whole and the part, seemed representative of the broader issues discussed earlier (Pliny *HN* VIII.78; Suet. *Tib.* XXXIV; Tac. *Ann.* III.52).

Conclusion

In this chapter, foods that were generally revered for their natural features and integrity were contrasted with more ostentatious varieties. The sumptuous Roman dining occasion was not always about foreign exotica. The degree of this respect for food integrity was contingent on the social philosophy of the food's consumer. For the poor and destitute, the food choice was easy, they ate almost anything. The Roman conservative aristocrat, one whose values emanated from the past, would likely prefer a food product that expressed that ideal: a rustic or wholesome food that required a minimum of preparation. Rustic foods in themselves did not necessarily represent luxury, but the local comestible could have been manipulated through the artifice of culinary preparation, taking it outside the context of simplicity. It was these manipulated foods in particular that evoked mixed messages: traditional by nature, novel through preparation. The end result, however, would obfuscate the historic meaning and as such, a clear sense of Roman aristocratic identity. The generally worldlier Roman social opportunist would, perhaps, identify himself or herself with an edible that evoked this progressive image; a fattened hen or a farm-raised lamprey might do. If he or she opted for a little more dazzle, perhaps a masticated product or spiced concoction from the *De re Coquinaria* would work best. Then again, we must be aware of an aristocratic divide between the public and private persona. What the Roman aristocrat did or said in public may not have been an indication of his or her life at home. This was particularly true when it came to food.

Part III

The Biological Sciences

Food Intake and Physiological Regulation: The Means and the End

6

France Bellisle

Contents

Abstract

The independent life of animals requires the active regulation of many critical parameters of the internal status of the organism, in other words, their maintenance within a narrow range of defended values. From the early days of research into homeostatic mechanisms, it appeared that food intake (FI) is not one of such parameters. FI is one of many effector mechanisms that contribute to the regulation of several internal parameters, such as glycemia and adipose stores. The science of the last century has clarified the fine machinery of regulatory processes, both at the periphery and in the brain. Beyond the early notion of feedback loops triggering regulatory responses to existing need states, research has documented how efficient regulation rests on learned anticipatory responses, both

physiological and behavioral, that are highly plastic and continuously shaped by the experience of environmental contingencies. Studies of eating patterns in free-living humans have revealed the significant influence of numerous factors, among which signals of physiological needs exert a modest role. In spite of the massive influence of environmental and social factors, regulatory adjustments can be detected in the FI of humans, including obese humans. These impressive developments in knowledge have paralleled an unprecedented increase in the frequency of obesity. In this field, knowledge does not equate power. Even in the obesogenic world, FI matches energy needs perfectly in many individuals. Understanding why regulation mechanisms allow body adiposity to drift upward in so many others remains a crucial question.

Introduction

Obtaining and ingesting sources of nutrients from the environment are critical behaviors that all animals have to perform in order to sustain life processes. This simple unquestioned observation raises the question of the signals that trigger and then inhibit ingestive responses. The worldwide "epidemic" of obesity questions our understanding of the critical mechanisms that should permit adequate nutritional status.

Scientific interest in the triggers of food intake (FI) is not novel. As early as the mid-nineteenth century, the physiologist Claude Bernard proposed key concepts in this area: the stability of the "internal milieu" is an essential condition for an animal's "free and independent live" (Bernard 1879). The "internal milieu," the internal environment of the organism, refers to the status of many crucial parameters (including body temperature, the fluid balance, blood pressure, and glycemia) that have to be maintained within narrow limits in order to maintain life functions. The notion of "homeostasis," proposed by Cannon in the early twentieth century (Cannon 1932), refers to the convergent action of many physiological regulatory mechanisms that maintain the internal environment in a stable state.

Regulatory mechanisms are well known not only in physiology. The thermostat that regulates the temperature in a room is a simple example of a regulatory system. A regulatory mechanism requires at least three elements: sensors that monitor the regulated parameter, a control center that compares fluctuating parameter values with the "optimal" one that is to be maintained, and effectors that can bring the deviant parameter back to "regulated" levels via a feedback loop. In physiology, all three elements can be immensely complex. Among the effector responses in particular, some are purely internal, such as the hormonal mechanisms that regulate the level of glycemia (insulin and glucagon) or the shivering response to cold. In some cases, their action is sufficient to restore the regulated status of the internal milieu, at least for a while; in other cases, however, their action is limited. When the organism needs energy, nutrients, fluid, or even oxygen, no internal response will adequately insure regulation. In those cases, behavioral responses are elicited by the control center, the brain, to obtain the required life-sustaining substances from the environment so that the vital parameters of the “internal milieu” can be maintained.

This rough sketch of a classic regulation system reveals that FI itself is not “regulated”. In fact, it cannot possibly be. Ingestive responses are the behavioral extensions of internal effector processes. Rather than being “regulated parameters” themselves, they are a set of tools among many in the effector tool box that the body uses in order to maintain its “free and independent life.”

If ingestive behaviors are effectors in regulatory mechanisms, what do they regulate exactly? This is a vast question to which the science of the last century has brought a large number of answers, well beyond the few classic parameters initially envisaged by the pioneers of homeostasis research. Actually, one increasingly pressing question, in the context of the worldwide epidemic of obesity, is whether FI actually regulates or dysregulates physiological processes.

Even scientists who believe that ingestive responses are organized by the brain to serve physiological regulation are not so naïve as to believe that this is the whole story. Studies of spontaneous ingestive patterns in free-living humans have revealed that a large number of factors, sometimes quite unexpected, exert a significant influence on eating and drinking (de Castro 2010; McKiernan et al. 2009). Not only is FI not “regulated,” but it is constantly affected by a host of stimuli that often have nothing to do with the maintenance of critical vital parameters, when they do not simply antagonize it.

In this chapter, two sources of scientific information will be examined. Firstly, the concept of homeostasis and its plethoric developments in the recent decades will be reviewed in order to illustrate the role of ingestive behaviors in physiological regulation mechanisms. Secondly, studies investigating the spontaneous eating patterns of free-living humans will be reviewed in order to identify the determinants of behavior, among which markers of homeostatic regulation. The converging lessons from these two fields of science will help us analyze the regulatory and dysregulatory influences on ingestive behaviors and the reasons for our continuing failure to cope with obesity.

Birth of a Notion: Early Views on Regulation and the Role of Ingestive Behaviors

Pioneer studies examined the role of ingestive behaviors in physiological homeostatic mechanisms. Early intuitions held that drinking was essential in the regulation of the body fluid balance and that eating was triggered by hunger in response to bodily needs. The nature of the “thirst signal” that triggers drinking was debated from the early twentieth century. The nature of the “hunger signal” also stimulated much research and debate. Early models proposed that a single factor was responsible for the periodic onset of eating.

According to Brobeck’s thermoregulatory hypothesis (1948), a low temperature of the body, caused either by low external temperatures or starvation, stimulates eating which stops when the heat generated during digestion inhibits the eating system. Mayer's glucostatic theory, based on the observation that blood glucose has to be regulated within narrow limits in order to maintain brain function, proposed that food consumption is triggered periodically by decreases in the rate of glucose utilization (Mayer 1953). One common observation is that experimental animals, after imposed periods of food deprivation or overfeeding, tend to return to their initial body weight as soon as the intervention has ended (Le Magnen 1971), which concurs with the well-documented difficulty of human dieters to maintain their weight loss after the end of their diet. These robust phenomena suggest that a homeostatic mechanism actively maintains the body reserves of energy. According to the lipostatic theory, originally proposed by Kennedy (Kennedy 1953), the amount of fat in the body is the regulated parameter that stimulates or inhibits eating in order to maintain the body fat mass constant at a physiologically determined level, or "set point."

For all of the above hypotheses, and a few others, experimental demonstrations confirm that acute or chronic changes in the hypothetic "hunger signal" trigger or inhibit eating in animal models or human subjects. From a simply homeostatic perspective, eating can be triggered by a variety of changes in the internal milieu.

The early homeostatic hypotheses stimulated the search for brain structures that could detect a critical deviation in one regulated parameter, compare it to a regulated value, and trigger the adequate physiological and/or behavioral corrective responses. Using the crude instruments available in the mid-twentieth century, a "hunger center" and a "satiety center" were identified in neighboring nucleuses of the hypothalamus (the lateral and the ventromedial nucleuses, respectively), whose activation/inhibition stimulated or inhibited eating. Of interest to the present discussion of regulatory mechanisms, animal works (Hoebel and Teitelmaum 1966; Powley and Keesey 1970) revealed that experimental lesions of the ventromedial nucleus (VMN), the "satiety center" of the hypothalamus, caused a change in the regulated body weight level rather than of eating behavior per se, so that lesioned animals would overeat only as long as their weight was lower than the new "set point" level, after which they would merely eat enough to maintain their elevated weight. This was an early experimental demonstration that food intake, rather than being regulated per se, acts as an effector in the regulation of body weight or body adiposity.

Classic homeostatic views were used to account for the ingestive patterns of animals observed under laboratory conditions (Le Magnen 1992). Typically, animals with a continuous access to food do not eat continuously. Their ingestive patterns are organized in a series of discrete ingestive events (eating/drinking bouts) interspersed by intervals of variable duration during which no ingestion is observed. In addition, ingestion occurs mainly during the active phase of the species-specific activity cycle (night time in rodents, day time in humans). This pattern was termed the "dual periodicity" of ingestive behaviors (Le Magnen 1992). According to this classic view, at various moments of the activity phase, a critical "hunger signal," arising from some homeostatic deviation, triggers meal onset.

As consumption progresses, signals originating from various parts of the gastrointestinal (GI) tract cumulate and progressively counteract hunger and bring ingestion to an end. This process that brings eating to an end and therefore determines meal size is called "satiation." Gastric distension and the release of "satiation hormones" such as cholecystokinin (CCK) triggered by the sensing of nutrients in the GI tract were identified as candidates to play this inhibitory role. Finally, consumption was thought to be inhibited following an eating episode by various post-ingestive and postabsorptive metabolic signals determining the duration of "satiety." The succession of stimulatory and inhibitory influences was conceptualized in the "satiety cascade," first described more than 30 years ago and periodically updated to integrate new findings (Blundell et al. 2010). Animal studies suggested that, after the fuels consumed in one meal had been used up by the organism, the critical hunger signal occurred again, in an all-or-none fashion, and triggered the onset of another meal (Le Magnen 1992).

The analysis of eating patterns in laboratory animals quantified two important parameters of intake: the daily number of eating events and the size of these eating events. These two parameters could potentially vary in response to regulatory challenges in the environment, for example, when animals were exposed to cold temperature, to changes in palatability or energy density of their foods, or to forced physical activity (Le Magnen 1971). Laboratory rats housed in small individual cages with little else to do but eat, drink, groom, and sleep, were found very competent in energy regulation and generally maintained a stable body weight. Meal size was found to be highly sensitive to the palatability and variety of the available foods; in turn, larger meal sizes determined a longer duration of post-meal satiety so that longer satiety corrected for increased meal size (Le Magnen 1971). The "postprandial correlation" between meal size and duration of the post-meal interval suggests that animals with constant access to food adequately adjust FI to energy needs mainly by modulating the duration of post-meal satiety: animals do not return to their food before they have used up the energy consumed in their previous meal (Le Magnen 1992).

A number of experimental situations, however, defeated the animals' adaptation capacities: for example, lesions or stimulation of brain structures commanding ingestive behaviors induced either massive obesity or extreme life-threatening hypophagia, whereas exposure to a "cafeteria diet," which consists in a continuous access to a variety of palatable foods typical of the human diet, stimulated ingestion and "dietary-induced obesity." Domesticated animals notoriously show the same obesogenic sensitivity to their masters' diet, and so do wild animals exposed to high-fat, high-sugar, and high-energy foods (Zheng et al. 2009). In addition, the celebrated ability of laboratory rats to adjust intake to changing energy conditions and maintain a "healthy" weight has proved to be limited to the usual duration of laboratory tests (a few days or a few weeks). When laboratory rats are allowed to age, they also tend to develop body adiposity, even when fed a boring laboratory chow.

Advances in Knowledge and Changes in Concepts

In the recent decades, the identification of regulated parameters and associated mechanisms has accelerated, facilitated by the phenomenal development of measurement instruments, such as brain imaging techniques. These major advances are beyond the scope of the present paper. Many excellent reviews of the cumulative findings have been published and are updated regularly (Berthoud et al. 2017). As a result of convergent progresses, the classic views of homeostasis and the role of ingestive behaviors have been entirely revisited. The next short sections address a few areas of specific relevance.

Perception of the External and Internal Environments

The Head

The response to foods depends on the perception of their sensory characteristics by receptors in the head, but not only in the oral cavity. The perception of foods results from a complex integration of various sense modalities. The senses of taste and olfaction and also vision, audition, and proprioception (for the perception of texture and temperature) all contribute to the identification of foods and determine their rewarding or "hedonic" levels. Importantly, the responses of sensory receptors in the head contribute to both stimulation and inhibition of food intake. The stimulation due to palatability is highest at the beginning of ingestion. As foods are being consumed, habituation to the hedonic value of the ingested food develops. "Sensory-specific satiation" and "sensory-specific satiety" (Rolls and Hetherington 1989) are inhibitory processes that specifically reduce the reward value of the sensory characteristics of the ingested foods but spare the attractiveness of foods with other characteristics, thereby facilitating the consumption of varied food sources.

Potential differences in sensory responsiveness between persons of different weight status are a continuing field of research. While recent studies have generally confirmed older data showing no difference in appreciation of foods (appetite for sweetness in particular) between normal-weight and obese persons, some studies suggest that certain aspects of appetite may be different: for example, satiation for sweetness at the time of ingestion might occur more slowly in obese than in normal-weight individuals (Pepino and Mennella 2012), possibly stimulating larger intake.

Beyond the Mouth: The Digestive Tract

One area of very rich scientific developments is the understanding of the sensors that respond to various parameters of the nutritional status in the GI tract and could contribute to regulatory signals. The entire GI tract is equipped with mechanosensors and chemosensors which can sense the volume and nutrient content of consumed food. For example, the same receptors responsible for the perception of sweetness in the oral cavity are found in numerous locations in the GI tract and signal the presence of sugars (Iwatsuki et al. 2011). The GI tract is densely innervated by sensory afferents of the vagus nerve, which are positioned to directly communicate nutritional information from the gut to brainstem structures (Berthoud et al. 2017). In addition to neural signals, the presence of food within the GI tract elicits the production of peptides and hormones that act locally to influence nutrient absorption and metabolism, and also directly in the brain to alter feeding behavior (Berthoud et al. 2017). As neural and hormonal satiation signals from the gut are generated during a meal, their impact gradually cumulates, ultimately activating brain circuits that cause individuals to stop eating, i.e., satiation (Woods 2009).

Early views of gut signals insisted on their potent contributions to satiation and satiety. More recent developments established that the presence of nutrients such as glucose in the upper intestinal tract, and even in the circulation, can also act to condition food preferences and stimulate appetite and food intake. This phenomenon is called “appetition” to distinguish it from the satiation process by which nutrients in the gut suppress appetite and intake (Sclafani 2018). Importantly, the post-ingestive signals from the GI tract can be both stimulatory and inhibitory and require the brain to integrate possibly antagonistic influences.

Body Fat Stores

The brain is informed of the present status of the adipose stores in the body via the secretion of various hormones by the adipose tissue itself, among which insulin (Woods 2013) and leptin (Zhang et al. 1994), allowing lipostatic mechanisms to influence behaviors. The status of the adipose stores in the body modulates the response to sensory factors such as palatability. For example, after weight loss, regulatory processes enhance the attractiveness of sensory signals so that more is consumed, progressively restoring the original level of body adiposity. This process is reflected in the activity of the “hungry brain” after weight loss, in which activation patterns are enhanced in response to food, a change that can be antagonized by the administration of leptin (Zheng et al. 2009).

The Role of Learning and Plasticity

One important adaptive skill of animal life is the capacity to learn. Animals can learn from previous experiences and adapt their responses to environmental cues in order to anticipate situations of need and minimize the impact on their vital functions or to avoid them altogether.

Learning shapes both behavioral and physiological responses. The conditioned reflex, whose mechanism was demonstrated at the beginning of the nineteenth century (Pavlov 1927), is one extremely useful tool in an animal’s regulatory arsenal. The brain associates stimuli that occur in contiguity in the environment, so that one (e.g., Pavlov’s bell) reliably predicts another (e.g., the meat served to Pavlov’s dogs). As a result, predictive conditioned stimuli acquire the capacity to elicit adaptive, homeostatic responses in anticipation of the contact with unconditioned stimuli.

Animals in the wild and humans living in organized societies learn to anticipate eating occasions in their particular environment. The circumstances of habitual food intake, the time of day, the smell and sight of foods, become conditioned stimuli that trigger a set of anticipatory metabolic reflexes before ingestion has even started in order to facilitate the absorption of nutrients by the body. This phenomenon is known as the “cephalic phase” of digestion (Powley 1977). Among many aspects, a neurally elicited insulin secretion occurs before or at the very beginning of meals (Teff 2011). The cephalic-phase insulin secretion in humans is small in magnitude, but its occurrence at start of meals is sufficient to minimize the metabolic deviations that follow the meal and enhance nutrient assimilation (Woods et al. 2018). Un-signaled meals or snacks result in higher postprandial hyperglycemia due to the lack of a cephalic-phase insulin response (Chapelot et al. 2004; Teff 2011). Other reflexes of the "cephalic phase" affect many other hormones and enzymes that aid the digestion and absorption processes. A common feature of these conditioned anticipatory responses is that they occur in the absence of any major deviation of regulated parameters; they act to prevent it or at least minimize its effects. An efficient regulator, animal or human, does not wait for critical situations to develop and uses prior experience to avoid or minimize need states (Ramsay and Woods 2016).

At the behavioral level, learning shapes an individual's hierarchy of food likes and dislikes, based on the association of sensory characteristics of foods with post-ingestive effects. Importantly, in the context of a discussion of regulatory influences, the appropriate amount of a particular food to ingest under particular need states, present or anticipated, is learned based on repeated experiences of the nutritive properties of the food: appetite and satiety are conditioned responses (Booth 1977). Ingestion stops long before most nutrients are digested and absorbed: learned associations between sensory cues and post-ingestive satiety allow an individual to stop eating with the assurance that sufficient calories have been acquired (Woods 2009). In much the same way, instrumental responses are learned to allow an animal or human to make optimal use of the resources of the environment and obtain a supply of food (via hunting, gathering, or shopping) before vital parameters deviate from life-sustaining levels.

Ingestive responses to homeostatic deviations do occur, for example, when blood glucose is severely reduced (Langhans 1996). However, eating most often happens at glucose levels considerably above critical values (Woods 2009), and most regulatory responses occur without using negative feedback (Somjen 1992).

As any learned responses, anticipatory regulatory responses are plastic as opposed to hard-wired reflexes (Woods 2013). Even the satiating action of digestion-related hormones (such as CCK) is actually a plastic conditioned response rather than a hard-wired unconditioned response. It is therefore subject to the process of extinction or modulation if ingested substances do not contain the expected amount of energy (Woods et al. 2018).

The Complex, Hierarchical Organization of Brain Function

The progresses of brain imaging techniques have allowed major advances in the identification and understanding of brain regulatory mechanisms. The hypothalamus together with the corticolimbic system and the hindbrain can be seen as the core processor in the control of appetite (Berthoud et al. 2017). The brain receives a continuous stream of diverse signals regarding the energy status throughout the body and monitors the entry of nutrients into the blood and their utilization by most tissues (Woods 2009). At the time of meal, the brain integrates signals reflecting energy input with the present and anticipated state of need and acts as a "homeostatic regulator," adjusting intake to needs in a flexible, largely anticipatory manner. Brain mechanisms at times must arbitrate among multiple possibly conflicting regulatory responses. For example, if chronic glucopenia is created in experimental animals, energy intake increases to maintain blood glucose even if the augmented energy intake induces significant weight gain (Langhans 1996): although both body adiposity and blood glucose are regulated parameters, protecting acute blood glucose levels takes priority over body weight control (Woods 2009).

The reward or hedonic value of food is represented in the brain. Food reward is a composite process that includes "liking" (hedonic appreciation), wanting (incentive motivation), and learning (reward value based on associations and predictions). All occur together, but the three components have separable brain systems (Berridge et al. 2010): conscious liking in humans is encoded in the prefrontal cortex; wanting is encoded by the mesolimbic dopamine system mainly projecting to the nucleus accumbens in the ventral striatum. Liking is relatively independent of the prevailing nutritional state. By contrast, wanting is greatly amplified by hunger (Berthoud et al. 2017), and satiety dampens the stimulatory impact of food cues (Berridge et al. 2010). Several brain regions and neurochemical systems mediate conditioned preferences based on postoral nutrient sensing (Sclafani 2018). Dysfunction in reward circuits might contribute to dysregulated eating and the rise of obesity, although it is still unclear whether the possibly faulty circuits are hypersensitive or hyposensitive to food reward.

Eating can be triggered by metabolic need, hedonic drive, or an interaction between the two, and there are several neural circuits that represent this interface. Metabolic signals of energy status modulate processing of cognitive and reward functions in corticolimbic systems (bottom-up processing), which influence regulatory processes including ingestive responses (Berthoud 2011). In turn, cognitive functions are capable of organizing food acquisition and consumption in order to optimize nutritional benefits, for example, when planning meals or finding information about the nutritional value of foods. In other circumstances, however, the cognitive and emotional brain can override homeostatic regulation (top-down processing) to yield an energy imbalanced state (Berthoud 2011).

As a result of these major scientific developments, it is now recognized that, in order to be efficient, an animal's vital regulatory system requires complex and redundant nutrient sensing and monitoring mechanisms, a flexible integrative mechanism that can learn from and adapt to changing external and internal conditions, and powerful effector mechanisms for energy intake and metabolism (Berthoud et al. 2017). The human organism is equipped with such highly competent mechanisms.

Regulatory Responses and the Control of Ingestive Behaviors in Free-Living Humans

The modern vision of regulatory mechanisms acknowledges that FI participates in the regulation of numerous internal parameters of vital importance. The ingestive responses are triggered, however, not only by simple feedback loops that correct an acute state of need or excess but, more generally and more efficiently, in an anticipatory fashion, after an organism has become accustomed to a predictable environment. States of need or excesses can be anticipated and partially or totally avoided, thereby insuring the stability of the internal milieu. How do actual ingestive behaviors in free-living individuals respond to these various mechanisms?

A number of methods developed over the years have investigated ingestive patterns in free-living humans and identified conditions or factors affecting the number of daily eating episodes, their size or duration, and their satiety effects. In particular, they examined the influence of thirst and hunger or other factors potentially reflecting regulatory needs. These methods require consumers to report all their consumption episodes over a number of days. In addition to what typical dietary surveys include, these methods obtain information about various circumstances of consumption, for example, time of day, day of the week or month, company sharing the meal, context, and palatability. In many cases, visual analogue scales (Stubbs et al. 2000) or other validated instruments that assess facets of appetite (hunger, thirst, fullness, desire to eat or drink, etc.) provide insights into subjectively experienced states of need.

The "Weekly Food Diary" method examines ingestive patterns over a whole week and computes a correlational analysis of the relationships between ingestive events (de Castro 1994). A different approach consists in gathering hourly appetitive ratings and dietary recalls for 7 consecutive days (McKiernan et al. 2008b). Such reports quantify the number of daily eating events (meals or snacks), the amount of energy/nutrient/fluid ingested in each event, the duration of consumption, and the duration of pre- or post-intake intervals.

Hunger and Thirst

These studies reported many unexpected observations. First, they provided little support for the intuitive notions that thirst is a major stimulus of drinking and that eating is a response to hunger states. A weak coupling appeared between the sensations hypothesized to signal biological need states and ingestive behaviors distributed over the waking hours. In a review covering 39 dietary surveys, it appeared that most (64%) did not observe any significant association between appetite ratings and actual intake (McKiernan et al. 2008b). Hourly reports revealed that patterns of hunger are only weakly predictive of energy intake ($r = 0.30$) and patterns of thirst fail to predict energy intake or fluid intake ($r = 0.08$ and $r = 0.03$, respectively) (McKiernan et al. 2008b). In Weekly Food Diaries, the intensity of hunger sensations recorded at the beginning of a meal and the duration of the interval since the previous episode of intake (an objective measure of food deprivation) show significant but very modest associations with the size of the meal, accounting for only 4–9% of the variance in meal size (de Castro and Elmore 1988). One internal factor, the estimated stomach contents at the beginning of consumption, shows a negative correlation (de Castro 2010) with the size of the meal. The correlation, however, accounts for less than 6% of the variance in meal size.

About 75% of all fluid intakes occur at the time of eating (McKiernan et al. 2009). The sensation of thirst at meal time is only weakly associated with total fluid intake. Relatively rare drinks occur independent of eating and are correlated with the degree of thirst (de Castro 1988). Drinking without eating leads to a decrease in thirst sensation whether or not the beverage contains energy; however, drinking without eating does not induce any reduction of hunger even when the beverage contains energy (McKiernan et al. 2009).

Environmental Influences

Beside these modest correlations with appetite sensations, the amount of energy consumed in one eating event is significantly affected by external factors such as time of day and day of the week and by the number of persons sharing the meal (de Castro 2010). The "social stimulation" of eating is a robust observation that varies qualitatively as well as quantitatively. Different social interactions (parental, friendship, work, etc.) affect meal intake in potent and complex ways (Herman 2015). Meal size appears to be a power function of the number of persons present. However, the magnitude of the correlation remains modest, accounting for 9% of the variance in meal size (de Castro and Brewer 1992).

Time of day is a major factor affecting daily eating patterns. Energy intake is not distributed evenly over the waking hours: meal sizes increase from morning to night. Breakfast, which occurs after the long overnight fast and in the most acute state of need, is often a relatively small meal. Satiety, the inhibition of ingestion induced by prior consumption, is not a stable phenomenon over the waking hours but rather seems to decrease in efficiency from morning to night. Breakfast produces relatively long-lasting satiety. As the day progresses, average meal size increases and intermeal intervals get shorter.

Short-Term and Long-Term Adjustments

Importantly, there is no evidence of adjustment of energy content, or compensation, on a meal-to-meal basis: no significant correlation appears between the size of a particular meal and the size of subsequent meals (e.g., a large lunch is not necessarily followed by a small diner) (McKiernan et al. 2008a; de Castro 2010). Another important aspect of ingestive patterns relevant to regulation is that food intake varies considerably from day to day (de Castro 2010). If the internal milieu must be kept constant, homeostatic mechanisms should compensate for these variations and adapt intake in response to a prior day's deficit or surfeit. Many studies report that correlations between 2 successive days are not significant (de Castro 1998). However delayed compensatory adjustments can be observed after 2 or 6 days and appear to be macronutrient specific (De Castro 1998; Champagne et al. 2013). These observations are consistent with the 2–3-day delays in adjustments in FI following changes in physical activity (Edholm et al. 1955). Each macronutrient exerts a maximal negative relationship with subsequent intake of that same macronutrient with 2-day lag (de Castro 1998). The 2-day delay eliminates acute GI, plasma, and hepatic factors as intermediaries. Rather it suggests that feedback from a long-term energy storage depot (fat) may be involved (de Castro 1998). Once more, these significant compensatory effects are small and account for less than 5% of the variance in daily intake (de Castro 2010).

Putting the Pieces Together

According to the General Control Model proposed by de Castro (2010), external factors such as daily, weekly, or seasonal rhythms, social facilitation, dietary restraint, cost and availability of food, palatability, energy density, culture, beliefs, etc. contribute to the control of ingestive behaviors along with a large number of internal compensated factors with regulatory feedback loops, among which stomach contents, blood glucose, free fatty acids, leptin, body weight, body fat mass, temperature, insulin in the central nervous system, and hypothalamic neuropeptide-Y concentrations (de Castro and Plunkett 2002). Each of these factors exerts a minute influence, although it may be significant in correlational analyses. The influence of any one factor can only be understood when considered in combination with many, if not most or all, of the other influential factors (de Castro 2010).

Food Intake and Regulation in the Contemporary World

Dietary reports in America and many European countries show that two to three main meals plus two to four snacks or more occur on most days in most adults and children (Bellisle 2014). FI occurs every few hours, when no major state of need has developed. Humans also work, study, commute, watch various screens, enjoy diverse forms of leisure activities, and devote time to family and friends. Time has to be shared between numerous activities, obligatory and/or optional. When to eat appears largely dictated by environmental and social constraints, especially time of day (socially determined time of main meals, time when foods are available for snacking).

Actually, in the twenty-first century, it may be more appropriate to say that time used to be shared between so many different activities: nowadays eating is often done while doing something else (e.g., watching various screens) (Kahneman et al. 2010). Cultural differences modulate this overlap of eating with other activities: in America eating is often considered an accessory activity that is compatible with other “main” activities, whereas in France eating is reported as the “main” activity that sometimes can be contemporary with other compatible behaviors (Kahneman et al. 2010). While the influence of significant regulatory factors appears to be modest in studies of eating patterns, it is likely that this modest influence can be diluted if FI itself is just one feature, and maybe not the main one, of the attention-requiring activities. Ample evidence has been obtained of the deleterious effects of distraction at the time of eating on both satiation and satiety (Higgs and Spetter 2018).

Surprising as it may seem, the action of regulatory factors, among this plethora of diverse and often antagonistic influences, is detectable. It is evidenced by the modest energy and nutrient-specific compensation phenomena observed over several days (discussed above) and also by the relative stability of body weight over long periods of time in most adults. Weight stability reflects a state of energy balance at all levels of the body adiposity spectrum; in overweight/obese individuals, this is achieved at a higher level of body fat (Hall et al. 2012), confirming very precise regulation. In many populations, however, body adiposity has increased to unprecedented levels in recent years, suggesting a strong positive balance and faulty regulation. Using a population-averaged model, Hall et al. (2011) established that the development of the obesity "epidemic" in American adults resulted from a small persistent average daily energy imbalance gap between intake and expenditure of about 30 kJ per day, a very small positive but cumulative deviation.

How can obesity develop then, if adiposity regulation remains active? Animal and human studies show that body adiposity regulation is asymmetrical: while the procurement of sufficient energy and nutrients are strongly defended, preventing decreases of body adiposity, the homeostatic defense of upper limits of adiposity is under no such critical constraints (Zheng et al. 2009). The critical pressure against elevated body weight during evolution is thought to be vulnerability to predation, a problem that has lost its selection power as human societies developed very efficient protection (Zheng et al. 2009; Speakman et al. 2011; Rogers and Brunstrom 2016), allowing body weight to drift upward progressively. The long-standing and successful efforts of sapiens to secure protection from famine, on the one hand, and from predators, on the other hand, have led to a progressive increase in body size over, at least, the past 300 years (Caballero 2019). The obesity "epidemic" of the recent decades is not a novel phenomenon but rather the ultimate development of this trend, facilitated by major social and economic progresses (Caballero 2019).

Given the changing survival pressures in human societies, a genetic drift may have allowed a progressive increase in the adiposity set point (Zheng et al. 2009). In addition, numerous aspects of modern lifestyle contribute to making FI escape the moderating influence of regulatory factors. Clearly, many of these factors are associated with food and eating patterns, for example: increased availability of palatable energy-dense foods; increased exposure to food cues; increasing portion sizes; increased variety of food options, more frequent eating outside the home; low-cost of high-fat, high-sugar foods and sweetened beverages; reward from comfort food; distracted mindless eating while watching one of many screens. The general increase of obesity in the American population, affecting all ages and social strata, has been attributed to the sudden increase in food supplies that took place first in the USA in the second half of the last century (Rodgers et al. 2018). A "vicious circle" effect is possible: over-ingestion of high-fat diets can rapidly produce hypothalamic inflammation and damage, causing the adiposity set point to change (Thaler et al. 2013). Other suspected obesogenic influences derive from non-food-associated aspects of lifestyle: decrease in energy expenditure below the point where it can exert a moderating influence on intake, use of artificial light and disturbed sleep patterns, screen exposure, central heating, disturbance of the microbiota, and cumulative epigenetic vulnerability developed in successive generation of sedentary pregnant women, among others.

As a likely consequence of the above obesogenic influences, it is now common in most developed societies that at least half of the adult population is either overweight or obese. It should not be overlooked, however, that the other half is not obese, in spite of the shared environment and the plethora of anti-regulatory influences. Individual risk factors for obesity are the focus of very active research, among which the many genetic variants that differentiate the obese from the nonobese (Speakman 2007). Many genes affect food selection, food intake, absorption, metabolism, and energy expenditure, including physical activity. Genetic factors modulate the response to most of the internal and external factors identified in analyses of free-living ingestive patterns (de Castro 2010). Of interest also is the strong social gradient observed in developed societies, with decreasing rates of obesity as income and education increase (Pavela et al. 2019). What makes certain social strata relatively immune to obesity deserves to be investigated: food choices and habits are different according to socioeconomic factors, while other aspects of lifestyle (access to sports and medical care) have the potential to make a significant contribution. Such differences could, at least hypothetically, facilitate a higher sensitivity to regulatory influences.

Conclusion

The study of regulation mechanisms has stimulated spectacular developments in many scientific fields: sensory physiology, digestive physiology, behavioral science, psychology, and brain structure and function, among others. Much has been learned. Food intake, in its immense complexity, is one important effector in the regulation of several important parameters of the internal milieu. The naïve view that hunger triggers eating while thirst prompts drinking finds little support in scientific reports of present lifestyle, perhaps because states of physiological need can be prevented by anticipatory intake responses. Regulatory responses to energy or nutrients needs are not perceived at the scale of 1 day. However, evidence of regulation becomes clearer when intake and weight are followed over longer periods. The classic notion of a fixed body weight set point preventing and/or reversing weight losses and gains has been replaced by the notion of a flexible regulator that learns from experience and adapts to changing environmental conditions, resulting in a “floating set point” (Zheng et al. 2009) that resists adiposity decreases but is very prone to increases under the influence of nutritional and non-nutritional influences in the obesogenic world.

The obesity “epidemic” in modern societies does not rule out the action of powerful regulatory mechanisms acting in present lifestyle conditions. Procurement of energy and nutrient to cover bodily needs are strongly defended, while an asymmetrical regulation of body adiposity stores allows a progressive upward drift of body weight in large segments of contemporary populations. Clearly, numerous nutritional and non-nutritional influences make body adiposity regulation difficult and imprecise. An important question remains of the critical factors that allow so many people to maintain a healthy weight under the very same obesogenic conditions. The contribution of FI, under genetic or socioeconomic influences, to these differences remains to be examined in this context.

Influence of Sensation and Liking on Eating and Drinking

John E. Hayes

Contents

Abstract

Flavor is an integrated unified perceptual phenomenon that arises from inputs across multiple sensory modalities, including taste, smell, chemical touch (chemesthesis), and oral somatosensation. The flavor of foods influences the decisions we make about what foods to eat, and in an environment with abundant options, this primarily occurs by causing us to reject certain foods because we do not like the sensations they evoke. In general, bitter sensations

tend to be disliked, while sweet sensations are liked; data on other taste qualities are less clear. Notably, there are substantial differences between people, both in their sensory and affective responses, and learning and exposure can decouple sensations from innate aversive responses. Further, dynamic changes in liking within a meal also influence the amount of food we eat.

Introduction

To the average person on the street, the flavor of a food is typically viewed as an inherent property of the stimulus (i.e., the food). That is, apple flavor comes from an apple, potato chips are salty, and sugar is sweet. A variant of this belief is also shared by many food chemists or product developers with in the food industry: if I wish to formulate a grape-flavored drink, I simply obtain a natural or synthetic flavor (like methyl anthranilate) from a supplier and add it to my product. However, this essentialist view misses a critical point: flavor is a perceptual phenomenon (i.e., a percept), meaning it occurs in the brain, not the bottle. That is, the percepts we experience from foods are not only the result of the integration of multiple physiologically distinct sensory systems but also prior experience and learning. If I have never been exposed to the odorant cis-rose oxide, I will likely struggle to describe it, but if I can, I will probably say it has a generic fruity odor. However, to other individuals, the sensation of cis-rose oxide is very clearly the characteristic flavor of lychee fruit or an Alsatian Gewürztraminer wine. As we chew the lychee, the overall flavor emerges from the volatiles sensed via olfactory receptors, but also the sweetness of the sugars and the sourness and astringency of the organic acids. A review of the biological and physiological processes that underlie these sensations is provided elsewhere in this handbook (see Duffy and Hayes forthcoming). The focus of this chapter is on flavor perception, the relationship of food sensations to liking and eating, and factors that complicate these relationships.

A General Framework Linking Sensation to Eating Behavior, via Affective (Hedonic) Responses

It is widely and broadly accepted that the sensory properties of food have a substantial influence on ingestive behavior: at home, parents add salt to cooked vegetables prior to serving; at the café, patrons add sugar and/or cream to their coffee; and in research and development labs around the globe, food companies spend millions of dollars each year to optimize their formulations. However, it is also fair to state that the sensory properties of food are only one small factor among many that influence behavior regarding the consumption of foods and beverages, as evidenced by numerous other chapters in this handbook. Still, a convincing argument can be made that the sensory properties of foods and beverages influence both food choices and termination of eating within a meal via changes in pleasure. This chapter provides a brief overview of these data.

When we add salt to our food, or sugar to our coffee, we change the amount of saltiness or sweetness in that food, and the lawfulness of these relationships has been studied for decades by psychophysicists, sensory scientists, and food technologists (e.g., Holway and Hurvich 1937; Schutz and Pilgrim 1956; Pangborn 1963). In turn, the observation that the pleasure arising from a sensation varies as a function of intensity or concentration is not new (e.g., Pfaffmann 1960). Indeed, in 1874, Wilhelm Wundt, the founder of experimental psychology, noted that pleasantness increased with sensation intensity, before peaking, and then falling as sensation continues to increase. For taste, this was first shown experimentally in 1928 by Engel for sourness and saltiness (see Pfaffmann 1980). Some have characterized the point of maximal pleasure, that is, the point at which the curve turns over (i.e., the second derivative) as the "bliss point" (Moskowitz 1981). However, in practice, this is probably a misnomer, as extant data indicate this region is more of a plateau in practice, as consumers are actually quite tolerant (i.e., insensitive) to formulation changes near this point (e.g., Li et al. 2014b; Rolon et al. 2017). Other data also indicates there are large and robust individual differences in the shape of the concentration-pleasure curve (e.g., Garneau et al. 2018; Iatridi et al. 2019a, b) that are largely obscured when only mean responses are considered (cf. Lundgren et al. 1978 and Moskowitz 1971). Still, if one assumes that humans are pleasure maximizing, or at least pleasure seeking, then it typically assumed that greater liking drives greater intake. This assumption is generally well supported by evidence in adults (de Graaf et al. 2005; Tuorila et al. 2008; Johnson et al. 2014; Byrnes and Hayes 2016; Park et al. 2018) and children (Caporale et al. 2009; Vosburgh et al. 2019) for both foods (e.g., Dinehart et al. 2006) and beverages (e.g., Lanier et al. 2005).

Collectively, the three pairs of relationships described above – concentration-sensation, sensation-pleasure, and pleasure-intake – result in a causal chain that links the formulation of a food product to consumption. However, the correlations of each step along this chain are far less than one, both due to statistical attenuation due to measurement errors (see Hayes 2015) and other factors that meaningfully modify these individual relationships (e.g., genetic variation, cost, availability, branding, dietary restraint, cultural factors, moral disgust, etc.). By one rough approximation, the total variance in intake that can be explained by formulation is actually quite low, somewhere between 2% and 22% (Hayes 2018). On the other hand, centuries of culinary traditions (including the historical quest for spices that quite literally drove exploration, colonization, and global trade), as well as the continual expenditure of substantial resources for formulation and reformulation over many decades by global food companies, imply the putative framework linking food formulation and sensation to intake via affective responses (see Fig. 1) must have some degree of face and predictive validity.

The following sections provide a discussion of various complications to the framework presented in Fig. 1. For additional information and discussion of this conceptual framework, the interested reader should also see Hayes (2015).

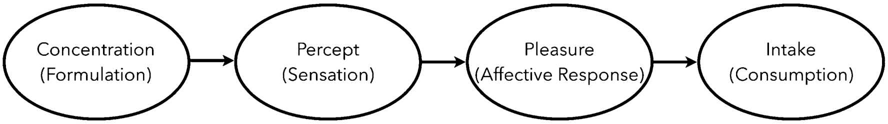

Fig. 1 A working model of how food composition is related to intake via pleasure

The Imperfect Relationship Between Food Liking and Food Selection or Intake

As noted above, most researchers accept that liking is positively (if imperfectly) related with intake. This has been repeatedly found by multiple researchers on multiple continents across multiple decades for multiple types of foods, with correlations in the literature ranging from +0.22 to +0.81 (e.g., Schutz 1957; Cardello and Maller 1982; Zandstra et al. 1999; Tuorila et al. 2008). For example, Lähteenmäki and Tuorila found the correlations between liking and use of chocolate, ice cream, licorice, flavored yogurt, cookies, and soft drinks were between +0.57 and +0.73 in Finish women (Lähteenmäki and Tuorila 1994), while Byrnes and Hayes found that the correlation between liking for the burn of a spicy meal and annualized intake of chili-containing foods was +0.58 in adults in the United States (Byrnes and Hayes 2013). These reports provide strikingly similar estimates to an early report from Schutz (Schutz 1957): he found that the now famous 9-point hedonic scale (Peryam and Pilgrim 1957; Meiselman and Schutz 2003) predicted both the amount taken and amount eaten by American military personnel in an ad libitum setting, with correlations between +0.51 and +0.77. More recent work suggests food liking questionnaires also predict dietary biomarkers (Sharafi et al. 2015) as well as aggregate measures of dietary quality in American adults (Zoghbi et al. 2017) and children (Sharafi et al. 2015) and Australian adults (Wanich et al. 2019).

As these examples illustrate, various studies have operationalized liking and intake in different and diverse ways – various consumption estimates include direct observation of amounts eaten or amounts taken, self-reported intake of specific foods, comprehensive diet records/food diaries, and data drawn from validated food frequency questionnaires, while affective responses are typically estimated from acute tasting of foods or longer surveys of multiple foods using some type of liking or pleasantness scale (i.e., so-called food preference questionnaires). While this heterogeneity complicates direct comparisons, it also provides some degree of convergent validity, which enhances the robustness and generalizability of the findings. Direct head-to-head comparisons of liking of sampled foods and surveyed liking (i.e., names on a list of foods) are far less common, although a few reports suggest this relationship is also positive, in the range of +0.43 to +0.64 (Hayes et al. 2010; Sharafi et al. 2012).

The consistent and robust positive association between various measures of liking and intake leads to the common conclusion that greater liking drives greater intake. At the extremes, this widespread assumption has led some to suggest that decades of optimization of foods by the food industry has somehow made these foods hyperpalatable or even addictive, thereby contributing to the obesity epidemic seen in industrialized nations (Kessler 2009; Moss 2013).

However, a deeper analysis of the liking-intake relationship suggests the common assumption that greater liking leads to greater intake, although extremely widespread, is incorrect, or at least, is insufficiently nuanced. Specifically, the relationship between liking and intake is heteroscedastic – that is, the data tend to have a cone shape when visualized in a scatterplot. As shown in Fig. 2, the variance in intake is quite small when liking is low, whereas the variance is much larger when liking is high. The data in the left and center columns show self-reported liking and intake data for a group of high-fiber foods (whole grains, fruits, and vegetables) and high-fat foods (fried foods, red meat, processed meats, oil and high-fat condiments, whole-milk dairy, cookies, cakes, and pastries) for 88 women from a worksite health promotion program in Connecticut (Duffy et al. 2009), while the rightmost column shows self-reported liking and intake data for chili-containing foods for 97 adults (18–45 years) in a laboratory study in Pennsylvania (Byrnes and Hayes 2013).

Practically speaking, the heteroscedasticity in these plots suggests that rather than being a driver of intake, affective responses act as a ceiling or break on intake – or to put it more simply, instead of the classical conclusion that more liking drives more intake, a better conclusion would be that *disliking drives nonuse*. Personally and intuitively, this should make sense. A person may really love large, well-marbled steaks and bold tannic Chianti wines from Italy, but still moderate their intake of each due to health concerns or cost or myriad other factors (e.g., Herman et al. 2019; Higgs and Ruddock 2019). Indeed, this point can be clearly illustrated in the bottom half of Fig. 2 by comparing the two shaded regions within each panel: when a food is disliked (i.e., is rated below neutral), almost no individuals consume it frequently (top left shaded region), whereas when a food is liked (i.e., is rated above neutral), many individuals still fail to regularly consume those foods (bottom left shaded region). For foods like fruits and vegetables, this discordance may represent cost or availability constraints or preferences of other members of the household. Conversely, for energy-dense foods, discordance between liking and intake may be an indirect measure (proxy) for dietary restraint in adults. Indeed, among American women, those who were discordant in this way (i.e., high liking/low intake) had significantly higher restraint scores on the Three-Factor Eating Questionnaire (Sharafi et al. 2018). In children, this same kind of discordance (i.e., high liking/low intake for high-fat/sweet/salty foods) associates with greater body mass index percentiles relative to the concordant low liking/low intake group, suggesting parents of these children may be restricting intake of foods they view as being unhealthful (Sharafi et al. 2015).

The idea that disliking discourages intake is not limited to self-reported assessments of chronic diet, as some controlled laboratory studies and naturalistic free-living feeding studies show similar effects on food intake and food choices. In one study of intake by US Army personnel under field conditions between 1995 and 1997 (de Graaf et al. 2005), the relationship between liking and intake was curvilinear, as is shown in Fig. 3. Critically, if a food was rated above neutral, greater

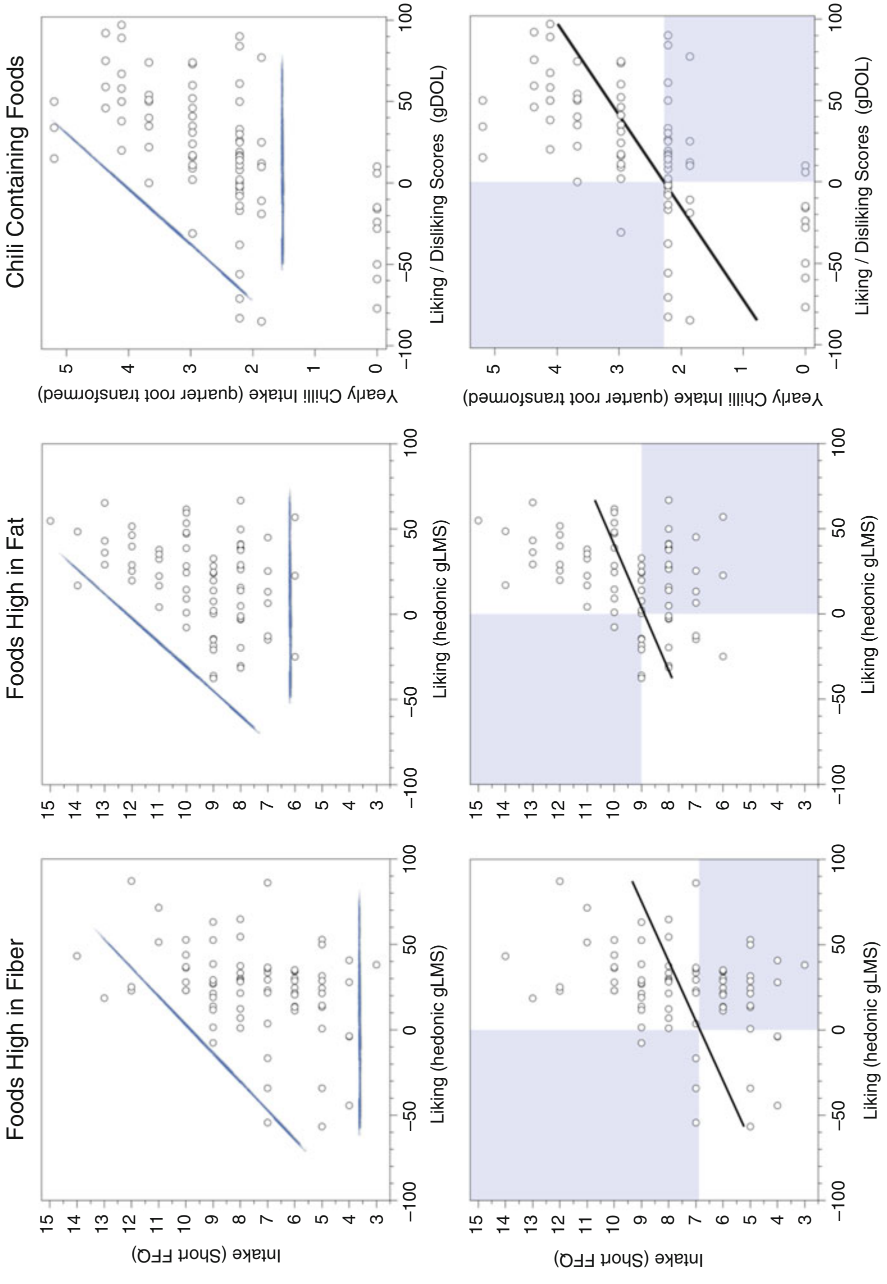

Fig. 2 (continued)

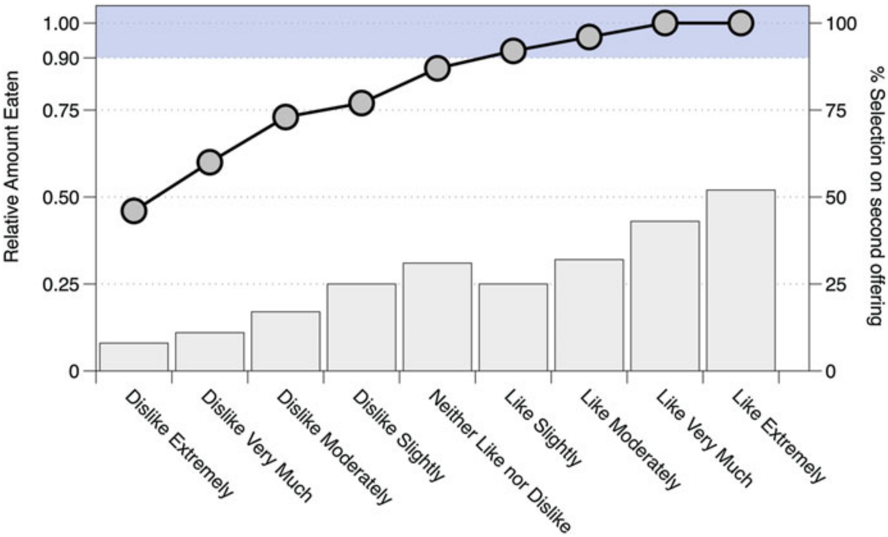

Fig. 3 Relationship between liking ratings and amount eaten on first offering (dots) and percentage of time selected on second offering (bars) under naturalistic feeding conditions with US Army personnel. The shaded region at the top indicates consumption of 90% or more of the food. (Data are replotted from de Graaf et al. (2005). See text for additional discussion)

liking was not a meaningful predictor of greater intake: for the top four categories on a 9-point hedonic scale (like slightly to like extremely), the average amount consumed exceeded 90%. Conversely, soldiers who rated a food as extremely disliked (i.e., a rating of 1 on a 9-point hedonic scale) consumed less than half of it (46%) on the initial offering. These data support the contention that disliking is more closely coupled with nonuse instead of greater liking driving greater intake – that is, disliking acts as a strong barrier to intake. One might argue that this represents a ceiling effect, as hungry troops may have eaten more of highly liked foods had they been available. Indeed, under laboratory conditions, Zandstra and colleagues did find a serving size effect on yogurt intake: under ad libitum conditions, almost all participants (Dutch students) stopped at the initial amount served (300 g), despite being told they could request more if they wished (Zandstra et al. 1999). However, for the soldiers, other data from subsequent offerings suggest that the curvilinear relationship shown in Fig. 4 is not merely an artifact due to serving size or availability. Specifically, when given the opportunity to select the same food a second time (from among several options), foods rated "dislike extremely" were

---

Fig. 2 Self-reported food intake as a function of liking. (Data are replotted from Duffy et al. (2009) (left and center) and Byrnes and Hayes (2013) (right). The relationship between liking and intake is positive but heteroscedastic, as the variance in intake across the range of liking is uneven. Specifically, the top left corner is empty, meaning people do not eat the food they dislike, whereas in the bottom right corner, some people like those foods but still fail to consume them frequently)

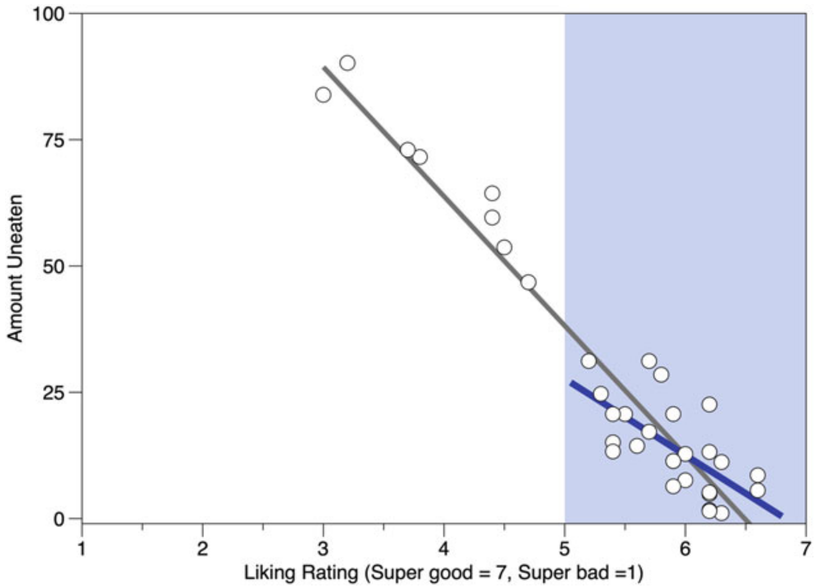

Fig. 4 Relationship between liking ratings and mean amount uneaten for 34 foods by 4- and 5-year-old Italian children under naturalistic feeding conditions (school lunch rooms). The gray line shows the strong negative relationship ($r = -0.96$; $n = 34$) between hedonic ratings and amount uneaten across all 34 foods reported by the authors. The blue line shows that that relationship is weaker, albeit still significant ($r = -0.66$; $n = 26$) when only the well-liked foods are considered (shaded region). (Data are replotted from Caporale et al. 2009)

only chosen 8% of the time, whereas even foods rated as "like extremely" were only chosen 52% of the time (de Graaf et al. 2005). The observation that highly liked foods were only selected about half of the time on a subsequent offering is wholly consistent with the idea that a food being highly liked is not, by itself, sufficient to drive choice or intake.

Nor are such effects limited to soldiers in the field. Mustonen and colleagues asked 62 Finnish women to rank 6 cheeses (full and reduced fat Edam, Emmental, and Havarti) for liking in the laboratory before having them choose three 150 g blocks of cheese to take home; their participants could select 3 of the same cheese, 3 different cheeses, or 2 of 1 and 1 of another. The two cheeses ranked as least liked were only selected ~12% of the time (Mustonen et al. 2007). As a final example, data from 4- to 5-year-old children in Italy also show a strong relationship between disliking and nonuse. Caporale and colleagues asked children to rate their liking of 34 different foods on a 7-point ("super good" to "super bad") scale and then monitored the amounts of these foods uneaten when served in the school lunchroom over the next 2 months (Caporale et al. 2009). Across all 34 foods, they observed a very strong linear relationship ($r = -0.96$) between hedonic ratings and amount uneaten. However, it also appears that the strength of this relationship was driven, in part, by massive underconsumption of the 8 least liked foods: the mean amount left uneaten for the

8 least liked foods was 68%, versus only 14% for the other 26 better liked foods. That is, as shown in Fig. 4, if the eight least liked foods are removed from the analysis, the relationship between liking and intake is weaker, although still significant.

In summary, simple correlations with group means can lead to the common but erroneous conclusion that higher liking leads to more intake, in part due the differential variance intake across the range of hedonic ratings. Instead, the data described here for both self-reports of chronic dietary intake and acute feeding studies under laboratory and naturalistic conditions each seems to suggest a better interpretation would be that disliking drives nonuse for both acute intake and food choices. And this disliking can often be related back to the sensations from the food.

Bitterness: A Signal for Pharmacological Activity and/or Toxicity

Chemicals humans describe as bitter are innately aversive, and stereotypical aversive responses are conserved across species (Ganchrow et al. 1983; Steiner et al. 2001); presumably, these innate responses help prevent ingestion of toxins (Scott and Mark 1987; Katz and Sadacca 2011). Indeed, numerous reports suggest bitterness leads to rejection and/or decreased intake in humans (e.g., Keller et al. 2002; Lanier et al. 2005; Dinehart et al. 2006; Duffy et al. 2010; Harwood et al. 2012a,b). The idea that bitterness is a gatekeeper that guards against toxin ingestion is not new. In 1975, Garcia and Hankins noted bitter stimuli are rejected in humans, and similar rejections are found in monkeys, birds, fish, invertebrates, and protozoa, causing them to conclude rejection of bitterness is a phylogenetically ancient response (Garcia and Hankins 1975).

However, other data challenge the common and persistent view that bitterness is a simple signal to reject a food entirely. In 1994, Glendinning noted many bitter stimuli are not actually toxic (Glendinning 1994), an idea that was recently revisited by Niv and colleagues. Using toxicity data and chemoinformatic tools (i.e., BitterDB (Wiener et al. 2012) and BitterPredict (Dagan-Wiener et al. 2017)), Niv and her team found only 60% of bitterants in BitterDB are toxic and that only 56% of toxic compounds are expected to be bitter (Nissim et al. 2017). This suggests classic assumptions about bitterness and toxicity may be an oversimplification. That is, instead of being a STOP sign per se, bitterness may instead be a CAUTION GO SLOW sign to allow us the opportunity to learn about the stimulus via controlled exposure. The potential medicinal properties of bitter stimuli have been noted for many decades (see Goodman's Pharmacopeia (Goodman and Gilman 1941)), and many beneficial phytonutrients are bitter (Drewnowski and Gomez-Carneros 2000). Likewise, folk medicines like woolly foxglove (digoxin) and cinchona bark (quinine) have a long history of use. Phlorizin, a phenol glycoside isolated from apple tree bark in 1835, was first used as an antimalarial due to its similarity in taste with known antimalarials (Ehrenkranz et al. 2005). The ability of bitterness to act as a marker of potentially desirable pharmacology (versus toxicity to be avoided) is even observed in nonhuman primates (Huffman et al. 2013) and other animals (Villalba et al. 2014). Such therapeutic self-medication by animals (i.e., zoopharmacognosy) presumably requires a mechanism by which the animal can learn to associate specific secondary plant compounds with the beneficial effects of their ingestion.

Similar learning can be commonly observed in humans, as should be apparent from the widespread consumption of black coffee and heavily hopped craft beers. That is, for coffee, the bitterness is aversive initially. But with repeated intake, positive response to caffeine decouples negative affective responses to the bitterness. That is, bitter coffee stops being aversive and may become desirable due to the pharmacological action of caffeine (e.g., Cines and Rozin 1982; Chambers et al. 2007). This process has been termed flavor-consequence learning (Yeomans et al. 2005). In summary, bitterness is innately disliked, and this appears to be evolutionarily important as it is found in multiple species; however, bitterness is not a simple break on intake, as innate aversions to bitter sensations can also be overcome via learning processes, including those involving reward.

Biological Differences in Bitterness Perception What Potentially Influence Food Liking and Consumption

In addition to experiential factors mentioned above, the influence of bitterness on food choice and eating behavior also varies across people due to normal biological variation. The systematic study of individual differences in chemosensation dates back almost a century (e.g., Blakeslee and Fox 1932), with the initial studies on diet and food liking coming later (Fischer et al. 1961; Glanville and Kaplan 1965). Multiple comprehensive reviews already exist elsewhere (Duffy 2007; Hayes et al. 2013; Keller and Adise 2016; Running and Hayes 2016; Ulla et al. 2016; Hayes 2018), so they will not be discussed here in great detail. As one example, the functional consequences of polymorphisms in the *TAS2R31* gene will be presented briefly here. Humans generally find sweetness appealing and desirable, but at the same time, consumers often do not want the calories that accompany bulk sweeteners like sugar, resulting in large commercial demand for various nonnutritive sweeteners (Sylvetsky and Rother 2016; Wee et al. 2018). The sulfonyl amide sweeteners saccharin and acesulfame potassium (Ace K) are widely used in tabletop sweeteners and diet beverages. However, these sweeteners also have a bitter side taste that is experienced by some individuals but not others (Schiffman et al. 1979; Horne et al. 2002); as would be expected, greater bitterness leads to lower liking ratings (Kamerud and Delwiche 2007). These phenotypic differences in sensation are caused by a single amino acid substitution (Arg35Trp) in the *TAS2R31* gene (Roudnitzky et al. 2011). Consequently, genetic variation in the *TAS2R31* associates with differences in suprathreshold bitterness intensity (Allen et al. 2013a,b) and differential liking of Ace K across individuals (Bobowski et al. 2016). The same gene variants also associate with substantial differences in the bitterness intensity of quinine, as well as the liking for grapefruit (Hayes et al. 2015). However, published data associating these variants with food intake is still lacking.

Notably, this specific genotypic variant and the resulting phenotypic differences are only one example of many. The *TAS2R31* variants are independent of variants in *TAS2R4* that are associated with stevia-derived sweeteners (Allen et al. 2013a; Risso et al. 2014) or *TAS2R38* variants that associate with liking and intake of vegetables (e.g., Duffy et al. 2010; Sandell et al. 2014) or alcohol (e.g., Hayes et al. 2011; Beckett et al. 2017; Hayes and Nolden 2017). Nor are such differences restricted to taste, as functional variants have been reported for starch breakdown (Perry et al. 2007; Mandel et al. 2010) and numerous odorants (Keller et al. 2007; Lunde et al. 2012; Jaeger et al. 2013; Mainland et al. 2014). This remains a highly active area of research (e.g., Trimmer et al. 2019), so it seems likely new relationships between genetic variation and eating behavior will continue to emerge.

Sweetness Is Widely Liked, but Optimums Differ Across People

Like bitterness, humans and other mammals show an innate response to sweetness, but unlike bitterness, this response is positive and presumably appetitive. When newborns only a few hours or day old are given sucrose solutions, they exhibit stereotypical facial responses that are interpreted as being positive (Steiner 1977; Steiner et al. 2001). Likewise, when given plain water or carbohydrate sweetener (i.e., glucose, fructose, lactose, or sucrose) solutions, healthy infants 1–3.5 days old drink more of the sweetened solutions than water, and the different intake increased as sweetener concentration increased (Desor et al. 1973), which has been interpreted to mean the newborns like the sweeter solutions more. Similarly, both healthy term and preterm infants increase their sucking rate and sucking intensity when sucrose is provided without any fluid intake (Maone et al. 1990). Other evidence indicates innate appetitive responses to sweetness even predate birth – if amniotic fluid surrounding a fetus is sweetened by injecting the nonnutritive sweetener saccharin into the amniotic sac, the fetus will increase their swallowing rate (De Snoo 1937).

As noted previously, affective responses to increasing concentration of a sweetener generally exhibit an inverted U shape. Notably, children tend to prefer higher concentrations of sucrose as compared to adults (Mennella et al. 2011; Garneau et al. 2018), and this appears to be a true affective shift rather than a mere cohort effect, as the same individuals show a decline in preferred concentration as they age (Desor and Beauchamp 1987). Within parent-child dyads, children also show greater liking for sweet foods (Vosburgh et al. 2019). There is some evidence to suggest increased liking for higher concentrations of sucrose is related to growth associated biomarkers (Coldwell et al. 2009), although other studies fail to confirm this effect (Mennella et al. 2014).

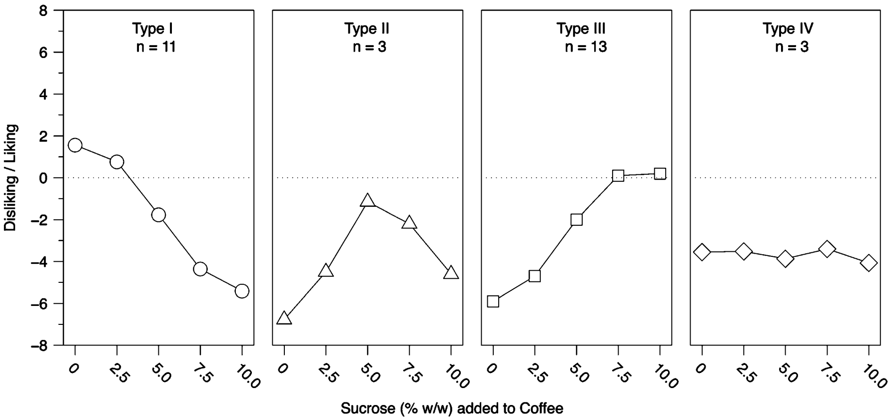

Fig. 5 Illustration of stereotypical patterns of hedonic responses: liking changes as increasing amounts of sucrose are added to instant coffee. (Data are adapted from Lundgren et al. (1978). See text for additional discussion)

While sweetness is innately liked, there are also a large body of work on individual differences in affective responses to sweetness (reviewed by Iatridi et al. 2019b) that dates back many decades (e.g., Pangborn 1970). Irrespective of the differences in sensation summarized in the previous section, individuals also show variation in their affective responses to stimuli. For sweetness, these types of studies have typically segmented people into two to four groups. One early example of this type of work is shown in Fig. 5 – for 30 participants in California in the 1970s, liking generally changes as increasing amounts of sucrose are added to instant coffee, but the patterns of responses also vary widely across groups (Lundgren et al. 1978). Specifically, Type I responders show a monotonic decrease in liking as more sugar is added, while Type II responders show an inverted U pattern. Type III responders show a monotonic increase, and Type IV responders appear indifferent to changes in sucrose, but also dislike all of the coffees. Critically, these data directly challenge the common belief that sweetness is universally liked. Indeed, the authors warn that individual variation needs to be accounted for in reporting sensory data, cautioning that "group averages may be misleading or even completely artifactual (Lundgren et al. 1978)." Regarding sweetness specifically, a recent review identified 71 different papers that segment individuals on the basis of hedonic responses using four major types of methods (Iatridi et al. 2019b). Contemporary methods have shifted toward using hierarchical cluster analysis rather than arbitrary groupings and typically identify three groups rather than four (Kim et al. 2014; Garneau et al. 2018; Iatridi et al. 2019a). The specific biological basis for differences in sweetness preferences has not been determined, but twin studies suggest it has a heritable component (Keskitalo et al. 2007). Several reports indicate that the phenotypic preference groups also differ in liking and intake of sweet foods (Kim et al. 2014; Garneau et al. 2018), and these differences cannot be attributed to simple differences in perceived intensity (Garneau et al. 2018).

Saltiness and Sodium

Using facial reactivity data from infants, multiple studies have found that human newborns do not provide clear affective responses to sodium chloride solutions (e.g., Rosenstein and Oster 1988; Zhang and Li 2006). When combined with older data that fail to show differences in intake for salt solutions versus water for newborns 1–3.5 days old (Desor et al. 1975), these observations are classically interpreted as indicating that responses to salty stimuli are not innate, in sharp contrast to the clear responses seen for bitter and sweet stimuli. Instead, it is assumed that preferences for salt depend on development, maturation, and/or learning, with a critical change occurring around 4 months of age. Specifically, when relative intake of salt solutions and water is compared for infants aged 2.5–6.7 months, it appears preferences for salt develops around 4 months of age (Beauchamp and Cowart 1985), a finding that has been replicated elsewhere (Schwartz et al. 2009). When exclusively breast-fed infants 4–6 months old are given salted and unsalted cereal, they eat more salted cereal (Harris et al. 1990). Similarly, when offered salted carrots versus plain carrots, 2-year-old children put more salted carrots into their mouths, and notably, preferences for saltiness appear to generalize, as the children who ate more salted carrots also consumed more salted foods, as intake of salted carrots was strongly correlated with greater intake of salted soup (Beauchamp and Moran 1984).

However, other data challenge the view that 2- to 4-day-old infants are indifferent to dilute salt solutions: when measures of sucking microstructure (i.e., mean sucks per burst) are compared for salt solutions and plain water, salt is less preferred, on average (Zinner et al. 2002). However, as noted previously, group means can be misleading, as a substantial number of the newborns appeared to prefer the salt solution to water, and strikingly, these preferences were related to both neonatal blood pressure and familial history of hypertension (Zinner et al. 2002). Indeed, newer data for infants tested at 2 and 6 months supports the existence of large individual differences in salt preferences, even prior to the critical 4-month window that is routinely cited (Stein et al. 2006). Looking more broadly across the lifespan, a preference for greater saltiness, like sweetness, appears to be elevated in children, who prefer higher salt concentrations than adults (Beauchamp and Cowart 1990); these shifted preferences may peak in the teenage years (Leshem 2009). In adults, adding salt to real foods like chicken soup or hash browns can increase liking (e.g., Hayes et al. 2010; Lucas et al. 2011), although as would be expected from Wundt, Engel, and Pfaffmann, there can be too much of a good thing, as liking drops when salt level exceeds some optimum (e.g., Hayes 2010; Drewnowski and Moskowitz 1985). There may also be sex differences in optimal levels of salt concentration, although data conflict as to whether men or women prefer higher levels of salt (cf. Hayes et al. 2010 and Leshem 2009).

When discussing salt and saltiness, it is also important to distinguish between the robust sodium appetite seen in some animals and the absence of similar behaviors in humans. Specifically, humans appear to consume salt for pleasure and not to meet a physiological need for sodium. That is, we fail to show clear sodium hunger: unlike many animals (including nonhuman primates), we do not increase our intake of salt when we are sodium deficient. In the words of Leshem (2009), "we will seek salt to please our palate, but not to save our life."

Sourness

Sourness is generally thought to be a negative taste quality (e.g., Desor et al. 1975; Rosenstein and Oster 1988; Steiner et al. 2001). As a consequence, it has received less attention than other taste qualities as a potential determinant of food preferences. However, sourness is seldom experienced in isolation, and sugar-acid balance is a major determinant of preference for a wide range of foods and beverages. For example, when liking of seedless table grapes by adults is modeled as a function of titratable acidity (which correlates with perceived sourness) and percent brix (i.e., sugar content, which correlates with perceived sweetness), liking rises with increasing sugar content and falls with increasing acid content (Jayasena and Cameron 2008). However, the ratio of brix to acid (i.e., sweetness to sourness) is a substantially better predictor of liking scores than either measure in isolation (Jayasena and Cameron 2008). Similar patterns have also been reported for chokecherry juice (Duffy et al. 2016).

Indeed, the global popularity of Margaritas, Caipirinhas, and lemonade suggests that sourness is not entirely negative, at least when paired with some sweetness. Liem and Mennella (2003) examined perception of and preferences for sour lemon-flavored gelatins in 5- to 9-year-old American children and their mothers. They found that 35% of the children selected the gelatin with highest citric acid concentration (i.e., the most sour sample) as being preferred, and this was not due to inability to sense the sourness, as almost all of the children were able to rank them from most to least sour. This aligns with data from 18-month-old Irish infants, where 23% readily accepted a blackcurrant-flavored drink (Ribena) with the highest levels of added citric acid; notably, fruit intake was greater in the sour-tolerant infants (Blossfeld et al. 2007). Similarly, in 8- to 11-year-old Dutch boys (but not girls), Liem and colleagues found that the preferred sour to sweet ratio for an orange-flavored drink was predictive of reported fruit intake (Liem et al. 2006). In one of the few studies on sourness preferences in adults, participants rated increasing concentrations of citric acid in water as less liked, regardless of age (Chauhan and Hawrysh 1988). Conversely, when presented within the context of an apple-flavored drink, liking first increased to an optimum and then fell as citric acid concentration increased (Chauhan and Hawrysh 1988).

Liking for Odors, Aromas, and Flavors

In direct contrast to the innate responses summarized above for prototypical taste qualities, affective (hedonic) responses to odors and aromas are almost exclusively learned, so no attempt will be made to systematically summarize them here. For more information, the interested reader should see numerous other works on this topic (e.g., Rozin and Vollmecke 1986; Rozin 1990; Birch 1999; Mennella et al. 2001; Sclafani 2004; Mennella and Beauchamp 2005; Yeomans et al. 2008; Prescott 2012; Yeomans 2012; Birch and Doub 2014; Nicklaus 2016). However, it should be noted that these effects are not entirely idiosyncratic and unpredictable across individuals, as shared environments from shared cultural contexts may also provide some degree of generalizability within groups from a specific region (e.g., Pangborn et al. 1988). For example, the affective responses to the presence of the odorant methyl anthranilate in wine appears to vary with geography (Perry et al. 2019). Also, the genetic variability mentioned previously can also interact with learning that may be culturally dependent. The ability to smell the odorants androstadienone and androstenone varies with two amino acid substitutions in the *OR7D4* olfactory receptor gene (Keller et al. 2007). Based on learned associations, some individuals describe these compounds as smelling like urine or body odor. Thus, it is quite understandable that normal variation in this gene can predict differential liking for cooked pork containing these odorants (Lunde et al. 2012).

Taste-Taste Interactions and Cross-Modal Effects

People generally eat foods, rather than tastants in water or simple model systems, and foods are perceptually complex stimuli. Even within very simple model systems with two components, perceptual interactions between sensations can substantially complicate attempts to predict liking (e.g., Lawless 1977). A detailed review of these interactions is beyond the scope of this chapter (and are available elsewhere; see Keast and Breslin 2003; Delwiche 2004). However, two key phenomena – mixture suppression and cross-modal enhancement – will be briefly discussed here.

When two qualitatively different stimuli like bitterness and sweetness are mixed, the perceptual intensity of each is lower in the mixture than the intensity that would be expected had they been presented separately. This is known as mixture suppression. One early example of this comes from Kamen, Pilgrim, Gutman, and Kroll: they found that sweetness from sucrose reduced the bitterness from caffeine, and a smaller suppressive effect was seen for the bitterness of caffeine on sucrose sweetness (Kamen et al. 1961). Subsequent work not only confirmed this effect but also showed that it was due to events in the central nervous system (Lawless 1979; Kroeze and Bartoshuk 1985) rather than being due to some chemical interaction in the mouth or some type of physiological interaction at the periphery. Notably, this effect is asymmetric, as sweetness suppresses bitterness more than bitterness suppresses sweetness (Lawless 1977; Green et al. 2010). Such effects are not limited to model systems, as they also occur in real foods (e.g., Hayes et al. 2011; Li et al. 2014a; Bakke et al. 2018). For example, sweetness suppresses sourness at moderate and high concentrations (Keast et al. 2003), so it should not be surprising that adding sucrose to overly sour chokeberry (*Aronia*) juice improves liking ratings (Duffy et al. 2016).

Taste-taste interactions are also extremely common, both in model systems and real foods (e.g., Frank and Byram 1988; Prescott 1999; Prescott et al. 2004). For example, in general, adding vanilla or vanillin tends to increase perceived sweetness (Lavin and Lawless 1998) regardless of whether participants are asked to use an analytic or synthetic strategy to assess products (cf. Wang et al. 2018, 2019), although these effects are not always observed for all stimuli (e.g., Labbe et al. 2006a; Green et al. 2012). Other odorants also appear to enhance sweetness (Frank et al. 1989; Stevenson et al. 1999; Labbe et al. 2006b; Bartoshuk and Klee 2013). Taste-taste interactions have also been explored as a possible means to facilitate sodium reduction (Lawrence et al. 2009; Nasri et al. 2011). This remains an active area of work, so additional progress is anticipated in the coming decade.

Food Liking Is a Dynamic and Transient Phenomenon

The previous sections have generally assumed that liking for a specific food is a static, stable phenomenon. However, this assumption is not always valid. In 1971, the physiologist Michel Cabanac reported that when a fasted participant was given a sucrose solution and asked to rate the pleasantness, pleasantness ratings dropped when the sucrose solution was swallowed, whereas pleasantness ratings did not change when the sucrose was tasted and expectorated and not swallowed (Cabanac 1971). Indeed, reports of this phenomenon are much much older – for example, the Christian bible notes: “He who is sated loathes honey, but to one who is hungry everything bitter is sweet (Proverbs 27:7).” Cabanac argued this type of shift was part of a regulatory mechanism related to the need state of the body. However, subsequent work by Rolls and colleagues demonstrated that the drop in liking that occurs with repeated exposure to a food within a single meal is due to the sensory properties of the food (Rolls et al. 1981) and not nutritional or metabolic signaling. This effect was thus termed sensory-specific satiety, although more precisely, it should be thought of sensory-specific satiation. (Satiation occurs during a meal and leads to termination of eating, whereas satiety refers to length of time before hunger returns.) This effect should be familiar to anyone who has survived an American Thanksgiving holiday (or any other large feast). After consuming a large amount of salty savory foods, any desire to eat is gone. However, if a sweet dessert like apple or pumpkin pie is offered, the desire to eat a sweet food is not depressed. In a laboratory setting, this is operationalized via a precise experimental paradigm. Moderately hungry participants are first asked to rate the pleasantness of small samples of a battery of foods that vary in their sensory profiles (e.g., sweet, savory, salty, etc.). They are then fed the test meal until the desire to continue eating is gone. Pleasantness ratings are then obtained again for all the foods in the initial battery. Thus, sensory-specific satiety is defined as the relative drop in liking for that specific food (Rolls et al. 1981), not the mere abatement of hunger.

Critically, careful experimentation using this paradigm indicates that these effects are specific to the sensory properties of the food, rather than metabolic signals as Cabanac had hypothesized. For example, pudding and gelatin (jello) sweetened with aspartame (a low-calorie sweetener) or sucrose each cause sensory-specific satiety (Rolls et al. 1988). Nor is this phenomenon restricted to prototypical tastes, as it also occurs for colors and even food shapes (Rolls et al. 1982). That it occurs for something like the shape of pasta is a strong indicator that the effect is cognitive and not physiological in nature and is presumably unrelated to the need state of the body. Separately, repeated exposure over multiple days can also alter liking ratings, as monotonous diets are known to depress intake (Hetherington et al. 2000; Meiselman et al. 2000; Zandstra et al. 2000).

Collectively, these data show that liking is not an immutable property of a food, even for a specific individual, but rather that liking of a food is a dynamic property that varies as a function of context and consumption frequency.

Overall Conclusions

Numerous studies over many decades suggest that greater food intake is positively correlated with greater food liking. However, this is misleading, as merely liking a food does not mean we will choose to eat it, even if we like it very very much. Rather, in an environment where diverse ample food options are available, it is more precise to say that we avoid what we dislike. This disliking is due, in part, to the sensations from food, and these sensations can differ across people.

H. L. Meiselman (ed.), *Handbook of Eating and Drinking*,
https://doi.org/10.1007/978-3-030-14504-0_22

Abstract

When we eat or drink, separate sensory systems carry taste, smell, irritation, and texture signals to the brain, where these signals are packaged into a composite flavor sensation. Each sensory system has specialized receptors that respond to a specific stimuli that can be chemical (taste, odor, irritant) or mechanical (texture) in nature. Variability in these sensory inputs can arise from genetics, environmental exposure, diseases, and aging. This variability influences the separate sensory inputs and composite flavor sensations with downstream implications for what we like and chose to eat, such as the quality of the eating experience, and our overall health. In some cases, sensory inputs can be altered or distorted (e.g., phantom sensations). Simple standardized measures are available for screening, such as in-depth assessment of separate sensory systems and integrated flavor sensations.

Introduction

Every time we eat or drink, we experience the flavors evoked by foods and beverages. While our attention to food flavors varies with the eating context (e.g., savoring a gourmet dinner vs. eating a donut on the run), these percepts arise from the integration of multiple sensory inputs from anatomically and physiologically distinct systems. In turn, our affective and hedonic responses to these perceptual events can drive eating behavior (see Hayes chapter, *Influence of Sensation and Liking on Eating and Drinking*, in this handbook). This chapter provides a general overview on the chemical senses – smell, taste, and chemical touch (i.e., olfaction, gustation, and chemesthesis) – as well as oral somatosensation. While discussions of flavor are classically centered on the chemical senses, it is important to note that mouthfeel, texture, temperature, and astringency are also critical to the eating experience and are perceived via somatosensory inputs. Thus, some researchers include overall texture as part of flavor, while others may treat it operationally as a related but separate phenomenon (see Delwiche 2003). Also, it is important to keep in mind that even pure chemicals are not pure stimuli in terms of the sensations they give rise to, for example, concentrated table salt can elicit both salty taste and oral burn, while menthol can evoke cooling sensations and a minty odor.

This chapter is one of the three related chapters that explore connections between chemosensory biology, flavor perception, affective responses, food choices, and dietary behavior, including individual differences, and chemosensory dysfunction. Here, the biological foundations of chemosensation and flavor perception and assessment of their function are reviewed.

Mechanisms of Olfaction, Gustation, Chemesthesis, and Oral Somatosensation

We smell food odors through the nostril as we breathe or sniff (orthonasal olfaction) as well as through the mouth as we chew and manipulate substances in the mouth (retronasal olfaction) . With a functional sense of smell and some prior experience, one can detect subtle differences in wine varieties, recognize a specific off note in a dairy product, or identify the flavor of a gourmet jelly bean solely with the olfactory cues. This process starts when volatile chemicals reach olfactory sensory neurons located in the olfactory epithelium at the top of the nasal cavity. The olfactory sensory neurons have long hair-like extensions (i.e., cilia) to increase their surface area. Specialized receptors are expressed on these cilia. These specialized receptors are one type of G-protein-coupled receptors (GPCRs) that are a part of a larger superfamily of membrane proteins. In 2004, Linda Buck and Richard Axel received the Nobel Prize in Physiology for their work on the genetic basis of olfactory receptors and the pattern recognition system across cells (Buck and Axel 1991). In humans, there are ~400 different olfactory receptor (OR) genes (Malnic et al. 2004), and each of these is an uninterrupted region 1000 bases (1 kb) long. The number of OR genes in other species is even larger, as a substantial number of the potential OR genes in humans are nonfunctional pseudogenes, possibly due to the relaxation of selective pressure concurrent with the evolution of color vision. By some estimates, the OR gene family may comprise 3% of the entire human genome (Olender et al. 2008).

In humans, the OR genes have numerous common variants (polymorphisms) (Mainland et al. 2014), leading to a potentially unique olfactory repertoire for each individual (Behrens et al. 2018). In one study that examined 356 OR genes believed to be functional (selected from a total of 851 different locations in the human genome), an average of 273 were expressed in the olfactory epithelium, and of these, only 90 were found in all participants (Verbeurgt et al. 2014). Each olfactory sensory neuron is believed to express a single olfactory receptor (Buck 2005), and the olfactory sensory neurons that express a specific OR are spatially distributed across the olfactory epithelium. All the olfactory sensory neurons that express a specific OR then project via the olfactory nerve (cranial nerve 1) to a common glomerulus in the olfactory bulb. Thus, a single OR is finely tuned to a specific motif on a ligand, and the aggregate pattern of activation across the glomeruli encodes the sensation that gives rise to a specific percept.

The considerable number of receptors, coupled with this combinatorial code across the glomeruli, implies that humans can respond to an extremely diverse range of potential odorants. To be odor active, chemical stimuli must be of low molecular weight, volatile, and hydrophobic and be able to bind to GPCR ORs. Common flavors may be comprised of tens or even hundreds of different volatile compounds. For example, one recent estimate suggests that strawberry aroma/flavor contains 360 different volatile compounds (Yan et al. 2018). Historical attempts to systematically determine relationships between chemical structure and perception were further complicated by factors like chirality (i.e., molecular handedness). For example, two otherwise chemically identical stimuli (D- and L-isomers of carvone) have completely different percepts: the D-isomer smells like caraway, while the L-isomer smells like spearmint (Pickenhagan 1989).

Just as smell occurs when a volatile chemical (an odorant) reaches and activates a specialized receptor in the nose, the same general process occurs when a soluble chemical (a tastant) reaches an activates specialized receptors in the mouth. However, unlike smell, these receptors are found on specialized epithelia cells, not true neurons. These taste receptor cells (TRCs) are bundled in small grape-like clusters called taste buds that are found in papillae on the tongue or on other oral surfaces including the roof of the mouth and the throat. The taste buds contain 50–150 cells that form a discrete ovoid structure. These cells are divided into basal cells (from which new taste cells originate) and three types of elongated bipolar cells (dark, intermediate, and light), which have microvilli that extend through a taste pore into the oral environment. The microvilli contain the taste receptors. To reach the microvilli, tastants dissolve in saliva and a mucus layer for transport to taste receptors (individuals with diminished salivary production can show impaired taste perception). Taste receptors for sweet, bitter, and umami/savory stimuli occur via GPCRs, while sour and salty tastes occur via ion channels. In contrast to the GPCRs encoded by the OR genes, there far fewer taste receptor (*TAS*) genes: in humans, the TAS1 family has 3 members, while the TAS2 family has 25. The T1R proteins (receptors) encoded by the *TAS1* genes form heterodimers to transduce sweet (T1R2/T1R3) and savory (T1R1/T1R3) stimuli. The T2R proteins encoded by the *TAS2* genes provide the ability to detect a wide range of structurally diverse chemicals that humans describe as bitter (Behrens et al. 2018). Notably, the *TAS2R* receptor genes contain polymorphisms that alter receptor functioning and explain individual differences in bitter perception (e.g., Hayes et al. 2011). Genetic variation in bitter taste receptors translates into differences in ability to taste bitters in the diet, dietary behaviors toward food/beverages with these bitter compounds, and diet-related diseases associated with ingesting these foods/beverages (Tepper et al. 2014). Despite having a single heterodimeric protein, the sweet receptor appears to have multiple binding sites, which allows it to respond to diverse chemicals of varying size and shape (DuBois 2016; Reyes et al. 2019). The bitter taste receptors may also show similar complexity (Fierro et al. 2019). The ion channels responsible for sour and salty taste are less understood, although some candidates have been identified recently. For sourness, the OTOP1 proton-selective ion channel appears to be involved in sour taste transduction, at least in mice (Teng et al. 2019). Regarding saltiness, lower concentrations of salt are sensed in mice via amiloride-sensitive epithelial sodium channels (ENaCs) (Vandenbeuch et al. 2008); however, other amiloride-insensitive channels also play a role in salt perception (Roebber et al. 2019). Additional work is needed to determine if these mechanisms apply in humans.

Once a taste receptor is activated, the taste receptor cell needs to transmit this signal to a neuron to carry the signal to the central nervous system. The chorda tympani branch of cranial nerve VII (CN VII) innervates fungiform papilla on the tongue tip, while the glossopharyngeal nerve (cranial nerve IX; CN IX) innervates the circumvallate and foliate papillae on the posterior side of the tongue, respectively; the superior laryngeal branch of the vagus nerve (cranial nerve X; CN X) carries taste signals from the throat (Snyder and Bartoshuk 2016). Humans show large variation in both the number of fungiform papillae and the number of taste buds located within these papillae (Miller and Reedy 1990). These sources of variation may to relate to sensory abilities: some reports suggest greater numbers result in great taste intensity although other studies fail to find this effect. Notably, the peripheral taste system is highly redundant: unlike olfaction, damage to a single nerve does not result in total loss of function, emphasizing the evolutionary importance of taste function as a gatekeeper of ingestive behavior. All three of the cranial nerves mentioned above project to the nucleus of the solitary tract (NST). This region also receives information from the somatosensory and the olfactory systems. From the NST, signals travel to the ventrobasal thalamus and then to the taste cortex, orbitofrontal cortex, amygdala, and lateral hypothalamus.

The third chemosensory system that contributes to flavor perception is chemesthesis (i.e., chemical touch). Sometimes referred to as oral irritation or the trigeminal sense, the term chemesthesis was coined in 1990 to describe the panoply of sensations that arise from chemical stimuli that activate the somatosensory system (Green 2016). Chemesthesis includes thermal sensations like the burn from capsaicin in chilies or the cooling from menthol but also mechanical sensations like the buzzing from Sichuan buttons (hao jiao). For the mouth and nose, these signals are largely carried by the trigeminal nerve (cranial nerve V; CN V) but also the glossopharyngeal nerve (cranial nerve IX; CN IX). In the nasal cavity, trigeminal receptors occur throughout, with the highest density toward the posterior nasal region (Poletti et al. 2019). The practical distinction between true smell and nasal irritation is blurred somewhat as many putative odorants also stimulate trigeminal receptors (Filiou et al. 2015). Still, the careful distinction between chemesthesis and oral somatosensation depends not on the anatomy, as the same nerves are generally involved, but rather on the nature of the stimulus (i.e., chemical vs. physical/mechanical). Thus, activation of the polymodal TRPV1 (transient receptor potential vanilloid 1) receptor on trigeminal neurons gives rise to hot painful burning sensations, regardless of whether the stimulus is the capsaicin in a habanero-laced salsa or a scalding hot cup of tea. Indeed, one study suggests a 4.9 uM capsaicin solution generates the same burning sensations as 52C water (Kapaun and Dando 2017). Likewise, the buzzing sensation from Sichuan buttons matches a vibrational frequency of 50 hz (Hagura et al. 2013).

Oral touch also plays a key role in the perception of foods and drinks, as somatosensory mechanoreceptors mediate sensations like grittiness (i.e., particle size), mouthfeel, and creaminess. Fat moving across the tongue during eating or licking stimulates trigeminal nerve fibers within fungiform papillae to provide sensations that are perceived as creamy or oily (Prutkin et al. 2000). Tactile acuity on the tongue is at least as good, if not better, than on the fingertip (Miles et al. 2018), and this leads to the ability to detect exceedingly small differences in particle sizes within foods, on the order of a few microns (Breen et al. 2019). The structures in the oral cavity that detect mechanosensation are similar to those found in hairless skin; like the fingers, the oral cavity contains Merkel's disk receptors (edge and point detection) and Ruffini endings (stretch), as well as Meissner corpuscles (pressure and flutter). However, it is not clear if the mouth contains Pacinian corpuscles (pressure and vibration).

Astringency has classically been considered a chemically initiated tactile event (Breslin et al. 1993) – that is, it is assumed drying and roughing sensations are purely mechanical phenomena caused by increased friction following delubrication.

Saliva contains multiple proteins that lubricate the oral cavity, and when acids or polyphenols react with and precipitate these proteins, lubrication is lost, and the mouth feels dry and rough (see Bajec and Pickering 2008). Indeed, those who are less able to replenish their salivary proteins report more astringency from tannic acid (Fleming et al. 2016). However, recent data also suggest some astringent stimuli may also activate specifically tuned chemoreceptors (Schobel et al. 2014), which would explain how high-fat foods like chocolate can still trigger dry and rough sensations, despite lubricity from the fat (Fleming et al. 2016). If confirmed, these findings would suggest astringency may be, at least in part, chemesthetic in nature, and not merely a simple mechanical consequence of delubrication.

Integration of Olfaction, Gustation, Chemesthesis, and Oral Somatosensation

Separate anatomical systems carry smell, taste, chemesthesis, and oral somatosensation from the periphery to the brain for packing or sensory integration with visual sensory input into a composite flavor sensation in the insular cortex (Gogolla 2017) and the orbitofrontal cortex (Rolls 2015). Eating an ice cream cone exemplifies the integration of physiologically distinct peripheral messages (Green 1984). When licking a scoop of coffee Oreo ice cream, sugar binds to the TAS1R2/R3 dimer and depolarizes the cell. The chorda tympani nerve (CN VII) carries the sweet signal centrally, while the trigeminal nerve carries information on coolness, creaminess, and texture of the ice cream and added cookies. As the ice cream is moved back through the mouth, more taste receptors are stimulated with recruitment of branches of cranial nerves IX and X, and mechanical action releases and pumps volatile odorants to the olfactory epithelium, where they bind to olfactory receptors, activating a specific pattern of glomeruli that we perceive as coffee and Oreo percepts from our prior learned experience. The visual, taste, olfactory, and touch signals are carried to the brain on separate pathways that are integrated by the orbitofrontal cortex into a composite flavor message and, with the amygdala and in the anterior cingulate cortex, to produce a hedonic and reward signal, and then to areas in the cortex for decisions about eating the ice cream (I will have more) and hypothalamus for satiety and fullness signals (Rolls 2015).

Sensory integration occurs when we perceive foods and beverages that are complex mixtures of stimuli for taste, smell, and touch receptors, and this process is mostly seamless and unitary: when I sip my Coca-Cola, I think “Ah, a Coke” without specifically noting the sweetness of the sugars, the bite of the phosphoric acid, the tingle of the carbon dioxide, or the individual contributions of the vanilla, cinnamon, nutmeg, and citrus aromas. Perceptual interactions occur frequently, with different combinations of stimuli showing enhancement or suppression. For combinations of prototypical taste stimuli, mixture suppression in the norm (e.g., Keast and Breslin 2003) although super-additivity (synergy) is seen for some combinations of sweeteners (Reyes et al. 2019) or savory (umami) (Zhang et al. 2008) stimuli. For cross-modal interactions, enhancement is commonly observed, as taste and retronasal olfactory input work synergistically to enhance overall perceived intensity from the oral cavity. Enhanced taste intensity (typically sweetness) in conjunction with a congruent food odor has been repeatedly observed (Duffy et al. 2016). For example, Bartoshuk and colleagues have aimed to breed better fruits and vegetables by enhancing the sweet volatiles to enhance the overall sweetness without adding sugar or debittering to remove important nutrients (Bartoshuk and Klee 2013). A similar phenomenon also is seen when adding vanilla to milk (Wang et al. 2019) or adding sweet-smelling volatiles to highly phenolic juice from the aronia berry (Duffy et al. 2016). However, enhancing sweetness via cross modal interactions may not be sufficient to increase liking, if other attributes like astringency are not reduced (e.g., Duffy et al. 2016). Increasing viscosity typically decreases taste intensity, and this appears a perceptual, not physiochemical effect, as the volatile concentration does not change with alteration in viscosity (Cook et al. 2003; Hollowood et al. 2002). In summary, given all the complex interactions that can occur, attention must be paid to the overall percept of a food product to assure it is acceptable.

There are clinical and experimental examples of altered oral sensations that occur with changes to sensory information received from the taste-related cranial nerves. One sudden source of taste loss occurs with severing of the chorda tympani nerve (cranial nerve VII) during middle ear surgery, such as to remove an acoustic neuroma (Kveton and Bartoshuk 1994). Early clinical reports showed this damage could influence more than just taste perception. In 1965, Bull (1965) observed two individuals with chorda tympani damage from middle ear surgery (out of three) who complained of alterations in true taste, oral somatosensation, and retronasal olfaction, including inability to differentiate between coffee and tea, but also that foods, such as bread and chocolate, were “doughy” and “greasy,” respectively.

The interactions between multiple sensory systems in the mouth can be shown experimentally with injection of a small amount of anesthesia into the middle ear to temporarily remove taste inputs that occur via the chorda tympani nerve (CN VII). This anesthesia does not numb the mouth overall but only serves to remove taste input from the anterior tongue. Anesthesia to CN VII on one side abolishes taste on that side simultaneously increasing the intensity of taste on the other side from a separate cranial nerve (cranial nerve IX) (Lehman et al. 1995; Yanagisawa et al. 1997). This phenomenon is thought to indicate release of inhibition. CN VII normally dampens down input from CN IX, but when input from CN VII is lost, this inhibition disappears, resulting in greater intensity from regions of the mouth innervated by CN IX and phantom oral sensations. Sensory interactions between taste and flavor is seen after modifications of taste with certain plant extracts (i.e., *Gymnema sylvestre* (“gymnema”) or *Synsetalum dulcificum* (“miracle fruit”)) (Hudson et al. 2018).

The chemosensory system shows plasticity or the ability to generate new cells, maturation, and programmed death. Neuroplasticity in the olfactory system, or the ability to make new functional neurons (neurogenesis), can occur throughout life (Brann and Firestein 2014) and is key to maintaining olfactory function throughout life. Extrinsic (e.g., exposure to microorganisms) and intrinsic (e.g., growth factors, sex hormones) factors can stimulate neurogenesis in the olfactory system. Olfactory sensory neurons that express olfactory receptors can regenerate across the lifespan, in contrast to sensory systems like vision and audition, which can generally only form new synapses during critical developmental windows (Coppola and White 2019). The ability of olfactory sensory neurons to regenerate these connections has fueled the concept of olfactory training to stimulate plasticity in response to damage as a means to recover the sense of smell (Hummel et al. 2018).

For taste, early experiences with diet may influence peripheral and central development. Children born of mothers who experienced dehydration during pregnancy due to excessive vomiting (hyperemesis gravidarum) report greater preference for salt during infancy (Crystal and Bernstein 1998) that can persist into adulthood (Leshem 2009). Sex hormones also appear to influence taste function. Taste function varies across the menstrual cycle (Prutkin et al. 2000), rising to a peak at the first trimester of pregnancy to the lowest point by the third trimester (Duffy et al. 1998), and then declines across menopause. Hormones and neuropeptides (e.g., insulin, ghrelin, and cholecystokinin) that regulate metabolism also influence taste perception and have implication for food preferences, diet behaviors, and risk of chronic diseases (Loper et al. 2015).

Disorders of Smell, Taste, and Somatosensation

Chemosensory disorders impair quality of life and can make it difficult to maintain a healthy diet and overall health. The reverse is also true, as many chemosensory disorders can be prevented through healthy behaviors and improved overall health. Indeed, population-based studies indicate that physical activity is associated with lower risk of olfactory dysfunction (Hoffman et al. 2016; Schubert et al. 2013), and a healthy diet consistent with public guidance such as the US Dietary Guidelines (https://health.gov/dietaryguidelines/2015/) prevents chronic diseases and obesity that are associated with chemosensory disorders. Further, smoking (Duffy et al. 2019) and excessive alcohol intake (Hoffman et al. 2016) each associate with olfactory impairment. Healthy behaviors including physician-recommended vaccinations, maintaining oral health, and healthy living environments can prevent viral infections and exposures that are associated with chemosensory dysfunction.

Clinically, disorders of smell are far more common than taste or oral somatosensory disorders. Notably, patient complaints of “taste loss” are almost always olfactory in nature, as the colloquial usage “taste” (i.e., flavor) differs from its use as narrow technical jargon. As noted previously, most individuals do not separate and distinguish true taste from smell, chemesthesis, or oral somatosensation when a food or beverage is consumed. Because of this understandable semantic confusion, patients often complain of “taste loss” when the fundamental cause is a disruption of olfaction, as this dysfunction is most apparent during eating. Olfaction is more vulnerable than taste to loss with aging because of its anatomical structure and because aging associates with changes in peripheral and central components.

Olfactory information is carried only by a single nerve (cranial nerve I), while taste is transmitted by multiple branches of three separate nerves (cranial nerves VII, IX, X). Olfactory sensory neurons pass through fine holes in the cribriform plate at the top of the nasal cavity. These neurons are directly exposed to environmental insults such as toxins and infectious agents, and their connections to glomeruli in the olfactory bulb at the base of the brain may even be severed with head trauma. These axons may fail to regenerate, causing loss of smell, or worse yet, regrow incorrectly, connecting to the wrong glomerulus, resulting in stimuli taking on the wrong olfactory quality (i.e., a parosmia).

Infection or trauma can cause generalized anosmia (i.e., inability to smell). In population-based studies, the prevalence of measured olfactory dysfunction ranges from as low as 3.8% (Schubert et al. 2012, 2015) in the Beaver Dam Offspring Study to 12.4% in the NHANES (Hoffman et al. 2016) and up to 19.1% in the Skövde study (Bramerson et al. 2004). Increased rates of olfactory dysfunction are seen in older adults (Hoffman et al. 2016; Murphy et al. 2002; Pinto et al. 2015), males (Boesveldt et al. 2011; Doty et al. 2011; Menon et al. 2013; Pinto et al. 2015; Roberts et al. 2016; Schubert et al. 2013), certain ethnic/racial minorities (Hoffman et al. 2016; Pinto et al. 2015), and those with lower income/educational attainment (Hoffman et al. 2016; Schubert et al. 2012). However, it should also be noted that many individuals retain a good sense of smell well into their seventh or eighth decade; rather, the prevalence of olfactory dysfunction (i.e., the number of people in the population with some sort of dysfunction) increases with aging, due to increased opportunity for trauma or damage from infection. That is, increasing prevalence with aging should not be interpreted as an overall gradual decline within an individual with aging.

Total ageusia ("taste blindness") is rarely seen. Data from the University of Pennsylvania Smell and Taste Center serve as compelling evidence in support of this statement. In over 1,000 individuals presenting to this Center with "taste loss," less than 1% had measurable taste impairment, while 32% had severe olfactory dysfunction (Deems et al. 1991; Pribitkin et al. 2003). The inability to distinguish sour from salty and bitter is more common (Cruickshanks et al. 2009; Welge-Lussen et al. 2011), although this may be a semantic labeling issue rather than a biological deficit (McAuliffe and Meiselman 1974). Because common conditions can influence both smell and taste function (e.g., mucus quality, viral infection, head trauma, cognitive function), individuals can suffer from simultaneous smell, taste, and oral sensory disorders (Walliczek-Dworschak et al. 2017).

Clinicians must use measures of self-report with functional testing to understand and be able to treat the disorder.

Smell

Individuals suffer from diminished (hyposmia) or absent ability to perceive and identify a few (specific anosmia) or all tested (general anosmia) odorants (Murphy et al. 2003). Specific anosmias are largely due to genetic variation across individuals.

For example, 6% of adults are estimated to have a specific anosmia to the musky compounds galoxide and androstenone (Amoore 1977; Bremner et al. 2003), which is explained by polymorphisms in the OR7D4 gene (Keller et al. 2007). These genetic variations are widespread and involve multiple olfactory receptor genes (Trimmer et al. 2019). Altered olfactory perception or dysosmia also exists. Dysosmia can be the distortion of odor quality (parosmia, e.g., smelling burnt paper instead of baby powder) or a phantom olfactory sensation with no apparent olfactory stimulus (i.e., olfactory hallucinations, termed phantosmia) (Murphy et al. 2003). Based on nationally representative data (NHANES 2011–2014), the prevalence of phantosmia was estimated at 6.5% of the population (Bainbridge et al. 2018).

As noted above, odorants reach receptors on olfactory sensory neurons via two routes: orthonasally (via the nostrils) and retronasally (from the mouth via the nasopharynx). Either route can be disrupted, causing olfactory dysfunction. Prior to placing food in the mouth, we may perceive food odors through passive breathing (i.e., orthonasally) and sniffing, which can increase perceived intensity. Foods and beverages that are cold or contain odorants trapped in the food matrix may provide little olfactory stimulation until they are warmed and/or released in the mouth. Notably, odorants delivered retronasally are perceived (localized) as occurring in the mouth, rather than the nose. This perceptual localization is attributed to concurrent touch and taste sensations taste (Snyder and Bartoshuk 2016). Patients report retronasal olfactory impairment with loss of taste from the anterior tongue that is medically (Bull 1965; MacCarthy-Leventhal 1959) or experimentally (Fast et al. 2000) induced. Conversely, individuals who have heightened taste response report greater retronasal olfactory intensity from model foods and beverages (Pickering et al. 2006), as the taste cortex is needed to integrate retronasal smell into a flavor percept (Blankenship et al. 2019). Taste and touch sensations may help to maintain the ability to perceive food flavor (and thus quality of life) even if the sense of smell is impaired (Oleszkiewicz et al. 2019).

The olfactory epithelium has olfactory sensory neurons, supporting cells, and basal cells. The supporting cells secrete mucus to protect against foreign agents, and basal cells serve to generate new olfactory receptor cells. Odorants must dissolve in mucus for them to interact with the receptors expressed by olfactory sensory neurons; this mucus also contains odorant-binding proteins that carry and concentrate hydrophobic odors, as well as xenobiotic-metabolizing enzymes that transform odorants (Heydel et al. 2013). There is genetic variation in odor-binding proteins that is associated with variability in olfactory ability, differentiating normal ability from hyposmia in healthy participants (Sollai et al. 2019). The metabolizing enzymes also may clear odors from olfactory receptors to increase olfactory acuity (Heydel et al. 2013). The size of the olfactory epithelial area varies. Individuals with congenital anosmia (i.e., born without a sense of smell) have reduced or absent olfactory epithelium (Moran et al. 1992). The nasal microbiome may also be key to developing a normal olfactory epithelium. Variability in this microbiome is associated with differences in olfactory ability in otherwise healthy individuals (Koskinen et al. 2018).

Taste

Individuals can also show diminished (hypogeusia) or absent (ageusia) taste perception. As noted above, total ageusia is very rare. The ability to taste with whole-mouth stimulation is maintained despite regional loss of input from damage to individual nerves that innervate different regions of the oral cavity (i.e., taste has redundant wiring). Individuals can suffer from taste altered perception, which is termed dysgeusia. Chronic dysgeusia (a persistent taste sensation) can result from a true stimulus in the mouth (e.g., the taste of an oral infection) or when stimuli reach taste receptors from the blood stream (e.g., persistent bitterness from some medications). Dysgeusia can also describe phantom sensations generated by spontaneous neuronal activity in the absence of a stimulus (analogous to phantom limb sensations) (Snyder and Bartoshuk 2016). Such sensations are often described as being metallic. A human metallic taste receptor has not yet been identified, but other data suggest metallic sensations in the mouth may be oral (taste or chemesthetic) in nature and not merely due to retronasal olfaction (Lawless et al. 2004).

Oral and Nasal Somatosensation

Oral somatosensation also can be altered. Individuals experience diminished touch sensations (numbness) and response to chemical irritants (desensitization). Individuals also perceive pain or hypersensitivity to stimuli, such as chronic smokers reporting intense sensations from concentrated salt (Duffy et al. 2019) as well as and oral pain syndromes (e.g., burning mouth syndrome (Imamura et al. 2019)). Interestingly, there is a rare syndrome called empty nose syndrome where patients perceive obstruction in their nasal passages, yet upon examination, the passages are clear. Trigeminal impairments could be part of the cause of this syndrome (Gill et al. 2019).

Assessing Chemosensory Disorders

There are a variety of questions and psychophysical tools available to assess chemosensory complaints, as well as screen for and fully measure taste and olfactory functioning. If a chemosensory dysfunction is suspected, additional physical examinations, including otolaryngologic, neurological, and dental evaluations, can assess probable causes of the disorder.

Determining if the Complaint Is Sensory or Non-sensory in Origin

Because of the tight integration of multiple sensory systems in flavor perception as well as the role of prior experience in our affective responses, individuals may complain about the “taste” of foods for a number of reasons unrelated to chemosensory dysfunction. Loss of pleasure from eating and loss of appetite can occur separately from altered sensory signals from foods and beverages. Simple questions can help to distinguish dysfunction that is sensory in nature from other non-sensory problems.

Self-Report of Chemosensory Disorders

Table 1 lists interview questions for assessment of chemosensory disturbances. Self-reported health status can provide important insight to understand how an individual evaluates and acts on symptoms as well as provides a historical complement to a single measure of function. Some clinicians favor quantitative assessment over self-report; however, asking about perceived changes provides additional information about how individuals attend to their health and health-

Table 1 Questions for a patient interview on possible chemosensory complaints

What does food "taste" like to you? Can you taste salt on snack foods or from the salt shaker, the sweetness of table sugar or honey, sourness of vinegar or lemon, and bitterness from strong coffee? Answers to these questions help determine if the complaint is sensory and help rule out a taste problem
When did you notice the problem? Did the problem come on at once or do you think it was a gradual change? Answers to these questions help determine if the complaint is a chronic versus an acute problem
Do you associate the complaint with any other problem? Answers to this and the proceeding question may identify if the condition is associated with events or exposures that cause chemosensory disorders. The question could then be expanded to request a history of specific chemosensory-related conditions
Is the problem better on some days or times than others? Individuals with olfactory dysfunction associated with nasal/sinus disease can report smell fluctuations. They may benefit from an otolaryngology evaluation to rule out nasal/sinus disease, a treatable cause of olfactory disorders
Do odors smell as they should? Does, for example, peanut butter smell like peanut butter? Do you think you could tell what you were eating if your eyes were closed? These questions address the sense of smell, not only diminished orthonasal olfaction but also odor distortions and retronasal perception
Do you have a persistent salty, sweet, sour, or bitter taste? This question should help determine if the individual has a dysgeusia. The individual may not be able to describe the quality as salty, sweet, sour, or bitter and may instead describe the quality as something vague (e.g., "yuk" or foul). This may be an olfactory sensation related to the smell of an infection
Are you suffering from oral pain, burning, prickling, or numbness on your tongue or in your mouth? These questions are designed to reveal a somatosensory disturbance associated with the "taste complaint." Individuals who respond positively to this question may benefit from further dental or medical evaluation

related behaviors. Self-report also is the only way to collect information on phantom chemosensations or altered function such as dysgeusia, phantosmia, and parosmia. Among those seeking treatment for chemosensory disorders, greater nutritional risk (e.g., weight changes) is seen in those who reported the disorder changed their interest in eating or felt that eating exacerbated the disorder (Mattes et al. 1990).

Self-rating of sensory function requires an individual to evaluate their own sense of well-being, rate a perceptual experience, and, in relation to aging, compare current function to that of an earlier age. Young and older subjects are equally unable to assess their olfactory abilities correctly, but each age group makes a different type of error in self-assessment: young patients underestimate their abilities, while older patients seem unaware of the deficit (White and Kurtz 2003). Discordance between self-reported and measured olfactory function may stem from the fact that olfactory testing is rarely part of routine health assessments. Individuals may notice a sudden loss (as with an insult such as head trauma) or a problem temporarily related to the sense of smell more easily than a gradual loss of function. Still, with dramatic changes in function, an individual may notice the change even if it occurs gradually. Finally, some people may neither assign value to their sense of smell nor exhibit overall health-seeking tendencies. Therefore, they may just assume that their sense of smell is adequate without really giving it much thought.

Standardized Survey Questions with US Nationally Representative Data for Comparison

The National Health and Nutrition Examination Survey (NHANES) included a chemosensory component for the first time in its 2011–2014 waves. NHANES is a continual, cross-sectional evaluation of the nutrition and health of the USA in a nationally representative sample (Centers for Disease Control and Prevention 2013); the protocols and data are available for review and analysis. The NHANES chemosensory component had a home interview with a Chemosensory Questionnaire (CSQ) that included items regarding self-reported olfactory, flavor and taste ability, problems such as phantom smells and dysgeusia as well as symptoms, changes notice with aging, medical treatments, and presence of related risk factors for chemosensory dysfunction that is available online (CDC 2013). These questions were content-validated by experts in chemosensation and tested to ensure consistency in participant understanding, processing, and interpretation (Hoffman et al. 2016). Combining items into an alteration score can increase the ability to detect normal function and dysfunction (i.e., specificity and sensitivity, respectively) (Hoffman et al. 2016; Rawal et al. 2014), although many people do not notice milder dysfunction (e.g., hyposmia). For example, only about 1/3 of smokers self-reported olfactory alteration despite having evidence of hyposmia upon examination (Duffy et al. 2019). Poorer sensitivity is expected of conditions, such as olfactory dysfunction, which are rarely measured (Oksanen et al. 2010).

Assessing the Complaint of Dysgeusia

Individuals who experience dysgeusia find it highly disturbing, and it can be difficult to diagnosis correctly. Unfortunately, much of the medical literature confuses taste and flavor, particularly in the cancer literature (Boltong et al. 2011), without accurately reporting dysgeusia. In practice, clinicians can use a combination of questions and testing methods to diagnose the origins of dysgeusia, as described elsewhere (Bartoshuk et al. 2005). First, determine if the patient has a persistent taste (salty, sweet, sour, bitter, etc.). Does gently swishing the mouth with water and expectorating or eating diminish the dysgeusia? If so, the source may be a stimulus in the mouth (e.g., infection, medication). Alternatively, a physician or dentist can apply a topical anesthesia to test the effect on the dysgeusia. If a topical anesthetic abolishes the persistent taste, then it may be due to a stimulus in the mouth. Addressing the source of the taste or changing the medication may alleviate the dysgeusia. If the sensation is not changed by rinsing or with a topical anesthetic, it may be a centrally mediated phantom sensation. There is evidence that dysgeusias and phantom oral pains may respond to stimulating taste, with a mild irritant, lozenge, or eating (Bartoshuk et al. 2005) or pharmacologically with low doses of clonazepam (Heckmann et al. 2012). The rationale for this treatment is that the oral pain is centrally mediated and possibly controlled by the trigeminal nucleus of the medulla. Taste appears to inhibit oral pain through gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter. Clonazepam, a GABA receptor agonist, intensifies the inhibition normally provided by GABA and thus can suppress the oral pain and taste phantoms. An individual who has intensification of a dysgeusia from a topical anesthetic should have further medical and dental evaluation.

Rapid Assessment of Screening for Taste and Olfactory Function

The sense of taste is the easiest to test with stimuli readily available food stimuli (table sugar, salt, white vinegar for sour, and instant coffee crystals or Angostura Bitters for bitter). Please see the NHANES chemosensory protocol manual for a standardized script (Centers for Disease Control and Prevention 2013). Patients who report a taste intensity below “weak” probably have taste damage.

Smell should be screened via both orthonasal and retronasal routes (i.e., via the nostrils and via the mouth, respectively). The simplest assessment is to use an identification task and add on an intensity measure as well. One odor identification test that uses common stimuli you can obtain at a typical grocery store is the Connecticut Chemosensory Clinical Research Center Test (Cain et al. 1988). This low-cost screening test uses baby powder, chocolate, cinnamon, coffee, mothballs, peanut butter, and Ivory® soap, as well as Vicks VapoSteam®, as a trigeminal probe. The stimuli should be visually concealed from participants: putting the stimulus in a jar and covering with cotton gauze or cotton rounds or cotton balls work well. The stimuli should be refreshed weekly. Unseal the jar right before testing and hold under the participant’s nose. Using a word bank, have the participant identify the odors; the word bank should include the 8 stimuli and 8 other distractor items, for a total of 16 choices (Cain et al. 1988). Because odor *identification* tasks measure both sensory function and cognitive ability (Lehrner et al. 1999), provide correct feedback, and present misidentified items a second time to minimize cognitive effects. If a participant misses four out of the seven non-trigeminal odors (even after giving correct feedback and presenting missed items a second time), they have probable hyposmia and should be referred for more in-depth evaluation by an otolaryngologist. If the stimuli for the olfactory testing are kept fresh, an intensity task can be added to the identification task with very minimal additional time. After the participant smells the odor, first ask an intensity judgment on the gLMS (Fig. 1), and then ask for the odor identification. Again, after excluding the trigeminal control (Vicks VapoSteam), participants who report more than half of the odor stimuli as less than moderate in intensity likely have depressed olfactory function. Commercially produced screening kits are also available, as a scratch-and-sniff (Brief Smell Identification Test) or capped markers (Sniffin' Sticks). The scratch-and-sniff version also comes in 2, 4-odor packets (Pocket Smell Test), and results can be compared with US nationally representative NHANES data (Centers for Disease Control and Prevention 2013).

To test retronasal olfaction, orally sampled jelly beans work well, and gourmet jelly beans work especially well, as their flavors can be highly distinctive. To distinguish taste from retronasal olfaction, have the participant pinch their nostrils, and then have them put the jelly bean into the mouth and chew fully. Then, have the participant unplug the nose. Plugging the nose allows only the taste and chemesthetic input (for jelly beans, this will be primarily sweetness and sourness unless cinnamon- or chili-flavored jelly beans are used). Opening the nostrils at the end of chewing should cause a rapid retronasal transport of odorants to the olfactory epithelium. Typically, this causes an "aha" moment. If the participant does not notice a stark difference between the plugged and unplugged nose, this suggests

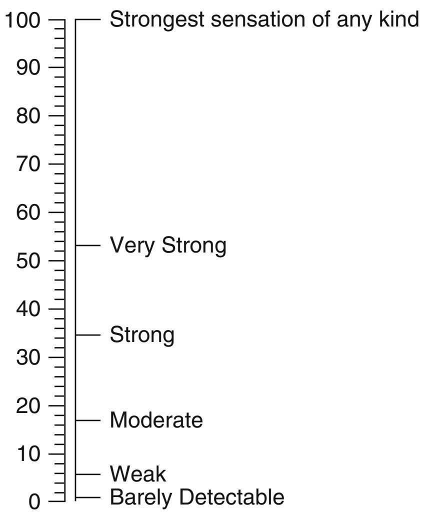

Fig. 1 The general labeled magnitude scale (Bartoshuk et al. 2004) for testing intensities

they have impaired retronasal olfaction. If more precision is required, have the participant judge the intensity of the sweetness of the jelly bean with the nose plugged on the gLMS (Fig. 1) and then the jelly bean sweetness and flavor with the nose unplugged. A rating below “moderate” that does not increase in perceived sweetness would suggest depressed retronasal olfaction. For screening, we have used chocolate, coffee, and cherry jelly bean flavors, as well as Tabasco®-flavored jelly beans, as a trigeminal probe (Hubert et al. 2019). Jelly beans also can be used in an identification task. Select the jelly bean flavors that might be most familiar to your participants, and set up a word bank that includes the correct labels and an equal number of distractors. Be sure to give feedback and retest missed items to maximize olfactory effects and minimize cognitive effects. Misidentification of more than half of the jelly beans probably would constitute olfactory impairment.

Measuring Taste and Olfactory Functioning

Thresholds provide a measure of sensitivity but critically may or may not reflect the ability to perceive stimuli at concentrations relevant to eating, at least for taste (Pangborn and Pecore 1982; Webb et al. 2015). The food and beverage world is one of suprathreshold sensation, rarely tapping sensations close to threshold (except perhaps when chemosensation is used to detect faint off flavors or spoilage). Conversely, suprathreshold tasks measure perception of ecologically relevant stimuli and include perceived intensity measures and identification tasks. For olfaction, threshold versus suprathreshold tests may help in the diagnosis of disorders that impair peripheral olfactory function (e.g., chronic rhinosinusitis) versus those that impair central odor processing and memory (e.g., Alzheimer’s disease) (Wu et al. 2018). Discrimination testing also may help track improvement in olfactory function related to peripheral olfactory disease (Wu et al. 2018). This is a nonverbal test where the participant smells a reference odor and then needs to match that reference odor out of four additional odor probes.

Measures of perceived intensity are preferred for the assessment of taste and can be useful in the assessment of olfaction if the testing stimuli are assured for quality and freshness. Identification tasks are not useful for the sense of taste as there is only four or five qualities and there is common confusion between sour and bitter (McAuliffe and Meiselman 1974). The perceived intensity method must (1) allow subjects to express the full range of their sensations (reducing ceiling effects); (2) avoid the use of a standard to assign a particular value or the limits of the scale; (3) use a scale that allows for ratio comparison of relative intensities within individuals; and (4) provide a valid way to compare perceived intensity across subjects (Bartoshuk et al. 2006; Hayes et al. 2013). The gLMS measure described above with standardized instructions and practice with non-taste or smell stimuli meets these four criteria. For identification tasks, the method must attempt to separate sensory influences from cognitive influences. Chemosensory tasks that utilize foods and beverages may have the most application in the exploration of the relationship between chemosensation and nutrition.

Comprehensive olfactory testing generally requires both threshold and identification tasks, including some measure of retronasal ability. Commercial odor identification tests are available, including The University of Pennsylvania Smell Identification Test (UPSIT) (Doty et al. 1984) and Sniffin' Sticks (Rumeau et al. 2016). Olfactometers also are available – these devices standardize the air flow, concentration, timing of when the odor is delivered and for how long, and when it is shut off. Research grade olfactometers have a high level of precision but are quite expensive; less expensive olfactometers that provide a reasonable level of stimulus control are also commercially available. Inclusion of an intensity judgment task extends the utility of the odor identification tests described above. The Sniffin' Sticks also comes with threshold modules of either n-butanol, which has a trigeminal component, or 2-phenylethanol, which is a floral odor and has no trigeminal component. The UPSIT is a commercially available test of olfactory functioning (www.sensonics.com). This test includes 40 "scratch-and-sniff" odors and a multiple-choice format; a brief 12-item test is also available. Normative data for these tests determine the level of olfactory functioning (i.e., anosmia, hyposmia) according to age range and sex. These tests are also available for different cultural groups. Individuals with evidence of olfactory dysfunction should be evaluated by an otolaryngologist based on medical history, the examination with nasal endoscopy, full olfactory testing, and imaging (CT scan, MRI, and EEG) (Boesveldt et al. 2017).

Taste tests are designed to assess dysfunction but also can test the wide range of normal ability, including those who experience "pastel" oral sensations (also referred to as nontasters) versus those who experience "neon" oral sensation (also referred to as supertasters). Thresholds for a particular compound may be useful to test a mechanism of taste receptor binding or in sensory analysis to assess for off-tastes. Taste thresholds are difficult to measure, requiring precise control of the stimulus and the non-stimulus for non-taste attributes (e.g., temperature), and are slow and labor-intensive. Perceived intensity measures, particularly that probe the cranial nerves that innervated taste, offer a useful measure of taste function as initially described by Bartoshuk et al. (1994) for full testing of cranial nerves VII, IX, and X and updated with improved intensity scaling in the National Institutes of Health Toolbox (Coldwell et al. 2013) and procedurally in the NHANES protocol. In the full spatial taste testing protocol, the researcher draws cotton swabs soaked in taste solutions (sweet (1 M sucrose), salty (1 M sodium chloride), sour (32 mM citric acid), and bitter (1 mM quinine hydrochloride)) unilaterally across different areas of taste nerve innervation before a measure of intensity with whole-mouth stimulation (Sipiora et al. 2000). The NHANES protocol is a briefer measure of taste function: it only includes the salt and bitter probes with bilateral stimulation of the tongue tip and the whole mouth. Participants report the intensity of the taste on the gLMS and the quality. Adding in a water probe may be able to provide additional information on dysgeusia if the participant reports a taste from the water applied to areas of taste nerve innervation. A brief test of the ability to taste the bitterness or propylthiouracil (PROP) can be added to the spatial taste test as a screening for the most common genetic variation in taste (Hubert et al. 2019) that has been associated with diet and health outcomes (Tepper et al. 2017). For further discussion of different functional measures of taste, see (Webb et al. 2015).

Biological Measures of Smell, Taste, and Somatosensation

These measures rely less on psychophysical testing and instead on the electrophysical measures of brain potentials, magnetic responses, and changes in blood flow in response to chemical stimuli. Olfactory event-related potentials (OERP) involve providing an odorant and asking the participant to respond to the stimulus while minimizing other visual, somatosensory, or auditory sensory inputs. The OERP provides information on the length of time it takes to show significant changes in neural electrical response to the odor (i.e., latency) and the magnitude of neural response (i.e., amplitude). However, interpreting the OERP is challenged by differentiating signals from noise via complex data analyses. Comparison of individuals with normal smell versus anosmia in an automated OERP correctly identified 75% of anosmics (Guducu et al. 2019), suggesting additional refinement would be required before clinical use is indicated.

Electrogustometry is frequently used in research and practice, but it only measures taste thresholds, which, as noted above, have limited utility in relation to eating behavior. The method usually involves localized testing by applying a mild electrical current to the surface of the tongue. However, the stimulation also captures multiple qualities of taste as well as irritation. Thus, electrogustometry may be somewhat misnamed in that it may not detect taste damage but can determine the integrity of cranial nerve VII (Snyder and Bartoshuk 2016). Electrophysical recording from the tongue also has been reported for assessing the ability to taste the bitter stimulus propylthiouracil (Sollai et al. 2017). This method involves placing silver electrodes on the dorsal and ventral surface of the tongue and analyzing bioelectrical potential variations for peripheral taste responses. Assessing fungiform papillae density on the tongue tip or taste buds within these papillae is difficult and requires magnification and a contrast agent. Even with an operating microscope, 10× magnification, blue food coloring, and the ability to video record the images for in-depth reviewing, it is challenging to identify fungiform papilla from filiform papilla (non-taste) because of their varying shapes and sizes (Miller and Reedy 1990). Assessing taste bud number requires 40× magnification of a few papillae and looking for shadows indicating taste pores on slow-motion replay. Confocal laser scanning microscopy is a newer technique that can examine singular papilla or area on the tongue over time with more accuracy (Saito et al. 2017).

Conclusion

Taste, smell, and oral somatosensation contribute to food enjoyment and nutritional health by receiving sensory input from foods and beverages. A significant amount of research has advanced our knowledge of the basic mechanisms of chemosensory perception from stimulus receptor binding, transduction, nerve transmission, and central nervous packaging into an integrated perceptual experience. Directed questioning, psychophysical testing, and biological assessment identify normal variation in chemosensory function and alterations associated with genetic differences, development, and exposures as well as diseases across the lifespan. Most common is alteration of olfactory perception and changes to olfactory component of food flavor. Poorly oral health may further increase the risk of olfactory dysfunction by reducing retronasal processing of olfactory food flavor. Loss of true taste as perceived with the whole mouth is rare because of the tremendous redundancy in cranial nerves that carry taste sensations from the periphery to the brain. However, recent evidence shows that localized loss of taste from individual areas innervated by cranial nerves can alter oral sensations from foods and beverages and change food preferences and patterns of food intake. Localized losses of taste, if extreme enough, can result in dysgeusia and oral pain syndromes that impair the quality of life and the ability to obtain oral nourishment. Individuals who complain of olfactory loss and oral sensory disturbances or complain that eating is not enjoyable deserve a thorough assessment. Chemosensory disorders can improve if the underlying cause is treatable, such as through the modification of medications or alleviation of the underlying condition (see ► Chap. 61, "Causes of Smell, Taste, and Oral Somatosensory Disorders Affecting Eating and Drinking" by Duffy in this handbook). Cross-disciplinary opportunities exist across the food, nutrition, and health spheres to personalize eating recommendations matched with chemosensory variation to support healthy eating and the quality of the eating experiences.

The Psychology of Food Choice: Anticipation and Mental Simulation

9

Betina Piqueras-Fiszman

Contents

Abstract

Throughout our lives we develop a system that helps us navigate in a food environment. In a routine where we are constantly thinking about food and making choices, ranging from whether we actually want to eat, through selection of food category and portion size, to eventual consumption, it is worth highlighting that many of those microdecisions are made without full awareness. Focusing on the situations of having to make a choice among foods, we would mainly rely on two sources of information: that of the product's intrinsic properties, and the additional information we get about it simultaneously (e.g., recommendations, or packaging information). However, most probably we have already consumed a similar product previously. Therefore, our brain will simulate the likely impact (hedonic and utilitarian) the product will have on us and, after experiencing it

(moment of truth), will determine whether it is congruent with the image or schema we had about it, and if not, to some extent, it will accommodate, and that image will be adjusted. Now, certain products inherently trigger predominantly certain types of simulations (e.g., a cake triggers simulations related more to short-term effects and fruit more longer-term effects), which depending on our own goals will result in certain behavior. This chapter will discuss the process of mentally simulating and anticipating different stages of food consumption and will provide novel evidence on the effect this has when used as a strategy to steer food choices in a desirable way.

Introduction

As one can imagine, the psychology of food choice is not straightforward, and entire volumes could be written on each of the multiple aspects that intervene on the decisions that people make about food. One of the reasons why there are nearly endless intervening factors is precisely that we are almost constantly making decisions about food throughout our day. Of course upon entering in a food outlet (e.g., a supermarket, a shop at the train station), consumers have a predefined idea of what they are going to take home (or consume on their way). But realistically speaking, going in and out is quite utopic; in many cases we inevitably spend additional time comparing certain options within a food category, "oh now it also comes in this flavor," "this one will give me the energy I need," or "this looks *just* too good." Naturally these quotes stay in the back of our mind, most likely while we are placing already some products in our shopping bag. These "go" decisions are based on the assumption that the product will fulfill the expectations raised by the packaging or by its exteroceptive cues, or, if it is a product that we are already used to, that it will still meet our utilitarian and hedonic standards (that we have stored in memory). In this sense, we will anticipate the effect that the product will have on us by quickly creating mental simulations about the product. There will be a moment of truth in which we will actually consume the product, and we will adopt it (or continue adopting it) if the expectations regarding the experiential attributes are satisfied. Particularly, this chapter will discuss the triggers of mental simulations about the sensory/consummatory but also of the outcome/consequential characteristics of the product and how these two types of characteristics influence subsequent food choice.

Anticipation and Mental Simulation

When faced with a choice of food products, either for immediate or later consumption, our brain anticipates the likely impact that the products will have on us. We will automatically mentally simulate the sensory pleasure we will obtain from the product but also the consequences of having consumed it. These mental representations will be based on the verbal or pictorial information available or the appearance of the product itself, and of course depending on the product, on olfactory and tactile input as well. Needless to say, the more familiar we are with the products, the clearer those representations will be because we will already have that sensory information stored in our memory from past experiences. Then our choices will be largely determined by those memories.

Most of the literature on anticipation is based on the anticipated pleasure (so, on the consummatory dimension). The reason is that it is assumed that pleasure, or liking, is the primary reason why people make a particular food (and portion) choice. That is, they would buy a product, sometimes in a large amount to be able to consume it in several days, with the idea that they will like it until the end of consumption. Note, however, that it has been demonstrated that people are quite bad at estimating predicted liking over time (Kahneman and Snell 1992; Rozin et al. 2006). Another major influence of food choice relates to the post-consumption consequences, which one may imagine once that, or a related product, has been consumed before. One can imagine the short-term post-ingestional effects of a food and/or the longer-term effects (what in other terms is referred to as "health" effect).

Food products have specific characteristics that make them appealing or desirable to consumers. Some products are more appealing for their long-term benefits, whereas others are commonly known to deliver direct gratification or a short-term benefit. Consumers can infer these based on the intrinsic properties of foods and/or on how the product is being promoted (e.g., the labelling provided). We could therefore say that products are usually more dominant in one aspect or the other and that the dominant aspect would trigger either stronger sensory-hedonic or more consequential-utilitarian mental representations. Apart from the product's properties, what is salient also depends on the eye of the consumer and the focus they have in mind. However, before delving into these aspects, let's define first what mental simulation is.

Mental representations can be characterized as images or can be embodied as a complete experience, including body sensations, feelings, and images. From a grounded cognition perspective, this imagination process is referred to as mental simulation, which allows us to recreate previous experiences that deepen our innermost self through perceptual, motor, and introspective states (Barsalou 2008). Additionally, mental simulation is multimodal and creates the experience of "being there" (Barsalou 2005; Kappes and Morewedge 2016); it can even activate the gustatory and olfactory cortices in the brain (Spence 2016). Moreover, imagining a favorite food (memory of food) may be more crucial in activating reward-seeking behavior than actual food. In the next sections, I will elaborate on these two types of anticipation regarding these food-specific benefits. Next, I will discuss novel strategies to possibly shift the mindset of consumers toward hedonic/short-term benefits or more utilitarian/longer-term benefits of foods to influence food choice.

Hedonic Anticipation

In a given context, what determines pleasure or the hedonic aspects of food is mainly its sensory properties (surely there are other factors, like environmental and social ones, but these are covered in other chapters of this volume). Surely before consuming something, we can already fantasize about the likely taste, aroma, texture, and sounds (overall flavor perception). Some product categories are inherently highly effective in evoking sensory imagery (bakery products, chocolate, etc.) in general and are commonly known to deliver direct gratification or a short-term benefit even before consumption. In fact, fantasizing about, or mentally simulating, appetizing food may activate the reward areas of the brain and provoke a strong motivational response such as increased desire for that food (Pelchat et al. 2004).

The Effect of Hedonic Mental Simulation on Food Choice and Portion Size Selection

Research has been consistent on the effects of mental simulations. However, at the outset it is worth highlighting that the strategies used by researchers to evoke mental simulations greatly vary among the studies. In some studies participants have to visualize appetizing food (well, considered appetizing for most people) directly or as part of a cover task, and in others the instructions are more explicit and ask participants to imagine the consumption thereof. Across studies, it has been shown that the appetizing foods induce salivation (Keesman et al. 2016) and trigger food cravings (Kemps and Tiggemann 2013; Schumacher et al. 2017). These findings are supported by the Elaborated Intrusion Theory of Human Motivation (EI Theory) which posits that thinking about a food increases desire for that food, as measured by means of motivation-related questions or tasks (May et al. 2015).

Some findings also point at mental simulation being an effective strategy to control food intake, potentially helping people make healthier choices. For example, Larson et al. (2014) conducted two experiments showing that repeated evaluations of food pictures led to lower consumption enjoyment on other foods sharing a sensory aspect (which is related to sensory-specific satiety). In Experiment 1, participants found eating peanuts less enjoyable after rating the attractiveness of pictures of salty foods versus rating pictures of sweet foods. In a second experiment, they replicated this finding when once again participants had to rate attractiveness or had to choose between two foods, but not when the task was unrelated to the taste characteristics of the food (e.g., rating the brightness of the images). The authors argue that simply exposing one to pictures of food is not enough to decrease enjoyment, presumably because it does not trigger the sensory simulations. It could also be that when people evaluated food pictures based on something completely unrelated to consumption in general, then goals related to consumption were also not activated. Perhaps judging them based on healthiness, for instance, would also trigger consumption-related thoughts and also impact a consumption-related variable, like enjoyment in this case.

Regarding amount consumed, the number of times people engage in imagining consuming a food is also important. Morewedge et al. (2010), for instance, asked participants to repeat the imagination of consumption of M&Ms 30 or three times and showed that imagining eating M&Ms 30 times resulted in a smaller amount of subsequently eaten M&Ms than in the latter case. Engaging in such a large number of repetitions requires time and a very high level of motivation and self-control, and it is conceivable that the difficulty of the task might cause reduced compliance and thus be a threat to the intervention's objective. Indeed, previous research showed that the availability of self-regulatory resources is necessary for the reduction in food intake induced by repeated imagined consumption to occur (see also Missbach et al. 2014, Study 2). Haasova et al. (2016) asked participants to imagine eating chocolate pudding 15 or 3 consecutive times. Results showed that participants who imagined eating the chocolate pudding 15 times ate more of the pudding than those who imagined consuming it 3 times. Taken together, the results of these studies suggest that there is an inverted U shape relationship between repetitions of imagined consumption of a particular food and the amount subsequently consumed. Other researchers have been working on reducing the "portion size effect" (Petit et al. 2017) and the portion size choice (Cornil and Chandon 2016; Petit et al. 2016). In a series of studies, Cornil and Chandon (2016) investigated the effect of multisensory imagery on portion size choice. Participants in their study were asked to imagine vividly the taste, smell, and texture of three hedonic foods before choosing a portion size of another hedonic food. The sensory imagery made non-dieters opt for smaller portions due to an increased expected enjoyment for a food (chocolate cake) but backfired dieters, who felt tempted to choose larger portions. In the case of health imagery, people saw the same three hedonic food pictures, but they were asked to imagine the negative impact of these foods on their health and body. No effects were found in expected eating enjoyment nor in actual enjoyment, but all participants chose smaller portions, and the effect was marginally stronger among non-dieters.

Although research in the food domain refers to an imagined food consumption experience as multisensory imagery (Cornil and Chandon 2016; Lacey and Lawson 2013), consumption imagery (Petrova and Cialdini 2005), sensory simulation (Larson et al. 2014), or eating simulations (Papies 2013), these seem to capture only one of two distinct types of mental simulation, known as "process" simulation (Taylor et al. 1998). Process simulation evokes the act of using or consuming the product, and for foods, this includes, for instance, the flavor of food, the sensations while eating, and also an affective component, which can vary from positive to negative. It should also be noticed that most of these cited studies have used high calorie, hence indulgent, food as stimuli (e.g., cakes, sweets, fries). Therefore the effects of imagining the consummatory aspects of eating a less indulgent product are not well known, but I will describe some recent findings on this in the following sections.

Utilitarian Anticipation

As mentioned above, individuals can also mentally simulate the functional and emotional consequences (e.g., recreating the satiation feeling and also the guilt or satisfaction) of having consumed a product, before even choosing it. In this case this mental simulation is called "outcome" simulation, and one could argue that it happens spontaneously more often (and in a more dominant way) in products that are categorised as being "healthy." Compared to the process simulation described above, it has received relatively little attention in the literature (though see Zhao et al. 2011). Yet there is plenty of research, albeit not referring explicitly to mental simulations, which touch upon this topic when discussing the effect of, for instance, calorie-related labels or visual volume of a product on satiation and satiety. For example, Yeomans et al. (2014) manipulated the "actual" and "perceived" amount of soup that the participants consumed. Before lunch, half the participants were shown 300 ml of soup, and half were shown 500 ml. During lunch, half of each group consumed 300 ml and the other half 500 ml, inversely. Immediately after lunch, self-reported hunger decreased as expected, and the differences observed were related to the portion of soup actually eaten. However, 2 and 3 h after the meal, the participants' hunger was determined by the portion of soup they had been shown before lunch. After 24 h, the expected satiation delivered by a 400 ml bowl of soup was significantly higher for those who had previously seen 500 ml of soup, regardless of the amount actually consumed. This seems to confirm that the memory of recent eating can influence subsequent expected satiation assessments through the participants mentally simulating the effects of the visually displayed amount of soup (see also Higgs 2002, 2008, for additional evidence on the effect of memory on subsequent intake). That said, and emphasizing the point above, in most of these studies, there are no explicit instructions to imagine the consequences of consuming the products.

Process and Outcome Mental of Simulation and Food Choice

Most studies described so far on the impact of (mainly) process simulation have focused on enjoyment of consuming a given portion or on consumption amount (portion), or selection thereof, as dependent variables. However, as mentioned in the introduction, we normally also make decisions on what to select, for instance, in a restaurant for dessert or at a train station as a snack. Many people, mostly us who have a "sweet tooth" (or salty or fatty, for that matter!), would give in to temptation and go for the most indulgent (vice) option. This is because we naturally tend to prioritize short-term goals, which provide immediate gratification (i.e., eating the mouth-watering snack) and delay long-term goals (i.e., dieting to achieve a fit body and health). Since long-term goals are further in the future, consumers are often faced with the dilemma of whether to eat or not to eat the mouth-watering snack or to choose a healthier (virtue) option. The dilemma in consumers' mind can be seen as the conflict between a long-term goal and a short-term goal.

Process and outcome simulation types may be associated with temporal patterns of activation (Trope and Liberman 2003), that is, activation of short-term and concrete (process simulation) versus long-term and abstract goals (outcome simulation). The activation of these two constructs in a food consumption event could shift the balance from more concrete and short-term goals toward an activation of abstract and long-term goals and vice versa.

One way to possibly shift the balance between short-term goals and long-term goals is to use people's imagination. In a recent study, imagining the eating consumption itself and imagining the benefits/consequences of consuming the food were differentiated (Muñoz-Vilches et al. 2019). The interest lied in investigating the effect of instructed process versus outcome mental simulation on food choice and how such effects differ between vice ("high-calorie") and virtue ("low-calorie") products. Moreover, we also looked at the moderating effect of the chronic orientation of people toward short or long-term consequences (i.e., level of health orientation).

For this purpose, the study followed a 3 (simulation type: control, process, and outcome) $\times$ 2 (product type – vice, virtue) within-subjects experimental design. The two products (crisps and a green smoothie, which were similarly liked) were presented to the participants as unbranded pictures. During the first session, all participants engaged in the control condition (i.e., no mental simulation) to provide baseline measures for both the vice and the virtue products. After they attended the first session, participants were randomly assigned to the process simulation or the outcome simulation condition. Once they had finished the second session, they were contacted again and scheduled for the third and last session. All the participants completed it within one week and had to complete the task roughly at the same time for all sessions.

To manipulate the type of mental simulation, specific instructions for process and outcome simulation were created ensuring that everyone thought of cognitive and affective aspects during both simulation sessions. In the context of food, Xie et al. (2016) proposed, based on the theory of grounded cognition (Barsalou 2008), that process simulation/outcome simulation of the food consumption experience includes sensory perceptions such as taste/aftertaste, motor states of chewing/feeling full, and introspection as enjoyment/satisfactory and energy levels. After the simulation, participants had to indicate how much they would want to eat the product they imagined at that moment, and finally they were given the choice between a green smoothie, a packet of crisps, or none.

The results of this first study showed that imagining the consumption of the vice product and the post-consumption of the virtue product increased the rate of wanting for that corresponding product; the same pattern was found for the choice but only for outcome simulation. In other words, when people had to image consuming the crisps or having had consumed the green smoothie, their wanting for these products increased, and in outcome simulation, it led to an increased choice for the virtue product. However, when the products and the mental simulations were less "matching," these effects were diminished. A possible explanation is that the perceived likelihood of the consumption event increased due to simulation heuristic, which is the ease in which people generated a mental script of the consumption event (Kahneman and Tversky 1982; Tversky and Kahneman 1973). When people were asked to simulate the consumption experience for a vice product, the accessibility of features related with the experience (such as sensory attributes, enjoyment of eating) would have been more salient and easier to imagine; the same outcome would be expected when imagining the consequences of having consumed a virtue food, resulting in a positive motivational reaction.

Impact of Health Orientation

The extent to which people are more or less health-oriented could also have a moderating role on wanting and choice. It would be plausible that people with a stronger goal, or more determined, to keep a healthier diet would be more resistant to change their wanting level and choice for a product. In Muñoz-Vilches et al. 2019, this hypothesis was only partially confirmed since health orientation (as measured with the Food Choice Questionnaire; Steptoe et al. 1995) moderated only when simulation and product type did not share the same dimensions (so when they had to imagine the consequence of a vice product and the consumption of the virtue product). Those less health-oriented people decreased their desire for the vice product possibly because the imagined consequences reminded them of a health goal. In a teleological system, behavior adjusts according to the revaluation of the goal that is triggered, either by an alteration in the state of motivation or because new knowledge is acquired (Dickinson 1985). It is likely that outcome simulation made the health goal more salient, permitted a revaluation of goals, and led this low health segment of people toward a behavior more compatible with their new goal, which led them to choose the virtue product. In other words, mental simulation could have activated and changed the initial goal of people. Research in goal prime showed that, indeed, goal primes increase attention for goal-congruent items and the likelihood of choosing them (van der Laan et al. 2017). Therefore, outcome simulation could have primed low health-oriented people with a healthier goal, which increased attention for the goal-congruent features (utilitarian) and led people to opt for the virtue and healthier product.

On the other hand, we hypothesized that high health-oriented people would be less likely to change wanting and choice, regardless of the product and the simulation they performed. However, although this group remained quite constant in their preferences (the virtue over the vice product) in both simulations, the wanting for the vice product was not constant, and indeed, they increased desire for that food equally in outcome and process simulations compared to the control condition. This result suggests that higher health-oriented people have a high self-control resource, since they get tempted with the vice product but they do not choose it over the virtue option. The relative importance of hedonic versus utilitarian product attributes changes across consumers, and, as one would expect, the importance of healthfulness is much higher among the health-conscious segments than other segments (Maehle et al. 2015). In the case of the virtue product, even though the results mirrored the ones of the vice product, they were not as pronounced. In this product, health orientation did not moderate when process and outcome simulations were compared to the control.

Role of the Valence of the Mental Simulation (Imagined Experience)

So far, in this chapter I have discussed variables like wanting or desire and choice, but the experience of the consequences of past eating can significantly impact subsequent intake or enjoyment of foods since the integration of internal and external signals that influence food intake relies on memory systems (Booth 1992). More specifically, it seems that the valence of the remembered experience is what determines subsequent behavior and/or enjoyment. For example, Robinson and colleagues showed that how we recall food enjoyment can influence subsequent enjoyment of foods (Robinson et al. 2011, 2012). Two studies examined whether remembered enjoyment of eating a food can be increased and whether this makes individuals more likely to eat that food in the future (Robinson et al. 2012). A simple manipulation of instructing participants to revisit what they found enjoyable about a food right after eating it was used to increase remembered enjoyment (relative to controls). This experimental manipulation successfully increased remembered enjoyment for the food. In the second study, they explored whether this very manipulation resulted in participants choosing to eat more of a food from a buffet lunch the following day, the results suggesting that it is the case. Taken together these findings suggest that remembered enjoyment can be modified by simply recalling a past occasion and that this act can increase or decrease the amount of food chosen and eaten later. Moreover, additional evidence suggests that memory of food, or thoughts of future meals, suppresses subsequent food intake (Vartanian et al. 2016).

Together with Sara Jaeger, the impact that food-related memories have on people's emotional state and how this state is projected in a subsequent evaluation of images pertaining to food and food-related behaviors was investigated (Piqueras-Fiszman and Jaeger 2016). Through an online survey, three memories were investigated (a positive meal, a routine evening meal, and an overeating occasion) among UK respondents. Participants had to recall one of these three memories and write it down. Following this, they evaluated images of food and food-related behaviors in terms of emotions conveyed (provided to them). Participants who recalled an overeating memory evaluated images related to junk food as conveying more feelings of guilt and shame than did participants primed with the memory of a positive meal. Moreover, this effect was moderated by participants' dietary restraint status. Participants classified as having a high dietary restraint had stronger associations with the emotions guilt and shame than participants classified as low in dietary restraint. In contrast, a memory of a positive meal did not lead to positive valuations of any of the food-related images shown. Overall, the findings from this study illustrate the partial impact that personal food memories have on people's emotional response toward food-related issues, which in turn has the potential to affect future behavior.

Now, in the context of the instructed mental simulations, one could argue that both process and outcome simulations would increase the desire for an imagined ambivalent product (which could be both vice and virtue) in a similar way since no negative imagination was imposed. People assign a positive value to things that are conducive for goal achievement and negative value to things that are detrimental for goals achievement (Förster et al. 2007). We further explored whether the valence of the imagined experience could modulate the desire for the imagined product (Muñoz-Vilches et al. submitted). Thus, we expected that in our case, the imagined experience would lead to a positive feeling, and it would increase wanting. Yet, having a negative feeling about the imagined experience (i.e., for a person the product might have negative sensory attributes or lead to post-consumption feelings such as guilt) would decrease wanting. Therefore, the valence of the imagined experience would mediate the effect of mental simulation on the wanting for the imagined product. Imagining a food experience evaluated as positive (negative) would increase (decrease) the motivation to eat the product they have imagined. Finally, we also hypothesized that upon a real choice of foods (a healthy and an unhealthier snack), performing process simulation with an ambivalent product would increase the likelihood of choice for the unhealthy product and that outcome simulation would increase the likelihood of choice for the healthier one.

The procedure was the same as with the other study described (Muñoz-Vilches et al. 2019). After the mental simulation phase, with a cereal bar (in this case as an exemplar of an ambivalent product), they evaluated the valence of the thoughts evoked by the imagined experience. At the end of the session, participants were presented with two transparent containers, one with 65 g of a healthy product (grapes) and another with 65 g of an unhealthier product (chocolate covered raisins). Participants were asked to evaluate the liking of both products before tasting them and had to choose one from the two products to do a "taste test" as part of a cover story. Only the choice was recorded, but participants did not notice any connection between the mental simulation phase and this "other" tasting test.

Participants under process simulation, that is, imagining the process of eating, had a higher desire for the imagined product compared to a control condition, but when having to choose between a healthy and an unhealthier product, more people chose the unhealthier product over the healthier one. On the other hand, outcome simulation, that is, imagining the outcome of eating, also generated a higher desire for the imagined product, but in this case, people chose the healthier option. The results also showed that the type of mental simulation indirectly influenced wanting for the imagined product through its effect on the valence of people's imagined experience. So, in other words, the more positive the imagined experience was, the more desire the participants had for the food.

The results highlighted the impact that mentally simulating the process of eating something versus its consequences has on the choices people make regarding snacks. Making people focus more on the consequences of the consumption, even if it is not a vice nor a virtue product what is being imagined and not being part of a choice, could lead to healthier choices, as our study suggested. This strategy, one could argue, makes people direct their attention toward different aspects of the product. Most importantly and in alignment with previous literature, if the imagined (post)consumption experience elicits positive feelings, we will be more inclined to eat that or a similar product, but if the experience elicits more negative feelings, then we will tend to not prefer that food (or perhaps even reject it).

Taken together, these findings highlight how important the memories we have of our eating experiences are. In fact, according to the cognitive psychological tradition that became known as "analysis-by-synthesis" (e.g., Gregorey 1980), our brain does not build its current model of how the world is simply by accumulating information from the bottom up (i.e., from low-level cues). Rather, it tries to predict the current incoming cues from its best models of the possible causes (see Hohwy 2007). Over the last decade, more and more neuroscientists have subscribed to this perspective using a Bayesian framework to suggest that our brain uses hierarchical or empirical Bayes to infer the causes of the sensations invading it (e.g., see Friston 2005; and Piqueras-Fiszman and Spence 2015 for a more elaborated discussion on this). Considering this we could say that we make decisions without much processing of incoming information and in a pretty automatic way by trying to predict whether the products we are choosing from will satisfy our hedonic and utilitarian needs, based on the priors stored in memory from previous experience. As part of this process, mental simulations contribute to us anticipating the likely (post) experience we will have with the product.

Conclusions and Implications

As mentioned at the beginning of this chapter, mental simulations occur naturally and automatically as soon as we encounter a product; however the behavioral outcome is then also mindless and greatly relies on our recall of similar experiences (hedonic and functional) we have had in the past. This highlights the importance that past experiences and our memory thereof have in our behavior.

This chapter also provided an overview of recent evidence highlighting the potential effects of instructing people to remember or imagine different aspects of the (post)consumption experience, mainly on wanting of food in general and in subsequent choice of different categories of foods (vice or virtue). Findings so far seem to suggest that making people focus on the consummatory/sensory experience of eating leads to choices related to a more hedonic experience, whereas focusing on the consequences would drive healthier choices. This is not to say that the first type of simulation is always linked to pleasure and the latter to more negative feelings, but there seems to be a congruity in terms of psychological distance or goal activation, which warrants further attention. Clearly, also the valence of what we reminisce plays a role, as has been demonstrated in enjoyment of subsequent eating episodes and in the emotions that food-related images convey.

The biggest potential of instructed mental simulation would be to aid people with a less salient health goal, to decrease their temptation and preference toward unhealthier and highly hedonic products, and to “persuade” them to make healthier choices. Moreover, industry could benefit by evoking more outcome-related thoughts when a virtue product is in question. Mental simulation could be used to shift attentional focus, at convenience, toward more hedonic or utilitarian features. Thereby, greater understanding of the impact of mental simulation on anticipated consumption may prove fruitful in individual strategies to regulate temptation, as well as in the creation of more effective communication strategies of healthier food.

Abstract

Understanding food and beverage preferences is important given the role that likes and dislikes play in our choices and, ultimately, in our health. While both genetic and environmental influences are important determinants of preferences, in this chapter, emphasis is given to the different processes that encourage and maintain preferences, commencing prior to birth and into adulthood. In particular, various forms of learning, including exposure, evaluative, and nutrient conditioning, are crucial, while culture provides the necessary specifics in terms of the actual foods that we learn to like. In turn, the learning processes and cultural influences are modified by our individual characteristics, including genetics and dimensions of our personality.

Introduction

Food and beverage preferences, like many complex human behaviors, result from the interaction of genetics and environmental influences. In turn, the environmental effects are mediated by learning processes that have evolved to deliver hedonic states that motivate us to select and consume some foods over others (Prescott 2012). While acknowledging that culture is overwhelmingly important in determining which foods are consumed, and therefore preferred, an account of cultural differences is not the aim of this chapter. Rather, the discussion will focus on the mechanisms that underlie the development of food preferences generally, irrespective of culture or demographic factors. For the same reason, short-term influences on food likes and dislikes, including such phenomena as sensory-specific satiety, alliesthesia, and the effects of actual or anticipated satiation or satiety, will also not be considered.

Innate Influences

Genetics

While exposure and learning are probably most influential in determining food preference, there is, nonetheless, good evidence for strong genetic influences on the foods we choose. Studies of monozygotic and dizygotic twins have shown heritability for specific foods, with the degree of heritability differing according to the category of foods (Falciglia and Norton 1994). Heritability appears to be strongest for proteins and smallest for desserts, and for fruit and vegetables, moderate–strong degrees of heritability are seen. In a series of studies of Finnish twin populations (see, for example, (Keskitalo et al. 2008; Tornwall et al. 2012) heritable components have been observed for preferences for a variety of the sensory qualities of foods, including astringency, sourness, oral pungency, and for “healthy” foods, high-fat foods, sweet foods, and meats.

What actually is being inherited? Some genetic influences on food preferences may arise from variations in perception. The most studied genetic variation in taste perception has been that underlying the bitterness of two thiourea compounds, phenylthiocarbamide (PTC) and 6-n-propylthiouracil (PROP), the taste of which is linked to polymorphisms in the bitter receptor gene, *TAS2R38* (Bufe et al. 2005). This gene and its associated phenotypic variations are of interest because of the fact that PROP/PTC sensitivity has been used as an index of sensitivity to other food qualities including tastes, oral pungency and tactile qualities (Prescott et al. 2004), as well as to specific food preferences and intake (Duffy et al. 2010). Therefore, some of the variations in heritability found in twin studies may reflect genetic variations such as these, and in particular for those foods that are bitter. Genetic variations in taste sensitivity may not only explain person-to-person differences in food likes, but they could also be responsible for some observed sex differences in food preferences, since being highly sensitive to PROP bitterness is more common among women than men.

Although PROP sensitivity has been extensively studied, it is not unique, in that other physiological/anatomical variations may have an impact on food preferences. We vary, for example, in the density of structures that contain taste buds, fungiform papillae (FP), on the tongue. Groups varying in FP density show differences in the sensory properties of, and preference for black coffee and in their addition of sugar to coffee (Masi et al. 2015). Vegetable preferences, too, have been linked to higher FP density, particularly in those individuals who were less sensitive to the bitterness of PROP (Duffy et al. 2010). Furthermore, nontasters with more papillae reported greater vegetable consumption than nontasters with fewer papillae, suggesting that when bitterness does not predominate, more papillae enhance vegetable liking.

Personality

The role of personality variables in determining the perception and preference of foods and their sensory qualities has received increased scrutiny in recent years. In particular, the trait of food neophobia (FN) is an important contributor to food preferences (Jaeger et al. 2017) and shows substantial heritability (Cooke et al. 2007), and thus may contribute to genetic influences on food preferences. Although FN was initially conceptualized only as a reluctance to consume unfamiliar foods, it has global impacts on food preferences, with higher FN being associated with reduced dietary variety, specifically in higher numbers of foods that have never been tried and the lower of number of foods liked overall. Highly neophobic children show reduced preferences for, and lower intakes of, vegetables and fruits in terms of both variety and amounts and reduced consumption of protein foods. FN persists into adulthood in a substantial proportion of the population, and increasing neophobia in adults, as with children, is associated with reduced acceptability and intake of vegetables, fruits and protein foods, as well as in higher numbers of disliked foods overall, even extending to reduced preferences for, and consumption of, familiar foods. The inherited factor in FN is uncertain but may be a tendency to experience high arousal in response to both unfamiliar foods and intense food flavors (Laureati et al. 2018). A number of other personality factors with strong heritability, including *disgust sensitivity* and *sensation-seeking*, are also linked to food choices, but it is probably premature to conclude just how important many of these are as independent determinants of food *preferences*.

Taste Preferences

The most ubiquitous preferences present at birth are those of the so-called basic tastes, in that we are born with established hedonic responses to sweetness, bitterness, sourness and umami (glutamate taste), while a preference for saltiness develops in the first few postnatal months. These fixed preferences are in contrast to our preferences for odors/flavors, which are molded by exposure and learning from an early age (see below). Taste preferences are reflected in distinct, and unambiguous, facial expressions to sweetness and bitterness that are present at birth in humans, monkeys, and rats and are essentially the same responses that we have as adults. Both in terms of willingness to ingest, and also in the quality of these characteristic facial expressions, sweetness is highly liked and bitterness rejected in human neonates (Desor et al. 1975). Sourness is also disliked, especially at high levels. Preference for glutamate (*umami* taste) is highly dependent on its context – in essence, it becomes highly liked when part of an overall flavor.

These stereotyped responses present at birth suggests that innate taste preferences are likely to have important roles in regulating the intake of nutrients and avoidance of toxins. Thus, the palatability of sweetness is thought to signal the presence of energy in the form of calories provided by sugars and other plant carbohydrates, which are crucial to survival. Saltiness signals the presence of the sodium ion (Na^+), crucial for maintaining the body's fluid balance. The strong dislike that we naturally have to bitterness is thought to be a protective mechanism: Many plants manufacture toxins as a defense against predators, and very many of these toxins are bitter. The significance of our dislike for high levels of sourness is not as clear-cut. It may be a signal for unripeness/spoilage in foods, or the fact that concentrated, and thus extremely sour, acids can cause tissue damage. The origins of umami preferences (like those of some other amino acids) are less clear, but may act to promote protein intake.

Sweetness remains preferred and is an important determinant of food preferences into adulthood, even though there is a general decline in the levels of sweetness preferred (Desor and Beauchamp 1987), and there is considerable person-to-person variation. A substantial proportion of adults still exhibit a "sweet tooth," but there are also large minorities who increasingly dislike sweetness as it becomes more and more intense, even if weaker levels remain liked. Studies of sweet liking have identified three to five groups that varying in their optimal sweetness level, at least in solutions and beverages (Kim et al. 2014). Indeed, in the case of both sweet solutions and foods, sweet liking, as distinct from our perception of sweetness, has been found to be partly heritable and may be linked to other genetic variations in bitterness sensitivity.

Exposure

It is clear that innate taste preferences undergo modification during the transition to adulthood and it may be the impact of differential exposure to taste qualities within the context of foods that produces subgroups based on taste preferences. In regard to other taste qualities, the aversion for bitterness present at birth remains, although adult bitter likers and dislikers, based on food preferences, have been identified. However, the initially aversive response to sour tastes is increasingly converted to a sour preference for some infants, over an initial timeframe of approximately the first 18 months, but increasing during infancy and into childhood. This is reflected in increasing acceptance and intake of sour-tasting foods.

Foods and Food Flavors

Flavor and food preferences vary as a function of many factors, including genetic status. However, the overwhelmingly largest influence on food preferences is exposure. At birth, each of us has already experienced some months of in utero exposure to food flavors through the common bloodstream of the mother and fetus. In the second trimester, swallowing and sucking by the fetus can be detected, and immediately prior to birth the fetus is actively swallowing considerable amounts of amniotic fluid. This fluid contains not only minerals but also compounds that stimulate both taste and olfactory receptors. Moreover, the results of this exposure have been demonstrated in the flavor preferences of the infant at up to 2 years of age (Mennella et al. 2001).

The maturity of the olfactory and taste systems at birth allows feeding experiences to have an immediate impact in development of later preferences. The fact that breast milk is both sweet and high in glutamate (and hence presumably in umami taste) means that it is immediately preferred. At the same time, the infant is being exposed to a variety of flavors from the mother's diet that are expressed in her breast milk. The impact of this is evident through studies in which flavors (e.g., garlic; vanilla) introduced into the mother's diet increase the duration of breast-feeding by the infant. An important distinction between bottle-fed and breast-fed infants is the degree of exposure to flavors. The fact that bottle-fed infants experience a relatively uniform taste and flavor environment is likely to be important in the extent to which these infants will later accept novel foods into their diet. In other words, early experience of flavor variety is associated with later acceptance of variety in food experiences.

Studies on both young infants and children (typically, 4–8 years of age), using both ratings of liking and amount consumed, have seen increases in acceptance with repeated exposure to novel vegetables, fruits and cheeses (Wardle et al. 2003). In most cases, it seems that amount of change in liking is a positive function of the number of exposures. The impact of early exposure can be seen into childhood and adolescence, with significant links between preferences for foods at 2–3 years old and those following puberty (Nicklaus et al. 2004).

Cultural Transmission of Flavor Preferences

Exposure both in utero and postnatally via breast and bottle feeding provides the infant with a set of preferred flavors, and these preferences can be seen to persist into the child's consumption of solid foods. We would expect, therefore, that initially at least the child's flavor preferences would match those of their mother. But there are broader implications of this transmission of flavor preferences. When seen in a cultural context, what is transmitted from mother to child is a set of preferences that define the flavor principles of the culture in which they live.

The idea of flavor principles was introduced as a means of characterizing how cuisines differ from one another (Rozin and Rozin 1981). The principles consist of particular ingredients – meats, vegetables, herbs, spices – as well as food preparation and cooking methods that will distinguish the cuisine of one culture from that of another. The flavor principle of a cuisine also performs a utilitarian function in that it allows a cuisine to be flexible in its ingredients (for example, swapping one staple protein for another in the face of changing availability) without eliciting neophobic responses.

The potential variations to which infants may be exposed is vast, but it can be expected that these will reflect to a great extent the adult diet. Thus, a preponderance of sour or fermented or spicy flavors within a culture will be reproduced in the preferences of infants. Likewise, the absence of certain foods or flavors with a culture will mean that the infant fails to develop preferences for those qualities. The relatively passive process of flavor exposure is also augmented by more active interventions – for example, the gradual access to chilli provided to young infants in Mexico by their parents (Rozin 1990). Much of this latter type of social learning – essentially modeling on the behavior of parents and other significant adults – takes place at the later stage of development.

Establishing Preferred Sensory Qualities

As noted above, saltiness is hedonically neutral at birth, but a clear preference for salty water over plain water develops by about the sixth month postnatally. More generally, infants begin to learn the appropriate levels of tastants and the qualities of flavors for different foods and beverages. This same process can be shown to operate in determining or modifying adult food preferences as well. Reducing sugar in tea to coffee, or salt in foods, for health reasons is an example of the impact of exposure to initially disliked levels of tastant on the development of a liking for that reduced level. Such effects have been shown experimentally with exposure to salt-reduced versions of foods (Methven et al. 2012). Similar effects can be seen with long term reductions in overall dietary sodium, which have been shown to reduce the optimal level of saltiness for multiple foods (Bertino et al. 1986).

Repeated exposure provides a context for a wide range of the sensory properties of foods, and can explain why there are variations in preferences across cultures even when the foods themselves are very similar. Expectations that a beverage will be served at a particular temperature, for example, reflects only one's prior experience with that beverage, and can be altered by repeated exposure to a new version served at a different temperature (Zellner et al. 1988). Similarly, a product's color will be seen as appropriate or not depending on prior experience. We also learn that a particular texture belongs with a particular food: There is nothing intrinsically likeable about *crunchy*, *mushy* or *flaky* as food qualities. Food textures are highly dependent on preparation techniques and meal context. In turn, these vary by food, a fact that is specified within each culture's cuisine.

Violating these expectations can be a potent source of food rejections. A study of a savory, smoked-salmon-flavored "ice cream/mousse" showed that its acceptance or rejection largely depended on the researchers' manipulation of the context. Telling participants in the study that they were consuming smoked salmon "ice cream" provoked considerable dislike for the dish, whereas it was much more acceptable when labeled as cold smoked salmon mousse (Yeomans et al. 2008a). The crucial difference here is that the information provides a way of interpreting what is being eaten as either consistent with what we expect (that a mousse can be savory) or not (that ice cream does not come in fish flavors) – based on prior exposure to multiple examples of both mousse and ice-cream.

Mechanisms of Exposure

Sections "Associative Learning" and "Post-Ingestive Learning" (below) discuss various mechanisms for producing changes in liking that occur through pairing with valenced (liked/disliked) stimuli or with the metabolic consequences of food ingestion (see also Fig. 1). In these cases, simple, repeated exposure to a food or flavor is a necessary precondition to facilitate learning. But, as in cases outlined above, it is sometimes sufficient to increase liking without additional processes. In fact, the idea that exposure to a stimulus alone can increases liking for that stimulus seems to be a general phenomenon, observed with a broad range of visual and other sensory stimuli (Bornstein 1989). Foods and food flavors are special stimuli because of their biological significance and their potential to be toxic. As such, exposure, may have unique effects. As noted earlier in the discussion of food neophobia, food novelty may be a source of unpleasant high arousal because it implies unpredictability in terms of its suitability as food. Conversely, repeated exposure (without negative consequences) is known to reduce arousal and is consequently rewarding. The impact of exposure on arousal in the context of foods is not primarily about conversion of disliked to liked stimuli. Rather, it can be seen as a means of dealing with novelty as a signal of unpredictability of flavor. If the flavor of a food might be unusual, and thus not previously tried, it can therefore be potentially dangerous, and it is this unpredictability that is the source of the arousal.

External signals of safety also encourage food trial, even among those that are highly neophobic. These signals include "models," for example, peers or an adult modeling consumption of novel food or information about the food's flavor, or linking the unfamiliar food with a familiar and liked food or ingredient such as a

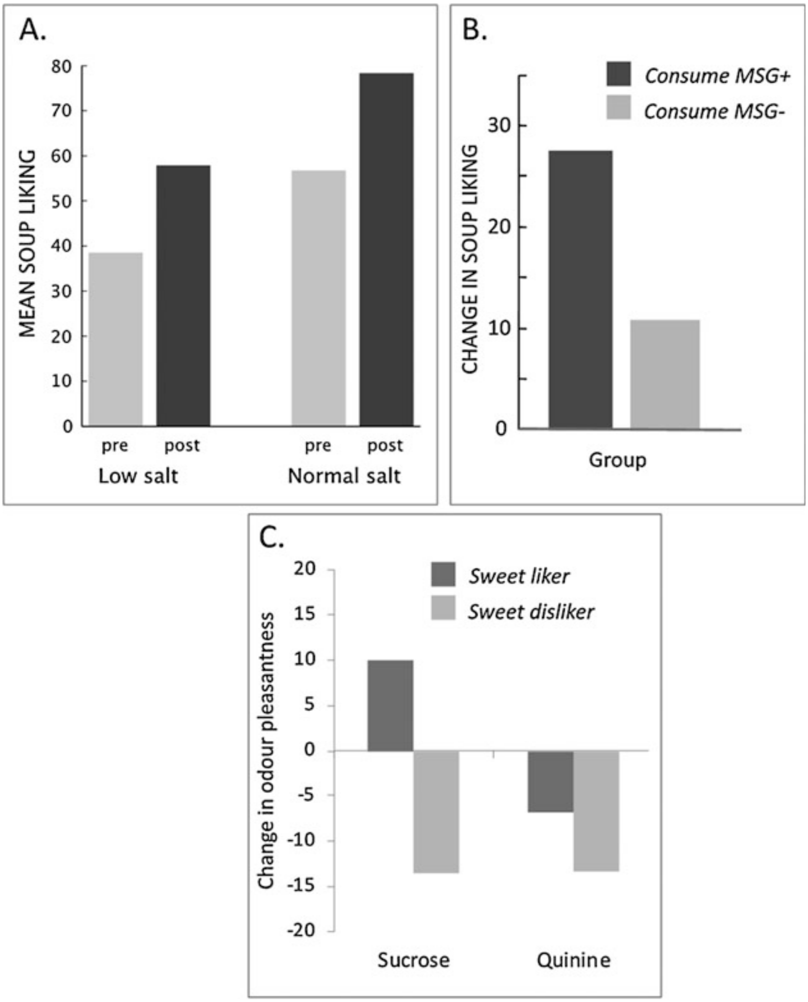

Fig. 1 Examples of changes in liking for flavors and odors via different learning processes. (**a**) Effects of **exposure** shown in changes in mean liking ratings prior to (pre) and following (post) repeated exposure to the taste (no consumption) of a soup flavor at either low or regular salt levels. (Data adapted from Methven et al. (2012)). (**b**) Effects of **post-ingestive (flavor–nutrient) learning** shown by changes (pre- to post-exposure) in liking for the flavor of a novel soup consumed while hungry either with (MSG+) or without (MSG-) added monosodium glutamate (MSG). (Data adapted from Prescott, J. (2004) Effects of added glutamate on liking for novel food flavors. *Appetite*, 42 (2), 143–150). (**c**) Effects of **evaluative (flavor–flavor) learning** showing through changes (pre- to post-exposure) in liking for novel odors that have been repeatedly tasted with either sucrose or quinine in solution. Data are shown for both sweet likers and sweet dislikers, illustrating the importance of the individual differences in the hedonic value of the taste to changes in liking. (Data adapted from Yeomans, M.R. and Prescott, J. (2016) Smelling the goodness: sniffing as a behavioral measure of learned odor hedonics. *Journal of Experimental Psychology: Animal Learning and Cognition,* 42(4), 391–400)

condiment or a sauce. In the latter case, the familiar item will be strongly influenced by culture. In fact, we can see this process as one in which consumption of a novel food is encouraged by the use of a “flavor principle” (see section “Cultural Transmission of Flavor Preferences”).

Associative Learning

Bitterness as a quality per se remains largely unpalatable into adulthood. Yet, at the same time, we willingly consume bitterness, at least in the context of other flavors such as coffee and beer. However, the fact that we typically experience bitterness in the context of other more liked qualities such as sweetness raises the question of how much this pairing is responsible for the development of liking for bitter foods and beverages.

Evaluative Conditioning

It is thought that repeated pairing of something that has valence – that is, is liked or disliked – with something that is novel (or disliked) will typically produce a change in the hedonic qualities of the latter. This type of learning, generally known as evaluative conditioning, is similar in procedure to classical (Pavlovian) conditioning, except that we are learning likes and dislikes rather than that one stimulus (a bell, for example) predicts the occurrence of another (the presentation of food). Evaluative conditioning has been shown with stimuli from a variety of sensory modalities, including visual, auditory and olfactory stimuli (De Houwer et al. 2001).

These same processes are at work during the development of food preferences, and evaluative conditioning commonly begins prior to consumption via a product’s image or through awareness generated by advertising. Advertisers typically embed the images of product presentation and/or consumption in a variety of what they judge are positive contexts that are being paired with the product. Marketers rise to the challenge of dealing with products that have aversive characteristics such as bitterness in beer through advertising that links preference for the taste for this bitter brew with the idea that it marks the drinker as having sophisticated tastes.

As well, brands and labels have an important role in that they can signal prestige or group membership or an important value for the consumer. Hence, foods with an organic label or labeled as “natural” or “healthy” can be evaluated as better tasting and promote increased consumption (Cavanagh and Forestell 2013). Many of these effects depend, though, on the consumer’s attitudes and values regarding that nutritional information. Those interested in health or nutrition may find added value in labels that signal such properties, but the same labels can also convey simultaneously a negative taste message since, for many consumers, “healthy” and “tasty” are perceived as incompatible.

The exposure to the product itself by eating or drinking is experienced in contexts, which can be social (dining with family or friends) or occur in pleasant environments, and in each case, the context can provide positive associations for food and drink flavors that encourage the development of preferences. In some cases, while a pleasurable context might produce liking for a food, the food becomes strongly linked only to that context. Hence, a familiar food or meal will be enjoyed more if it is eaten in an environment that is highly regarded, such as a restaurant, than if the same meal is consumed in a student cafeteria (Edwards et al. 2003). This is probably the reason why restaurant evaluations often emphasize the "atmosphere" – which might include location, noise level, lighting, other diners, image, and so on.

Individual foods can also become part of the overall enjoyment of special occasions, as in popcorn at the cinema, and various, otherwise inedible, items at sporting events; while on vacation, a local wine or *aperitivo* becomes paired with a bustling taverna or trattoria on a warm summer evening. The key to forming such strong links between the event or context and the food or drink is the positive emotion that is experienced at the time. Indeed, evoking positive emotions and pairing these with foods can increase liking for those foods (Kuenzel et al. 2010). We can understand the almost universal liking – particularly at times of stress – for comfort food, food that is not only familiar but part of our childhood and culture and that reminds us of "home."

The sources of positive associations for foods can include role models. For example, children who repeatedly watch their peers at school consume a food that they do not particularly like become more likely to select that food if given an opportunity (Birch 1980). It is possible in such cases both that the child is learning that a food is safe to consume (and hence can be regarded as an exposure effect) and that the liking that they have for their friends is being "transferred" to the food and thus an example of evaluative conditioning. Certainly, in some studies of observational learning, others' facial expressions – acting as cues to the acceptability of the flavor – have been shown to influence liking for a novel drink, suggesting that signals for safely are being assessed. Models showing dislike appears to be particularly effective, probably because such negative facial expressions are less ambiguous (Baeyens et al. 1996).

Flavor–Flavor Conditioning

The presence of innate responses to taste – both acceptance and rejection – provides a means by which we can develop hedonic responses to the vast range of foods that are available to us as omnivores. Food flavors are unique primarily because of their odor volatiles, and while exposure alone will generate preferences for odors, in the context of foods, these odors are always paired with tastes that are already pleasant or unpleasant. The impact of such pairing was first demonstrated in humans in a study in which novel tea flavors were mixed with sweetened or unsweetened water (Zellner et al. 1983). Following repeated pairing, the participants revealed a clear preference for the flavors previously paired with sugar – an effect that was over and above any increase attributable to simple exposure to the flavors. Flavor dislikes can be formed using exactly the same mechanism, by pairing a flavor with a disliked taste, typically bitterness. In practice, though, the impact of bitterness in foods on preferences is likely to be offset by other mechanisms such as post-ingestive effects (see section "Post-Ingestive Learning").

The natural history of the development of preferences for initially aversive flavors provide indications that we tend to instinctively employ such "flavor–flavor" conditioning to establish liking. Thus, sweeter beers such as lager are often drunk prior to developing a taste for ales and more bitter beers. Similarly, novice wine drinkers tend to favor sweeter wines, probably because initially unpleasant qualities like sourness and astringency are less prominent, and the subsequent development of a preference for wine flavors is supported by this pairing with sweetness. Paradoxically, this leads to the development of a liking for the flavor of wines that are dryer, less sweet and less fruity as the wine flavor itself, and not just its sweetness, becomes preferred. Coffee, in contrast, is commonly adulterated. Adding cream or milk, plus sugar, a common combination for novice drinkers, not only reduces the bitterness, but also provides the necessary positive tastes to produce liking for coffee flavor itself. This is why, even if you drink your coffee white and sweetened, the smell of black coffee brewing is so appealing. This also explains why the transition in coffee drinking is overwhelmingly from sweetened coffee to unsweetened coffee, rather than vice versa. There are indications, too, that evaluative conditioning processes are also sometimes understood and consciously applied to influence the preference of others. Favored methods for promoting food likes in children included demonstrating that target foods are liked by the parents, as well as involving the child in the (presumably) enjoyable activity of food preparation. Some part of this may reflect the fact that adult attention is generally positive for children, and has been shown, in itself, to promote liking for unfamiliar foods with which it is paired.

Evaluative Conditioning Processes

How exactly does the increased like or dislike become attached to the novel/neutral stimulus? The mechanism behind evaluative conditioning is still a matter of debate (De Houwer et al. 2001). Perhaps the most widely accepted model suggests that in pairing the already-valenced stimulus with one that is neither especially liked nor disliked, we are in fact encoding a compound stimulus of both stimuli in memory; in a food, this would be equivalent to the taste + odor/flavor. What is important in such a model is that each odor occurs together with a specific pleasant/unpleasant taste (strawberry + sweet) very frequently and with other tastes (strawberry + bitter) very infrequently. Subsequent to the pairings, it is this compound – which contains a liked or disliked element – that is liked or disliked.

Evaluative conditioning may explain how many of our food preferences develop without any apparent effort or conscious awareness, and indeed why they are long-lasting. It is thought that evaluative conditioning does not require an individual to be conscious of the pairing between the two stimuli – which explains how it is possible for an infant's early experience of vanilla in milk to manifest as a preference as adults for tomato sauce containing trace amounts of this same flavor (Haller et al. 1999).

A key to the effectiveness of evaluative conditioning in foods is that the taste with which the flavor is paired is perceived as positive or negative. However, as discussed in sections "Genetics" and "Taste Preferences" above, there are differences between individuals both in the intensity of tastes, particularly bitterness, and also in the extent to which sweetness is liked. Hence, whether or not a change in liking for a flavor occurs will depend upon an individual's characteristics. It can therefore mean that liking for an odor paired with sweetness, for example, will not occur (or occur to a lesser extent) in those who are "sweet-dislikers." For the same reasons, insensitivity to bitterness will undermine any conditioning that might occur in pairing a bitter taste and a flavor (Yeomans et al. 2009).

Reinforcement

It is easy to view the pairing a pleasant stimulus with a neutral stimulus, in order to change preference for the latter, in terms of the pleasant stimulus acting as some sort of reinforcement or reward that promotes liking for the neutral stimulus. However, in theoretical terms, associative learning and reinforcement learning are quite distinct. More specifically, reinforcement is used to increase (or decrease) the likelihood of a behavior. Its relevance to food preferences lies in its use to encourage consumption of (and, ultimately, preference for) particular foods, thereby allowing simple exposure to increase liking.

The general consensus of the use of rewards (positive reinforcement) to encourage food consumption is that it is relatively ineffective, or at least not as effective as other approaches such as simple repeated exposure (Wardle et al. 2003). In fact, studies have concluded that positive reinforcement using praise, access to preferred activities, rewards such as movie tickets, or negative reinforcement using parental pressure may actually be counterproductive, reducing preference for the food or beverage with which they are paired. One implication of this conclusion is that using one food as a reward (e.g., ice cream) to increase consumption of another – a green vegetable that the adult wants the child to eat, for example – is also likely to fail, mainly because the relative value of the foods soon becomes apparent. This may be due, too, to the *overjustification effect*, in which an activity undertaken because of the promise of a reward is actually valued less than if it were undertaken for its own sake – that is, where the reward comes from enjoyment of the activity itself.

In other specific cases, reinforcement may influence food preferences. Thus, negative reinforcement – the failure to experience something unpleasant – has been invoked to explain the preference for chilli, despite its often painful burn, as an exemplar of "benign masochism" (Rozin and Schiller 1980). One theoretical view of positive reinforcers is that they are valued precisely because access to them is restricted. This *response deprivation hypothesis* appears to be borne out in studies of children's food preferences, in which restricting access to a food increases preferences for it when compared to other initially equally liked foods that were more easily available (Fisher and Birch 1999). The implications of such findings for preferences for high sugar, high fat foods that the parent may wish to restrict are obvious.

Post-Ingestive Learning

The innate preferences for basic taste qualities – in particular, sweetness and bitterness – and the early emergence of sodium preference are typically interpreted in terms of the nutritional significance of these taste qualities. During development, however, we come into contact with a substantial repertoire of foods that, irrespective of the taste qualities present, will vary in terms of their nutritional consequences. In addition, metabolic needs vary considerable over the short and long term, and survival requires responsiveness to such changing needs. To achieve this, largely automatic processes link food flavors with their metabolic consequences, a process known as post-ingestive conditioning or, alternatively, flavor–nutrient learning.

Signals for Energy and Other Metabolically Useful Nutrients

In a very general sense, our body's needs can regulate the development of food preferences by pairing flavors with the consequences of eating, most obviously relief from hunger (satiation) or from thirst. In addition, though, there are specific nutrients that are effective in promoting flavor preferences. The ability of a sweet taste to produce liking for an odor with which it is paired in a flavor relies on the fact that sweetness is very commonly a signal for the energy value of a carbohydrate. However, this learning is considerably enhanced when our experience of the flavor is followed immediately by the *actual* energy – that is, once the food is consumed. Such flavor-nutrient learning appears to be a universal mechanism of food preference development since few, if any, foods contain no nutrients of potential value to the body. But, from a survival perspective, the body values nutrients that supply such energy and the mechanism for promoting consumption if energy is the development of preference for associated flavors.

In animal studies, where more direct demonstrations are possible, carbohydrates, fats, starches, and proteins introduced directly into the stomach increase liking for flavors that the animal had just experienced (Sclafani 1997). In studies with humans, these same nutrients all promote flavor liking. The effects of energy consumption of carbohydrates can be shown to be an additional influence on flavor preference beyond pairing with the liked sweet taste. This is achieved by comparing changes in liking for a novel food/flavor that contains an energy-containing sweetener such as sucrose, with the food/flavor when it is tasted but not consumed, or when it is consumed but contains a sweetener such as aspartame, which is sweet but provides no calories. Such studies do indicate that consuming a valued nutrient provides a stronger or quicker increase in liking than pairing with a liked taste alone (Yeomans et al. 2008c). The difference is essentially between a taste that is *usually* a reliable signal for calories to come versus the presence of the calories themselves. Importantly, too, flavor–nutrient learning is only really effective when the body values the calories, such as when we are hungry (Mobini et al. 2007).

Fat is an even more dense form of energy than sugar, and it is therefore unsurprising that, at least in Western countries, some of our strongest preferences are for foods – chocolate, desserts, cakes – that are high in both fat and sugar. These foods are extremely palatable precisely for the reason that the body places such a high value on concentrated energy sources. Any flavor paired with fat becomes an important signal for calories to come, and this is reflected in increased liking for that flavor (Johnson et al. 1991). In the same way, we can explain why pairing with a number of other sources of energy (the alcohol in beer and wine) and other positive benefits (alertness due to caffeine in coffee) can result in liked flavors (Mobini et al. 2005). The worldwide affection for these beverages reflects not only the processes of evaluative conditioning through pairing with liked sweet tastes, but learning about their physiological consequences following consumption as well, and it is probably this last effect which allows us to develop liking despite the presence of significant bitterness in many popular beverages.

Novel flavors repeatedly combined with glutamate (the prototypical *umami* taste) also become similarly liked, although the metabolic benefits are less obvious than with sugars or fats. Unlike the taste of sweet carbohydrates, glutamate by itself is not an inherently pleasant taste. But adding glutamate to suitable meat- or vegetable-based savory foods – soups, stews, pasta, and other sauces – makes them richer and *fuller* tasting, and much more liked than those without added glutamate. Unlike salt or the energy that is signaled by sweet or fat tastes, we do not need to take in glutamate in the diet to survive, so it is unclear why glutamate promotes flavor preferences. It has been suggested that because glutamic acid is an amino acid present in animal and vegetable protein, umami taste may act as a signal for the presence of protein, with its effects on palatability therefore promoting consumption. Hence, people with very low protein intakes prefer higher concentrations of glutamate than those whose protein intake is adequate (Vazquez et al. 1982), although glutamate can also increase food palatability irrespective of the taster's nutritional state.

Wanting

An important distinction that is gaining traction in efforts to understand food choices is between *liking* and *wanting* (Havermans 2011). Although it is clear that foods that we want to consume are most often liked, and vice versa, there are times when wanting might be influential independently of whether or not a food is liked. In particular, the idea of wanting involves the central idea of motivation. One obvious example would be that, if we were exceptionally hungry, we might be strongly motivated to eat foods that were unpalatable. Conversely, chocolate is typically consumed in relatively small amounts even though it is consistently rated as many people's most liked food.

Typically, wanting can be shown to be modulated by degree of hunger, and it can be distinguished most easily from liking by determining desire to consume or actual amounts consumed. Recent studies have supported the importance of post-ingestive conditioning in the development of wanting. Thus, repeatedly pairing food flavors with MSG within a soup was shown to increase subsequent ad libitum soup intake, while the taste of a soup previously MSG-paired also increased ratings of hunger, suggesting increased motivation to consume the soup (Yeomans et al. 2008b). Another conditioning study has demonstrated changes in wanting in hungry elderly participants, as reflected in increased intake, in the absence of changes in liking, for novel flavored soups repeatedly paired with added MSG (Dermiki et al. 2015) possibly because the MSG added soups were unpalatably salty.

Preferences Based on Correcting Nutrient Deficiencies

The fact that nutrient conditioning using calories is effective primarily during hunger suggests that specific nutrient deficiencies may also provide opportunities for flavor conditioning to occur. However, the evidence for this comes primarily from animal studies. There is one exception, namely, the human appetite for salt, which far exceeds what is physiologically necessary, suggesting that salt intake in driven by taste. Sodium depletion can be an immediate threat to health and there is ample evidence from humans and other animals that saltiness is both highly palatable and highly sought after in such circumstances (Beauchamp et al. 1990). This effect has also been seen in humans following sodium depletion due to perspiration following vigorous exercise (Wald and Leshem 2003), with greater flavor conditioning for a novel drink being evident in those showing the greatest sodium loss, as reflected in higher levels of perspiration.

Learned Aversions to Flavors

The most dramatic example of post-ingestive learning involving odors or flavors is the development of "taste" aversions that follow pairing of a flavor and subsequent nausea (Garcia et al. 1985), a pairing that can result from incidentally occurring illness, and chemotherapy-induced or motion-induced nausea. Studies on population samples in the USA have suggested that at least 40% of the population will develop a learned aversion to one or more flavors during their life. Such aversions are not merely dislikes but rather a viscerally unpleasant reaction to a food that may have been liked previously. Meats and fish, particularly in a main course meal context, are particularly vulnerable to aversions, while intermediate rates are found for vegetables, desserts, and alcohol, with potatoes, bread, and rice all showing low rates.

This classic form of taste aversion learning seems to be an automatic process that typically occurs following a single nausea plus flavor pairing, and it also tends to be very long-lasting. Being aware that the nausea/illness was produced by, say, a bout of influenza rather than by the consequences of the food associated with that flavor, has no impact on the development of this type of aversion. But humans also experience taste aversions that are essentially cognitive in nature, that is, involving associations between foods and either feelings of disgust or negative information about the food (Batsell and Brown 1998). For some, reactions to certain foods are clearly sufficiently potent to produce an aversion without the food having been consumed or even without direct contact with those foods. In such cases, modeling others' reactions to foods or being emotionally upset by some aspect of a food are involved. Estimated at around 20% of all human aversions, cognitive aversions are thought to be even longer-lasting than traditional, nausea-based aversions. Another major difference between cognitive and nausea-based aversions is that, for most of us, nausea will reliably induce an aversion to a recently experienced flavor. In contrast, a characteristic of cognitively mediated aversions is that the same experience of a food can be disgusting to one person and not to another. For example, aversions have been linked to instances of "moral vegetarianism," in which the idea of killing animals is so unpleasant that the flavor or even odor of meat can become highly unpleasant.

Relative to the numbers of different foods that we eat, taste aversions are rare. The vast majority of foods or meals are not followed by illness, and those with aversions typically have them for a single food. One group that is severely affected by taste aversions is patients undergoing treatment for cancer. Severe nausea is often a consequence of chemotherapy treatments and, as a result, aversions to foods eaten prior to treatment sessions are common, particularly in children. Even in adults, it has been estimated that as many as 50% of those receiving chemotherapy will develop an aversion to one or more foods.

Other sources of learned dislikes have also been reported, and they reflect flavors acting as signals for bodily needs. Regular caffeine consumers repeatedly exposed to a novel non-caffeinated drink when caffeine-deprived develop a dislike for that flavor, although this is not evident when these individuals are not caffeine-deprived (Yeomans et al. 2002). Flavors that have been paired with exercise also become disliked relative a control flavors, an effect that appears unrelated to any discomfort produced by the exercise (Havermans et al. 2009). Instead, this appears to be due, not to gastrointestinal upset, but rather to the net loss of energy (calories) that physical activity produces. It is thought that the body may be seeking to protect itself by avoiding any signals – in this case, flavors – that might predict such energy loss. It is not clear, in either of these cases, whether such effects are commonplace or a major influence on food preferences.

Conclusion: Do Learned Likes and Dislikes Last?

Food preferences can, of course, change, but research on learned likes and dislikes suggests that, once acquired, preferences typically persist in the absence of active intervention. Data for the impact of exposure over time are scarce, but the demonstration that the effects of the addition of a vanilla flavor to infant formula can influence responses to vanilla in foods decades later (Haller et al. 1999) suggests the potential for exposure effects to be effectively permanent. Unlike classically conditioned responses, preferences formed by evaluative conditioning do not appear to extinguish. That is, they does not decrease once the pairing is no longer in place (Baeyens et al. 1988). For example, an odor paired with a sweet taste will become liked, but once this has occurred, further links to the sweetness seem to be unnecessary for the odor preference to be maintained. With coffee, for example, the initial pairing of the flavor with a sweet taste has the effect of producing a permanent liking for the flavor, with or without added sweetness. So, while foods may fall out of favor for various reasons, foods that we have learned to like tend to stay that way, as do those we have learned to dislike, unless there is some strong additional association operating in the other direction. The important caveat is that data for estimating the impact of evaluative conditioning exist only for the short to medium (months) term.

Dislikes formed by taste aversions are notable for their longevity, but there is at least anecdotal evidence that they can be overcome with sufficient motivation and effort. It can be assumed that the effects of post-ingestive conditioning of preferences are also persistent, although one study does suggest that liking can be adversely affected with repeated exposure to a familiar and liked food whose energy content has been reduced (O'Sullivan et al. 2010). Whether this reflects a reversal of post-ingestive conditioning (that is, extinction) or an acquired dislike based on an energy reduction is unclear, and may be of little practical importance, given its implications for the impact of foods formulated for energy reduction diets.

Normal Eating

Contents

Abstract

We present a theory of normal eating, based on three fundamental elements: hunger, palatability, and norms of appropriateness. These three elements can account for food intake and choice, although not all three elements are equally important and they vary in terms of their importance in different situations. We suggest that various factors that are regarded as influential in food intake and choice (e.g., dieting, emotional arousal) may be understood in terms of our three basic elements.

In this chapter, we present a theory of normal eating. There has been surprisingly little formal or theoretical attention paid to normal eating, perhaps because researchers (and people in general) assume that everyone already knows what normal eating is and how it works. A "negative" approach to the understanding of normal eating is evident in discussions of eating disorders, which are often seen as pathologies of normal eating but without specifying what normal eating

is other than the default condition from which the pathologies deviate (Herman and Polivy 1996). Researchers and people in general – when asked to explain why people (and they themselves) eat the way they do, why they choose (or reject) particular foods to eat, and why they eat as much (or as little) as they do on a given occasion – tend to fall back on two explanations, hunger and palatability (Vartanian et al. 2008). These explanations are taken for granted and rarely explored, because they are assumed to be self-evident. When given a choice of foods to eat, people (believe that they) choose the foods that they find most palatable. If given a choice among equally palatable foods, people may explain their choice in terms of hunger: a hungry person will often select the food that is higher in calories or at least perceived to be more satiating. In the absence of choice of food, people will typically explain why they ate a lot of the available food by claiming that they were particularly hungry or that the food was particularly palatable. Reduced intake is conversely attributed to low palatability or an absence of hunger (Vartanian et al. 2017).

We have recently outlined a theory of normal eating (Herman 2013; Herman et al. in press) in an attempt to provide a positive and comprehensive analysis of why people eat the way they do. This theory is not derived from the absence of disordered eating. It likewise does not assume that "everyone" already knows what normal eating is. Rather, it starts with the basic elements of normal eating and describes how they are related to each other and how they operate in particular eating situations. This theory is not self-evident. We hope to draw attention to aspects of eating that are generally taken for granted or overlooked altogether.

Normal Eating

We propose that there are three principal factors that govern normal eating: hunger, palatability, and norms of appropriateness. These three factors all have an impact on normal eating, but they are not equally powerful. Once we have described these three factors, we shall elaborate on them by postulating how they operate conjointly. For the record, we define normal eating as how people in modern societies eat when there is sufficient, culturally acceptable, and at least minimally palatable food. We acknowledge that many people in the world do not have the luxury of engaging in normal eating.

Hunger

Hunger is experienced subjectively as a desire to eat, sometimes with accompanying symptoms such as stomach pangs or light-headedness. This desire presumably reflects an underlying biological need for food. The intimate connection between the need for food and the desire, pursuit, and consumption of food is thought to reflect the "wisdom of the body," (Cannon 1932) which has evolved to detect an energy deficit and to remedy that deficit. Historically, most research on hunger and eating has been conducted on animals who cannot report on their internal states – not that humans are particularly adept at reporting on their internal states. In the case of rats, for instance, researchers have tended to beg the question of the connection between hunger and eating: if the rat eats, it is assumed to be hungry. Correspondingly, if it doesn't eat, or stops eating, the rat is assumed to be not hungry, or sated. This tautological connection between hunger and eating quickly falls apart upon inspection. First, we can all think of times when we were hungry and nevertheless did not eat. This disconnect between hunger and eating may arise because, even though the individual feels hungry, the available food is unpalatable or perhaps the individual is on a diet or perhaps no one else in the group is eating and so the individual feels awkward giving in to her hunger or perhaps the individual is so focused on some event or activity that she doesn't attend to her hunger sensations. By the same token, there are situations in which people continue to eat despite feeling sated – perhaps because the food is simply irresistible or because of social pressure to eat.

Hunger as perceived or reported at the beginning of an eating episode is often not a good predictor of how much food will be consumed (see ▶ Chap. 6, "Food Intake and Physiological Regulation: The Means and the End" by Bellisle in this volume). If hunger or food deprivation is the only variable involved, then there is a reasonable correspondence between hunger/deprivation and intake (Kissileff and Thornton 1982), although Le Magnen (1971) suggests that hunger may be more evident in terms of latency to eat than in terms of amount eaten. Moreover, hunger/deprivation is rarely the only factor involved, and the effect of hunger on food intake is often overridden by other factors (in particular, palatability and norms of appropriateness), with the result that more often than not hunger/deprivation is ultimately only weakly reflected in the actual amount of food consumed.

Weingarten (1985) distinguishes between depletion-based hunger, which is how we normally think about hunger, and externally controlled hunger. He has demonstrated that rats will act as if they are hungry, eating additional food, if they encounter a stimulus (e.g., a visual or auditory cue) that has previously been paired with eating. Thus, you can make a sated rat start to eat even more if you provide an "eating cue." This situation certainly forces us to reconsider whether hunger as traditionally understood – arising from a true nutritional deficit – is always present when people (or rats) eat. Another example of eating that does not reflect hunger as we traditionally understand it is temporally conditioned hunger. We tend to become hungry as mealtime approaches. Of course, this could simply be equivalent to saying that we tend to become hungry as more time goes by since we last ate; in that case, the traditional depletion/repletion view of hunger would apply. But if for some reason – something comes up – you fail to eat at your normal mealtime, you may well find that your hunger, instead of continuing to grow, abates. Note also that "hunger is not at its daily peak upon awakening" (Mattes 2010, p. 24), even though the interval since the last meal is generally longer than just before lunch or dinner. And despite the lengthy interval since the last meal, breakfast is typically not the largest meal of the day. This phenomenon certainly defies the depletion view of hunger; it suggests instead that mealtime itself acts as an "eating cue," much like Weingarten's visual or auditory stimuli, and that once the cue is no longer there, cue-based hunger subsides.

There is some debate about whether most of us ever experience "true" hunger. Rogers and Brunstrom (2016) argue that whatever caloric deficits we experience over the course of hours or even days are insignificant compared to our basic energy stores. "Energy requirements meal-to-meal are trivial compared with total body energy stores, and energy supply to the body's tissues is maintained if a meal or even several meals are missed" (p. 465). It may be that only when we are truly deprived of food for days on end will we experience genuine hunger of the sort that drives the frantic food intake of starving people, food intake that proceeds irrespective of the palatability of the food and the behavior of other people. (Needless to say, it is virtually impossible to study such extreme food deprivation in the laboratory.) In any case, it is evident that hunger is not a simple matter and that we may need to develop a vocabulary that distinguishes between "true" hunger and the sort of everyday hunger that we experience most of the time. How everyday hunger drives eating remains a matter of debate. For now, suffice it to say that it may not be as unambiguously important a driver of eating as is usually assumed.

Palatability

Like hunger, palatability is generally acknowledged as a principal factor governing eating. Palatability refers to the extent to which the eater enjoys the sensory properties of the food. Palatability is often considered to be equivalent to taste, but it is a broader construct and also includes aspects of food enjoyment such as texture, temperature, and appearance. As with hunger, researchers often beg the question of how palatability affects food intake, especially when studying animals who cannot provide us with independent measures of those two constructs. If a rat eats a lot of a particular food, it is assumed that the rat finds it palatable. If it rejects the food, we may be tempted to infer that the food is unpalatable. Of course, in making these inferences, we often forget that we are prepared to make parallel inferences about hunger; so if a rat rejects a particular food, is it because the food is unpalatable or because the rat simply isn't hungry? It is possible to devise studies that separate these two influences on eating, but we are often careless about distinguishing them in real life. Thus, when we ask people why they ate so much, they are likely to cite hunger and/or palatability, more or less indiscriminately.

Palatability is more obviously in play when we present a rat or a human with two different foods and assess which one is chosen. In such a study, hunger (or at least food deprivation) can be held constant, allowing us to ascribe higher palatability to the more frequently chosen food. There are two qualifications here, however. First, we all acknowledge that one man's meat is another man's poison, so judgments of palatability are to a large extent idiosyncratic. Even though we can combine judgments over several raters to document that chocolate is generally more palatable than is broccoli, their relative palatability may be reversed for a handful of individuals, particularly if we are talking about humans. Also, we must acknowledge that the choice of chocolate versus broccoli may be driven by considerations other than palatability. Some people will select the broccoli, even though they prefer the taste and other properties of the chocolate; considerations of health or social appropriateness will sometimes lead people to select the less palatable option. For example, Sullivan et al. (2019) found that when presented with a choice between a food item that was tasty but not healthful versus an item that was healthful but not tasty, 78% of their sample chose the tasty-but-not-healthful item, but 22% chose the healthful-but-not-tasty item. The same considerations may lead people to behave "perversely" in terms of amount eaten, with health or appropriateness considerations leading them to eat less of their preferred food and more of their non-preferred food.

Just as hunger declines over the course of a meal, so does palatability. Rolls (2000) has studied "sensory-specific satiety," the phenomenon whereby an initially palatable food becomes less palatable over the course of the meal. This decline in palatability arises from repeated exposure to the same taste (and to some extent other sensory properties such as texture). This reduction in palatability acts as a brake on eating, whence it is referred to as "satiety," although it is acknowledged that the satiety here is largely metaphorical. The fact that true satiety has not developed is evident when the individual is offered food that differs dramatically in its sensory properties from the original food (Pliner et al. 1980). This "variety" induces a resumption of eating, which presumably would not occur if true satiety had been achieved.

We refer to the decline in the palatability of a particular food over the course of a meal as sensory-specific satiety. There is a similar decline in palatability when the same food is served repeatedly, meal after meal. This effect is referred to as monotony and can be reversed by providing distinctly different foods (see Remick et al. 2009 for a review).

People often cite palatability when explaining why they ate as much or as little as they did (Vartanian et al. 2017). We concur that palatability is an important driver of food intake and food choice. In the research literature, however, palatability is often neglected as a principal factor governing food intake for the simple reason that research participants are usually offered palatable food to eat. The role of palatability in food intake becomes evident only when it is manipulated over a large range of values; we can then observe that people eat more palatable food than unpalatable food. If palatability is held constant at a high level, as it often is in research studies, its importance in controlling eating will be masked (Pliner et al. 1990).

Norms of Appropriateness

The last – but by no means the least – driver of food intake and choice is norms of appropriateness. Norms of appropriateness are rarely cited by researchers or eaters themselves as important in the regulation of eating, but we maintain that they are very important, at least in humans. "Norms of appropriateness" refer to people's concerns about eating in a manner that is socially approved. People are social creatures, and they are sensitive to the judgments of others. They want to be seen as – and see themselves as – eating appropriately. When it comes to food choice, there are widely shared cultural norms about which foods are suitable for consumption, and people tend to feel some pressure to eat suitable foods. This pressure is strongest when the individual is eating in a group and everyone else has chosen to eat the "appropriate" food and to reject the "inappropriate" food. It takes a strong individual – someone who doesn't care what others think – to order a rich dessert for himself when everyone else at the table is ordering something "healthy" or not ordering dessert at all.

Insofar as culture affects eating, then, we suggest that it does so through the inculcation of norms of appropriateness. Cultural variations in eating – the particular foods that are eaten, how food is eaten, how much is eaten, and so on – are evident in the variations in norms of appropriateness from one culture (or subculture) to another.

Norms of appropriateness apply to food intake as well as to food choice. For instance, one powerful norm in our culture involves people's fear of being seen as having eaten excessively. People who eat excessively are judged negatively; they are viewed as less attractive, less intelligent, less moral, and generally less worthy as individuals (see Vartanian et al. 2007, for a review). Women who eat excessively are seen as less feminine (Chaiken and Pliner 1987). The only positive trait associated with excessive eating is "fun-loving."

Avoiding the imputation of eating excessively is thus an important consideration affecting how much people eat. The problem for the eater, however, is to figure out how much she can eat without eating excessively. Unless she is on a diet that specifies food intake for each eating occasion – and most people aren't on such a diet – it's not intuitively obvious how much one can "safely" eat. What happens is that people eating with co-eaters learn to observe the co-eaters' intake; and they use that intake as a measure of what is "allowed." If you eat no more than your co-eaters do, then you may avoid the imputation of eating excessively (Herman and Polivy 2008). Note the opportunity here for collusion by the group eaters, who may explicitly or tacitly agree to eat more food than they would normally eat. If they all go along, "permissible" food intake increases, with everyone enjoying the splurge. There are some complications in the group scenario, as when your co-eaters eat varying amounts, muddying the line beyond which eating becomes excessive; but these complications can generally be handled by our theory of normal eating – or at least studied.

It is worth noting that social norms are typically internalized, which means that the individual may be governed by these norms even when eating alone (Feeney et al. 2017). Thus, people judge themselves and are concerned to avoid eating excessively even when they are eating alone. In one research paradigm – what we call the "remote confederate" paradigm – the research participant eats alone but is provided with information about how much others have previously eaten in the same situation. This information is concocted by the researcher; there are no other “prior participants.” Participants are powerfully affected by this information (e.g., Feeney et al. 2011; Roth et al. 2001), even though there is no chance that these other people will be judging them. Of course, in this situation, as in most studies of food intake, research participants are led to believe that the researchers are not judging – or even measuring – their food intake.

The concern to avoid eating excessively represents only one social norm, albeit a norm that pervades the domain of food intake. Other norms that we might mention include:

- Politeness/consideration, as when we feel compelled to eat *more* than we might otherwise be inclined to and to eat foods that we might otherwise avoid, when we find ourselves in a situation in which our host enjoins us to “have another helping” or serves us something that we do not like. A variation on this normative pressure was documented by Exline et al. (2012), who found that at least some people eat more than they otherwise would simply in order to make their large-intake eating companions feel more comfortable.
- Regulatory balance, as when we believe that we ought to eat less if we have recently eaten a lot. Thus, if we mislead research participants into believing that what they recently ate was highly caloric, they will eat less in a subsequent eating situation (Wooley 1972). A variation on this theme is provided by Higgs (2008), who has demonstrated that if people are asked to recall their lunch today, they will eat less in a mid-afternoon snack than if they are not asked to recall their lunch today or are asked to recall their lunch yesterday.
- Portion size (see ▶ Chap. 34, “The Influence of Portion Size on Eating and Drinking” by Rolls, this Handbook). People eat more when served larger portions, and there is accumulating evidence that this effect is driven by the fact that people who are served larger portions consider larger portions to be “appropriate” (Herman et al. 2015; Robinson and Kersbergen 2018). This conclusion is reinforced by recent evidence that rats do not eat more when portion size is increased, suggesting that the effect in humans is mediated by higher cognitive processes (Naneix et al. 2019).
- Segmentation effects. People eat more when presented with one large item of food than when the same item is subdivided into segments. Kerameas et al. (2015) demonstrated that this effect is mediated by changes in the perceived appropriateness of eating a single larger (unsegmented) item versus several small (segmented) items.

Drivers and Inhibitors

We have identified hunger, palatability, and norms of appropriateness as elements governing food intake and choice. It should go without saying that these factors do not operate unopposed. Indeed, our description of norms of appropriateness has already included several examples of norms that inhibit eating: concern about eating excessively is basically an inhibitory factor, setting an upper limit on how much one may eat without making a negative impression on observers and even on oneself. Some norms of appropriateness may increase the likelihood of selecting a particular food (see ▶ Chap. 14, "Social Influences on Eating" by Higgs and Ruddock's in this volume) or the likelihood of eating more than one normally would (e.g., the politeness norm mentioned above), but norms of appropriateness more often act as inhibitors of eating; they allow a certain intake but no more. Hunger, of course, normally drives eating and has an "opposite," satiety, which terminates eating. Technically, satiety is not quite the opposite of hunger, either in terms of its basic nature or its parameters. For instance, hunger arises much more slowly as a function of time spent continuously not eating than satiety does as a function of time spent continuously eating. Still, for our purposes, we may say that whereas hunger promotes eating, satiety inhibits eating. Palatability, likewise, has its opposite. Unpalatable food suppresses eating. In research studies, the food is typically palatable, but occasionally researchers will explore the effects of unpalatable food (see Pliner et al. 1990, for a review). Of course, there is a continuum of palatability, ranging from highly palatable to highly unpalatable, and we all acknowledge that the palatability of a particular food may vary from individual to individual.

Relative Weight of the Three Factors

Of the three main drivers of eating, hunger is the weakest. This assertion is based not on people's reports – recall that people tend to identify hunger and palatability as the principal reasons for eating as much as they do – but on a more careful examination of the research literature. We ourselves, making the same assumptions that most people (and researchers) do, were relatively slow in coming to the realization that hunger is a weak influence. Several years ago, for instance, we outlined a "boundary model for the regulation of eating" (Herman and Polivy 1984). This model proposed that eaters, at any given moment, were either hungry, sated, or in a "zone of biological indifference," neither hungry nor sated. When in this zone of indifference, we argued, people's food intake is affected by all sorts of factors, including palatability and what we would now call norms of appropriateness. Moreover, we argued that most of us spend most of our time within that zone of indifference, so that our eating is affected by factors other than hunger/satiety. If, however, we allow ourselves to drift into a state of hunger (by eating too little or too late) or satiety (by eating too much or too soon), then these powerful biological conditions would take over and either (in the case of hunger) drive eating regardless of palatability or norms of appropriateness or (in the case of satiety) suppress further eating regardless of palatability or norms of appropriateness.

We conducted (and replicated) a study designed to demonstrate that sufficiently hungry people would eat even if the food is unpalatable (Kauffman et al. 1995). That prediction followed from our commonsense boundary model and had been articulated earlier by Jacobs and Sharma (1969). In the Kauffman et al. study, participants were deprived of food for up to 24 h and then given access to either a good-tasting milkshake or to a bad-tasting milkshake (the same milkshake but adulterated with bitter quinine). Across two versions of the study, hungry participants ate more of the good-tasting milkshake than did non-hungry participants, as expected; but contrary to common sense and contrary to our boundary model, hungry participants ate *less* of the bad-tasting milkshakes than did non-hungry participants. Jacobs and Sharma, who found the same thing in dogs, suggested that this "paradoxical" effect of hunger on intake of bad-tasting food may stem from bad-tasting food being potentially toxic and thus being particularly dangerous to those eating on an empty stomach. (Note that this effect does not require conscious awareness; people and dogs have evolved to reject bad-tasting food when they are hungry.) In any case, it is evident that when we examine the effect of hunger conjointly with the effect of palatability, the effect of palatability on intake dramatically overrides the effect of hunger. It is worth noting that in our study, people were food-deprived for 24 h, which is considerable but by no means comparable to what some people have endured under conditions of extreme starvation. We concede that truly starving people might be more enthusiastic about eating bad-tasting food, but 24 h worth of hunger is apparently not enough to increase intake of bad-tasting food in people who are otherwise not undernourished. In other words, hunger is not as powerful as is palatability in normal people.

Another set of two studies (Goldman et al. 1991) examined food intake in hungry and non-hungry people. In these studies, we did not manipulate the taste of the food; rather, we manipulated the food intake of an experimental confederate who ate alongside the naïve participant. The boundary model and common sense both predicted that the (large versus small) intake of the confederate would have an effect on the intake of the naïve participant, but if the naïve participant was hungry – again, up to 24 h without eating – then she ought to eat enthusiastically even if the confederate ate sparingly. What we found, however, was that the confederate's intake strongly influenced the naïve participant's intake, irrespective of the naïve participant's hunger level. A very hungry person eating with someone who eats sparingly will herself eat sparingly. Indeed, the impact of the confederate's intake was so strong that hunger/deprivation had virtually no impact whatsoever on intake. These studies demonstrate that norms of appropriateness – in this case, the example set by a confederate eating a lot or a little – powerfully influenced food intake, whereas up to 24 h of food deprivation had virtually no impact on eating. Again, hunger is not as powerful as are norms appropriateness in normal people.

These studies provide convincing evidence that hunger is not a powerful driver of normal eating, certainly not when compared directly to the influence of palatability or norms of appropriateness. We concur with Mattes (2010, p. 30), who concludes that "hunger and thirst are only weak predictors of energy and fluid intake, respectively." (See also Mattes 1990, who found at best very weak associations between hunger reports and intake occurrences and amounts in free-living humans.)

If palatability and norms of appropriateness are both more powerful than is hunger in the acute control of eating, we might now ask which of these two powerful factors is *more* powerful. At this point, we are reluctant to pursue this question, because it is probably unanswerable. Palatability drives eating in a direct fashion – the more palatable food, the greater the intake – but norms of appropriateness do not drive eating in the same way. Occasionally a norm of appropriateness requires that we eat more than we otherwise might; the politeness/consideration norm cited above would be an example. Most of the time, however, norms of appropriateness do not drive intake so much as *permit* it. An experimental confederate's intake indicates an upper limit of intake beyond which one may not proceed; but there is no requirement that the limit be reached. Indeed, in most experiments involving large-eating confederates, the intake of the naïve participants increases above control levels but does not come close to matching the inflated intake of the confederates. In other words, whereas highly palatable food directly promotes increased intake, high-intake norms only *allow* increased intake; they do not drive it in the same way. Thus, palatability and norms of appropriateness are incommensurate. They both override hunger, but we cannot regard one as more powerful than the other. Highly unpalatable food will suppress eating even if confederates eat a lot of it (Pliner and Mann 2004), and confederates who eat minimally will suppress intake even if the food is highly palatable, as we saw in the Goldman et al. (1991) study.

A Dynamic Theory of Normal Eating

Having provided a rough weighting of the three factors driving eating (with hunger relatively weak compared to palatability and norms of appropriateness), we may now turn our attention to how these factors combine dynamically to control eating. In our review of the effects of social factors on eating (Herman et al. 2003), we postulated that "in the presence of palatable food, and in the absence of inhibitory forces. . ., people continue to eat indefinitely." This deceptively simple formulation includes just about everything required to account for food choice and food intake.

Food choice is the simpler case, with palatability accounting for most decisions. Some inhibitory factors – say, a concern about how observers (or you yourself) might judge your choice of a highly palatable but unhealthy food – may interfere with food choices based entirely on palatability; but by and large, people tend to select the food that has sensory appeal for them. (Of course, in the real world, factors such as cost and convenience may affect food choice, but these factors are rarely studied in the lab.) Pliner and Mann (2004) found that people tend to disregard the example of others when those others select a disliked food. We may imagine an obverse case, in which the individual is confronted with a relatively unpalatable food (which she normally would not be eager to eat) but experiences pressures to eat it nevertheless. Considerations of politeness or health may drive food selection. For example, Girz et al. (2012) found that in the absence of caloric information about menu items, people concerned about their weight chose the "healthy" salad option rather than the (more palatable) pasta option. When they were told – correctly, as it happens – that the salad and the pasta were equally caloric, however, people shifted their choice to the pasta. So here we have an instance of "the presence of norms of appropriateness that promote the choice of an unpalatable food," which may then be overcome by information suggesting that the less palatable food is not actually more calorically appropriate.

When it comes to food intake, palatability is again crucial, in the sense that it is a precondition for further eating. If the food tastes bad, people won't eat (much of) it. Most of the time, however, both in the lab and in the real world, people have at least reasonably palatable food available to them. What is crucial to note here is that our formulation requires the presence of (reasonably) palatable food, but it does not require the presence of hunger. We thus acknowledge what has become increasingly evident recently – namely, that many of us eat in the absence of hunger. The mere presence of attractive food appears to be enough to drive eating. As Fay et al. (2015, p. 156) put it, "increased frequency of eating in the absence of homeostatic need, notably through snacking, is an important contributor to overconsumption and may be facilitated by increased availability of palatable food in the obesogenic environment."

Our dynamic theory suggests that palatability alone will drive intake and drive it indefinitely. People do not eat indefinitely, though, so we must now turn our attention to the "inhibitory factors" that terminate eating, sooner or later. The most obvious terminator of eating is satiety. Even though satiety often lags intake – it can take 20 min or more for inhibitory feedback from ingestion to trigger feelings of satiety (Booth et al. 1970), and so people often eat more than they wish they had – eventually satiety registers, and the eater will stop. (Our theory, then, weighs satiety as a "stop" signal more heavily than hunger as a "start" signal.)

Although satiety is the ultimate backstop, intake often ceases well before satiety occurs. Other inhibitory forces often come into play earlier. We have already discussed sensory-specific satiety, the metaphorical satiety that we experience when our meal is dominated by a single food or flavor. We may think of sensory-specific satiety as a preemptive form of satiety or, alternatively, as a decline in palatability; in either case, it stops food intake before true satiety occurs. This is one instance of an inhibitory force.

One prevalent reason for stopping eating is when we run out of food, as happens, for instance, when we have cleaned our plate. In the lab, researchers usually try to ensure that there is more food available that can be eaten. In any case, if all the food is gone, then the eater is no longer "in the presence of palatable food," and so the basic precondition for eating is no longer satisfied.

Other forces that inhibit eating may be found among the many norms of appropriateness that govern eating, many of which reflect the appropriateness of eating moderately or even sparingly, usually with the goal of making a positive impression on our co-eaters, on observers who are not eating alongside us, or even just on ourselves.

Elements of the situation that convey norms of appropriateness almost always establish an upper limit of food intake beyond which we dare not go. Even when the situation appears at first glance to encourage eating, it nevertheless entails a maximum permissible amount. Thus, large portions encourage more eating than do small portions, but even the large portion must not be exceeded. Research participants eat more when they eat with experimental confederates who eat a lot than when they eat with confederates who eat only a little; but even when the research participants eat a lot, they do not eat more than the large-eating confederates (Vartanian et al. 2015).

We are aware of only one study in which the amount eaten by large-eating confederates did not establish an upper limit for naïve research participants (Leone et al. 2007); and in that case, we argued, the ambiguity in the conflicting amounts eaten by the various confederates prevented the naïve eaters from perceiving a clear upper limit on intake. In our previous list of norms of appropriateness, we included politeness/consideration as a norm that could lead people to eat more than they might otherwise be inclined to. Obviously, we cannot argue that eating more as a way of complimenting the host or making a large-eating companion feel better is an inhibitory factor, but we do suggest that these examples of eating more than one really wants to are exceptional. Moreover, concern-about-excessive-eating norms of appropriateness ensure that our politeness and consideration for others do not lead to any more eating than is absolutely necessary to discharge these social obligations and may even dictate eating less than we would prefer, so as to leave enough for others to eat.

Extensions and Distortions of Normal Eating

Now that we have established the basic drivers (and inhibitors) of eating, we are in a position to enquire about problematic eating.

Obesity: Normal eating is not necessarily optimal eating. Consider the obesity epidemic. While we cannot say with certainty what is responsible for the epidemic (see Herman 2018; Keith et al. 2006; and McAllister et al. 2009), it is easy to see how normal eating processes might lead to overeating.

Consider palatability. Nisbett (1968) served ice cream varying in palatability – using the same quinine adulteration that Kauffman et al. (1995) later employed – to normal-weight, overweight, and underweight people. As palatability increased, people ate more of the ice cream, but the precise pattern for the different groups showed an interesting anomaly. Whereas normal-weight and underweight people ate more ice cream as a continuous function of increasing palatability, the overweight people showed what Nisbett called a "step function": once the palatability level rose above neutral, the overweight people ate a lot of it; and further increases in palatability made no difference. This finding suggests that obese people do not discriminate between decent-tasting food and highly palatable food; alternatively, it suggests that people who do not discriminate between decent-tasting food and highly palatable food are prone to becoming obese. This is a simple example of how an anomaly in the domain of palatability might produce overeating and weight gain.

Overeating may arise from "inappropriate settings" in norms of appropriateness. We have already discussed how the intake of your eating companions can influence your own eating; so if you regularly eat with people who eat a lot, odds are that you will end up eating a lot as well. In fact, simply eating with other people seems to lead to greater eating. There is a sizable literature documenting the social facilitation of eating (Herman 2015): people eat more when they eat with others than when they eat alone. One interesting explanation for this effect is that, when people eat in groups, they arrange for more food (per capita) to be available; in effect, groups arrange for larger portions. More generally, if we are constantly served (or serve ourselves) large portions, it stands to reason that we will end up overeating. These examples of “inappropriate norms of appropriateness” have not yet been shown conclusively to lead to overeating (Herman 2018; Herman et al. 2016), but the notion is tantalizing.

Dieting or restrained eating: Restrained eaters (dieters; ▶ Chap. 59, “Dieting and Overeating” by van Strien in this volume) are committed to suppressing their food intake, owing to their conviction that it is desirable and appropriate to eat less than hunger and palatability considerations would otherwise demand. Indeed, restrained eaters struggle to overcome the hunger produced by whatever success they have in suppressing their intake; and they struggle to overcome the pervasive lure of palatable food, which is often high in calories and which may become even more alluring as one’s weight decreases and/or as one expends more energy avoiding such desirable foods (i.e., psychological deprivation).

Polivy and Herman (1987) note that restrained eaters comprise a large proportion of some populations, including females in Western societies. Indeed, one could argue that in many subpopulations, restrained eaters are in the majority, and so we might consider dieters to be normal eaters, at least statistically. Polivy and Herman invoke our boundary model (Herman and Polivy 1984) to explain how dieters differ from nondieters. Specifically, dieters have a “diet boundary” that sets an upper limit on their permissible intake and that is reached well before satiety. Thus, dieters will often eat less than will nondieters; and yet, they often eat more. This breakdown of dietary restraint may be explained in terms of the elimination of the diet boundary. This may happen in situations in which the dieter breaks her diet by eating more than the diet allows; once the diet boundary has been breached, there is nothing to stop additional eating until the satiety boundary is reached. (Herman and Polivy argue that the satiety boundary is displaced for dieters, so that dieters experience satiety later – after more food is consumed – than do nondieters.) Another scenario in which the diet boundary becomes inoperative is when it is temporarily abandoned altogether in favor of more urgent priorities; for instance, when the dieter becomes emotionally agitated, she may abandon her diet, at least temporarily. This analysis allows us to interpret the behavior of dieters as “normal,” both in the sense that it is statistically prevalent and also in the sense that it is responsive to the sort of controls or boundary pressures that regulate eating in (almost) everyone, the only difference being the presence of a “diet boundary” that reflects the dieter’s commitment to eating less, a commitment that is vulnerable to being overridden.

Thus, problematic eating may arise both when the normal controls on eating are “broken” and when the normal controls are intact but set at levels that conduce to overeating and/or choosing unhealthy foods. Normal controls may also be set at levels that conduce to undereating. Most analyses of the classic eating disorders (i.e., anorexia nervosa, bulimia nervosa, binge eating disorder) depict these disorders as stemming from true pathologies of hunger, satiety, emotion, and body image. Our theory of normal eating does not specifically pertain to these eating disorders, but it is interesting to speculate as to how these recognized eating disorders might arise not because of pathology but through extensions of normal eating mechanisms. Crandall (1988), for instance, discusses how binge eating can spread through a sorority through the enforcement of social norms. Websites promoting certain eating disorders may serve to normalize these pathologies (Norris et al. 2006). In short, certain forms of abnormal eating may just be extensions of normal eating, making it all the more important for us to understand normal eating and how it operates.

Emotional eating: It is a common belief that eating is driven by emotions; and indeed, emotional arousal can both promote and suppress food intake and certain food choices (e.g., Macht 2008). Bruch (1973) speculated about the possibility that some people confuse other internal or emotional states with hunger, with resultant overeating. At the same time, clinical depression has been associated with both weight loss and weight gain (Polivy and Herman 1976). We concur that emotional arousal affects food intake and choice. We propose, however, that the effect of emotional states on eating is not direct but rather is mediated by the effects of emotional states on the basic factors that control eating. Thus, insofar as emotional arousal suppresses food intake, it may do so by inducing satiety, as Schachter et al. (1968) argued, citing Cannon (1915). Insofar as emotional arousal increases food intake, it may do so by altering (or removing) inhibitory norms that typically keep food intake in check (Polivy and Herman 1999). In short, we do not deny that emotional eating can have a strong effect, but we suggest that this effect is best understood in terms of our basic theory of normal eating. Indeed, we suggest that virtually every aspect of eating can be best understood in terms of our theory of normal eating, whose relative simplicity offers a concise approach to what has heretofore been an unduly complicated analytic enterprise.

Measuring Liking for Food and Drink

12

Gastón Ares and Leticia Vidal

Contents

Abstract

The hedonic component of food reward is the result of an integrative process where the sensory and perceptual information about the food or drink is combined with a range of factors unrelated to the product itself, such as the individual's physiological status, personal experiences, culture and context. This perceptual and evaluative component of reward has been regarded as a key predictor of food consumption. Hedonic measures obtained in response to food and drink products have great importance in sensory and consumer science and are used to inform decision making in the food industry. In this context, the aim of the present chapter is to review methodological approaches to measure liking for food and drink. The most popular direct and indirect (i.e., implicit) methods are presented.

Advantages and disadvantages of the methods are discussed from a critical perspective and recommendations for practitioners are provided.

Introduction

The reward system of the human brain has been hypothesized to evolve to promote engagement in behaviors that can be beneficial and to discourage potentially dangerous behaviors (Blaukopf and DiGirolamo 2007). Considering that eating sufficient and varied food is essential for our survival, it is not unexpected that food intake is regulated by both the homeostatic and the reward systems (Lutter and Nestler 2009). The rewarding nature of food consumption has been associated with eating foods that may be beneficial for survival and avoidance of potentially dangerous foods (Saper et al. 2002). Although the reward system was highly important for survival in an environment characterized by food scarcity, in the context of a food environment characterized by the wide availability of calorie-dense food, it is being increasingly recognized as a key determinant of the growing prevalence of overweight and obesity (Berthoud 2011). In this sense, recent research has shown that the brain's reward system can lead to excessive food intake, even in the presence of satiety signals (Berthoud and Morrison 2008).

Reward has three interrelated psychological components: (i) learning, (ii) liking, and (iii) wanting (Berridge and Robinson 2003). Learning refers to knowledge about the relationships between stimuli and actions, which is necessary for making anticipatory responses and for goal-directed action (Dayan and Balleine 2002). Liking is basically the hedonic component of reward, i.e., the degree of pleasure or displeasure associated with a stimulus or a behavior. In the context of food and drink, liking has been conceptualized as the pleasantness of eating, the immediate qualitative, affective evaluation of food and drink, or the pleasantness of the food or drink in the mouth (Mela 2006). Finally, wanting is the motivation to perform a behavior or the conscious desire to translate affect into action (Berridge 2009). According to Berridge and Robinson (2003), wanting may be a separate psychological component from "liking" to facilitate comparison and choice among competing rewards.

The hedonic component of food reward is the result of an integrative process where the sensory and perceptual information about the food or drink is combined with a range of factors unrelated to the product itself, such as the individual's physiological status, personal experiences, culture and context (Cardello 1996). This perceptual and evaluative component of reward has been regarded as a key predictor of food consumption (Tuorila 2007). Hedonic measures obtained in response to food and drink products have great importance in different fields related to food and eating behavior and are used to inform decision making in the food industry (Cardello and Jaeger 2007).

The aim of the present chapter is to review methodological approaches to measure liking for food and drink and to discuss their advantages and disadvantages from a critical perspective.

Methodological Approaches to Measure Liking

Liking for food and drink is a psychological process with neural mechanisms that has objective markers in the brain as well as accompanying cognitive experiences (Berridge 2009). This affective process can be represented on multiple conscious and unconscious levels (Winkielman and Berridge 2003). The processes underlying liking can produce conscious pleasure but can also occur without it (Berridge and Robinson 1998).

Liking measurements have mainly focused on the conscious or cognitive aspect of the hedonic experience (Cardello 1996). For this reason, self-reports are the most popular methodological approach for measuring liking for food and drink (Tuorila 2007). They basically require respondents to indicate their personal impression of how much they like a target food or drink. However, this cognitive representation of pleasure may not be a faithful reproduction of the underlying affective processes (Berridge 1996). Thus, methods that do not require people to report their conscious experience have been developed and are being increasingly used (Pool et al. 2016).

Hedonic Scaling

Most methodological approaches to measure liking for food and drink derive from the developments of psychophysics to assess the intensity of sensory experiences (Berlyne 1973). The most common approaches rely on the evaluation of the magnitude of liking and/or disliking using hedonic scales (Lim 2011). In the following sections, the most popular scales for measuring liking are described and their theoretical and practical differences discussed.

9-Point Hedonic Scales and Its Variants

The 9-point hedonic scale is the most popular methodological approach to measure food liking. This scale was developed between the late 1940s and the 1950s at the Quartermaster Food and Container Institute for the Armed Forces, in the United States (Peryam and Girardot 1952; Peryam and Pilgrim 1957), motivated by the need for a tool to measure the hedonic response of soldiers to various food items. Early research compared different scale lengths, wording, and presentation formats, leading to the present form of the scale, which is shown in Fig. 1a (Lawless and Heymann 2010; Lim 2011).

The 9-point hedonic scale is a labeled category scale, composed of nine phrases which are intended to cover a continuum of likes and dislikes. It is arranged as a balanced bipolar scale, with four positive (like) and four negative (dislike) categories around the neutral "neither like nor dislike." The use of the scale is simple as participants are only asked to select one of the nine categories according to their degree of liking of the focal sample. In most applications, samples are served one at a time, and a response is required after the evaluation of each sample (Lawless and Heymann 2010).

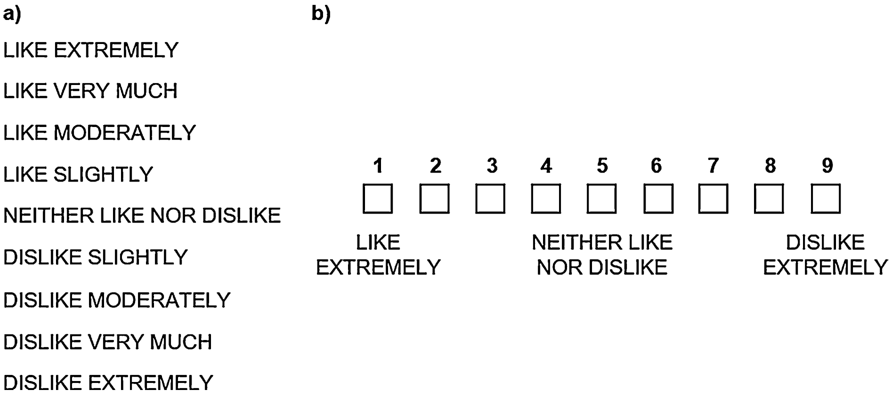

Fig. 1 Example of 9-point hedonic scales: (**a**) original version developed by Peryam and Girardot (1952), (**b**) alternative format

Although in theory data collected using the 9-point hedonic scale (as well as with any category scale) are ordinal, it is common practice to assign the numbers 1 to 9 to the categories, with 1 being "dislike extremely" and 9 being "like extremely," and to treat the responses as points in a continuum (Lim 2011). Thus, mean ratings are usually calculated, and parametrical statistics, such as t-test or analysis of variance (ANOVA), are used to evaluate product differences in liking. This practice is usually justified by the robustness of techniques such as ANOVA, and the fact that affective consumer tests involve large sample sizes, which allow to obtain meaningful results even though discrete data are being analyzed as if it were continuous (Schutz and Cardello 2001; Lawless and Heymann 2010).

After its development, the 9-point hedonic scale was rapidly accepted internationally by both industry and academia. Alternative presentations to the original format of the scale have been used, with the categories arranged either vertically or horizontally, using simple check-boxes with anchors in the extremes and sometimes in the neutral point, and with or without integer numbers in each category (Fig. 1b; Lawless and Heymann 2010; Yao et al. 2003; Wichchukit and O'Mahony 2014). The 9-point scale and its variants is by far the most popular tool to measure liking and it has been extensively used to assess the hedonic response to food and beverages, as well as many nonfood products (Lawless and Heymann 2010; Stone et al. 2012).

The main reason for the great popularity of this scale is probably its simplicity, both for participants and researchers. With only minimal instructions, naïve consumers can easily understand the task, and it is also simple for researchers to record and analyze the resulting data (Lim 2011). Besides, results obtained with the 9-point hedonic scale have been reported to be stable and reproducible (Lawless and Heymann 2010; Stone et al. 2012), while comparisons with other scales have shown that it is as sensitive for product discrimination as other methods (Lim 2011).

In spite of being a simple and effective measuring instrument for liking of food and beverages, the 9-point hedonic scale has some disadvantages that should be acknowledged. First of all, the intervals between the scale labels are not equal, as was recognized by its developers (Jones et al. 1955; Jones and Thurstone 1955) and later confirmed by other authors (Moskowitz and Sidel 1971). From a mathematical point of view, this means that the obtained data are ordinal, and consequently nonparametric approaches (such as Friedman's test) should be used for their analysis. Besides, conclusions on the ratios of degree of liking of different samples cannot be drawn with this type of scale, as well as meaningful comparisons between individuals and groups (Lim 2011).

Another shortcoming of this scale, which is common to all category scales, is the existence of the "central tendency" bias (Hollingworth 1910), meaning that assessors tend to avoid using the end, i.e., extreme, categories. The underuse of the extremes reduces the effective number of categories of the scale and limits its ability to differentiate products which are highly liked or disliked (Schutz and Cardello 2001). Moreover, the small number of available categories limits the expression of a full range of hedonic responses, as two products under the same category are not necessarily equally liked (Lim 2011; Wichchukit and O'Mahony 2014). Besides, most commercial food products receive hedonic scores that range between 6 and 8, which makes it a small scale for product discrimination. Furthermore, the presence of the neutral category "neither like nor dislike" has been show to decrease the efficiency of the scale (Jones et al. 1955), probably by encouraging certain degree of complacency among assessors (Schutz and Cardello 2001).

Lastly, it should be noted that although the scale has been translated into many languages (Curia et al. 2001; Yao et al. 2003; Yeh et al. 1998), this has not been done without issues related both with translation of the labels as well as cultural differences in the use of the scale. For example, research has pointed out that Japanese, Korean, Chinese, and Thai consumers tend to use a smaller range of the 9-point scale compared to American consumers (Yao et al. 2003; Yeh et al. 1998), which has been attributed to Asian cultures presenting acquiescence and polite response styles as well as a tendency to avoid extreme responses. The translation of the nine category labels to other languages is also problematic in some cases. For example, in Korean, the translation of "extreme" has a stronger semantic weight compared to English (Yao et al. 2003; Wichchukit and O'Mahony 2014). Similarly, Curia et al. (2001) evaluated different versions of the translation of the 9-poinit scale labels to Spanish, asking people of different ages from two towns in Argentina to rank the phrases from "like least" to "like most." The authors found that a large percentage of participants inverted the order of two or more phrases and called for caution when using the scale in languages other than English, suggesting that number or unstructured (without labels) versions of the scale might be more appropriate in such cases.

Labeled Affective Magnitude Scale

The known drawbacks of the 9-point hedonic scale have motivated the search for alternative tools which could overcome issues such as the limited response options, the central tendency bias, and the unequal spacing of categories with the consequent inability to use parametric statistics. Among the proposed alternatives, the Labeled Affective Magnitude (LAM) scale (Schutz and Cardello 2001) has gained its place in the sensory and consumer science toolbox (Cardello and Jaeger 2010; Lawless and Heymann 2010; Stone et al. 2012).

The LAM scale was developed by Schutz and Cardello (2001), who extended the idea of category-ratio scales, which had been proposed for the measurement of perceived exertion (Borg 1982) and oral sensations (Green et al. 1993, 1996), to the hedonic domain. The LAM scale is a bipolar continuous scale with 11 labels describing the magnitude of (dis)liking, which are located at specific positions. The position of the labels was derived from a study in which the affective meaning of 44 positive, negative, and neutral semantic labels were rated using magnitude estimation. Subsequent studies on the reliability and sensitivity of different alternatives led to the selection of the labels from the 9-point hedonic scale, plus the two extreme anchors: "greatest imaginable (dis)like" (Fig. 2; Schutz and Cardello 2001). As the location of the labels on the line scale was based on the ratios obtained by magnitude estimation, the scale is assumed to have ratio properties, which enables the use of parametric statistics for data analysis (Lawless and Heymann 2010; Lim 2011).

Hedonic tests involving LAM scales are conducted in a similar fashion to those in which the 9-point hedonic scale is used, with the difference that, instead of selecting the category that best describes their degree of liking for a sample, assessors are

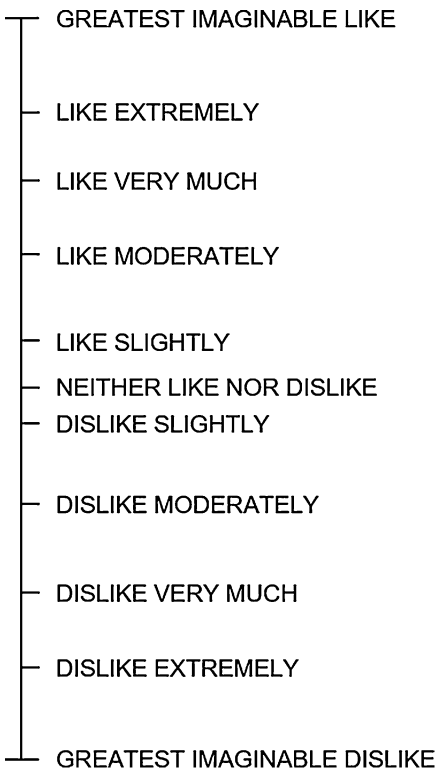

Fig. 2 Labeled Affected Magnitude (LAM) scale, developed by Schutz and Cardello (2001)

instructed to make a mark on the line scale to indicate how much they (dis)liked the sample. Thus, the problem of limited response possibilities associated with the 9-point hedonic scale is overcome. Besides, the inclusion of an extreme label ("greatest imaginable (dis)like") enables assessors to rate products higher (or lower) than "(dis)like extremely," which reduces the "ceiling" or avoidance of end use effect that the 9-point scale poses on responses (Cardello and Jaeger 2010). These facts might explain why Schutz and Cardello (2001) found that the LAM scale performed slightly better than the 9-point scale in the discrimination of highly liked products. Moreover, the LAM scale has been reported to be as easy to use as the 9-point scale for consumers (Schutz and Cardello 2001; Hein et al. 2008). Another point raised as an advantage of the LAM scale is that it reduces the percentage of ratings that fall near the neutral point, thereby minimizing the complacency bias (Schutz and Cardello 2001).

The wording of the most extreme categories of labeled magnitude scales has been a matter of discussion. Bartoshuk et al. (2002), when working on category-ratio scales to measure sensory intensities, argued that the end anchor should be the "strongest imaginable sensation of any kind," in order to extend the frame of reference out of the specific sensation being measured. Although this anchor is supposed to enable the scale to provide valid comparisons across individuals and groups with different sensitivities, it may be difficult to conceptualize for participants. In the case of hedonic scales, more extreme anchors to those of the LAM scale, such as "greatest imaginable (dis)liking of any kind" and "most (dis)liked imaginable sensation" have been proposed (Cardello 2017). However, research on the effect of different frames of references for the extreme anchors of the LAM scale, varying from "greatest imaginable (dis)like" for experiences of any kind, for foods or beverages in general, or for foods or beverages from a specific category, showed that a compression effect of the hedonic rating may occur with more extreme anchors (Cardello et al. 2008; Lawless et al. 2010a). This may result in lower product discrimination compared to the use of less extreme anchors.

Another criticism that the LAM scale has received is the potential misuse of the scale by consumers, who might use it as a category scale (only marking on the points where there are labels) instead of a continuous one. Thus, it is extremely important to give clear instructions to participants involved in test with the LAM scale and to ensure they understood the task (Cardello and Jaeger 2010; Lim 2011). Finally, from a practical point of view, the LAM scale has the disadvantage of requiring more time to process the results if data are collected on paper ballots, as the exact position of the marks on the scale needs to be measured. The construction of the scale with the exact label positions may also be difficult in some cases (Cardello and Jaeger 2010).

It should be noted that although the LAM scale and other similar category-ratio scales have been used by several authors (Cardello and Jaeger 2010), its use is not as widespread as the 9-point scale. This is probably because, from a practical point of view, the advantages of the LAM scale have not proven to be sufficient to justify the substitution of the 9-point scale. The slight advantage of the LAM scale over the 9-point scale for product discrimination found by some authors (Schutz and Cardello 2001; Greene et al. 2006; El Dine and Olabi 2009) has not been found by others

(Hein et al. 2008; Lawless et al. 2010b). In addition, the conclusions on the rankings of sample liking have shown to be equal for both scales (Hein et al. 2008; Cardello and Jaeger 2010; Lawless et al. 2010b). Thus, the advantages of the LAM scale do not seem to be enough to compensate the increased complexity of the scale and potential misunderstandings by consumers.

Bi-dimensional Measures of Liking

Concerns over the unidimensional nature of the underlying mechanisms of liking have been raised (Diener and Emmons 1984). Pleasure and displeasure have been argued to be not mutually exclusive and it has been suggested that hedonic and aversive reactions may vary according to two orthogonal processes (Berridge 1996). For this reason, the use of two unipolar scales (one for liking and the other for disliking) or bivariate grids composed of liking and disliking dimensions has been proposed (Kwak et al. 2013a, b; Kwak and Lee 2016). The authors reported that unipolar and bipolar scales showed similar ability to discriminate among products and low correlations between liking and disliking. However, the results reported in that work have raised concerns due to some methodological decisions involved in the experimental design (Cardello 2017). From a practical point of view, the use of bidimensional measures of liking increases the burden for both consumers and researchers, as they increase the time and effort needed to complete the task. In addition, it is not clear if consumers can simultaneously evaluate liking and disliking for a focal stimuli without the use of satisficing response strategies.

Best-Worst Scaling

Best-worst scaling is an indirect form of scaling in which scale values are derived from a choice-based task instead of a direct measurement of degree of liking (Lim 2011). The method, also called maximum difference of max-diff, was formally introduced by Finn and Louviere (1992) and started to be used in the context of food and drink liking about a decade ago (Hein et al. 2008; Jaeger and Cardello 2009; Jaeger et al. 2008).

Basically best-worst scaling is an extension of the paired preference test. Assessors are presented with a series of sets of three or more samples and are asked to choose among them the most and the least liked (Cardello and Jaeger 2010). A proper experimental design needs to be selected to establish the sets of samples to be presented, taking into account that each sample must be evaluated an equal number of times. A simple example is the case of 4 samples (A, B, C, D), which can be presented in four triads (A, B, C; A, B, D; A, C, D; C, B, D) where each individual sample will be tasted three times (Jaeger and Cardello 2009). Each consumer should evaluate the four sample sets in random order.

Data from best-worst scaling can be analyzed using two different approaches. One of them is to calculate the difference between the number of times each sample has been selected as "best" and "worst" for each assessor, which leads to individual-level scales. These scales can be easily compared across participants and may be aggregated to provide overall scores for each sample (Jaeger et al. 2008). These best-worst scores are assumed to have interval properties, and thus can be subject to ANOVA or other parametric statistical tests (Marley and Louviere 2005). The other approach is to apply a multinomial logistic regression to the pairs of "best" and "worst" choice frequency data, which in theory leads to data with ratio properties (Finn and Louviere 1992; Marley and Louviere 2005).

It has been argued that it is easier for people to identify stimuli at the extremes of a continuum than in the middle, and consequently, the best-worst method would require assessors to perform a more natural task from a cognitive point of view (Jaeger et al. 2008; Lawless and Heymann 2010). In fact, Hein et al. (2008) reported that consumers found best-worst scaling easier to use than direct scaling methods such as the 9-point scale and the LAM scale and were more confident they had provided accurate information during the test. Another advantage of best-worst scaling over direct ratio scales is that the method provides true, and not assumed, interval or ratio data (depending on how data are analyzed). Compared to other preference methods, such as paired comparison, best-worst scaling is more efficient in the sense more information is provided with fewer responses (Jaeger and Cardello 2009). Also, compared to the direct measurement of liking using hedonic scales, some authors have provided evidence of a slightly better discrimination power (Hein et al. 2008; Jaeger et al. 2008), especially in studies involving stimuli that do not require testing (food names; Jaeger and Cardello 2009), although other authors found different results (Mueller et al. 2010). Moreover, one of the most salient advantages of best-worst scaling is its potential for use in cross-cultural research. Issues that are common to most hedonic scales, such as the translation of anchors and intermediate labels, and cultural differences in scale use, do not affect the best-worst scaling method (Cardello and Jaeger 2010).

On the other side, a limitation of best-worst scaling is that no liking score is produced, so an absolute degree of liking of each sample cannot be inferred. Due to the indirect nature of the method, only the relative degree of preference among the samples considered in the study is obtained, which makes comparison across studies less intuitive, though possible (Cardello and Jaeger 2010). Also, the method requires assessors to evaluate each sample many times, unlike direct scaling methods in which each stimulus is presented only once. This increases the time and effort needed to set up and conduct a test and may pose additional challenges when dealing with samples that require strict control of serving temperatures or volumes (Jaeger and Cardello 2009; Lim 2011). This also represents a great disadvantage when samples need to be tasted, especially when working with fatiguing products such as wine (Mueller et al. 2010).

Regarding the comparison of best-worst scaling with direct scaling methods, such as the 9-point and the LAM scales, research has shown that the main conclusions on sample preferences are comparable (Hein et al. 2008; Jaeger and Cardello 2009).

Indirect Methods

Direct methods only focus on the conscious component of liking and do not capture unconscious hedonic processes (Berridge and Robinson 1998). In addition, self-reported measures of liking can be affected by several biases, including social desirability (i.e., tendency to give socially desirable answers, regardless of their true perception, feelings or attitudes; Crowne and Marlowe 1964), demand characteristics (i.e., tendency to give responses that please the researcher; Orne 1962), and consistency motif (tendency to appear consistent and rational in the responses to a questionnaire; Podsakoff et al. 2003). Implicit methods that do not require consumers to provide answers to questions can be used to overcome rationalization and response biases that diminish the validity and reliability of liking measures. These methods measure constructs using automatic processes, i.e., unintentional, uncontrollable, effortless, and fast processes (De Houwer and Moors 2007). Different implicit methods have been used to measure consumers' liking of food and drink, including implicit association tests, facial expressions, pupil dilation, and functional magnetic resonance imaging. Although the popularity of these methods has increased in the last decade, applications are still limited and mainly related to the academic context.

Implicit Association Test

The implicit association test (IAT) was developed to identify unconscious associations that are usually not accessible through introspection (Greenwald and Banaji 1995). This test involves two binary computer-based categorization tasks. In each task, participants have to classify a series of stimuli into one of two response categories, defined as combinations of an attribute dimension (e.g., pleasant and unpleasant) and a target dimension (e.g., water and soda) (Kraus and Piqueras-Fiszman 2018). The two tasks correspond to the two possible groupings of the attribute and target dimensions (e.g., pleasant/water vs. unpleasant/soda and pleasant/soda and unpleasant/water) (Fig. 3). The response categories are displayed on the right and left side of the screen and are assigned to specific response keys. Participants have to look at the stimuli (which can be words or pictures) and complete the task as fast and accurately as possible. The classification of each stimulus and the time needed by participants to complete the task are registered. The underlying assumption of the IAT is that participants would complete the categorization faster and more accurately when the response categories are composed of congruent concepts compared to when they are composed of incongruent concepts (Greenwald et al. 1998). An in-depth discussion of IAT and its variations, as well as applications in the food domain, can be found in Kraus and Piqueras-Fiszman (2018).

IAT has been used to evaluate consumers' liking of food and drink concepts, although comparisons with explicit scales are not frequent yet. For example, it has been recently used by Connell et al. (2018) to evaluate consumers' liking of fresh and frozen vegetables using fresh/frozen as the target dimension and pleasant/unpleasant as the attribute dimension. Participants were asked to classify a series of pictures of fresh and frozen pre-packaged vegetables as well as positively/negatively valenced

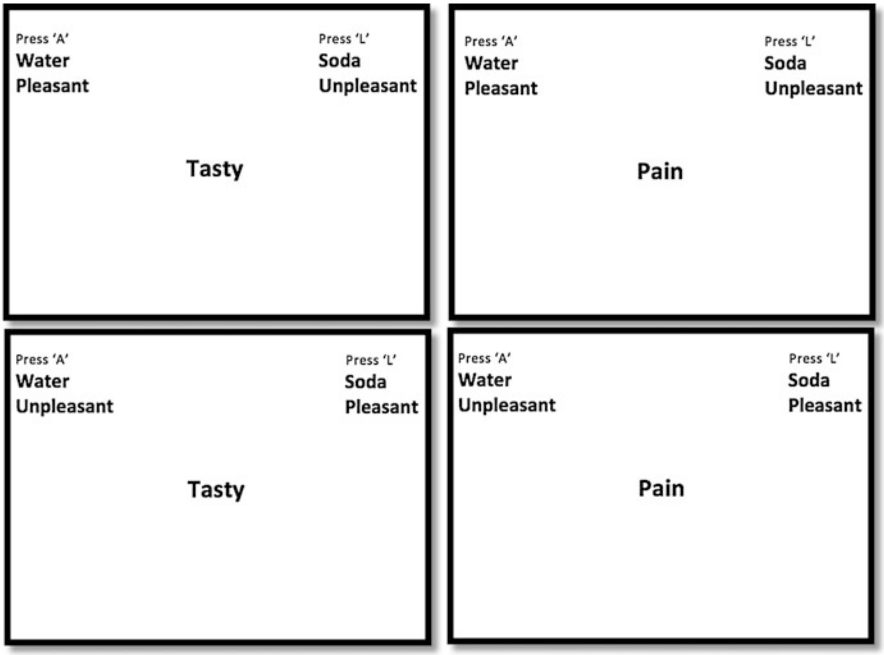

Fig. 3 Example of four classification tasks in an Implicit Association Test with pleasant/unpleasant as attribute dimension and water/soda as target dimension

words. Results showed that response times were shorter when participants completed the task using the categories fresh and pleasant versus frozen and unpleasant, compared to when the categories fresh and unpleasant versus frozen and pleasant were considered. This suggests an implicit negative hedonic attitude towards frozen vegetables compared to fresh vegetables.

Facial Expressions

Facial expressions have been regarded as the richest channel for non-verbal communication (Burgoon and Hoobler 2002). In the context of food consumption, they have been associated with the communication of warning signs related to the consumption of potentially harmful substances or facilitation of consumption of nutritious liquids (Oster 2004). For this reason, facial expressions are usually interpreted as expressions of liking (e.g., lip corner puller, smiling, lip smack) or disliking (e.g., nose wrinkle, outer eyebrows raised, brows pulled together and lowered) (Steiner 1973; Danner and Duerrschmid 2018). Facial expressions have been used to study innate liking for basic tastes in human infants: sweet taste has been associated with facial expressions related to liking (e.g., tongue propulsions), whereas bitter taste has been associated with facial expressions denoting disliking (gapes) (Berridge and Robinson 2003). Research with both children and adults has confirmed the potential of negative facial expressions to disliked foods, whereas positive facial expressions have not been found to accurately discriminate among liked foods (Danner and Duerrschmid 2018; Zeinstra et al. 2009). This reduces the applicability of facial expression for commercial product testing as product development is focused on liked products.

The analysis of facial expressions involves three basic steps: face acquisition in high-quality pictures or video recordings, identification of facial expressions (facial movements and facial feature deformations), and classification of the facial expressions (Tian et al. 2005). Although this analysis can be done manually, several commercially solutions are available for consumer research (Danner and Duerrschmid 2018). It should be noted that measurement of facial expressions face several challenges when evaluating liking for tasted food and drink as participants should be instructed to limit their movements while eating and drinking.

Pupil Dilation

The pupil, the circular opening in the center of the iris of the eye, regulates the amount of light that enters the retina by changing its size (Andreassi 2000). Constriction and dilation of the pupil is controlled by the sympathetic and parasympathetic nervous system in response to three stimuli: luminosity, emotions, and cognitive activity (Seeber and Kerzel 2011). Early research by Hess and Polt (1964) showed that the pupil dilated when people looked at pleasant pictures. More recently, Steinhauer et al. (1983) and Bradley et al. (2008) reported that pupil dilated when viewing affective pictures, regardless of whether they were pleasant or unpleasant.

Pupil dilation has not been frequently used to evaluate liking for food and drink. An exception is reported by Graham et al. (2011). These authors compared pupil dilation when viewing high-calorie savory foods (e.g., bacon cheese burger) and high-calorie sweet foods (e.g., chocolate cake) across women with different body mass index (BMI). The authors reported an interaction effect between BMI group and food type. Low BMI women did not show differences in their pupil diameter when viewing high-calorie sweet and savory foods. On the contrary, high BMI women showed larger pupil size when viewing high-calorie sweet foods compared to high-calorie savory foods, which indicates differences in implicit liking for these two types of foods.

Functional Magnetic Resonance Imaging

The pleasure associated with food consumption activates specific regions of the brain related to reward networks, which include anatomical regions of prefrontal cortex, such as portions of orbitofrontal, insula and anterior cingulate cortices, subcortical limbic structures, and amygdala (Berridge and Kringelbach 2015). Therefore, brain imaging techniques can be used to study the brain processes underlying hedonic reactions towards food and drink.

Functional magnetic resonance imaging (fMRI) is used to investigate where information is processed in the brain, how different brain areas are connected and how these connections are influenced by characteristics of the product or the individual (Dalenberg et al. 2018). This technique allows the identification of brain areas that are activated for processing information about a specific stimulus through changes in oxygen consumption (Huettel et al. 2014). During the experiment, which usually last 1–2 h, participants lie in a supine position on a bed inside the scanner and engage in a computerized task (Dalenberg et al. 2018). This limits the application of fMRI to visual stimuli, olfactory stimulation, or liquid foods that do not require chewing. In addition, despite the potential of fMRI to improve our understanding of food liking, its application is limited to basic research due to its cost, limited availability, and complex data analyses (Dalenberg et al. 2018).

An example of the application of fMRI to evaluate liking can be found in Jiang et al. (2015). Participants completed a liking task of 28 odorants while their brains were scanned using fMRI. Results showed that brain activation in the bilateral posterior OFC was correlated with subjective liking ratings. In addition, these authors provided evidence of the partial dissociation of liking and wanting within the cortico-striatopallidal circuit.

Liking for Sensory Characteristics

The sensory characteristics of food and drink are one of the main determinants of liking (Cardello 1996). For this reason, consumer studies usually include questions about liking for specific sensory characteristics to obtain insights on how these characteristics can be changed to increase liking (Lawless and Heymann 2010). One of the simplest approaches is to use hedonic scales to evaluate liking for sensory modalities (e.g., appearance, flavor, texture) or liking for specific characteristics (e.g., color, sweetness, creaminess). Despite the popularity of this approach, research has shown that a halo effect may exist and that consumers may not be able to evaluate liking for different sensory characteristics independently from each other. Ares et al. (2009) asked consumers to evaluate overall liking and liking for flavor and texture of a series of vanilla milk desserts formulated following a Taguchi experimental design with 5 2-level variables (starch, vanilla, sugar, carrageenan, and fat). Results showed texture, flavor, and overall liking scores were highly correlated to each other (R higher than 0.91), providing the same information.

Just-about-right (JAR) scales are another popular approach to evaluate liking for specific sensory characteristics. They can be regarded as a combination of intensity and hedonic scales as they involve the evaluation of intensity of sensory characteristic relative to consumers' ideal level (Lawless and Heymann 2010). JAR scales are bipolar: they are anchored in "just-about-right" and each side indicates that the intensity of the sensory characteristic is weaker or stronger than the ideal (Fig. 4). Although these scales are popular in the food industry to obtain insights for product formulation and reformulation, concerns have been raised over the fact that they could bias consumer perception (Popper et al. 2004).

According to Prescott et al. (2011), asking consumers to focus their attention on specific sensory characteristics can induce an analytical mind-set that reduces their ability to engage in the synthetic attentional processes that underlie hedonic responses. They argued that concurrently eliciting overall hedonic scores and

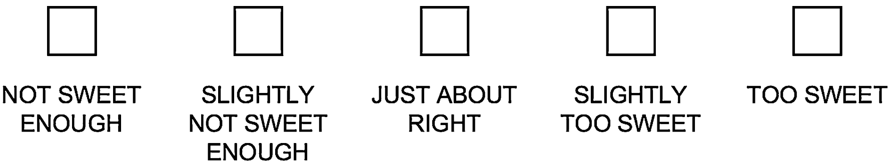

Fig. 4 Example of a Just-About-Right (JAR) scale to evaluate the adequacy of sweetness

attribute information can undermine the ability of hedonic scores to provide useful insights for decision making.

Contextual Effects on Liking for Food and Drink

Liking for food and drink is not absolute. Context, defined as the physical, social, and situational conditions under which products are consumed, has a strong effect on how consumers perceive food and drink (Cardello and Meiselman 2018). In this section, two types of contextual effects are discussed: contextual effects of the test and consumption contexts.

Effect of Contextual Effects of the Test on Liking Measurements

Several contextual effects influence liking scores, including the number of samples, stimulus range, contrast and frequency effects, end effects, centering biases, and stimulus-spacing biases (Lim 2011). Many of these effects involve the external frames created by other stimuli that are evaluated concurrently with a target stimulus in a consumer test (Cardello 2017). For example, contrast effects imply that a target stimulus is expected to show lower liking scores when evaluated after a better-liked stimuli and to show higher liking scores when evaluated after a less-liked stimuli (Zellner et al. 2006). This contrast effect has been demonstrated to be affected by the frame of reference. According to Zellner et al. (2002, 2003), contrast effects can be modified by adjusting the frame of reference. Contrast effects are expected to be higher if all samples are regarded as representatives of the same product category (e.g., fruit juices) or of different categories (e.g., fruit juice and fruit drinks).

Range and frequency effects imply that a target sample may be evaluated differently depending upon the range of samples included in the set that is evaluated (Lim 2011). Range effects imply that participants tend to subdivide the available stimulus range into equal segments and assign them to subranges of the hedonic scale, whereas frequency effects imply that the different subranges of the scale tend to be used equally often. These effects are expected to increase with the number of stimuli (Parducci and Wedell 1986).

The instructions of the test also influence consumers' liking scores. If consumers are not given a specific frame of reference for the evaluation, they may assume different consideration sets, which may increase the noise in the data. Research has shown that instructing consumers to rate their liking within the frame of reference of any food gives lower scores compared to when they perform the rating task considering foods like this as frame of reference (Cardello and Schutz 2007).

Effect of Consumption Context on Liking Measurements

Most research on consumer liking for food and drink is carried out in laboratory settings (Meiselman 2013). Although this approach allows to control for extraneous and confounding sources of variation, it lacks external validity as consumers do not usually eat in individual sensory booths (Cardello and Meiselman 2018). According to Lyman (1989), removing products from their habitual consumption context can change the meaning consumers attach to them. For this reason, the absence of a context can hinder consumers' ability to give valid responses about how they perceive products (Köster 2003). In addition, the food that is served in the laboratory usually differs from food served in natural settings in terms of several variables, including portion size, food combinations, presentation, and the length of exposure to the target product (Cardello and Meiselman 2018). In this sense, research has shown that liking for food and drink can differ with context (Stelick and Dando 2018).

The need to increase the ecological validity of liking measurements has been highlighted as a priority of the development of sensory and consumer science (Jaeger et al. 2017). This has prompted the use of natural or pseudo-natural settings in consumer studies, as well as the development of novel approaches to mimic specific consumption contexts within the sensory booths (Jaeger and Porcherot 2017). Considering the challenges associated with consumer testing under controlled conditions in natural settings, the use of evoked, immersive, and virtual contexts has become popular (Stelick and Dando 2018).

Consumption contexts can be evoked using written descriptions of situations consumers are asked to image when testing a product in laboratory settings (Hersleth 2018). This can include specific situations (e.g., when wanting something refreshing or while watching a movie) or each consumer description of their usual consumption context or the last time they consumed the product. This approach is expected to help consumers to mentally create a frame of reference for the evaluation, reducing the artificiality of central location tests (Jaeger and Porcherot 2017). Research has shown that evoked contexts can lead to differences in liking scores and discrimination (e.g., Hein et al. 2010, 2012; Hersleth et al. 2015). However, the modulation effect of evoked contexts on liking is still unpredictable and not consistently demonstrated (Stelick and Dando 2018).

Considering that consumers may not invest the cognitive effort required to vividly imagine a consumption context (Köster 2003), visual, auditory, tactile, and/or olfactory stimuli have been used to create immersive contexts for product testing. These contexts have been generated using video projections of natural consumption situations in laboratory settings or virtual reality (Porcherot et al. 2018). These approaches can increase consumers' motivation and interest in the study, increasing their ability to discriminate among samples (Bangcuyo et al. 2015). However, immersive or virtual context can also diminish consumers' attention on the products, which can be detrimental for product discrimination (Sinesio et al. 2018).

Individual Differences in Liking

Liking for food and drink strongly differs between individuals due to perceptual and socio-psychological differences (Tuorila 2007). For this reason, aggregated liking measures may mask consumer heterogeneity and reduce the accuracy of the results and, therefore, segmentation is strongly recommended to improve understanding of consumer perception.

An example of the benefits of segmentation for gaining a deeper understanding of consumer perception can be found in Oliveira et al. (2018), who studied consumer perception of sugar-reduced fruit nectars. These authors reported no significant differences between fruit nectars when liking data were analyzed at the aggregated level. However, segmentation demonstrated the existence of two consumer groups with opposite behavior: one of the segments increased their liking scores with sugar reduction, whereas the other showed the exact opposite behavior.

A priori and a posteriori segmentation methods can be used (Næs et al. 2010). A priori segmentation is based on the identification of consumer segments based on consumer personal characteristics, such as gender, age, habits, attitudes, or psychological traits. Consumers with similar characteristics are grouped and their data are analyzed separately. On the contrary, in a posteriori segmentation consumer segments are identified based on their liking data using cluster analysis. In this approach, consumer characteristics are used to interpret the differences between the groups. An in-depth discussion of clustering approaches for consumer liking can be found in Berget (2018).

Conclusions and Recommendations

Liking for food and drink is highly relevant in both industrial and academic settings and has been one of the central topic of sensory and consumer science for more than 80 years. The present chapter provides an overview of the most popular methodological approaches that are being used for measuring liking. All methods have advantages and disadvantages and practitioners should select the most appropriate method for answering the specific objectives of the study, taking into consideration the characteristics of the samples and consumers.

Direct or explicit methods provide actionable information about the most/least liked samples in a set, being particularly useful for most applications in the food industry. Following the psychophysics tradition, measurement of liking has been traditionally based on scaling. Hedonic scales are recommended when the degree of liking of individual samples is of interest. However, practitioners should be aware that hedonic ratings are not absolute and depend on contextual effects created by both the test instructions and the other samples included in the set. Although different hedonic scales have been developed, research has shown that they all provide similar results in terms of sample ranking. However, small differences among scales have been reported in terms of sample discrimination. The LAM scale may offer advantages over the 9-point hedonic scale in terms of ability to discriminate among well-liked samples. Best-worst scaling is an alternative approach for direct measurement of consumer liking. This method is useful when only information about the relative preference among a group of samples is sought, and has great potential particularly in cross-cultural research. However, its application is not advisable for large sets of tasted samples, particularly if they are fatiguing.

Indirect methods are being increasingly used to obtain a deeper understanding of liking. These methods open the possibility to evaluate unconscious aspects of liking and are particularly useful for projects in which self-report bias needs to be avoided. Although the popularity of these methods is expected to continue growing, it should be acknowledged that the information they provide is less actionable, more difficult to analyze and interpret, particularly in industrial settings, than that from direct methods.

Liking measurements collected under laboratory settings are still the most frequent methodological approach. Therefore, a strong need to increase the ecological validity of these measurements exists and several approaches have been proposed for this purpose. Evoked and immersive contexts are increasingly used to take into account the consumption context in central location tests. Despite the potential of these approaches, their effect on liking data does not seem to be consistent and an in-depth understanding of the mechanisms underlying their effect on consumer responses is still lacking to develop recommendations for best practice. In addition, the reaction after the first impression of a product may differ from the hedonic reaction after a long exposure to the product in normal consumption situations. In this sense, the development of methodological approaches that measure hedonic reactions to products under natural consumption conditions and after long exposures is still necessary. Purchase decisions are usually made based on recalled liking for products and not on the basis of immediate hedonic reactions to tasted products.

In closing this section, it is important to acknowledge that liking is only one of the components of reward. Although it is usually correlated with wanting, the motivational component of reward, it is not necessarily the case. Wanting has been generally overlooked in sensory and consumer science and further research on this component is needed. A deeper understanding of the distinction between liking and wanting is particularly relevant in the wake of the increasing prevalence of overweight and obesity worldwide. In addition, there is also a need to broaden our understanding of consumers' perception of products and to include to a larger extent other measures, such as emotional associations, perceived benefits, and perceived wellbeing.

Atmospheric Effects on Eating and Drinking: A Review

13

Charles Spence

Contents

Abstract

Whenever, wherever, and whatever we choose to eat and drink, one thing is for sure, we will do so in an environment that has a certain atmosphere. And while most consumers tend to feel that they are in charge of their own food and beverage choices, a growing body of empirical evidence now supports the view that the multisensory environments/atmospheres in which we consume influence our eating and drinking behaviors to a greater extent than any of us probably realize. In this chapter, key findings illustrating just how profoundly the auditory, visual, olfactory, tactile, and multisensory attributes of the environment affect human behavior are summarized and a number of the putative underlying mechanisms outlined. Atmospheric effects on choice behavior, product perception, and

patterns of consumption are discussed. Furthermore, attention is drawn to the palpable tension that exists currently between the sensory marketing approach to atmospherics (that may be encouraging us all to consume more than perhaps we should) and the emerging sensory nudging approach to modifying the environment (in order to try and help bias us toward slightly less unhealthy food behaviors).

Keywords

Atmospherics · Eating · Drinking · Consumer behavior · Multisensory · Sensory marketing · Sensory nudging

Introduction

There has long been a fascination with the impact of the atmosphere on consumer perception and behavior, with much of the contemporary interest in this area being stimulated by Kotler's (1974) seminal early paper on "atmospherics." In the years since its publication, researchers have studied the impact of the visual, auditory, olfactory, and even tactile aspects of the environment on various aspects of consumer behavior around food and drink. Much of this research has tended to focus on the effects of the atmosphere in diverse retail environments that include supermarkets, smaller stores, bars, and restaurants (see Spence 2017a; Spence et al. 2014b, for reviews). Ultimately, and perhaps worryingly, the suggestion is that atmospheric cues may be influencing our consumption behavior (and not, it has to be said, in a good way, at least as far as our waistlines are concerned). Understandably, the practitioners (e.g., restaurateurs) have also been interested in how the atmosphere in the spaces they manage can be used to influence sales (e.g., Anon 1965). On the flip side, however, there is now growing interest in the question of whether (sensory) nudges can also be used to help consumers eat and drink a little less and/or make healthier food choices (e.g., Guthrie et al. 2015; Kroese et al. 2016; McKie 2017; Campbell-Arvai et al. in press).

The majority of the empirical research that has been published to date on the topic of atmospherics (what is sometimes referred to as "context" effects; Sester et al. 2013; Meiselman in preparation) has tended to focus on trying to demonstrate, and thereafter to understand, the effects of varying just one sense at a time (perhaps changing the color or brightness of the lighting, or else varying the ethnicity, or type, of music playing in the background). More recently, however, researchers have also started to investigate whether multisensory modifications of the environment may exert a bigger effect than unisensory changes (Sester et al. 2013; Spence et al. 2014a; Wansink and Van Ittersum 2012). The limited evidence that has been published to date suggests that such combined multisensory atmospheric cues, at least when congruent (Helmefalk and Hultén 2017), may indeed be even more effective in biasing people's behavior (than are unisensory manipulations). And while any attempt to consider more than one atmospheric cue at a time undoubtedly constitutes a more complex undertaking, ultimately there can be no doubting the fact that the consumer responds to, and is influenced by, the total multisensory experience resulting from the combined influence of the various visual, auditory, olfactory, and tactile aspects of the environment (Spence 2002).

At the outset here, it is important to stress that there are at least three different stages (or ways) at which atmospheric (or contextual) cues influence the consumer's eating and drinking behavior: They may bias the food and drink choices that the consumer makes; they may bias the perceived taste and flavor of food and drink, as well as the consumer's hedonic response to whatever they are consuming; and third, atmospheric cues have also been shown to influence how quickly people eat and drink (and possibly also how much they end-up consuming/spending).

Over the years, various mechanisms have been put forward in order to try and help explain why it is that atmospheric cues influence us in quite the way that they do: They may, for instance, prime a certain idea (e.g., Italian, French, or expense/quality, as a function of the type of music playing) and by so doing bias consumer behavior (Areni and Kim 1993; North et al. 1997, 1999); meanwhile, an emerging body of empirical research now suggests that sensory (especially auditory) cues can also change the perceived taste/flavor of food and drink (a phenomenon that goes by the name of "sonic seasoning"; e.g., see Crisinel et al. 2012; Wang et al. 2017); alternatively, however, atmospheric cues may induce a particular mood or emotion (relaxed/aroused) that can, in turn, bias the consumer's choices (e.g., Edwards et al. 2013; Gardner et al. 2014; Giboreau and Meiselman 2018; Leenders et al. 2016; Meiselman 2016), not to mention their hedonic response upon tasting/consumption (e.g., Kantono et al. 2015, 2016; see also Petit and Sieffermann 2007); There is also a sense in which people's behavior may, to a certain extent at least, be entrained to atmospheric cues (i.e., consumers appear to end-up drinking and dining to the beat; Milliman 1986); finally, atmospheric cues (such as desirable food aromas) have even been shown to stimulate our hunger/desire to eat and drink more directly (Zoon et al. 2016; see Spence 2015a, for a review).

Early research showed that dishes were sometimes rated very differently as a function of the particular environment in which they happened to be served (e.g., Bell et al. 1994; Edwards et al. 2003; Meiselman et al. 2000). So, for instance, the very same food has been shown to be rated more highly when it is served in a 4-star restaurant than when evaluated in a private boarding school dining hall, say (Edwards et al. 2003). While such results clearly do, in a sense, demonstrate the impact of the atmosphere on the tasting experience, such findings perhaps have less to do with the specific sensory attributes of the environment than they do with people's expectations concerning the standard of food that one normally finds in different kinds of eating establishment (see Spence 2017a). Hence, while such findings are undoubtedly important/relevant, in this article, the focus will instead be on the psychological effects of those atmospheric sensory cues that are not necessarily associated with any specific kind of dining environment. At the other extreme, low-level (literally) atmospheric cues including everything from the ambient humidity (e.g., Kuehn et al. 2008) through to any changes in air pressure (Burdack-Freitag et al. 2011) have been shown to influence taste/flavor perception. In fact, the profound changes in taste/flavor perception that are observed between the evaluation of food and drink on the ground versus when sampled up at 35,000 feet, say, has attracted much comment/discussion (see Green and Butts 1945, for early work; and Holthuysen et al. 2016, for more recent work). However, once again, such physico-chemical effects will not be discussed here either (see Spence 2017b, for a review). Instead, this review focuses squarely on the more psychological impact of atmospheric cues on consumer behavior around food and drink.

Having outlined the relevant scope of the review, the next section summarizes the evidence relevant to the atmospheric influence of each of our senses in turn (i.e., audition, vision, olfaction, touch, and finally taste), before turning to the few multisensory studies of atmospherics that have been conducted (or, better said, published) to date. One motivation underlying this review relates to the question of whether we should all be worried about the potential influence of sensory marketing to bias our behavior and perhaps make us consume more than is necessarily good for us (some talk of obesogenic environments; Lieberman 2006; see also Wansink 2004). On the other hand, though, if atmospheric cues really do influence consumer behavior anything like as much as the sensory marketers would have us believe then there may also be scope to use environmental cues to help nudge us all toward more healthy/sustainable (both for us and for the planet) food choices in the future.

Auditory Atmospheric Effects on Eating and Drinking

Auditory cues are among the most important as far as the study of atmospherics is concerned. Note here only how it is normally so much easier to change the music playing in a given environment than it is to change the color of the walls, say, or to ensure an even distribution of ambient scent throughout a large retail space. Certainly, the impact of auditory atmospheric cues is the easiest to study empirically, and perhaps for this very reason there is simply far more research concerning sonic context effects than there is for any other type (or modality) of sensory intervention. Crucially, the majority of the evidence that has been published to date demonstrates that auditory atmospheric cues do exert a significant influence over our food and beverage choices, our perception, and ultimately, our consumption behavior (Lock et al. 2016). Furthermore, such effects appear to occur no matter whether we (as consumers) are aware of them or not, and mostly the evidence suggests that we do not believe that auditory atmospheric cues influence us.

Type of Music

In their now classic study, North et al. (1997, 1999) demonstrated a marked reversal in sales of French and German wine in a British supermarket as a function of whether French accordion vs. German bierkeller music happened to be playing in the background. What is more, only six of the 44 consumers who agreed to be questioned after leaving the tills thought that the atmospheric music had influenced their purchasing behavior. This despite the fact that the till receipts told a very different story. More recently, Zellner et al. (2017) demonstrated that people ($N = 275$ students and faculty) given a choice of Spanish vs. Italian meals (seafood paella vs. chicken parmesan; or other dishes) in a university canteen were significantly more likely to choose the former dish when instrumental Spanish rather than Italian music was playing (34% vs. 17%, respectively). Once again, the majority of diners (82 out of 84) quizzed in this study denied that the background music had influenced their meal choice. And while no effect of musical congruency on hedonic responses to the chosen dish was reported (cf. Yeoh and North 2010, for some weak evidence on this score), this latter null result may simply reflect the fact that (as the authors themselves readily admit) the music was not especially audible in the dining area. Other laboratory research, meanwhile, demonstrates that the type (or genre) of background music can modulate flavor pleasantness and people's overall impression of food stimuli (Fiegel et al. 2014).

While not much hangs on the consumer's choice of French vs. German wine in the supermarket, or Spanish vs. Italian meal selection at the cafeteria, there is a question here as to wonder whether there is not a danger that the global popularity of North American pop music might not be subtly biasing people toward American fast-food offerings (which are not known for being especially healthy; see Schlosser 2001; Spence 2012a). Were Mediterranean music to be more popular, might not more of us be benefiting from the well-established health benefits of the Mediterranean diet (e.g., Bonaccio et al. 2017)? While such a suggestion might seem far-fetched, I do think it is, at the very least, worth considering. Of course, one also needs to remember that not all of the foods we associate with the Mediterranean, think only of pizza, pasta, salami, are necessarily particularly healthy.

The available research also demonstrates the influence of classical music on people's behavior. In particular, classical (as compared to other styles of) music (e.g., Top-40 type tracks) has been shown to result in people spending significantly more on their food and drink purchases, in venues as diverse as a wine shop (Areni and Kim 1993), the student cafeteria (North and Hargreaves 1998; North et al. 2016, 2003), and even in an African-themed restaurant (Wilson 2003). Specifically, Wilson's research showed that, on average, the 300 diners whose behavior was assessed spent significantly more when classical, jazz, or popular music was played than when there was easy-listening music, or else when the music was turned off. The suggestion is that this style of music is associated in the mind of consumers with notions of class, and so primes notions of quality/expense (that, in turn, leads to increased spending; though see also de Wijk et al. 2018a, for a recent null result). At the same time, however, it is important to bear in mind that classical music is certainly not to everyone's taste. According to a recent press report, one fast food chain here in the UK has been experimenting with the broadcasting of classical music as a means of deterring feral youths from lingering around the premises (Taylor 2017)!

Musical Tempo and Loudness

Several studies have demonstrated that a range of consumer behaviors are entrained to the tempo of the background music (Roballey et al. 1985). So, for instance, laboratory studies show that people drink faster when high tempo music is played. Intriguingly, similar results have also been reported in restaurants (e.g., Bach and Schaefer 1979; Caldwell and Hibbert 2002; Milliman 1986). In one of the largest studies of its kind, Milliman reported a 30% increase in average dollar spend on the bar tab among 1,400 diners when slow- (rather than fast-) tempo music was played, the idea being that it encouraged them to linger for longer. That some food chains really do control the flow of customers in this way is suggested by the following quote from Chris Golub, the person responsible for selecting the music that plays in all 1,500 Chipotle branches in the USA: "*The lunch and dinner rush have songs with higher bpms because they need to keep the customers moving*" (quoted in Suddath 2013).

Laboratory research has also demonstrated that increasing the loudness of the background music may result in people drinking more (e.g., McCarron and Tierney 1989). Real-world studies confirm that people tend to drink more when the loudness of the music is turned up (Guéguen et al. 2004, 2008). Interestingly, according to a report that appeared in *The New York Times,* the Hard Rock Café chain plays loud music because of the positive effect they believe that it has on sales. Just take the following quote from the newspaper article itself: "*[T]he Hard Rock Café had the practice down to a science, ever since its founders realized that by playing loud, fast music, patrons talked less, consumed more and left quickly, a technique documented in the International Directory of Company Histories*" (Buckley 2012). Meanwhile, according to another report: "*When music in a bar gets 22 per cent louder, patrons drink 26 per cent faster*" (Clynes 2012). That said, the most appropriate loudness level for the music may depend on the style of restaurant or bar. So, for instance, the 80 diners in a study by Lammers (2003) spent around 15% more when quieter (as opposed to louder) background classical or soft rock music was played. According to the author, this result might reflect the fact that quieter music better matched the "serene" atmosphere of the oceanside California restaurant than did the louder music.

There is a growing groundswell of opinion out there suggesting that many restaurants/bars in North America, the UK, Australia, and beyond are becoming louder (e.g., McLaughlin 2010; Moir 2015; Sietsema 2008a, b). It should be noted, though, that this is not solely due to the result of chefs/restaurateurs deciding that loud music in the dining room is a good idea (Spence 2015b). Rather, part of the blame should also be placed at the doors of those who believe that removing all those sound-absorbing soft furnishings (curtains, cushions, and carpets) and replacing them with hard reflective surfaces is a good idea (see Spence and Piqueras-Fiszman 2014). Of course, that being said, the sonic racket is sometimes used as a means of deterring a certain section of the populace from drinking/dining there (Forsyth and Cloonan 2008).

When the music or background sound level becomes too loud, it is classified as "noise" (i.e., sound that is unpleasant), and this may negatively impact people's perception of food and drink. For instance, loud noise (be it white noise or the sound of the engines while flying) actually suppresses our ability to taste sweet and salt while enhancing the perception of umami (Woods et al. 2011; Yan and Dando 2015). Similarly, loud music also appears to interfere with people's ability to determine the alcohol content of drinks (Stafford et al. 2013, 2012; see also Pellegrino et al. 2015). Given the evidence from studies of airline noise just mentioned, one might wonder whether similar increases in sugar/salt might also be needed to make the food stand up to the auditory atmospheric onslaught in overly loud restaurants? Hypothetically, it might also be speculated that those cuisines that are naturally umami-forward would do especially well in such noisy dining environments.

Sonic Seasoning

Recent empirical research has demonstrated that the sensory attributes of music playing in the background can also influence taste/flavor perception via what has come to be known as "sonic seasoning." While much of this research has been conducted in the laboratory and/or at experiential experimental events, the findings have now been extended to the retail environment too. For instance, Wang et al. (2017) recently demonstrated that when "spicy" music was played in a restaurant (in Nashville, TN), diners rate a spicy salad as tasting significantly spicier than when compared to putatively "sweet" music, white noise, or silence was presented instead. Elsewhere, researchers have provided evidence to show that a range of other taste/flavor attributes (including sour, creamy, bitter, and sweet) can also be modulated by what we hear. Taking things one stage further, Blecken (2017) reports on a café in China that plays high-pitched music all day long with the idea that it will help make the cakes, pastries, and drinks taste a little sweeter, and by so doing allow the owners to reduce the sugar content in their product. It is, though, a little harder to say whether this is more marketing-led story than a serious long-term strategy to help with the growing obesity crisis!

Interim Summary

Taken together, it can be seen that the results of a large number of studies published in recent decades have demonstrated the profound impact of the auditory environment on people's behavior around food and drink (see Spence 2012a; Spence and Shankar 2010; Spence et al. 2011; Stroebele and de Castro 2004, for reviews). While the majority of this research has been conducted in the setting of the science lab, there is now a growing body of evidence suggesting that auditory cues also influence the consumers' perception of taste/flavor, as well as their food and drink behavior in restaurants and bars too (see Spence 2017a, for a review). That being said, before closing this section, it is worth noting that not every study has demonstrated a significant effect of the background auditory atmosphere on people's consumption behavior (e.g., see Mamalaki et al. 2017; Peneau et al. 2009; Pettit 1958, for a few null results). It is also important to bear in mind that there may well be a “file drawer problem” in this area, as in many other areas of science (e.g., Rosenthal 1979). Namely, null results are far presumably far less likely to be published than are those studies showing a significant impact of the atmosphere on people’s eating and drinking. So, for instance, Mamalaki et al. reported recently that varying the loudness of the background music (Smokey Bandits’ 2010 debut album played at 67 vs. 90 dB vs. no music) had no observable impact on people’s *ad libatum* consumption at a buffet lunch in a carefully controlled crossover study conducted in a laboratory study in Greece. That said, the number of participants was very low (only 16 normal weight individuals and 10 obese participants were tested). Similarly, in one of the earliest studies to have been published on auditory atmospherics, Pettit (1958) reported that playing prerecorded restaurant noises had no effect on people’s ratings of tomato juice.

Visual Atmospheric Effects on Eating and Drinking

The research that has been conducted to date in order to assess the impact of ambient visual cues on eating and drinking has primarily focused on studies of the brightness (Gal et al. 2007; Xu and Labroo 2014) and hue of the ambient lighting (e.g., Cho et al. 2015; Spence et al. 2014a), on wall/fixture color schemes (Jacquier and Giboreau 2012a, b; Robson 1990). Other researchers, meanwhile, have tried to create a particular ethnic feel in a canteen restaurant by means of the use of semantically meaningful visual cues – think Italian flags, red and white checkered tablecloths, and wine bottles on the tables (Bell et al. 1994). In an unpublished laboratory study, Gal et al. (2007) reported that those who liked strong coffee tended to drink more under conditions where the ambient lighting was bright, while those who preferred weaker coffee drank more under dim conditions. Meanwhile, Xu and Labroo (2014) demonstrated that people tended to order significantly spicier chicken wings under conditions where the ambient lighting was brighter. (Note that chicken wings are ideal for this kind of research since they come in a wide range of spiciness levels.) Interesting here is the suggestion that high-turnover restaurants like Hard Rock Café and Planet Hollywood do not have windows to better control the ambient light levels (Robson 1999; see also Lampi 1973).

Several studies have demonstrated that changing the hue of the ambient lighting can influence people’s perception of the taste/flavor of wine (e.g., Oberfeld et al. 2009; Spence et al. 2014a). Elsewhere, researchers have reported that Scandinavian men consume less breakfast under blue lighting than under regular white lighting (Cho et al. 2015). As yet, however, it is unclear why the latter atmospheric manipulation should only have influenced male participants. According to a number of anecdotal reports, painting the walls Baker-Miller pink (which is close to bubble gum pink) suppresses appetite (cf. Alter 2013; Ferrier 2017). However, there does not appear to be any sound peer-reviewed scientific research to back up this particular assertion. According to other research, yellow lighting increases people’s appetites, whereas red and blue lighting decrease their motivation to eat (see Spence

2017a, for a review). Furthermore, when the color of the food and of the ambient lighting match, it appears to stimulate appetite, whereas complementary colors suppress it (Suk et al. 2012; see also Robson 1999). Although variations in the color of the walls are likely to be an important element of atmospherics, it is somewhat harder to study (or rather, to manipulate, experimentally). That said, there has not been so much published research concerning other visual cues either.

In one early study, though, Bell et al. (1994) were able to demonstrate that giving a cafeteria an Italian theme (with Italian flags on the walls; wine bottles and red and white checked table cloths on the tables) led to more customers choosing the Italian option from those that were available. That said, the names of the dishes were also changed so as to give them more of an Italian flavor. Hence, it is simply not possible to determine the relative importance of these manipulations to the pattern of results that were reported. In summary, then, while visual cues are likely very important in terms of modulating the atmosphere, they have not been studied empirically anything like as thoroughly as have auditory cues. That said, what evidence there is, supports the view that visual atmospherics (be it is terms of lighting, wall color, and / or decorations) does indeed influence people's choice behavior, their flavor perception, and ultimately their consumption of food and drink.

Olfactory, Gustatory, and Tactile Atmospherics

The presence of ambient food aromas often influences people's food and drink choices (e.g., de Wijk et al. 2018b; De Wijk and Zijlstra 2012; see Spence 2015a, for a review). Furthermore, there is plenty of anecdotal evidence to suggest that companies have been strategically using ambient food-related scent in a variety of retail contexts (Nassauer 2014). That said, it is important to stress the discrepancy between the claims of some of those companies that provide the technical solutions to help others release food aromas in various retail settings (and who would, for example, have us believe that aroma release can have a really dramatic effect on sales) and the much more modest effects that have been documented in well-controlled peer-reviewed academic research. According to one company, for instance, introducing a coffee scent at the service station apparently led to a 300% increase in sales of coffee (see Spence 2015a, for a review). Meanwhile, research by Leenders et al. (2016) documented that consumers spent more when there was a fruity aroma in the air. Specifically, the 300 supermarket shoppers whose behavior was assessed in this study ended-up spending 14% more when there was a melon scent in the air as compared to a baseline no-scent condition. What is more, the more intense the scent, the longer the shoppers stayed in store. This aroma intensity-related behavioral response might then help to explain why de Wijk et al. (2018a) observed no effect of the addition of congruent or incongruent scent versus no scent in their Dutch supermarket study. For, as the authors of the latter study themselves stated, they adjusted the intensity of the aroma release until it was barely noticeable even by someone standing directly in front of the relevant display. Elsewhere, Guéguen and Petr (2006) conducted a small study ($N = 88$ diners) in a pizzeria in

Brittany, France. These marketing researchers demonstrated that the scent of lavender resulted in the customers staying longer and spending more than when a citrus scent (or else no scent) was present. In this case, the suggestion was that the lavender might have exerted its influence over diners by relaxing them.

In terms of gustatory atmospherics, there is not much to say other than to think about how offering food and beverage product samples in store may provide an effective means of encouraging exposure to a product or brand and hence increase purchase likelihood (see Spence et al. 2014). One might also perhaps think about the growing tendency to offer amuse bouche in high-end restaurants too (see Spence 2017a).

To date, there has been far less research on the tactile side of atmospherics. However, it would seem reasonable to assume that changes in the ambient temperature might well exert some influence over people's eating and drinking behavior (e.g., Gómez-Corona et al. 2017; Motoki et al. in press; Zwebner et al. 2014; see also Brobeck 1948; Campbell-Arvai et al. in press; Stroebele and De Castro 2004). The use of seating that is more or less comfortable to encourage consumers to linger or not, as the case may be, has also been discussed (Robson 1999; Spence 2017a). It may, of course, also be relevant here to consider interpersonal touch as part of tactile atmospherics. There have, after all, been a number of studies of the "Midas Touch" effect (see Gallace and Spence 2014, for a review). Specifically, people appear to engage in more pro-social behaviors, to tip more generously, and be more likely to go with the waiter's suggestion if they have just been casually touched by another person (Guéguen et al. 2007). What is more, there is evidence to suggest that being touched by the waitress influences alcohol consumption too (Kaufman and Mahoney 1999; though cultural factors will undoubtedly play a role here; see Gallace and Spence 2014, for a review). According to one press report, a number of CEOs actually insist that their staff engage in more interpersonal touch in store. Just take the following from one newspaper article concerning what happens whenever Pret a Manger's chief executive, Clive Schee, visits a branch: "*the first thing he checks is whether staff are touching one another, declaring: 'I can almost predict sales on body language alone*'" (McDermott 2013). At the same time, however, it is important to bear in mind that too much touch from other customers can be stressful in a retail setting (Martin and Nuttall 2017). This is also likely to be true in those environments where people eat and drink as well. In summary, then, olfactory, tactile, and to a lesser extent gustatory atmospherics are an important part of the total multisensory atmospheric offering.

Multisensory Contributions of the Atmosphere to Eating and Drinking

As mentioned already, there have been fewer studies that have manipulated atmospheric cues in two or more senses at one and the same time. That said, one illustrative example of just how profoundly taste/flavor perception can be changed by such interventions is illustrated by Velasco et al. (2013). These researchers demonstrated that simply by changing the auditory, visual, and ambient olfactory atmosphere in a somewhat caricatured manner (to create a grassy room, a sweet room, and a woody room) their participants ($N = 500$) rated a glass of whisky as tasting 10–20% more grassy on the nose, sweeter on the palate, and/or textured on the aftertaste as a function of the multisensory atmosphere in which the whisky was rated. Meanwhile, in another study, Spence et al. (2014) combined red/green lighting with sweet/sour sonic seasoning (i.e., music that had been specifically composed in order to match a specific taste) in order to deliver a 15–20% change in the ratings of over 3000 people who evaluated a glass of red wine served in a black tasting glass. And while the majority of that effect could be put down to the change in the ambient lighting (from red to green or vice versa), these researchers were able to show that adding congruent music led to a significantly larger change in people's rating of the drink.

Wansink and van Ittersum (2012) tested the impact of changing both the lighting and music on diner behavior in a restaurant. There were two dining areas in Hardee's, a North American fast food restaurant. The lighting in one was set at its normal bright level, the color scheme was also bright, and the background music was loud. The other "fine dining" environment had a much more relaxed atmosphere with pot plants, paintings on the wall, blinds on the windows, and indirect lighting. The tables were covered with white-tablecloths and there were candles and soft jazz instrumental ballads in the background. Those who ate in the more relaxed side of the restaurant rated their meal as significantly more enjoyable, while at the same time consuming less (their calorie intake was reduced by an average of more than 150 calories, or 18%). Sester et al. (2013) reported on a couple of studies showing that they were able to bias which beer people chose at a bar by means of different immersive audiovisual environments.

Finally, here, it is important to note (once again) that not everyone has demonstrated an impact of multisensory atmospheric cues on the tasting experience. Jiang et al. (2017), for instance, recently reported that changing the visual atmospherics in a room (introducing flowers, pictures, and colored lighting) did not influence people's ($N = 105$ wine consumers) rating of a red wine. One atmospheric condition had a floral theme, the other, a "green" theme, with the researchers wanting to know whether they could bring out the floral or green notes in the three Cabernet Sauvignon wines that the participants got to taste. Taken together, though, the limited evidence published to date clearly supports the view that the multisensory atmosphere can influence people's taste/flavor perception, their choice behavior, and even how much they end up consuming. When thinking about the design of multisensory atmospherics, the aim is normally to try to ensure that the various sensory cues converge on a particular feeling or mood (Spence 2002; cf. Helmefalk and Hultén 2017). At the same time, however, it is also important to make sure that the combined pattern of multisensory stimulation does not give rise to sensory overload (Malhotra 1984; cf. Rupp 2014).

Sensory Marketing Versus Sensory Nudging

Before closing, it is worth drawing out the tension that can be seen to exist here between the sensory marketing approach to the design of retail atmospherics and the emerging sensory nudging approach to modifying the food environment/landscape.

The stated aim of sensory marketing is, not to put too fine a point on it, to get consumers to buy more "stuff" (e.g., Cooper 2013; Hilton 2015; Lipman 1990; Stevens 1980). To the extent that such strategies are successful, they presumably encourage many of us toward consuming (or at least purchasing) more food and beverage products than perhaps we otherwise might. Intriguingly, one of the few complaints resulting from the release of ambient scent occurred was when a cookie aroma was emitted from bus shelters in California some years ago. The suggestion was that this was insensitive to the homeless who often use such shelters for shelter (Cuneo 2006). By contrast, the stated aim of sensory nudging is to try and help the consumer toward making slightly less unhealthy food choices/behaviors. Achieving that goal is not always as easy as one might wish. For example, Kroese et al. (2016) reported that moving the fruit closer to the till in a supermarket food outlet did indeed nudge customers toward buying more fruit than they otherwise would have done. Unfortunately, however, the consumers also bought the same amount of the less healthy foods as before, thus meaning that this particular nudge led to an increase in the overall amount of food purchased. Not exactly the ideal outcome!

When thinking about the relation between sensory marketing and sensory nudging, it is also worth drawing attention to the fact that sensory marketers often argue that their effects operate at a non-conscious level (see North et al. 1997, 1999; Zellner et al. 2017, for evidence on this score). As such, the consumer may not be aware that their perception/behavior is being affected and hence will, as a result, presumably find it difficult to ignore such effects voluntarily (i.e., at will). By contrast, time-and-again the proponents of nudging (be it of the choice architecture or sensory variety) stress the "libertarian paternalism" underlying their approach (Mathis and Tor 2016; Thaler and Sunstein 2008). Specifically, they want to emphasize that their interventions are for the "greater good" and that they rely on inertia on the part of the consumer/general public. But the key point to remember is that they are said to operate at a conscious level and hence can be ignored or overridden at will (i.e., it is not a matter of removing any choices or options, but rather on making the default choice/behavior the easiest one).

While the majority of the commercial sensory marketing research would appear to have been directed toward increasing sales, it is worth noting that modifying the auditory atmosphere (e.g., by playing the sounds of the sea) has been shown to play a potentially beneficial role in terms of improving the nutritional intake among older patients (Ragneskog et al. 1996) and even psychiatric patients (Goddaer and Abraham 1994, p. 150). The suggestion in the latter case was that the music helped relax the agitated patients and by so doing resulted in their consuming more. There is an emerging literature on enhancing the multisensory design of hospital/care facilities more generally, and part of that revolves around ensuring adequate nutrition through environmental manipulations (see Spence 2017b). In this case, some of the techniques would appear to come straight out of the sensory marketing textbooks but to have an aim (enhancing people's well-being) that is more in line with the principles underlying the sensory nudging approach. Indeed, looking to the future, there may be a fruitful interplay between marketing and nudging, using the most effectively techniques of marketing to more effectively nudge the nutritional behavior of the consumer.

Conclusions

Most people believe that they are in control of their eating and drinking behavior, that they decide what to eat and drink and when, and that they choose when to stop. However, the research that has been published over the last half a century or so clearly demonstrates that atmospheric cues (no matter whether they are auditory, visual, olfactory, tactile, gustatory, or multisensory) can exert a significant influence over many aspects of our eating and drinking behavior. What is more, sometimes at least they can do so without consumers having any awareness that their behavior has been influenced (e.g., see North et al. 1997, 1999; Zellner et al. 2017). So, to the extent that one believes in the power of the sensory marketing approach (see Spence 2015a, on this point), we should all perhaps be rather more concerned about the potential danger of being encouraged, almost subliminally (Spence 2012b), to eat and drink more than perhaps we should (cf. Spence et al. 2016). (Here, it is worth noting that while much of the research on atmospherics has been conducted on student populations (the so-called WEIRDo's; Henrich et al. 2010) in laboratory studies (and hence are of questionable real-world relevance), there are now a growing number of studies demonstrating similar effects in naturalistic environments too.) On the flip side, however, there is also growing interest in the intelligent modification of environmental sensory cues (not to mention the "choice architecture" in those situations where food choices are salient) in order to try and nudge us toward healthier food behaviors (e.g., Guthrie et al. 2015; Kroese et al. 2016; McKie 2017; Campbell-Arvai et al. in press). In the future, it will be interesting to see how "the good and the bad" sides of multisensory atmospheric design play out. And no matter how things turns out, one clear end result would appear to be that people become more aware of the power of atmospheric effects to bias their eating and drinking.

Social Influences on Eating

14

Suzanne Higgs and Helen Ruddock

Contents

Abstract

Eating plays a central role in many social activities, and there is ample evidence to suggest that social context exerts a pervasive and powerful influence on what, and how much, people eat. This chapter presents an overview of the research on social influences on eating, with a specific focus on three main areas. First, we present evidence that people tend to adapt their food choices to those of other people, which is known as modelling. Second, we discuss evidence that people use their eating behaviors to convey a favorable impression of themselves to other people, which is known as impression management. Third, we present evidence on the social facilitation of eating, which is the tendency for people to eat more when eating with friends/family than they do

when they eat alone. Throughout the chapter, we discuss the factors which may moderate the strength of these social influences on food intake and consider the mechanisms through which social influences affect eating.

Introduction

Eating is often a social activity. Sharing a meal with friends, family, or work colleagues is common in many areas of the world including the USA, Europe, and Thailand (Oh et al. 2014; Davidson and Gauthier 2010; Yiengprugsawan et al. 2015). Indeed, some people would consider that a meal that is not shared is not really a meal at all (Fischler 2011). Eating with others plays a role in reinforcing social connections, and food choices can be used to communicate and express ourselves to others (Murcott 1983). The social context in which we eat or make food choices also influences what and how much we choose to consume. A large body of evidence has now accumulated to suggest that other people influence our food intake and choices in a variety of ways (Higgs and Thomas 2016). For example, there is a general tendency for people to use others' eating as a guide for what and how much to eat, which is known as modelling. People also use their eating behavior to convey a particular impression of themselves to others and may make particular food choices because they think those choices will portray themselves in a favorable light, which is known as impression management. Another example of how social context affects eating is that when eating in a group of friends, people are likely to eat more than they would if they ate alone, which is known as the social facilitation of eating. The aim of this chapter is to present an overview of research into social influences on eating. We consider the three main research areas of (1) modelling of eating, (2) impression management, and (3) the social facilitation of eating.

Modelling of Eating Behaviors

The decisions that people make about what and how much to eat are influenced by their perceptions of the choices of others. The tendency to adapt one's behavior to be similar to that of other people is known as modelling (Vartanian et al. 2013). It has been suggested that modelling occurs because other people provide a guide as to appropriate behavior (Herman et al. 2003). The appropriate behavior, or what is known as a social norm, can be set by another present person (i.e., another person present at the eating occasion), but may also be communicated by environmental cues (e.g., portion sizes) or by the transmission of information about how other people behave (e.g., messages/text describing the behavior of others). A robust finding from studies conducted in controlled laboratory settings is that both adults and children model the consumption of others. That is, they tend to consume *more* when they eat with someone who is eating a large amount and *less* when they eat with someone who is eating a small amount, compared with when they are eating alone (e.g., Bevelander et al. 2012; Robinson et al. 2013; Salvy et al. 2008).

There is evidence from lab-based experimental studies that people also model the food choices of others. A study of food choices at a buffet found that the choices made by a confederate (a person known to the experimenter who was pretending to be another participant in the study) influenced the food selection of participants who observed these choices. Relative to a choosing-alone condition, and a condition in which the confederate chose predominantly low-calorie food items, the presence of a confederate who made high-calorie choices resulted in the participants choosing and consuming significantly fewer low-calorie items (Robinson and Higgs 2013). Conversely, choice of low-calorie vegetable items at a buffet was increased after students who were low habitual consumers of vegetables were informed about the relatively high vegetable consumption of other students (Robinson et al. 2014). However, Pliner and Mann (2004) found that when the communicated norm was consumption of a "healthy" bad tasting cookie, participants in a lab-based experiment were not inclined to follow this norm and instead chose to consume an "unhealthy" but good tasting cookie. These data suggest factors such as the palatability of food may override the influence of social norms under some circumstances. If someone is sure of what they like to eat, then that person may not look to others to guide their own preferences.

Evidence from field studies supports the suggestion that people do model the food choices of others outside of the laboratory. Teenage girls who shopped with a peer who made high-calorie purchases were more likely to purchase high-calorie food products relative to girls who shopped with a peer who made low-calorie choices (Bevelander et al. 2011). Diners in a restaurant were more likely to make healthier choices when they were provided with information about the healthy choices of other diners in that restaurant (Mollen et al. 2013; Thomas et al. 2017; Collins et al. 2019). Christie and Chen (2018) reported recently that customers in a restaurant modelled the main lunch choices of the person ahead of them in the lunch queue; customers were more likely to choose a vegetarian option if the person in front of them in the lunch queue chose that option.

Data from observational studies further support the idea that modelling of food choices occurs in real-life social relationships. It has been noted that the diets of socially connected individuals tend to be correlated and that people's eating choices are similar to the eating choices of those with whom they are socially connected (de la Haye et al. 2013; Pachucki et al. 2011). For example, it has been reported that women who dined more often with healthy eaters reported a higher diet quality than women who shared meals more frequently with unhealthy-eating companions (Mötteli et al. 2017). In addition, it has been observed that food choices of married couples tend to converge over time (Bove et al. 2003).

Why Model?

One reason why people model the eating behavior of others is because imitating the behavior of another person serves to smooth the social interaction (Chartrand and Bargh 1999). Humans have a strong desire to be liked and this goal may be achieved through modelling (Baumeister and Leary 1995). As the saying goes, imitation is the sincerest form of flattery. The idea that people model the eating behavior of another person in order to affiliate with that person is supported by evidence that traits linked to the need for affiliation, such as self-esteem and empathy, are associated with the tendency to model food intake (Robinson et al. 2011). In addition, modelling of eating behavior has been found to be particularly pronounced in social situations that demand effort to affiliate (e.g., in a situation in which the model is acting in an unsocial manner), relative to situations in which there is less of a need to ingratiate oneself (e.g., when the model is already acting in a friendly manner) (Hermans et al. 2009; Robinson et al. 2011). The results of these studies are consistent with the idea that modelling is a means of gaining acceptance from others (Higgs 2015).

Modelling also occurs because others provide information about what is the "right" way to behave and people are generally motivated to behave in a way that is "correct" (Deutsch and Gerard 1955). We know this because modelling can occur in situations where the social norm is conveyed by *information* about how other people have behaved rather than by *another present person*. In these situations, modelling cannot promote affiliation or a sense of belonging, because there is no other person present to impress. One type of study design that examines how people behave when exposed to such "informational social norms" is known as the remote confederate design. In these types of studies, participants "accidentally" see fictitious accounts of the amount of food consumed by previous participants in that study (e.g., see Feeney et al. 2011; Pliner and Mann 2004; Roth et al. 2001). Amounts consumed by previous participants in a study can also be communicated via cues such as empty food wrappers (assumed to have been left by previous participants) or by text-based descriptive norm messages conveying information about the eating behavior of others. In all cases, there is evidence that people follow the norm provided. For example, people are more likely to choose a "healthy" versus "unhealthy" food item if they see evidence that previous participants have chosen "healthily" (Prinsen et al. 2013), and they are more likely to choose a large amount of cookies to eat if they see that other participants have done so and choose a small amount of cookies if that is the norm in that situation (e.g., Robinson et al. 2013; see Fig. 1). In these cases a likely explanation for the modelling observed is that the normative information that is provided indicates the "right" way to behave (e.g., Roth et al. 2001).

According to the normative account of modelling (Herman et al. 2003), people are often motivated to eat as much palatable food as they can without appearing greedy. In a social situation, the amount that one can eat without appearing to be eating excessively is set by the amounts that other people are eating such that a dining companion with a small appetite will result in a person eating very little, whereas dining with someone who is eating a large amount gives a person license to eat a large amount too. Data to support the normative account come from a study which found that perceived norms of appropriate intake mediated the effects of the social model on participants' food intake (Vartanian et al. 2013).

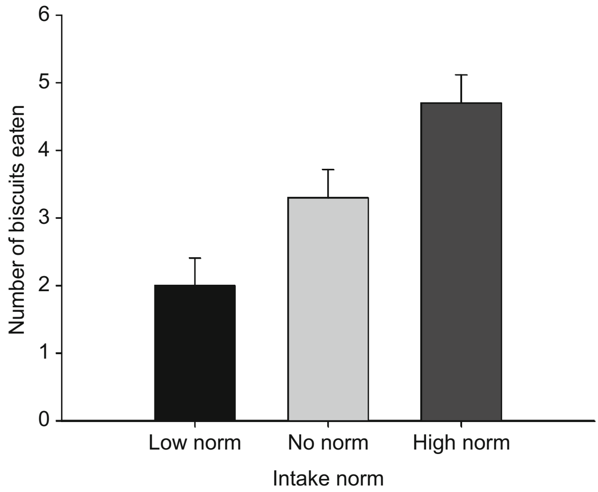

Fig. 1 Number of cookies eaten according to condition: participants eat fewer cookies in the low norm condition compared with the no norm condition, and they eat more cookies in the high norm versus the no norm condition. (Adapted from Robinson et al. 2013)

Factors that Affect Modelling

The results of two systematic reviews of a large collection of studies suggest that modelling of eating behavior is not dependent on current hunger state, dieting status, or familiarity with the model (Cruwys et al. 2015; Vartanian et al. 2015) (Fig. 2). However, there are some circumstances under which modelling is less likely to occur. If the model is from a social group that the participant does not feel a strong connection with, or the model is perceived as dissimilar to the participant, then modelling is reduced (McFerran et al. 2010; Stok et al. 2014; Cruwys et al. 2012; Liu and Higgs 2019). This is probably because the model is not thought to provide a relevant norm. For example, when participants were told that the size of a portion served was based on the behavior of group to which they did not belong, they were less likely to use that portion size as a guide to appropriate consumption (Versluis and Papies 2016).

Modelling is also less likely in situations for which there are established eating habits (Hermans et al. 2010; Leone et al. 2007). There is evidence that people are less likely to model the breakfast consumption of others than they are to model snack intake (Hermans et al. 2010; Leone et al. 2007). Many people have a clear idea about what constitutes appropriate consumption at breakfast as it is an habitual behavior, but they are perhaps less sure about what is "normal" when it comes to snack consumption and so more likely to use the behavior of others to guide their own intake.

Mechanisms Underlying Modelling

The mechanisms underlying modelling have not been fully elucidated, but it is possible that people directly mimic the behavior of others by copying their actions, a tendency that may occur automatically and outside of conscious awareness

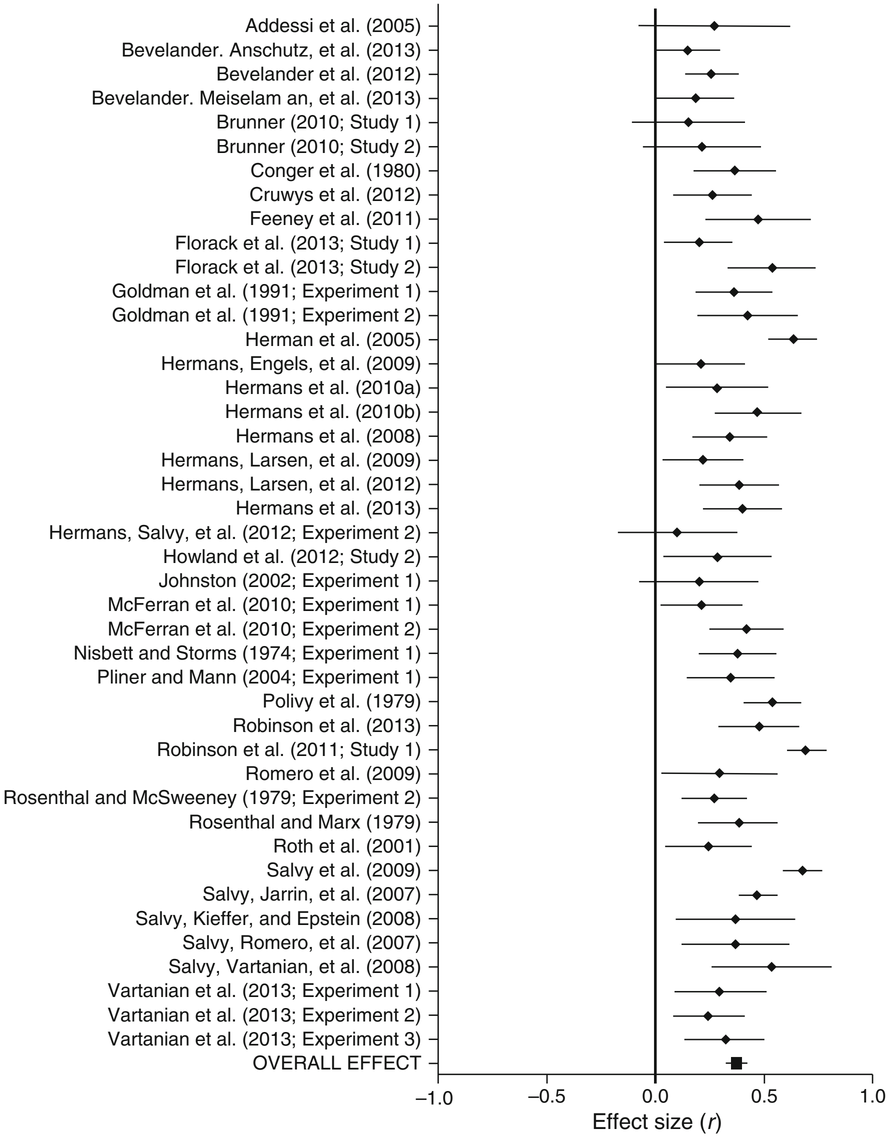

Fig. 2 Forest plot of effect sizes for all studies included in the meta-analysis. For ease of presentation, an average effect size is provided for each individual study. (Source: Reprinted from Vartanian et al. 2015, with kind permission from Elsevier Science Ltd., The Boulevard, Langford Lane, Kidlington OX5 1GB, UK)

(Chartrand and Bargh 1999). In support of this idea, it has been reported that co-eaters coordinate their eating-related actions and take a sip of a drink or reach for food immediately after a model performs the same behavior (Hermans et al. 2012; Sharps et al. 2015). There may also be some explicit tracking of the consumption of another person that facilitates modelling (Vartanian et al. 2013).

Modelling may be facilitated by changes in preferences for food/drink items. Bringing behavior in line with a norm has been reported to be a rewarding experience (Nook and Zaki 2015), and eating in the presence of someone else has been shown to enhance the pleasure derived from eating (Boothby et al. 2014). If we are told that our peers have a preference for a specific food, then we expect to like it too (Robinson and Higgs 2012). These data suggest that modelling is a behavior that is reinforced because it has positive consequences.

Impression Management

Impression management is when we behave in a particular way to convey a specific impression of ourselves to others (Leary 1995). Impression management concerns are usually highest when we are interacting with people whom we do not know very well, and in these situations we are usually motivated to present ourselves in a positive light (Baumeister and Leary 1995). One way in which we can manage the impression we give to others is via the decisions we make about what and how much to eat (Vartanian et al. 2007). This is because we hold shared assumptions with others about the characteristics that are associated with people who make certain consumption choices. These assumptions are known as consumption stereotypes. We tend to make judgments about others based on these stereotypes, but we also use them to manage others' perceptions of ourselves (Vartanian et al. 2015). For example, we may choose to eat a salad over a pizza in some social situations because we know that eating the salad will convey something to those around us about our personality. Interestingly, even children have been found to judge others based on their food choices and to make negative judgments about people who deviate from conventional eating habits (DeJesus et al. 2019).

Consumption Stereotypes

There is ample evidence that certain foods and food choices are associated with specific characteristics, particularly attributes associated with gender. For example, meat eating is associated consistently with masculinity (Rozin et al. 2012; Rothgerber 2013), whereas meat avoidance and consumption of vegetables, salad, fish, and sweet foods are associated with femininity (Cavazza et al. 2015; Jensen and Holm 1999; Rothgerber 2013; Ruby and Heine 2011). In general, eating "good/healthy" foods is seen as feminine, and eating "bad/unhealthy" foods is seen as masculine. Men who ate "bad" foods (i.e., high-calorie foods thought to be bad for health) were rated as more masculine (and less feminine) than were men who ate "good" foods (i.e., low-calorie foods thought to be good for health) (Stein and Nemeroff 1995). Consumption of low-fat foods is seen as more feminine and less masculine than is eating high-fat foods (Barker et al. 1999). This may be because people automatically think of foods as either feminine or masculine and attribute these characteristics to the eater (Kimura et al. 2009). Similarly, consumption of "good" foods may result in the eater being perceived as having a "good" character.

People who eat “good” foods are perceived as being “better” people than are those who eat “bad” foods: they are rated as more attractive, healthier, more moral, and more intelligent than are consumers of “bad” foods (Stein and Nemeroff 1995). On the other hand, consumers of “good” foods are also judged as more serious and less likable (Barker et al. 1999), whereas consumers of “bad foods” are perceived to be fun-loving, happy, and sociable (Barker et al. 1999).

People also hold stereotypes about the characteristics associated with eating small versus large amounts of food. Eating a large portion is associated with masculinity and eating small portion is associated with femininity (Bock and Kanarek 1995). Women who eat small meals are rated as more attractive than are women who are depicted eating large meals (Chaiken and Pliner 1987; Bock and Kanarek 1995).

Do Consumption Stereotypes Guide Behavior?

The majority of studies on eating and impression management have focused on the consumption stereotypes that people hold rather than investigating whether these consumption stereotypes actually explain eating choices. However, some studies have found that women tend to eat lightly in the company of men, and this may be motivated by attempts to portray an impression of femininity and behave in a socially desirable manner (e.g. Pliner and Chaiken 1990; see Table 1). Cavazza and colleagues (Cavazza et al. 2015) reported that women’s intentions to consume particular dishes were influenced by the perception of the dish as feminine or masculine: women reported that they intended to consume a small portion of salad when it was elegantly presented, because they perceived it to be more feminine. There is also evidence that the food choices made by men may be motivated by impression management under some circumstances (White and Dahl 2006; Gal and Wilkie 2010). In one study, participants were asked to imagine that

Table 1 Mean cracker consumption as a function of participant sex and partner sex. Females but not males ate less in the presence of a desirable partner than in any other conditions. (Source: Reprinted from Pliner and Chaiken 1990, with kind permission from Elsevier Science Ltd., The Boulevard, Langford Lane, Kidlington OX5 1GB, UK)

		Male subjects		
		High desirability	Low desirability	Combined
Sex of partner	Male	12.5(11)	17.3(14)	15.2(25)
	Female	14.3(15)	12.4(9)	13.6(24)
		Female subjects		
		High desirability	Low desirability	Combined
Sex of partner	Male	8.8(10)	12.1(14)	10.7(24)
	Female	12.5(13)	14.0(10)	13.2(23)

Note. Amounts are expressed in terms of number of crackers. *N*’s are in parentheses they had been in workshops all day as part of a training course and that they were planning to order from the room service menu for dinner. To encourage choice of a small steak, the participants were told: “You aren’t feeling too hungry because you had a late lunch; however, you are tempted to select steak for dinner.” They were then asked to select from a hypothetical menu and to evaluate each menu option. Men were less likely to choose a small steak (versus a large steak) when it was described as a ladies’ cut than when it was described as a chef’s cut, but only when they thought they would be eating the steak in public and not when they thought they would be consuming it in private, which suggests that their choice was motivated by the effects they thought their choice would have on others (White and Dahl 2006). In another study, men who had their masculine identity challenged as part of the study were less likely to choose stereotypically feminine foods, compared with those who had their masculine identity affirmed, perhaps because they were motivated to counter the challenge to their identity using their food choices (Gal and Wilkie 2010).

Social Facilitation of Eating

The mere presence of other people at a meal can result in increased food intake relative to eating alone, which is known as the social facilitation of eating. The first studies that documented the social facilitation of eating were food diary studies that involved participants recording what and how much they ate over 7 days and with whom they ate (de Castro and Brewer 1992; de Castro and de Castro 1989). It was a surprise to the researchers that one of the most significant influences on food intake was the social context in which people said they ate: people reported eating much more food when they ate in company than when they ate alone. Social facilitation appears to occur at all meal types including breakfast, snacks, meals eaten at home, and meals eaten without alcohol (de Castro 1991). Social facilitation also occurs for meals eaten at the weekends and weekdays. These findings are particularly interesting because they suggest social facilitation of eating is not an artifact that arises because people eat more, and are more likely to eat with others, during certain meals/eating occasions, e.g., meals taken at the weekends or meals taken with alcohol (de Castro 1991).

The conclusions based on the data from diary studies have been corroborated by results obtained from studies examining social facilitation within laboratory and field settings. For example, Berry et al. (Berry et al. 1985) found that participants ate much more ice cream in three- or four-person groups than when alone. Similarly, Klesges et al. (1984) found that people dining out in a restaurant ate more in groups than when eating alone. Evidence to support the suggestion that eating in a group facilitates intake comes from numerous studies employing different methodological approaches (see Herman (2015) for a review). However, it is important to note that social facilitation of eating is confined to meals that involve friends/family (see Fig. 3).

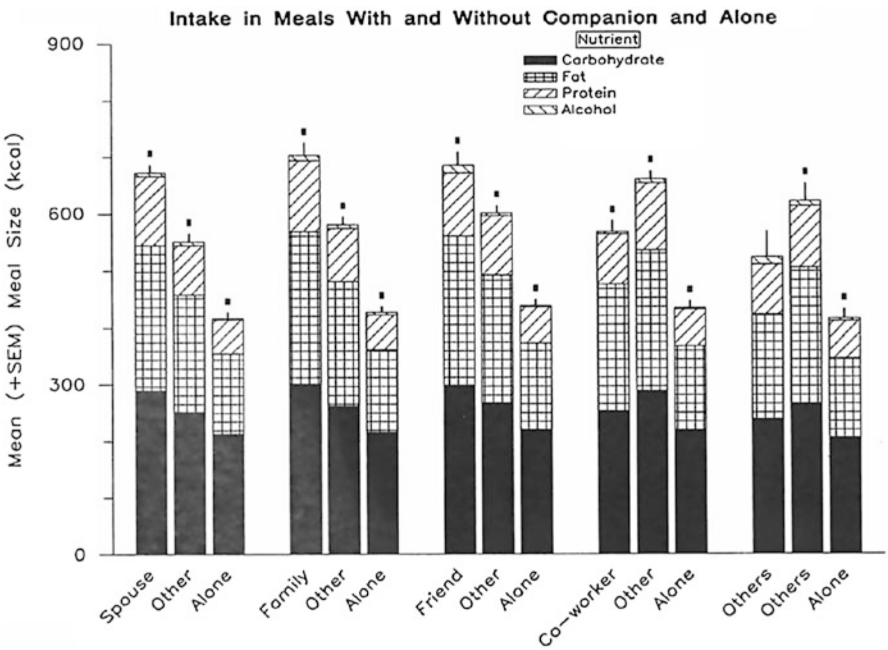

Fig. 3 Mean (± SEM) amounts (kcal) ingested per meal of carbohydrate (solid portion of each bar), fat (crosshatched portion), protein (hatched upward), and alcohol (hatched downward) for meals eaten with a particular companion type (first bar of each set of three), with others but not that companion type present (second bar of each set of three), and alone (third bar). The above the bar indicates a significant difference ($P < 0.05$) between the total meal sizes as assessed with a *t*-test. The above the first bar signifies the "with companion-with other" comparison, above the second bar signifies the "with other-alone" comparison, and above the third bar signifies the "with companion-alone" comparison. (Source: Reprinted from Physiol. Behav., 56(3), J.M. de Castro, Family and friends produce greater social facilitation of food intake than other comparisons, 445–455, 1994, with kind permission from Elsevier Science Ltd., The Boulevard, Langford Lane, Kidlington OX5 1GB, UK)

When Does Social Facilitation of Eating Occur?

Social facilitation of eating appears to occur only in groups of people who are known to each other (de Castro 1994). When people eat in a group of strangers, they may actually eat less than they would if they were eating alone (e.g., Hetherington et al. 2006; Péneau et al. 2009). When eating in a group of strangers, some people may restrain their intake to convey a positive impression (and avoid appearing "greedy"), and this tendency to restrain may be the overriding factor affecting total intake. In other words, social facilitation of eating in this context is trumped by impression management concerns (Herman 2015). Impression management concerns, and in particular, concerns about the stigma associated with appearing to eat excessively, might also explain why people with obesity have been observed to consume fewer calories in a group than when dining alone (Krantz 1979; Schüz et al. 2017).

Similarly, an observational study found that, unlike males, female diners eating in larger mixed-sex groups did not eat more than those eating in same-sex pairs (Brindal et al. 2015). This may be because they are restricting their intake to convey a feminine impression (Pliner and Chaiken 1990).

Why Does Eating in a Group Facilitate Consumption?

Several explanations for the social facilitation of eating have been forwarded, but to date few studies have formally examined the underlying mechanisms. One explanation that has been suggested is that social meals are longer than are solo meals and this extended meal duration provides greater opportunity for eating (e.g., Feunekes et al. 1995; Pliner et al. 2006). However, this explanation does not account for the fact that, in order for people to eat more, there is probably more food available at social meals. Indeed, given that most people tend to clear their plates (Hinton et al. 2013), it is unlikely that lone eaters serve themselves (or order) the same amount of food as social eaters, but do not finish all of their portion. A more likely explanation is that people anticipate that they will eat more at social meals, and so they plan to provide more food or order more food when they know they will be eating socially (Herman 2015). In support of this idea, Cavazza et al. (2011) observed that customers in a restaurant ordered more dishes as the number of people in the party increased. In other words, more food was made available for consumption in larger versus smaller groups. However, this social "precilitation" hypothesis remains to be investigated experimentally.

Another explanation of the social facilitation of eating that has yet to be formally tested is that social context affects eating via its effects on hunger, satiety, or food reward. For example, social facilitation may be due to an increased "liking" for foods eaten socially. This is supported by evidence that eating in company enhances food palatability (Boothby et al. 2014). Furthermore, social interaction during social meals may distract people from monitoring how much they are eating or their awareness of internal cues that might inhibit eating. Indeed, one study found that people spent longer looking away from their meal and ate more food, when eating with a friend, relative to when eating alone (Hetherington et al. 2006). Another possibility is that meals eaten alone are smaller than are social meals because eating alone is not as enjoyable as eating with company. However, there is only indirect evidence in support of this assumption. de Castro (1990) found that people were generally happier when eating with others than when eating alone, but his analysis found that mood and the number of people present contributed independently to variance in intake.

Conclusions

Social context plays an important role in determining what, and how much, we eat. Research has highlighted the tendency for people to model their food intake on the consumption patterns of other people, to eat *more* when with friends/family relative to when alone, and to use food to convey positive impressions to others. While the relative contribution of each of these factors varies across individuals and situations, together they exert a pervasive and powerful influence on food intake.

Contents

Abstract

When we consume any nutritive product (i.e., foods or drinks), those ingested nutrients provide signals that act to reduce our desire to eat and drink for some time after consumption. This is captured by the concept of satiety, the state of

inhibition of appetite post-ingestion. Likewise, our desire to eat decreases during a meal, and the processes which lead to that reduction are referred to as satiation. Simplistic models have traditionally interpreted satiation and satiety simply as a function of ingested nutrients. However, there is now an abundance of evidence that both satiation and satiety are influenced by multiple factors, including beliefs and information about products prior to ingestion, the specific sensory characteristics of the product experienced during ingestion, and the volume, weight, macronutrient profile, and energy density of the consumed product and the social context in which food is ingested. Thus satiation and satiety are viewed as the product of a cascade of signals which interact to generate the overall satiety state. Expectations about how filling a product will be modifies portion size selection and influences subsequent satiety. Sensory cues such as oral processing time and flavor intensity modify satiation, while liking for the consumed product, but not unrelated products, decreases. Once ingested, gut-based signals, including the release of satiety hormones stimulated by nutrient sensing, interact with cognitive and sensory cues from ingestion to produce satiety. But how much individuals respond to these cues varies, with weak satiety responsiveness a risk for subsequent weight gain. Overall, satiation and satiety are highly complex phenomena, but our increased understanding of this complexity paves the way for the food products of the future.

Introduction

Why and when we initiate and end a particular eating episode involves highly complex processes, yet the outcome of decisions about what, when, and, critically, how much we eat ultimately determines our overall intake. Satiety, the state of inhibition of our desire to eat in the period after ingestion, is one of the key motivational processes controlling the amount we consume. Behaviorally, the importance of satiety can be seen in the patterning of meals, where consumption of large meals may be followed by longer intervals before eating again and/or subsequent smaller meals, although it is important to recognize that satiety is just one of the many factors underlying decisions on what, when, and how much to eat (de Castro 2013). This chapter sets out to summarize our current understanding of satiety from a sensory, psychological, and physiological perspective.

Defining Satiety

Satiety has been an important concept underpinning theoretical models of appetite control for as long as researchers have tried to explain what makes us start and stop eating. The idea that the brain has separate “centers” for hunger and satiety (Stellar 1954) was one of the most influential neural models of appetite control, and although neural models of satiety have moved away from the concept of a “center” per se to a more complex and detailed neural network approaches involving feedback and feedforward processes (see Andermann and Lowell 2017; Berthoud 2011), the basic premise of a key role for satiety in determining overall intake is enduring. Surprisingly, however, the precise definition of satiety is subject to debate. Even dictionaries struggle to give a consistent definition: Webster's defines satiety as the quality or state of being fed or gratified to or beyond capacity (Satiety 2006); the Cambridge English gives a broader definition of "the state of being completely satisfied, especially with food or pleasure, so that you could not have any more" (Satiety 2012); and Oxford English defines satiety as the "feeling or state of being sated" (Satiety 2012), a definition which requires an understanding of "sated" and which is close to a circular argument! What these attempts have in common is that satiety represents a markedly reduced desire to eat, in contrast to hunger, the desire to eat. But the subtle differences in meaning reflect considerable confusion in the lay and scientific literature about the nature of satiety, probably arising from the inherent complexity of the factors that are involved in the suppression of appetite. The current separation of the processes leading to meal termination (satiation) and the inhibition of appetite post-ingestion (satiety) was largely founded in the detailed analysis of animal feeding patterns (Le Magnen 1971). Both satiation and satiety are now recognized to reflect a multitude of influences arising from cognitive, sensory, post-ingestive, and postabsorptive signals arising as the stimuli from the ingested food are detected at various stages of the ingestive process, from the first sight of food to the final stages of processing of the ingested nutrients (Bellisle and Blundell 2013). It is probably this complexity that has made satiety such a debated phenomenon, but the current consensus suggests satiety is best defined as the suppression of appetite after the termination of ingestion, with satiation defined as the processes leading to the cessation of ingestion.

The Satiety Cascade

Although a lay interpretation of satiety might be that it reflects our awareness of the presence of ingested nutrients in our gut (i.e., our awareness of a state of "being full"), a plethora of data argue against such a simplistic model. The multifactorial nature of satiation and satiety was captured elegantly by John Blundell and colleagues (1987) over 25 years ago. Their initial "satiety cascade" model has subsequently been refined as more has been learned about the signals that modify satiety into a widely cited descriptive account of the multiple factors that interact to generate satiety (Fig. 1) and has been the subject of several more recent reviews (Blundell 2010; Tremblay and Bellisle 2015), which provide more detailed descriptions. Blundell and colleagues highlighted that even before food arrived in the gut, cognitive and sensory signals generated by the sight and smell of food, and by the sensory experience of food in the oral cavity, influenced not only how much was eaten at that eating episode (moderating satiation) but also afterwards (influencing satiety). In their descriptive model, satiety then is the sum of the effects of sensed signals from ingestion which suppress appetite. This approach further recognized

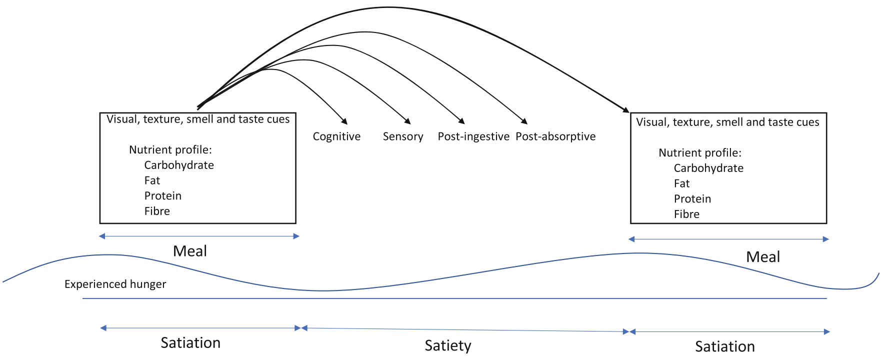

Fig. 1 The satiety cascade. (Blundell 1995)

that satiety does not reflect an absolute state of inhibition over eating, evincing the common experience that even when feeling "full" after eating a large meal, it remains hard to resist a particularly tasty morsel.

Measuring Satiation and Satiety

How satiation and satiety can be measured in humans has been the subject of a detailed recent review (Forde 2018). In studies with humans, satiation is indexed in some way by measuring behavior during an eating episode. Since satiation is defined as the process leading to the cessation of eating, the amount of food consumed at a particular eating episode can be used to infer satiation. For example, if we contrasted intake of two or more products differing on a dimension that theoretically might relate to the processes that generate satiety (example might include the overall energy density of the product or the relative amount of protein or fiber it contains, etc.), and people voluntarily consumed less of the version that contained more of the component predicted to impact satiety, we could interpret that as support for the role of the manipulated component on satiation. In practice, however, changing the level of any ingredient that might impact satiation may also alter other features of the product which in itself might impact intake. The biggest potential confound is palatability: people reliably consume more of products that they find more palatable (Yeomans et al. 2004). How then to dissociate whether altered meal size is due to altered satiation or palatability? One approach has been to incorporate more detailed behavioral measures, such as the rate of eating, bite size, and the intensity of self-reported measures of appetite collected within that meal (Yeomans 2018). These measures allow further inferences about the mechanisms that drive satiation, allowing satiation to be separated from other influences, such as the enhancement of appetite by palatability. Typically, altering palatability modifies the initial increase in appetite when food is first tasted, whereas satiation is reflected more in the rate at which appetite declines as a meal progresses, and these effects are behaviorally dissociable.

The assessment of satiety also involves measuring appetite and food intake, but now this is in the period after a particular ingestive episode. The general study design used here is widely described as a "preload" experiment, with the impact of a fixed amount of one food (the preload) measured by assessing appetite in the period after ingestion. By altering different aspects of the test preload (e.g., macronutrient profile, caloric content, energy density, sensory characteristics, labelled information, etc.), it is possible to explore how different features of that product influence satiety. After the preload has been ingested, satiety can be inferred by the suppression of appetite, relative to an appropriate control, in the period immediately after preload. Appetite ratings have been used widely to assess satiety, and the questions which should be asked are standardized to allow clearer comparisons between studies (Blundell et al. 2010). However, while measures of the subjective experience of satiety have value, the extent to which manipulation of the features of the fixed test preload alters subsequent intake at an ad libitum test meal or meals arguably provides a more objective measure of the likely impact of that manipulation on energy balance. The satiety preload design is one of the most widely used experimental approaches to the study of satiety.

To give some idea of the degree to which different versions of a product generate satiety, the relative reduction in ad libitum intake at a test meal relative to a control can be converted into a measure of compensatory eating or satiating efficiency (Kissileff et al. 1984). As an example, consider how much might be eaten at a test meal consumed 2 h after a preload which contained 100 kcal on the first day and 300 kcal on second day. If on average the test meal was 200 kcal smaller on the day the 300 kcal preload had been consumed, the inference is that the level of satiety that preload had induced was sufficient to allow the consumer to fully compensate for the extra preload energy by adjusting their intake by the exact amount of energy needed to maintain a perfect energy balance. Many studies use a simple equation (the "satiety quotient") to calculate the percentage compensation seen with different foods (Green et al. 1997), and these values in turn can offer insights into the extent that different nutrients, etc. generate short-term satiety signals. Perfect (100%) short-term compensation is rarely seen. A systematic review of 256 studies using the preload method (Almiron-Roig et al. 2013) found an average (median) of only 62% of preload energy compensated for, but the range of outcomes in those studies varied from −370% (undercompensation) to 450% (overcompensation). Thus, short-term compensation is highly variable and affected by numerous factors including the time between the preload and test meal, the form (solid, liquid, etc.) of the preload, and numerous individual difference factors. These variations in turn provide further insights into the factors that drive the experience of satiety.

As food progressively enters the digestive system, the detected nutrients trigger the release of a cascade of chemicals from various cells, many of which are the key enzymes which help break down the ingested nutrients into the form the body needs for processing and storage. Among these chemicals are specific hormones which have been demonstrated to play roles in the gut-based signalling of satiety: cholecystokinin (CCK), glucagon-like peptide 1 (GLP), pancreatic polypeptide (PP), and peptide YY (PYY) have all been demonstrated to involved in satiety signalling

(Zanchi et al. 2017). Our current understanding of the role of these key satiety hormones is discussed later, but the measurement of the circulating levels of these hormones post-ingestion can be useful adjunct measures of satiety, although they cannot be seen as a substitute for behavioral measures (de Graaf et al. 2004).

The Need for Multiple Measures to Assess Satiation and Satiety

Because of their multifactorial and subjective nature, no single measure of behavior or physiology can in itself fully capture satiation or satiety, and so most studies use multiple measures. For example, if we relied solely on food intake as a measure, it is possible that a particular manipulation could cause people to eat less not by enhancing the state of satiety, but by producing other effects which indirectly cause people to eat less, such as inducing nausea. This problem is highlighted in Fig. 2: here two manipulations had almost identical effects on food intake but through different mechanisms. The first manipulation (Fig. 2a) altered the sensory appeal of the

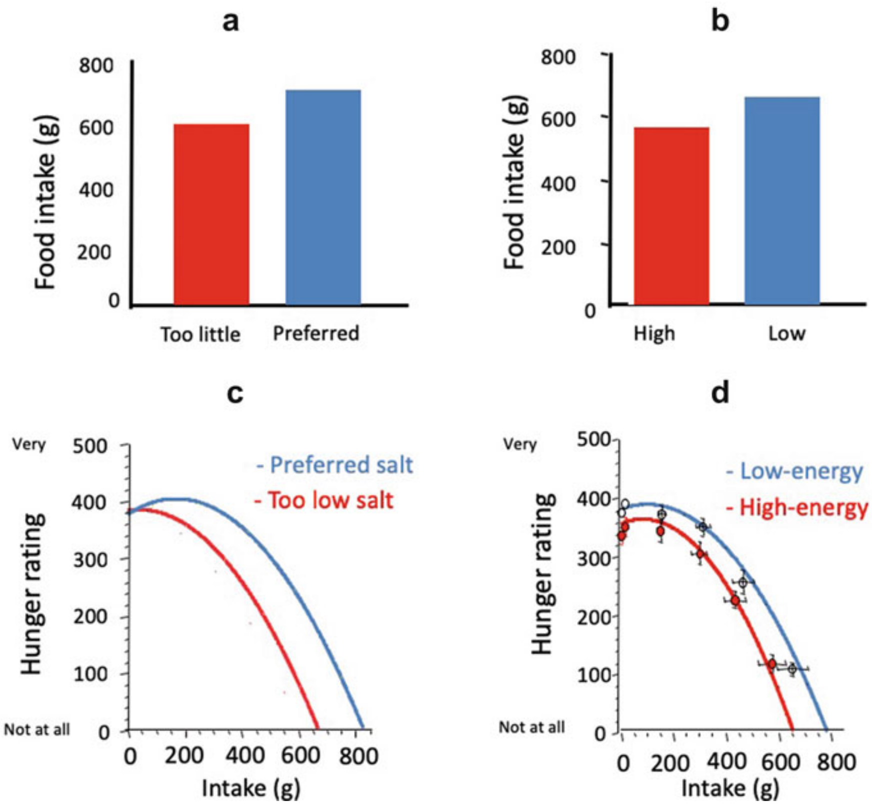

Fig. 2 The effects of manipulating salt content (panels **a** and **c**) or preloading with high- or low-energy soup (panels **b** and **d**) on intake and the rated experience of appetite within a meal

food by modifying salt content, while the second had the same food consumed after either a low- or high-energy soup preload (Fig. 2b: Yeomans et al. 1998). Analysis of the pattern of change in rated appetite within these meals clearly shows different causes for the reductions in intake: when salt content was altered (Fig. 2c), the rated hunger was the same at the onset of eating but increased during the early phase of the meal with the more liked food. In contrast, consumption of a higher-energy soup preload 30 min before the meal resulted in lower hunger at the start of the meal (Fig. 2d), which can be interpreted as satiety. The key point is that manipulations that reduce food intake need to be interpreted with some caution to exclude extraneous causes if we are to truly understand the key drivers of satiety.

Understanding Satiation

What factors ultimately determine the size of an eating event? The widespread lay belief is that meal size is the direct consequence of the accumulation of food in our stomach as we eat: these cues make us feel full and so cause us to stop eating. But in practice, cues from the gut are likely to play a minor role only in determining how much we consume at most meals. How little impact postoral cues have on immediate meal size is illustrated in Fig. 3. These data came from a study where healthy volunteers ate ad libitum, while at the same time, different amounts of soup varying in energy density and volume were infused into their stomach: either a small (150 ml) or large (450 ml) volume of soup with lower (1.4 kJ/ml) or higher (4.2 kJ/

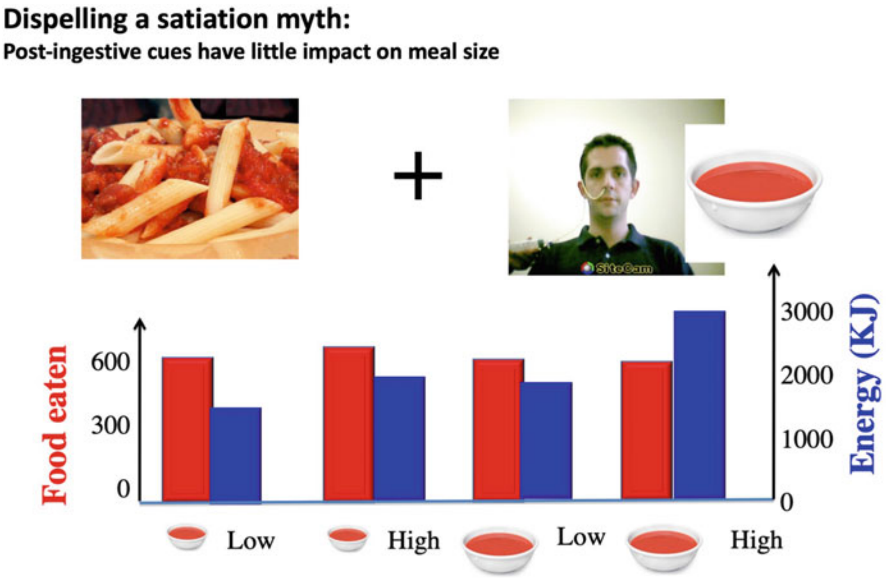

Fig. 3 The effects of intragastric infusions of soup varying in volume and energy density on voluntary intake (red bars) and total energy consumption (blue bars) for a lunchtime meal

ml) energy density (Yeomans 2010). The amount of food consumed was virtually unaffected by these infusions, even though actual energy intake (the sum of food consumed and soup infused) more than doubled from 343 kcal to 702 kcal. One obvious suggestion might be that participants used the served portion as the cue to determine intake, but while portion size is a strong predictor of intake in general, the procedure used in this study prevented participants having an empty bowl. These data and others show that feedback from detection of ingested nutrients probably only contributes to satiation for very large meals, and the general consensus is that normal meal size in humans is determined by a combination of pre-planning, portion size, sensory factors, oral metering, and cues from the social context.

Expected Satiation and Satiety

One of the key cognitive factors now known to influence meal size is the expectations that the consumer has about the product prior to ingestion, which are used to plan the appropriate portion to consume. These expectations have been separated between the expectation of how full the consumer will feel immediately after product ingestion (expected satiation) and the extent to which ingestion will suppress their appetite after a product has been consumed (expected satiety). These expectations are activated by the visual appearance of foods, and perceived volume and variety are some of the visual cues now known to influence these expectations (Brunstrom et al. 2010; Keenan et al. 2015). Likewise, these expectations can be modified by the weight of the serving vessel (Piqueras-Fiszman and Spence 2012), showing that these cognitive components of satiety are malleable beyond the nature of the food itself. But the key food-related factors that drive these expectations include flavor characteristics like creaminess, oral processing time, and the overall protein content and energy density of the product (Forde et al. 2013; McCrickerd et al. 2015).

Both expected satiation and satiety have been shown to modify self-determined portion size (Brunstrom 2011; Forde et al. 2015). Once the portion has been selected, the typical consumer habit is to eat that portion in full: one study found that 91% of meals were consumed in their entirety, and how much was consumed was pre-planned in 92% of cases (Fay et al. 2011). This habit of plate-clearing is likely to explain why people reliably consume more when served larger portions, but the work on expectations also suggests that where the consumer has control of portion size, these expectations can promote appropriate choices.

Satiety-related expectations are a product of the knowledge consumers have about the effects that different foods and drinks are likely to have on their personal experience of satiety (Brunstrom 2011): critically, the mismatch between measures of expected satiety and actual energy content of foods is greater when foods are unfamiliar. Interestingly, evidence suggests that in general we overestimate how filling a novel product will be and then adjust these expectations through a learning process that aligns the expectations more closely with actual nutrient content (Yeomans et al. 2014). In this way, expectations become an important cognitive component of our nutrient regulation.

Sensory-Specific Satiety

In relation to sensory influences on satiation, an important early observation was that although the desire for the specific sensory characteristics of the food being eaten decreases to a point where ingestion stops, other foods with different sensory characteristics retain the ability to stimulate further intake (Rolls 1986), a phenomenon defined as sensory-specific satiety (SSS: see Hetherington and Havermans 2013). SSS as a phenomenon further highlights the importance of sensory control of ingestion: if consumption ended through a generalized inhibition of appetite (as satiety is commonly conceived), then the nature of the food on offer should have little influence. SSS is expressed at the level of sensory characteristics: thus, SSS for a consumed savory food generalizes to other savory items, but sweet items are largely unaffected. In this way, SSS promotes dietary variety and also explains the tendency in human cuisine to serve contrasting courses of food within a meal. The traditional explanation for SSS was that it is a form of habituation to the effects of the sensory characteristics of the food being ingested on appetite, although more recent studies suggest that a simple habituation model is inadequate and SSS may be better characterized as satiation to the sensory characteristics of the ingested food (Hetherington and Havermans 2013).

Specific Sensory Drivers of Satiation

Whereas SSS reflects a broader process of progressive reduction of interest in the sensory characteristics of the food being ingested, another evidence suggests that certain aspects of those sensory characteristics can result in faster or slower satiation, implying a more direct role for some sensory characteristics in satiation. In particular, texture cues have been shown to be important in satiation (James 2018) and in particular that more solid items lead to earlier meal termination than do more liquid items across a wide range of food products (Tucker and Mattes 2013). The critical factor underlying this effect appears to be oro-sensory exposure time (de Graaf 2012), defined as the degree of contact time of the ingested food with the key sensory systems (taste, touch, etc.) in the oral cavity. According to this theory, solid foods require greater oral processing and so lead to greater overall stimulation of the oral sensory systems that perceive flavor and texture. This enhanced oro-sensory exposure could then lead to more rapid SSS but has also been shown to lead to more rapid satiation beyond SSS (de Graaf 2012).

The role of specific taste cues (sweet, umami, etc.) in satiation is still subject to debate. However, most data suggest that while these taste cues may act as nutrient predictors, the evidence that modify satiation beyond more general SSS effects is limited. For example, sweet taste is known to promote appetite, but satiation for sweet-tasting products does not obviously differ from any that are seen from non-sweet carbohydrates (Hogenkamp 2017), and sweetness itself is not a strong predictor of satiety expectations. There is stronger evidence for certain taste cues influencing post-ingestive processing of the ingested foods, so affecting satiety, as discussed later. Although taste cues do not appear to have a specific role in satiation, they may do so indirectly by contributing to overall flavor intensity, which is now believed to be an additional sensory factor which can modify the rate of satiation and so affect meal size (McCrickerd and Forde 2016), again with oro-sensory exposure a plausible explanation for why more intensely flavored products lead to more rapid meal cessation independently of effects of palatability. Since many of the sensory cues that impact on meal size also have been shown to generate satiety expectations (Forde et al. 2015), it may be that these sensory factors impact on meal size through the same cognitive mechanisms combined with SSS, although this is less clear with flavor intensity.

Social Influences on Satiation

Although the traditional approach to appetite control has focused on cues from the food being ingested, ingestion usually occurs in a social context, and an additional perspective on satiation relates to the extent to which consumers judge their fullness by reference to the amount being consumed by the people they are eating with. The two key social influences are firstly that people consume more in groups than when alone (social facilitation: Herman 2015) and secondly that the amount consumed can be specifically altered by modelling a confederate who eats more or less than would be consumed when eating alone (Cruwys et al. 2015). These issues are covered in full elsewhere in this handbook (see ▶ Chap. 14, "Social Influences on Eating"). However, in relation to satiation, it is notable that where people's intake has been altered by modelling a confederate, their state of satiation at the end of the meal is the same as if they had eaten their normal meal size. Thus the experience of fullness at the end of a meal is partly contextually derived. This effect is most pronounced where people overconsume and suggests that in a social context, people are less able to pay attention to the cues that normally drive satiation (Higgs 2015). Notably, when people have consumed more by modelling the behavior of a confederate, when asked what factors determined how much they consumed, they typically refer to the food (taste, liking, etc.) and rarely note the social influence (Vartanian et al. 2008). This suggests that social influences have a pervasive effect on intake, reducing the individual ability to respond to food-derived satiety cues and thereby promoting overconsumption.

Satiation in Summary

Satiation is a complex process, where signals arising from expectations, sensory exposure, oral nutrient detection, and the oral sensing of food volume all contribute to the increasing desire to terminate ingestion. However, for the vast majority of meals, ultimately humans are driven more by how much food they have served themselves, where they have that choice, or the amount they are served where that is externally determined and the social context in which they are eating, than they are by the myriad signals that arise during ingestion. Thus, the processes involved in satiation do not regulate energy intake directly, but once food is consumed, the effects of having consumed that food on subsequent appetite (satiety) have much clearer effects on overall energy balance, and so next we consider in detail what drives satiety.

Understanding Satiety

Whereas satiation appears to be controlled mainly by cognitive and sensory influences, satiety is more complex, with evidence for cognitive, sensory, and nutritional cues all interacting to generate how full people feel after consuming a particular food or drink. The volume, energy density, macronutrient profile, food form, sensory characteristics, and satiety expectations of an ingested product have all been shown to impact on subsequent satiety, with these factors interacting in complex but predictable ways. To illustrate this point, varying the form of a food alone can have a major effect on how filling it is. For example, the same amount of apple was more filling when consumed as apple pieces, than as apple puree or apple juice, despite the same nutrients being ingested in all three versions (Flood-Obbagy and Rolls 2009). To unpack this complexity, first the key evidence for cognitive, sensory, and nutrient influences on satiety are summarized in turn, and then current ideas on how these different components are integrated are explained.

Cognitive Influences on Satiety

Since how filling we believe a food to be has a major influence on how much we serve ourselves, could it also influence our experience of satiety after consumption? Particularly striking evidence that beliefs impact satiety came from a study where volunteers consumed the same product (a fruit smoothie) but with the (misguided) belief that the product contained either a small or large amount of actual fruit (Brunstrom et al. 2011). Participants consistently reported greater satiety (i.e., lower levels of rated hunger) across the 3 h after consuming the smoothie when they believed it had contained a larger rather than smaller amount of fruit even though the actual product was the same in both conditions.

However, simply telling someone that a product will be more filling in itself does not necessarily generate satiety by itself, but rather expectations modify the way the sensed nutrient signals arising from actual ingestion are interpreted. A powerful demonstration of that effect came from a study where participants consumed the same level of nutrients either as a liquid or jelly (Cassady et al. 2012), under the belief that the product either was liquid or jelly once in the stomach (in practice all versions would have been liquified by the acid in the stomach). Both the actual form of the ingested product and the belief of whether it was solid or liquid affected satiety: satiety was strongest when ingested jelly was believed to be jelly in the stomach and weakest when a liquid product was expected to liquid in the stomach. This elegant study demonstrates the power of top-down control on satiety. But in that study, the same level of nutrients was ingested in all conditions. Another research has since demonstrated that satiety is maximized when the expectation generated by label and sensory cues implies a product will be filling and crucially the product contains sufficient nutrients (Chambers et al. 2015; McCrickerd et al. 2014). Where a product generates an expectation of satiety but the level of ingested nutrients generates weak post-ingestive physiological satiety responses, the mismatch between expected and actual satiety can lead to rebound hunger and overconsumption. This critical interplay between expectation- and nutrient-based signals may explain why beverages tend to generate weaker satiety but soups stronger satiety even when the actual energy content is similar: drinks are not expected to be filling but soups are.

Beyond the role of expectations at the point of consumption, explicit memory for what has been recently consumed also plays a role in determining the amount consumed at the next meal (Higgs and Spetter 2018). The most striking evidence for this comes from studies of meal taking in amnestic patients. For example, Henry Molaison (HM) was left with severe amnesia following brain surgery to relieve intractable epilepsy. Notably, HM rarely reported feeling hungry or full, and when tested, he readily ate a second main meal almost immediately after eating a first (Hebben et al. 1985). Although the extent of HM's damage has suggested possible effects beyond amnesia (Eichenbaum 2013), a subsequent report of multiple meal consumption in other amnesiac patients with more defined impairments lends further support to a memory effect (Rozin et al. 1998), and notably these patients also showed no evidence of changes in the experience of appetite as a consequence of food ingestion. While these studies demonstrate the importance of the neural circuitry involved in memory and also in regulating awareness of interoceptive states including satiety, it does not in itself demonstrate memory is normally involved in the experience of satiety. But more recent data suggest this is so: asking people to recall what they consumed at a previous meal just before they have an eating opportunity reliably reduces intake, while a lack of attention to what is being consumed by being distracted during one meal can cause reduced satiety and increased intake at subsequent meals (Higgs and Spetter 2018). Thus, processes of memory and attention are important elements of the cognitive systems underlying satiety. One of the brain regions known to have been damaged in HM is the hippocampus, an area long known to be important in many aspects of memory. The hippocampus is also now thought to play an important role in regulating food intake, integrating information about cognitive and sensory aspects of the food to be ingested with the interoceptive signals relating to hunger and, crucially in this context, satiety (Stevenson and Francis 2017). Indeed, one theory of obesity is that excessive intake of an unhealthy diet leads to dysfunction in the hippocampus and reduces individual sensitivity to interoceptive satiety cues (Hargrave et al. 2016).

Taste and Satiety

Of the five primary tastes, the only taste which appears to have a role in satiety is umami (Yeomans and Masic 2017), and although sweet taste is often discussed as having evolved to enhance engagement with potential foods that will be a safe source of nutrients, there is no clear evidence that sweet taste or associated sugar ingestion has effects on satiety which differ from that of non-sweet carbohydrates (Bellisle et al. 2012). However, one possible role of taste in relation to satiety is that the savory "taste" of protein-based products acts as a cue for the likely presence of protein which triggers changes in post-ingestive processing of the ingested food which in turn result in a modified satiety response. In line with this, the finding that the addition of MSG, the compound most closely associated with umami taste, to protein-enhanced, but not carbohydrate-enhanced, soups increases the satiety response suggests that the detection of MSG orally might act as a taste cue for protein, and there is now growing evidence that the umami taste may itself enhance satiety (Yeomans and Masic 2017).

Nutrient Cues and Satiety

Ultimately satiety is primarily a state generated by the effects of ingested food, and the degree to which foods generate satiety has been shown to vary depending on the volume, nutrient density, and overall nutrient profile of the ingested food or drink. A full discussion of all of the evidence for these factors is beyond the scope of this chapter and has been subject to many valuable and detailed reviews (e.g., Benelam 2009; Tremblay and Bellisle 2015). The focus here is to provide sufficient summary of the current state of understanding to allow a more detailed evaluation of how these more physiological aspects of satiety integrate with the cognitive and sensory influences which are the primary focus of this chapter.

Some of the key nutrient-derived signals that contribute physiologically to satiety are generated by the ingestion and digestion of the three main macronutrient energy sources (carbohydrates, fats, and proteins), supplemented by actions of other food components such as fiber. A large body of satiety-related research has focused on these signals and the relative efficiency of the different macronutrients in generating satiety. This led to the suggestion of a hierarchy of satiating effects of macronutrients in the order protein > carbohydrate > fat (Poppitt et al. 1998), and it is now widely accepted that, when matched by caloric content, protein-rich products are most effective at generating satiety (Johnstone 2013). Likewise, there is good evidence that the addition of fiber can also enhance satiety (Wanders et al. 2011). These different nutrient effects then interact: for example, a recent study contrasted different reformulations of pasta supplemented with different sources of protein and fiber and found significant effects of both protein and fiber, with the strongest satiety when protein and fiber were combined (Martini et al. 2018).

There have been many theories of how different nutrients generate satiety, with the current view that nutrient detection in the gut leading to release of satiety hormones that then act to suppress appetite is the most widely accepted mechanism, and these effects are detailed more fully later. Satiety has also been related to the extent to which ingested food results in changes in glucose availability, with the classic glucostatic theory of appetite control positing that higher levels of glucose suppressed appetite but lower levels induced hunger (Mayer 1955). Although a simplistic model of appetite control based on glucose as a regulated signal remains controversial, there is evidence that the pattern of glucose release from foods does modify the way that they generate satiety. Here, a key concept is the glycemic index, which describes the pattern of change in circulating glucose across the time period post-ingestion. Products that cause a rapid rise and then fall in glucose are referred to as high glycemic, while those causing a lower but more sustained rise in glucose as low glycemic. Notably, low-glycemic foods tend to cause stronger satiety responses (Anderson and Woodend 2003).

Cognitive Nutrient Interactions in Satiety

There has been a tendency to assume that effects of nutrients on satiety are purely derived from gut-based signals during digestion, but there is increasing evidence that the sensory and expectation cues discussed earlier also play a role in modifying the effects of nutrients. A key issue is that it is very hard to modify the macronutrient or fiber content of a product without also altering its sensory characteristics, and these often subtle sensory changes can themselves then influence satiety, and indeed subtle flavor cues have long been known to modify satiety responses (Warwick et al. 1993). For example, when the sensory characteristics of a carbohydrate-enriched drink were manipulated to match the sensory characteristics of a similar drink fortified with whey protein, the two products generated the same satiety response (Bertenshaw et al. 2013), suggesting that the apparent enhanced satiety usually seen with protein may have been generated by the oro-sensory rather than post-ingestive effects of the protein. Similarly, satiety expectations are related to perceived creaminess in products (McCrickerd et al. 2015), and this percept may be in part driven by oral sensing of protein. But creaminess is a complex percept, and there is also the possibility that detection of fat in the mouth may act as a cue which could in turn modify the way the gut processes ingested fats. Whether the ability to detect fat orally can be described as the sixth dimension of taste remains unclear (Keast and Costanzo 2015); however some data on individual differences in oral fat sensitivity do fit with the notion that an enhanced ability to detect ("taste") fat orally is associated with lower body weight (Costanzo et al. 2017) which could be caused by stronger fat-based satiety responses. For this to be plausible, there would need to be evidence that oral detection of fat increased satiety. Again, recent evidence suggests this may be so. Varying the droplet size of oils in a water-oil emulsion changed the perception of how "creamy" these stimuli were, with smaller oil droplets leading to enhanced creaminess, and these small-droplet emulsions generated stronger expected and actual satiety responses than did the same water-oil emulsion with larger oil droplets (Lett et al. 2016).

Gut-Based Signalling Systems for Satiety

One of the key ideas in current biological models of satiety is that the sensed presence of ingested nutrients in the gut triggers the release of specific endocrine signals, the satiety hormones, which feedback to key regulatory structures in the brain and thereby inhibit our desire to eat. A large body of physiological research has started to unravel the complex detail of these signalling pathways, and here there is space to highlight the key findings only. The first satiety hormone to be identified, cholecystokinin (CCK), is now known to be released from specific endocrine cells in the small intestine, particularly the duodenum, in response to the sensed presence of nutrients, with stronger responses to fat and protein than to carbohydrates (Karhunen et al. 2008; Zanchi et al. 2017). Consequently, the concentration of CCK in blood increases after food consumption, and circulating levels of CCK correlate negatively with rated hunger (Sepple and Read 1989). Glucagon-like peptide 1 (GLP-1) is also established as a satiety hormone, with GLP-1 injections reliably reducing rated hunger and subsequent food intake in humans (Flint et al. 1998) and circulating levels of GLP-1 rising after meals, particularly with carbohydrate and fat intake. Finally, two related compounds, pancreatic polypeptide (PP) and peptide YY (PYY), also act as satiety signals. PP is the least understood of the satiety hormones and is released from the pancreas in response to nutrient ingestion. Low circulating levels of PP have been reported in obese individuals, while injection of PP has been shown to suppress appetite (see Hellström 2013). PYY is a more established satiety hormone, and suppresses rated appetite and food intake in humans (Batterham et al. 2002). PYY is secreted into the bloodstream by cells in the ileum and colon, so it appears to have a role in the later stages of satiety.

Even this very short summary illustrates the complexity of physiological satiety signalling: different mixtures of nutrients will cause subtly different patterns of release of multiple satiety hormones, which differ in time profile after ingestion and effects on appetite. We are still some way from clearly establishing the exact role of each hormone and from understanding how these different signals interact.

There is also now evidence that release of these gut-based satiety hormones is not simply a response to locally sensed nutrients but may be in part mediated by the sensory and cognitive cues experienced during ingestion. Traditionally, the idea that gut-based responses can be cued by pre-gastric signals was encapsulated in the concept of cephalic-phase responses (Smeets et al. 2010), founded in the principle of Pavlovian conditioning, suggesting that cues that predict the arrival of nutrients in the gut cause conditioned preparatory responses including hormone secretion (Woods 1991). There is now, however, evidence that these effects extend beyond conditioned responses, which are acquired by repeated cue-nutrient associations, to more cognitive control. Thus, believing a food would be solid in the stomach moderated GLP-1 release (Cassady et al. 2012), and the belief that a product would be filling stimulated PP release and enhanced the CCK response to nutrient ingestion (Yeomans et al. 2016). Thus gut-based signalling of satiety is in part controlled by people's beliefs and experiences with a food, with clear top-down modulation of the gut-based satiety response.

Individual Differences in Satiety Sensitivity

One important idea in our understanding of the relationship between satiety and ingestion is that people vary in the extent to which they are aware of, or respond to, satiety signals. In the earliest theory of individual differences in this context, it was suggested that normal-eating control involves a balance of sensitivity to internal appetite cues, including satiety, and external food cues (Schachter 1968). According to this externality theory, people who are prone to overeat and so gain weight were conceived as over-responding to external cues and under-responding to internal cues. Although the original externality theory fell out of favor, the key idea of a role for individual differences in satiety sensitivity relating to propensity to become obese is now attracting considerable attention. In adults, satiety responsiveness has been tested using the preload method, and here there is evidence of reliable individual differences, with those with weaker satiety responsiveness (the low satiety phenotype) more prone to weight gain (Dalton et al. 2015). Satiety responsiveness in children has been assessed using a standardized questionnaire measure, and scores on that measure predict subsequent weight gain even in very young children (e.g., Mallan et al. 2014). Whether sensitivity to satiety is a trait, or is a product of the way we have been exposed to foods, remains unclear, although there is some evidence that satiety responsiveness can be retrained if people are placed on diets which have been designed to generate stronger satiety signals (Arguin et al. 2017), suggesting that the extent to which an individual experiences satiety is to some extent malleable, so opening up the potential to retrain satiety responsiveness as a way of counteracting overeating.

Satiety in Summary

Unlike satiation, which appears largely controlled by cognitive, sensory, and behavioral factors, satiety is primarily a response to ingested nutrients, with a sequential series of post-ingestive signals arising from effects of nutrients at different stages in transit through the gut. However, whereas there has been a tendency to focus exclusively on these post-ingestive effects, there is now clear evidence that this gut-based processing can be affected by cognitive and sensory factors at the point of ingestion and that these factors alone can influence satiety both independently and in interaction with gut-based signalling. Moreover, the finding of big individual differences in satiety responsiveness which cannot be explained by differences in gut-based signalling clearly shows that satiety ultimately depends on the way these different signals are processed in the brain. Thus satiety is not a simple result of intrinsic cues generated by actual consumption but is a more complex interaction between these intrinsic cue and extrinsic cues relation to what the consumer knows about that product before it is consumed. Whether social context acts as an additional extrinsic influence on satiety is less clear: the majority of work on social influences have focused on satiation (Cruwys et al. 2015), and whether adjustments to meal size through social facilitation and modelling result in modifications to subsequent satiety remains unclear.

Integrating Multiple Cues: Optimizing Satiation and Satiety in Product Development

As knowledge about the cognitive, sensory, and nutrient-based signals that lead to satiation and satiety become clearer, it is increasingly possible to make predictions about how different changes in the way food is formulated, marketed, and served are likely to impact on our ability to regulate food intake. A perhaps surprising conclusion from some of the influences summarized here is that reducing the nutrient content of a product may not always be a helpful approach to regulating overall energy intake: if a product is consumed under the belief that it is a diet version, it may generate expectations of low satiety, which may be reinforced by changes in sensory characteristics and the actual experience of weaker post-ingestive satiety. Consequently, diet products may lead to rebound hunger and greater temptation to overconsume later (Chambers et al. 2015). The recent finding that people lost weight when placed on a diet which did not reduce their overall energy intake directly, but instead was designed to increase satiety (Arguin et al. 2017), reinforces the idea that re-establishing a strong satiety response in those prone to overeat may be the way forward in behavioral approaches to counteracting obesity.

Conclusions

Our understanding of satiation and satiety has come a long way from the simplistic idea that they reflected the impact of ingested nutrients on our appetite. As more evidence emerges that beliefs about products, and the sensory experience products provide during ingestion, modify the way we subsequently experience satiety, so the underlying models of satiety have to become more complex and nuanced. The effects of ingestion of a particular product on satiety will, ultimately, depend on the consumer's familiarity with that product, their individual sensitivity to satiety, and the actual nutrient profile of the product. Social influences clearly impact satiation, and all of these factors interact to modify overall appetite. Our increased understanding of these complex interactions is paving the way towards innovative approaches to producing products of the future which consumers will be able to enjoy without the concomitant risk of overeating and obesity.

Disgust and Eating Behavior

16

Christina Hartmann and Michael Siegrist

Contents

Abstract

Disgust is a human emotion that prevents us from having contact with something that might be pathogenic, because it triggers behavioral avoidance of the stimulus. People can vary in their tendency to react with disgust towards cues that indicate the presence of pathogens such as certain odors (e.g., smell of decayed food) or visual cues (e.g., mold, runny nose). This disgust sensitivity was linked to a broad range of behavioral and attitudinal concepts in previous research. After an overall introduction to the concept of disgust, the present chapter focuses on the measurement of disgust sensitivity in adults and the various tools that are available to measure disgust sensitivity. A special focus will be on the domain of

eating and food behavior and the introduction of a new scale that enables measurement of disgust sensitivity in the domain of food. Furthermore, the influence of disgust sensitivity on eating behavior in a functional and dysfunctional way will be outlined. In particular, its relationship with selective eating behaviors (e.g., food neophobia) and the acceptance of new food sources (e.g., insects) and food technologies (e.g., cultured meat) will be highlighted. Lastly, the relationship between disgust and hygiene behavior, food hygiene behavior in particular, will be outlined.

Introduction

Functional Domains of Disgust

When considering evolutionary processes and the drivers of natural selection, we would expect that humans have developed threat-detection systems and responses. Evidence suggests that a disgust reaction is one such highly functional system that aims to reduce the contact with and thus the likelihood of infection from bacteria, parasites, and viruses. Researchers consider disgust to be a component of the so-called behavioral immune system, which aims to avoid health threats by cognitively triggering disease preventive behavior (Terrizzi et al. 2013).

A commonly known first line of defense is distaste. In particular, bitter-tasting compounds can be found in unpalatable plants and are prototypical stimuli for innate oral rejection. This can naturally be observed in children who have an innate preference for sweetness and an inborn dislike of bitter tastes (which makes acceptance of certain liquid formulations such as medicine and of certain foods such as dark-green vegetables rather difficult during childhood) (Mennella and Bobowski 2015). Bitter taste typically leads to spitting out the unpalatable, probably toxic material (Chapman and Anderson 2012). Apart from distaste, disgust is triggered by cues that symbolize hazardous items and the presence of pathogens such as certain odors (e.g., smell of decayed food) and visual (e.g., mold, runny nose) and tactile (e.g., slime) cues as well as auditory input (e.g., clear one's throat) (Curtis and Biran 2001). Likewise, objects that have had contact with a disease vector can become contaminated and a trigger of disgust. Disgust is not restricted to the oral route, and the role of contamination and contact disgust in defending against infectious diseases might relate to the perceived invisible spread of microorganisms from one substance or organism to another (Chapman and Anderson 2012).

Individuals differ in their concerns about disease transmission and their perceived vulnerability to diseases. Persons with higher germ aversion reported heightened discomfort in situations with an increased likelihood of disease transmission such as having a sneezing person around or sharing a water bottle with a friend (Duncan et al. 2009). These individual differences in germ aversion also predicted variability in people's sensitivity and reactivity towards potential disgust elicitors (Hartmann and Siegrist 2018). Disgust is an emotional response that triggers disease avoidance behavior (Curtis et al. 2004). However, very low disgust sensitivity and heightened disgust or disgust oversensitivity can become dysfunctional. On the one hand, insensitivity to disgust cues might inhibit the necessary preventive behavior, and people might expose themselves to higher risks. On the other hand, oversensitivity to cues that are not pathogen-related or overgeneralization based on crudely defined cues triggers false alarms and might lead to neglecting viable resources. Heightened disgust responses have even been linked to the development and maintenance of various psychopathological symptoms related to anxiety disorders. In particular, disgust sensitivity seems to be involved in the etiology and maintenance of blood-injection-injury phobia, spider phobia, and obsessive-compulsive disorder (for a review see Olatunji et al. 2010). Disgust is considered a regulatory emotion, and rejection of ingestion of substances is a prominent behavioral domain. Therefore, researchers have also investigated a potential influence of disgust oversensitivity in the development and maintenance of eating disorders (Bell et al. 2017; Troop et al. 2002). Recent research has also shed light on disgust sensitivity and its effects on everyday food choices in nonclinical samples. Later in the present chapter, new findings in that area will be outlined. Noteworthy, some researchers also proposed a link between disgust and attitudes and behaviors in non-food-related domains encompassing social interactions such as sexuality, moral evaluations, and political orientation (Oaten et al. 2011; Rottman 2014; Tybur et al. 2009). However, within the course of the present chapter, we focus predominantly on the domain of eating. Disgust sensitivity in other domains such as moral or sexual disgust is not part of the present chapter (Tybur et al. 2009).

The “Disgust Face”

A typical “disgust face” has certain main characteristics expressed in combination or alone depending on the context: retraction of the upper lip, nose scrunch, narrowed eyes, lowered brows, as well as a tongue extension (Pochedly et al. 2012; Rozin et al. 1994). All the activities center around the face orifices nose, mouth, and eyes in order to hinder entry of dangerous agents. They also have an informational function by indicating to group members that something should be avoided (Rozin et al. 1994). Variations of facial expressions of disgust are considered as having different communicative values. For example, the nose wrinkle was recognized as a sign of a bad smell, while the tongue extension was linked more to oral irritation (Rozin et al. 1994). Next to happiness, anger, fear, and surprise, disgust is one of the emotions that are reliably recognized by facial expression in people from a variety of Western and non-Western societies (Ekman and Friesen 1971; Hadit and Keltner 1999). Technological advances nowadays allow coding and analyses of facial expression for research purposes. This enables researchers to observe, for example, the different variations of a disgust face in behavioral experiments. The intensity of a disgust response or variations in facial expressions depending on the elicitor can be studied.

Development of Disgust in Children

Disgust activates cognitive and affective mechanisms that motivate the avoidance of, e.g., pathogen cues. Individuals can differ in what they find disgusting as well as the intensity of their experienced disgust. The ability to experience disgust is innate, and researchers stated that genetics also determine an individual's disgust sensitivity (Sherlock et al. 2016). However, disgust evolves within cultural boundaries and is primarily shaped through social learning (Rottman 2014). Parental influences during early childhood play a substantial role (Stevenson et al. 2010). Disgust reactions to, for example, bitter substances are an innate response to distaste in children, but apart from distaste, new disgust elicitors are probably learned during the first developmental stages of the child. Stevenson et al. (2010) provided a good example of a situation in which a parent-child transmission might lead to the acquisition of a new disgust elicitor: "The child encounters a stimulus (e.g., a dirty candy on the ground) and begins to make contact with it. The parent then facially (disgust face), vocally ("Urghh, don't touch that!"), and behaviorally (moves stimulus or child away) intervenes." (Stevenson et al. 2010, p. 166). Another argument for a parental impact in the acquisition of disgust elicitors is the observed positive parent-child correlation for disgust sensitivity and contamination sensitivity (Rozin et al. 1984). Unfortunately, the evidence described so far does not necessarily explain why people then vary in the intensity of experienced disgust and which other environmental factors shape people's disgust experiences (Tybur et al. 2018). Future research is needed in order to better understand the developmental stages of such a highly functional system as the disgust emotion.

Factors Influencing Disgust Responding

Researchers argue that an individual's level of immunocompetence is linked to disgust sensitivity. The more susceptible an individual is to infections, the higher the value of behavioral avoidance of potential health threats and dietary selectivity (Fessler et al. 2005). Following this argument, a compensatory behavioral prophylaxis theory was suggested which proposes that progesterone-linked decreases in immune functioning during pregnancy should be accompanied by elevated levels of disgust and behavioral avoidance (Fessler et al. 2005). Especially during the first trimester of pregnancy, when immunosuppression is most pronounced, Fessler and co-workers found heightened disgust sensitivity (Fessler et al. 2005). Food-borne illnesses in particular pose a hazard for both the mother and the fetus, and increases in disgust sensitivity should predominantly occur in the food domain (Fessler et al. 2005). Moreover, some researchers even found a link between women's stage in the menstrual cycle and the accompanying changes in immunocompetence and disgust sensitivity (Fleischman and Fessler 2011; Zelazniewicz and Pawlowski 2015), while others did not find such a relationship (Jones et al. 2018). Nevertheless, a well-established and reliable finding across different assessment methods is that women are more disgust sensitive than men. This holds true for state (e.g., Rohrmann et al.

2008) and trait disgust sensitivity (e.g., Berger and Anaki 2014; Hartmann and Siegrist 2018) as well as for Western and Eastern cultures (Olatunji et al. 2009). However, this gender pattern was not observed in children (Stevenson et al. 2010). Al-Shawaf et al. (2017) proposed different hypotheses that might explain women's higher pathogen-related disgust sensitivity. The most important one is based on the mothers' central role and close physical contact with the offspring during gestation, lactation, and parenthood and thus their greater impact on the health of the offspring (Al-Shawaf et al. 2017). However, based on cross-sectional data, the level of pathogen disgust sensitivity seems not to further increase after the birth of a child (Prokop and Fančovičová 2016). Only longitudinal studies might reveal how strongly disgust sensitivity might fluctuate over a women's life span and the influence of different life stages such as motherhood on disgust sensitivity.

Apart from sex, the relationships between other demographic variables and disgust sensitivity are not clear or rather weak. For instance, weak negative correlations were found for education: those with lower education levels were more disgust sensitive (Berger and Anaki 2014). However, this finding might suggest that disgust is a basic emotion that might not be easily changed through knowledge (Berger and Anaki 2014). Likewise, no correlation (Petrowski et al. 2010), a weak positive correlation (Eickmeier et al. 2017), as well as a negative correlation (Curtis and de Barra 2018) between measures of disgust sensitivity and age were reported. Therefore, no overall conclusion can be drawn regarding the relationship between education and age on the one hand and disgust sensitivity on the other hand.

Measuring (Food) Disgust Sensitivity

Disgust sensitivity is defined as an individuals' tendency to respond with disgust to aversive stimuli (Haidt et al. 1994; Olatunji et al. 2007). Haidt et al. (1994) asked university students to list disgusting items and another sample to rate these items related to their disgust response. Based on factor analyses and theoretical considerations, Haidt et al. established a 32-item disgust scale (DS) that measures disgust sensitivity in eight domains: *food*, *animals*, *body products*, *sex*, *body envelope violations*, *death*, *hygiene*, and *sympathetic magic/contagion* (contact with or visual appearance of a disgust elicitor). Later on, Olatunji et al. (2007) proposed a revised version of the DS-scale (DS-R) with a reorganized item structure and a reduced number of subscales (*core disgust*, *contamination-based disgust*, *animal-reminder disgust*). Subsequently, various researchers suggested new disgust measures (Table 1). For example, Tybur et al. (2009) proposed a disgust model based on three domains of disgust. Their 21-item Three Domains Disgust Scale (TDDS) measures disgust sensitivity in the domain of *pathogen disgust*, *sexual disgust*, and *moral disgust*. van Overveld et al. (2006) published a disgust propensity and disgust sensitivity scale (DPSS, revised by Fergus and Valentiner 2009), which aims to measure the frequency of experiencing disgust and the bodily and emotional impact of experienced disgust. A rather new developmental approach was used by Curtis and co-worker (Curtis and de Barra 2018), who identified main transmission

Table 1 Scales to measure disgust sensitivity in different domains for adult populations. The different measurement scales show similarities and differences in the domain-specific conceptualization of disgust

Author	Abbr.	Domains
Haidt et al. (1994)	DS	Disgust scale: food, body products, sex, death, body envelope violations, animal, hygiene, contagion
Olatunji et al. (2007)	DS-R	Disgust scale – revised: core disgust, animal-reminder disgust, contamination disgust
Kleinknecht et al. (1997)	DES	Disgust emotion scale: animals, injections, blood draws, mutilation, death, rotting food, smells
Tybur et al. (2009)	TDDS	Three domain disgust scale: pathogen disgust, sexual disgust, moral disgust
Curtis and de Barra (2018)	–	Six-factor model: hygiene disgust, animal disgust, sex disgust, atypical appearance disgust, lesion disgust, food disgust
Hartmann and Siegrist (2018)	FDS	Eight different categories of food disgust: animal flesh, poor hygiene, human contamination, mold, decaying fruit, fish, decaying vegetables, living contaminants
Ammann et al. (2018a)	FDPS	Food disgust picture scale based on pictures that display disgust cues from the categories of the FDS

pathways for human pathogens and then generated a set of cues derived from five diseases from each of these identified transmission pathways. They developed a six-factor model that categorizes disgust cues in six categories: hygiene disgust, animal disgust, sex disgust, atypical appearance disgust, lesion disgust, and food disgust.

Recently, a new disgust scale was published that focuses on the domain of food (Hartmann and Siegrist 2018). This new scale enables measurement of an individual's tendency to experience disgust when confronted with various food-related cues that indicate, for example, pathogen presence, unhygienic food preparation, or animal origin of the food. The food disgust scale is a reliable and valid self-report measure for adults which can be applied as an 8-item short version or a comprehensive 32-item long version. Figure 1 shows the distribution of food disgust sensitivity among a sample of Swiss adults. The long version consists of eight subscales with which eight distinct factors of food disgust can be measured: animal flesh, human contamination, poor hygiene, decaying fruit, decaying vegetables, mold, fish, and living contaminants. The food disgust scale was tested in different countries around the world including France, China, and England. Figure 2 displays that the results are quite similar in the different countries, and only small deviations in the mean values for the eight subscales between countries were observed.

In a subsequent study, a picture-based food disgust scale was developed to supplement the word-based food disgust measure (Ammann et al. 2018a). The Food Disgust Picture Scale presents participants with eight pictures that depict a range of potentially disgusting food items (Fig. 3). In contrast to the word-based food disgust scale, participants' perception of certain disgust cues is not subject to imagination, they are directly confronted with pictures that show potentially disgust eliciting food items. However, Descriptions of foods and food situations can evoke

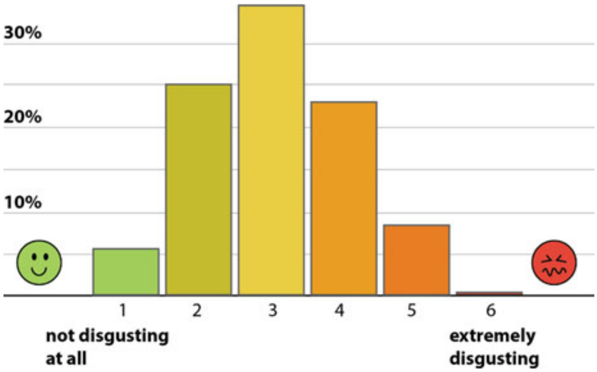

Fig. 1 Percentage distribution of overall food disgust sensitivity (FDS total score) among a sample of Swiss adults. Some people are not food disgust sensitive at all, most participants are medium disgust sensitive, and a few are very disgust sensitive. (Based on data from Hartmann and Siegrist 2018)

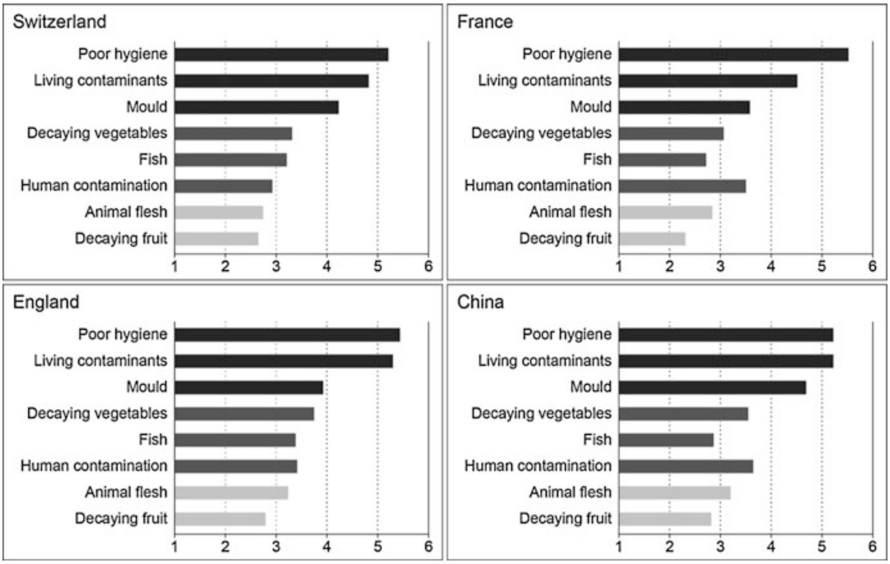

Fig. 2 Mean values for the eight subscales of the food disgust scale measured in Switzerland, France, England, and China. Poor food hygiene, food contamination, and mold on food were considered as most disgusting in all four countries. (Data from Swiss adults are published in Hartmann and Siegrist 2018)

more powerful salient memories and emotional responses that specific food preparations or pictures might not evoke (Cardello et al. 2012). This might explain why the Food Disgust Picture scale and the Food Disgust Scale correlated highly in previous research (Ammann et al. 2018a), but not as highly as expected. Nevertheless, both food-related scales were comprehensively tested, and it was shown that they correlate with eating behavior (Ammann et al. 2018b; Egolf et al. 2018).

All disgust scales and their underlying conceptualizations of disgust introduced above were developed in Western societies such as England (Curtis and de Barra 2018), Switzerland (Hartmann and Siegrist 2018), or the USA (Olatunji et al. 2007).

Fig. 3 Three pictures from the Food Disgust Picture Scale measuring disgust sensitivity in the domain of food (Ammann et al. 2018a). Studies showed that the worm-contaminated maize received the highest disgust scores. Cues related to decay or aging of fruit are considered disgusting by some persons. The old tomatoes were considered as medium disgusting by study participants. The situation depicted in the third picture points towards an unhygienic food behavior with raw meat. The rings as potential germ carriers, the direct contact with the hands, and the slightly gray color of the meat are potential disgust cues. The picture was, however, rated as least disgusting by study participants. (Picture source: Jeanine Ammann (picture 1, 2), Pixabay.com/yaron86 (picture 3))

Some of them were also successfully tested in other cultural contexts than those in which they were developed, however (e.g., Olatunji et al. 2009). Culture shapes the stimuli that provoke a disgust reaction and the behavioral consequences. Therefore, differences in mean values for disgust sensitivity between different cultural contexts are reasonable and were observed in previous cross-cultural studies (Olatunji et al. 2009). However, the results of the food disgust scale in different countries suggest that the ranking of various disgust elicitors (i.e., what people consider most disgusting and what they consider least disgusting) seems to be rather similar in different cultural contexts.

Disgust and Eating Behavior

Culture and social influences play a huge role when it comes to food that we consider acceptable or unacceptable, those food sources we like and those we dislike. Aversion and disgust towards certain foodstuffs might correspond to a personal or a collective attitude that certain foods are considered edible while others are considered disgusting. But apart from the cultural basis of food-related disgust, certain food-related cues indicate the presence of pathogens (e.g., mold) on a food or give an indication about aging of the food. People can react differently to these cues and consequently vary in their sensitivity to experience food-related disgust. However, disgust sensitivity comes with a trade-off between neglecting valuable food sources and potential benefits of avoiding risky items. Therefore, disgust sensitivity exerts functional and dysfunctional effects on eating behavior. Studies that directly assessed the influence of disgust on eating behavior in nonclinical populations are scarce, however. One problem was that there was no food-specific disgust scale available that measures individual differences in disgust sensitivity in the food domain. Disgust scales that assess overall disgust sensitivity or disgust sensitivity in certain domains apart from food might not capture relevant relationships. The newly developed food disgust scales with a particular emphasis on food items enables specialized research related to the link between eating behavior and food disgust sensitivity.

Disgust, Selective Eating Behaviors, and Food Choice

Human ability to adapt to new environments and potential new food sources was a big advantage for our species. However, it poses the risk of consuming potentially toxic plants and animals. Thus, humans show an ambivalent reaction towards new foods, a mixture of fear and interest. A psychological and behavioral tendency to reject unfamiliar food is called food neophobia (Pliner and Hobden 1992). Food neophobic behavior is a stable part of children's eating behavior development. Between the ages of 2 and 6 years, they show the strongest food neophobic reactions and reject unfamiliar, new foods. With age, food neophobic tendencies normally decrease, and strong food neophobic behavior in adults is even considered pathological. Aspects such as perceived mouth feeling, aversive textural properties, or a product's animal origin are considered main drivers of food rejection based on food neophobia (Martins and Pliner 2006). Considering the functional basis of disgust to prevent contact with potential disease vectors, a link between disgust sensitivity and food neophobia seems reasonable (Al-Shawaf et al. 2015; Nordin et al. 2004). In one study, Al-Shawaf (2015) found – utilizing the Three-Domain Disgust-Scale by Tybur et al. (2009) – a small correlation in women between food neophobia and pathogen disgust as well as sexual disgust. Utilizing a food-specific disgust scale, correlation coefficients between the FDS and food neophobia were as high as 0.37 in a survey study (Hartmann and Siegrist 2018). Further results showed that when it comes to willingness to eat unfamiliar foods, food disgust sensitivity explains variance over and above food neophobia (Ammann et al. 2018b; Hartmann and Siegrist 2018). Thus, the two constructs seem to be associated, and high disgust sensitivity might be a motivational force behind food neophobia.

The opposite of food neophobia, variety seeking, defined as the willingness to try new unknown foods (Lenglet 2018), was linked to disgust sensitivity too in previous research. Utilizing the Varseek-scale by Van Trijp and Steenkamp (1992), results of a survey study in Switzerland showed that food disgust sensitivity explained 4% of the variability in variety seeking. Food disgust is a defense mechanism that aims to avoid risks, while variety seeking in new food comes with an increased risk taking. Hence, the relationship between both constructs was negative (Egolf et al. 2018). Also, picky eating in adults, which is defined as aversion to or refusal to eat a wide range of virtually familiar foods, has been associated with disgust (Egolf et al. 2018; Kauer et al. 2015). Kauer et al. (2015) suggested that picky eating may be based on a hypersensitivity to certain sensory properties (e.g., texture, taste, appearance), and the rejection of certain textural properties was also linked with food disgust sensitivity (Egolf et al. 2018).

On the level of everyday food choices, disgust seems to have a small but relevant influence too. In one of the first studies that investigated the link between food disgust sensitivity and food choices measured with a food frequency questionnaire, results showed that food disgust sensitivity was associated with lower consumption frequencies of foods that pose high contamination risks and have special textural properties such as eggs and seafood (Egolf et al. 2018). Similarly, negative correlations between food-related disgust and consumption of several types of meat and fish products were observed in another study from Germany (Eickmeier et al. 2017). Moreover, lower consumption frequencies of vegetables were observed in high food disgust sensitive people. From the previous mentioned research, one might conclude that disgust sensitivity is not linked to food groups in general (e.g., meat) but that people may avoid certain preparations or special kinds of foods (e.g., animal innards).

Today, there is a clear separation between meat consumption and meat production, and modern meat marketing reduces, for good reason, evocative cues that remind consumers of the slaughtering procedure of the animals. It has often been reported that seeing, handling, or the idea of eating meat provokes disgust reactions in some people. In a study with university students, next to aversive textural properties, reminders of livingness/animalness accounted for most of the variance in disgust ratings for certain food-related scenarios. In particular, disgust sensitive participants were susceptible to react with disgust when they were confronted with cues that reminded them of the animal nature of the foods (Martins and Pliner 2006). Disgust reactions also come into play when people avoid meat based on moral convictions. Moral vegetarians find meat images more unpleasant and more disgusting and seem to avoid a wider range of animal foods than health-motivated vegetarians (Anderson et al. 2019; Rozin et al. 1997). Vegetarian-induced disgust reactions towards meat seem to be a consequence of the moralization of meat eating and the accompanied conversion of preferences into values (Fessler et al. 2003; Rozin et al. 1997). Research into promoting meat reduction within public health campaigns has even used disgust-oriented persuasive messages to influence meat attitudes (Palomo-Vélez et al. 2018). However, it is not completely clear why people are more susceptible to experience disgust when it comes to meat and animal products, and different explanations are possible. In the end, it might be a mixture of moralization and the idea of incorporating another living creature as well as the higher pathogen and contamination risk associated with animal-based foods.

Disgust and Acceptance of New Food Sources and New Food Technologies

Our daily food choices have a huge impact on the environment. Production of meat has a much larger impact compared with the production of vegetable-based proteins, for example. New food technologies (e.g., cultured meat, genetic modification) and new food sources (e.g., insects) may help reduce the environmental impact of people's food behavior (Bonny et al. 2015; Smetana et al. 2015). However, consumer acceptance of these new food sources is a challenge, and among other factors, disgust plays a role in the rejection of novel foods and technologies.

To feed a growing population worldwide, researchers around the world are searching for new food technologies and resources. Interest in alternative protein sources of high nutritional value, such as edible insects, has increased remarkably in recent years (Huis et al. 2013). A positive attitude towards such novel foods is a prerequisite for consumer acceptance. Factors such as food neophobic tendencies, previous experiences with eating insects, male gender, and attention to the environmental impact of food influence consumers' readiness to eat insects (Hartmann et al. 2015; Hartmann and Siegrist 2017; Verbeke 2015). Even though insects are a valuable food source in many cultural regions around the world (Costa-Neto and Dunkel 2016), a lot of people in Western societies are disgusted by the prospect of eating insects and by the insect itself (La Barbera et al. 2018). Not surprisingly, insects were long considered more as an indicator for food contamination and a health risk than as a valuable food source in most Western societies (Kellert 1993; Looy et al. 2014), and the presence of insects might even be considered as an indicator for low hygienic standards. Accordingly, an individual's susceptibility to be disgusted by poor food hygiene (subscale of the food disgust scale) was a significant predictor for willingness to eat products made with processed insects (Hartmann and Siegrist 2018). Moreover, food disgust sensitivity and food neophobia together explained 37% of the variance in the willingness to eat insect products. In another study, consumers were confronted with chocolate, which was decorated with dried mealworms. In this behavioral experiment, participants' food disgust sensitivity was strongly inversely correlated with the amount of the insect chocolate consumed (Ammann et al. 2018b). Therefore, food disgust sensitivity in previous research was not only linked to the hypothetical consumption of insect products but also proved to be a significant predictor for actual eating behavior. In addition, disgust was by far the most frequently mentioned reason for rejecting eating insects in another study with Indian and US adults (Ruby et al. 2015). Results of that study further showed that those persons who scored high on the core disgust subscale of the disgust scale (Haidt et al. 1994; revised by Olatunji et al. 2007) were less willing to eat insects. Core disgust sensitivity even reduces the likelihood that people get in contact with insect eating events (Hamerman 2016). An individual's disgust sensitivity is an important predictor for willingness to eat when it comes to insects. Whether it has a similarly high relevance for the acceptance of other familiar or unfamiliar foods needs to be determined in future research.

Disgust has also been proposed as one of the factors that influence acceptance of gene technology (Scott et al. 2016). According to these authors, gene technology is often perceived as unnatural, and it may be perceived as contaminating consumers by ingesting GM (genetically modified) foods. Furthermore, the idea that a gene from animals may be inserted in a plant may increase the disgust reaction. Scott and colleagues (Scott et al. 2016) showed that disgust evoked by gene technology was associated with support for GM restrictions. In other words, people who experienced a high level of disgust by GM food were more in favor of restrictions related to GM foods compared with people who experienced a low level of disgust. Even more interesting, people's general disgust sensitivity influenced people's acceptance of GM foods. Overall, the available evidence suggests that people with a higher affective disgust response towards a food technology (state disgust) and people who are generally more disgust sensitive (trait disgust) seem to report lower acceptance ratings to new food technologies (Clifford and Wendell 2016; Prokop et al. 2013). Even evoked disgust by elicitors that are unrelated to the food technology of interest, slightly motivates opposition to GMO containing food (Clifford and Wendell 2016).

The most important motivations underlying consumer's everyday food choices are sensory and health factors (Martins and Pliner 2005). Likewise, "natural" seems to be a positive quality for most people in Western countries (Rozin 2005). For example, a survey conducted in the USA showed that consumers perceived pesticide-related risks as greater than either natural toxin or microbial pathogen risks (Williams and Hammitt 2001). Perceived naturalness is an important factor when it comes to consumer acceptance of foods and food technologies. The attributes that are used for defining a food as natural vary between stakeholders and consumers (Román et al. 2017). Perceptions of naturalness are also relevant when it comes to the acceptance of cultured meat. Cultured meat was developed as a substitute for conventionally produced meat that exactly mimics meat but is less resource consuming and may be more morally justified from various ethical perspectives (Hopkins and Dacey 2008; Pluhar 2010). It is based on stem cell technology (Post 2012), and if technological hurdles could be overridden, cultured meat might be a promising approach for the production of so-called clean meat. Consumers' willingness to eat cultured meat considerably varied between study samples and countries (Bryant and Barnett 2018). Some reported an overall positive view among US consumers (Wilks and Phillips 2017), while others concluded that acceptance ratings are rather low (Hocquette et al. 2015). Focus groups in Belgium, Portugal, and the UK revealed that after being informed about cultured meat, perceived unnaturalness and feelings of disgust towards the novel meat product are prevalent initial reactions of consumers towards the idea of consuming it (Verbeke et al. 2015). Moreover, study results showed that perceived naturalness of cultured meat had a direct and an indirect effect via disgust towards that meat on the participant's willingness to eat it (Siegrist et al. 2018). The production process characteristics of cultured meat seem to evoke a disgust reaction which is probably related to the heavy processing and consumer's perception of humans tampering with nature (Siegrist et al. 2018; Verbeke et al. 2015).

Disgust and Hygiene Behavior

Hygiene behavior is, next to healthy eating, regular physical activity and medical checkups, a fundamental part of health behavior. It aims to avoid infections and illness by preventing contact with potential pathogens. Hygiene behavior is relevant in different domains such as the body or food preparation. Food preparation in particular is a risk area where a lack of hygiene could have detrimental health effects. Food-borne diseases are a serious public health problem, and more than 200 diseases are spread through food via microorganisms (e.g., fungi). They can even lead to deaths in vulnerable population groups such as the elderly, children, or immunocompromised persons. A relationship between disgust, which aims at avoiding infections and illness, and hygiene behavior was suggested (Curtis 2007). Initial studies showed that disgust is one motivation among others for hand washing behavior in developing countries (Curtis et al. 2009), and it was also shown to be a key driver in nurses infection control behaviors (Jackson and Griffiths 2014). However, there has been little discussion on the relationship between disgust sensitivity on the one hand and hygiene in food preparation, an essential behavior for health promotion, on the other hand. In a recent study, 1122 participants in the German-speaking part of Switzerland were asked how frequently they practice 24 different hygienic behaviors in the kitchen (Ammann et al. 2019). The behaviors varied from washing fresh fruit and vegetables before consumption, checking for insect contamination in dry products, cleaning the refrigerator to changing the tea towel regularly. Results showed that people's food disgust sensitivity, i.e., their disgust responsiveness following exposure to food-related potential disgust elicitors, was strongly correlated with kitchen hygiene behaviors. Those who were more food disgust sensitive also practiced these hygiene behaviors more frequently. Another important outcome of that study was that people who were more food disgust sensitive reported heightened disgust responses following descriptions of situations that included food-related unhygienic behavior (e.g., food that dropped to the floor). Thus, disgust sensitivity leads to both stronger disgust reactions towards unhygienic food behavior (by others) and more frequently practiced hygiene behavior. Very low disgust sensitivity seems to inhibit necessary preventive hygiene behavior and adequate evaluation of the behavior of others, and consequently people might expose themselves to higher risks of food-borne diseases.

Nevertheless, disgust sensitivity comes with a trade-off between preventive behavior and neglecting valuable resources. In the domain of food, a small but significant positive relationship between people's food disgust sensitivity and their frequency of throwing away food was found (Egolf et al. 2018). This is of high relevance considering the fact that food waste accounts for the largest percentage of food losses in the value chain in industrialized countries (Parfitt et al. 2010). People with high levels of food disgust sensitivity seem to react more strongly towards cues related to decay or the aging of the food. Food that is not as fresh anymore might then be considered inedible or dangerous. It is probably rather difficult, if not impossible, to convince people to eat food that is still edible but that they consider disgusting. Therefore, it seems more promising for educational campaigns aiming at reducing food waste production in the domestic area, to focus on processing techniques for old food so that disgust-eliciting cues are not visible anymore (Egolf et al. 2018).

Conclusion

Disgust is a protective rejection mechanism that is supposed to decrease the likelihood that we have contact with or even consume potentially risky items. Disgust is linked to psychological constructs of selective eating behavior. In fact, food-related disgust sensitivity exerts an effect on food choices, eating habits, textural preferences, and even food hygiene behavior. A growing body of literature has suggested that especially animal-based foods can provoke a disgust reaction. Disgust is a factor that might even prevent people from making favorable food choices. Nevertheless, the link between disgust sensitivity and how it shapes our eating behavior is still under researched, and future research will provide more insights into how disgust shapes our eating behavior in functional and dysfunctional ways. In addition, consumer acceptance of new food technologies and resources is an obstacle not least because of product attributes or characteristics of the production technology that provoke disgust in consumers. People with a higher affective disgust response towards a food technology, and people who are generally more disgust sensitive reported lower acceptance ratings to new food technologies. Overcoming such negative affective reactions in consumers is a challenge, and marketing approaches need to prevent evocative cues that provoke a disgust response.

The Role of Ritual in Eating

17

Jonathan Brumberg-Kraus

Contents

Abstract

Rituals of eating refer to the behaviors regarding what, with whom, when, where, how, and why people eat. They are patterned, repeated, sometimes automatic, sometimes intentionally mindful, often talk-enhanced practices that *humanize* the ways people nourish themselves. Rituals of eating might be, but are not necessarily "religious" in that they are associated with specific religious traditions. The difference between religious and nonreligious rituals of eating is better understood as between "rituals in a strong sense" and in a "weak sense" (Kripal et al. 2014). On one hand, they may be intentional "reenactment of myths – sacred

stories – that make worlds come into being" or they may be something like the daily cycles of breakfast, lunch, and dinner with appropriate foods at appropriate times.

Eating rituals also can be classified more specifically according to their form and sequence, their function, the emotions they evoke, and their meaning. This chapter addresses the roles of ritual in eating in the following: (1) as types of behaviors (order of meals, seasonally cued practices, table etiquette, taboos, eating, and reading); (2) as rituals of different kinds of relationships (to nature, to other humans, and to the supernatural); (3) as components of meals besides eating (preparation, acquisition, and cooking of food); (4) in the emotional affect they encourage (rituals of disgust, elevation, and gratitude); and (5) as the different strategies and contents of meaning they create. The role of ritual in eating is to make it meaningful to people – affectively, cognitively, socially, culturally, and religiously.

Introduction

Margaret Visser suggests in her book *The Rituals of Dinner* (1991) that table manners originated to curb human instincts to use one's knives on their fellow diners rather than on their dinner. Table manners however are but a subset of the many different rituals people apply to what, with whom, when, where, how, and why they eat. All animals eat, but rituals, that is, patterned, repeated, sometimes automatic, sometimes intentionally mindful, often talk-enhanced behaviors are apparently what *humanize* the ways the human species nourishes itself. Jean Anthelme Brillat-Savarin (1825/1986), the early nineteenth-century father of modern Euro-American gastronomy and food writing, famously distinguished "the pleasures of the table. . .from the pleasure of eating, *their necessary antecedent*," as follows:

The pleasure of eating is the actual and direct sensation of satisfying a need.

The pleasures of the table are a reflective sensation which is born from the various circumstances of place, time, things, and people who make up the surroundings of the meal.

The pleasure of eating is one we share with animals; it depends solely on hunger and what is needed to satisfy it.

The pleasures of the table are known only to the human race; they depend on careful preparations for the serving of the meal, on the choice of place, and the thoughtful assembling of the guests.

The pleasure of eating demands appetite, if not actual hunger; the pleasures of the table are most often independent of either one or the other...

During the first course, and at the beginning of the feast, everyone eats hungrily, without talking, without paying any attention to what may be going on about him, and no matter what his position or rank may be he ignores everything in order to devote himself to the great task at hand. But as these needs are satisfied, the intellect rouses itself, conversation begins, a new order of behavior asserts itself, and the man who was no more than an eater until then becomes a more or less pleasant companion, according to his natural ability. (p. 182)

What are "careful preparations for the serving of the meal, on the choice of place, and the thoughtful assembling of the guests. . .[and] conversation . . .a new order of behavior" but rituals that not only shape the meal as a communal activity, but also enhances the *pleasure* of those eating at it?

Eating rituals, therefore, can be classified according to their form and sequence, their function, the emotions they evoke, and their meaning. To be more precise, one can categorize the roles of ritual in eating by as types of behaviors (order of meals, seasonally cued, table etiquette, taboos, eating, and reading); as rituals of different kinds of relationships (to nature, to other humans, and to the supernatural); as components of meals besides eating (preparation, acquisition, and cooking of food); by the emotional affect they encourage (rituals of disgust, elevation, and gratitude); and by the different strategies and contents of meaning they create.

Religious and Nonreligious Rituals of Eating: Rituals in the Strong Sense and in the Weak Sense

The word ritual often leads many to assume it refers to religious activities and interactions with deities. On the contrary, implicit in any discussion of ritual, including food rituals, is (or should be) the distinction most assume between "religious rituals," like Christian Communion or the Jewish Passover Seder, and more ordinary ritual patterns of behavior, like breakfast in the morning, lunch midday, and dinner at night (which nowadays in modern industrialized societies are more honored in the breach than observed).

A more precise way to describe this sort of difference in rituals, which is especially applicable to the role of rituals in eating, is the distinction the critical scholars of the comparison of religions Jeffrey Kripal et al. (2014) draws between "ritual in the weak sense" and "ritual in the strong sense." The weak sense of ritual "encompasses virtually all of human social behavior, taken as a coded and scripted set of actions that serve particular social and psychological functions" (Kripal et al. 2014, p. 117). The strong sense of ritual "requires something else: an invocation of superhuman powers and a fundamental orientation toward an order of reality and an eventual state of salvation that transcends the social world and its material and pragmatic needs" (Kripal et al. 2014, p. 117). This clearly corresponds to the differentiation between ordinary daily rituals and religious rituals made above but are preferable, because not all "religious" rituals, that is, rituals in the strong sense, can be associated with specific recognizable religious traditions. For rituals in this strong sense are "re-enactments of a myth," with a myth being "a sacred story that founds and grounds a particular world" (Kripal et al. 2014, p. 116). Thus, this kind of a ritual is "is the reenactment of the myth that makes that world come into being." The North American Thanksgiving dinner is a good example of a nonreligious ritual that nevertheless reenacts a myth that makes the world come into being, in this case the world of the US nation. Though ostensibly associated with American Protestantism (a commemoration celebrating the Puritan pilgrims' meal with the native Americans who helped them survive their first winter in Massachusetts according to legend), both historically and in practice is far from that. Indeed, Gurinder Chadha's movie *What's Cooking?* (Taylor & Chadha 2000) delightfully demonstrates how four contemporary quite ethnically different families in LA, African American, Jewish American, Mexican American, and Vietnamese American, each make try to make the "traditional" American Thanksgiving turkey dinner their own. In other words, it is precisely because of its symbolic significance as the myth of American origins that the ethnically diverse families in the movie appropriate the Thanksgiving turkey dinner to enact their American identity as participants in America's story.

Eating Rituals in the Strong Sense

What's Cooking?'s representation of multiethnic American Thanksgiving rituals and "religious" meal rituals have in common two features Kripal defines as characteristic of ritual in the strong sense. First, as already stated, they are rituals that reenact a myth, that is, "a sacred story that founds and grounds a particular world" in order to make "that world come into being." In other words, when modern Mexican Americans roast a turkey on Thanksgiving for a big family meal (even if they adapt it to their own flavor preference) or when Christians eat bread and drink wine in the ritual of communion or when Jews reenact the Biblical Exodus story at the Passover Seder meal, they are in effect "inscribing" themselves in the same stories and therefore in the same worlds imagined and mapped in those stories. Meals like this, ritualized in the strong sense, are thus important mechanisms for what modern sociologists call "the social construction of reality" (Berger 1990). In these kinds of meal rituals in the strong sense, participants get to make their worlds and eat them, too, that is, make them so real they can taste them. A second feature religious and nonreligious meal rituals in the strong sense share is that they accomplish this "*through scripted and repeated actions* (*"ritual"*), *usually performed in a culturally prescribed space and time* and often by a religious specialist, who performs the myth through this ritual" (Kripal et al. 2014, p. 116). In other words, they take place at special prescribed times (e.g., religious and secular holidays or life cycle events) at special places (e.g., a church, a temple, a family dining room) and are conducted by "specialists" knowledgeable in the sacred lore (family matriarchs or patriarchs – keepers of the family recipes – or a priest, a rabbi, a religiously skilled layperson, etc.). These kinds of rituals do not happen at random places and times, nor are they conducted without some sort of expert exercising quality control. These specialist experts end up being boundary keepers, the ones who assure that the social groups the meal rituals are intended to form and the social worlds they are intended to enact maintain their integrity – so that they are perceived as authentic. But perhaps most importantly, it's these specialists who accentuate the specialness of the eating rituals in the strong sense by evoking or literally invoking "the something else," the "superhuman powers and a fundamental orientation toward an order of reality and an eventual state of salvation that transcends the social world and its material and pragmatic needs" (Kripal et al. 2014). Thus often rituals in the strong sense have participants say certain words over foods to attribute to them their special symbolic quality, such as repeating the words of Jesus saying "This is My body, this is My blood," over bread and wine in the Christian Eucharist ritual, or Jewish Passover Seder participants applying verses from the Biblical story Exodus like "The bitter herb, because *the Egyptians embittered our lives*" to bitter greens or horseradish root. Or sometimes the context or occasion, not to mention the officiation of ritual specialists like priests or shamans, is enough to convey the symbolic quality of foods for the gods, even if words do not make it explicit, as in sacrifices when one is sharing food at a temple or shrine devoted to one or more gods. Indeed, the context and choreography of most food sacrifices, e.g., sending food "up" cooked in smoke, "bringing it near," or "setting it apart" (to use the literal translation of some of the typical Biblical Hebrew verbs for sacrificing: *le-ha'alot, le-hekriv,* and *le-hakdish*, respectively) to where God or the gods "dwell," imply the logic of what scholar of religion Ninian Smart (2000) calls "*do ut des*" [Latin for "I give so that you give"]. In other words, in sacrificial settings, participants understand that they're giving something to the gods with the expectation that they will get something back in return: "material and pragmatic needs" like ecological and climatic conditions conducive to the fertility of their crops and livestock (or to their own fertility), forgiveness or atonement, victory in battle, or simply the pleasures of God or the gods' company (etymologically, "sharing bread").

Perhaps by this standard, Thanksgiving dinners like those in *What's Cooking?* are not quite eating rituals in the strong sense, since the family dinner specialists don't notably invoke superhuman powers or suggest that observance of the Thanksgiving meal festivities will brings about a "state of salvation that transcends the social world and its material and pragmatic needs." Or don't they? What if the American nation were to be substituted for superhuman powers, and the sense of belonging to the America of the Thanksgiving story were a kind of salvation for the Black, Mexican, Vietnamese, and Jewish families not so secure about their status as real Americans? However one answers this, it's important to make the point that the distinction between eating rituals in the strong sense and in the weak sense is not meant to be a value judgment that one type is more important or more meaningful than the other. Rather, it's meant to acknowledge differences in the consciousness, intentionality, and relationship to recognizably acknowledged religious traditions in the practices of those who perform eating rituals when describing them. In a certain sense, all eating rituals are both weak and strong. They are weak in the sense that they are all "coded and scripted set of actions that serve particular social and psychological functions." They are strong in the sense that they all "re-enact myths that make the world come into being," even if strictly speaking, in rituals in the weak sense this is not a particularly conscious intent. Thus, Kripal correctly summarizes the ritual functions of food when he says, "Food helps make a world. Food is belonging. Food is boundary. Food is story. Food is performance. Food is self (p. 149)."

Eating Rituals in the Weak Sense

The point of calling attention to food rituals in the weak sense is that they do not only have to be experienced as extraordinarily special or “sacred” (to use the religious studies term) to nevertheless convey these world-making, belonging-making boundary-making, and story-making, self-performing powers of food. There are many day-to-day ritual practices of food taboos which habituate patterns of preferences for some foods over others. Some, like Jewish “keeping kosher,” Muslim observance of the rules of halal or daylight fasting during the month of Ramadan (the reader is referred to the Handbook Chapter by Regenstein on kosher and halal food), Indian Brahmin or Jain avoidance of meat, or Catholic fish on Friday and no meat all during Lent are religiously motivated, at least in their origins. However, even among members of those religious communities, there is a wide variation of practice. Some follow the rules out of custom or habit rather than for consciously “religious reasons,” and some even deliberately transgress them to express their identity (like Jews who eat pork to make a point that they are not bound by religious law or Muslims who drink alcoholic beverages for similar reasons). And people practice many other day-to-day food taboos and preferences that are not necessarily religiously motivated, such as vegetarianism and veganism done for ethical, ecological, health, and aesthetic reasons (the reader is referred to the Handbook Section on Ethics); eating local, sustainably produced, and/or organic foods; various diet regimens intended for weight loss or other health concerns; paleo diets; raw food diets, etc. Carbs, fats, and sugar can be just as taboo to practitioners of these diets as pork chops are to observant Jews, Muslims, or Jains.

Another significant example of regular food rituals in the weak sense is the daily cycle of breakfast, lunch, and dinner typical in many societies around the world, which do vary from culture to culture (such as continental vs. full breakfasts, lunch as the main meal of the day vs. dinner, or even what constitutes typical breakfast, lunch, or dinner foods). For example, Americans who are used to eggs or cereal for breakfast are often surprised when travelling to Middle Eastern countries how much more prominent vegetables are on the breakfast menu. And in much of modern western industrialized, workaholic cultures today, the three-meals-a-day pattern is observed more in the breach than in actual practices. People skip meals, substitute a power shake for meals with courses, and grab something to eat on the work commute. Or they may “graze” throughout the day at their own pace, eating when they’re hungry, rather than at the societally specified breakfast, lunch, and dinner times, or at high and low tea times in places still under the influence of the of the meal culture of the British Commonwealth. And yet, institutions such as schools, colleges, restaurants, hospitals, prisons, and airline companies (albeit less so recently) still tend to structure their service of meals around the basic ritually repeated practice of morning, midday, and evening meals.

The most well-known and influential discussion of this sort of regular system of daily, weekly, and seasonal meals is the anthropologist Mary Douglas’ classic essay “Deciphering a Meal” (1972). By analyzing the typical patterns of the British meals of her native culture, Douglas demonstrated that the system of meals worked a lot like a language, in which the order, number, and specific components of a meal, and of meals during the day, week, and year functioned like syntax or grammar, to make meals and their parts follow very predictable patterns. All meals, from the simplest breakfast to the most complicated Sunday or Christmas dinner, were more or less related to one another, through the multiplication of dishes with varying connotations. "Mains," "sides," soups, drinks, sweets/desserts, starches, vegetables, and fruits each have a significance in comparison to one another, as well as in combination. Breakfast, a lighter meal, may have very few courses, a main that is not a meat (eggs, a cereal), though meat (like sausage or bacon) may be as a side, and a drink (juice, coffee, tea). But compare that to a Sunday dinner, or something like an American Thanksgiving dinner that might have a soup or other appetizers, two meat mains, two starch sides, two vegetable sides, more than one sweet for dessert, and different kinds of drinks (some alcoholic, some not) served at the beginning, during, and after the main course. Moreover, mains and sides are usually savory (though sometimes sweetened to mark a special holiday meal); desserts sweet. Sides are usually a combination of starches and vegetables, not just only one or the other. Nor would one normally expect to have scrambled eggs or hot oatmeal as a main for a Christmas or Thanksgiving dinner or chocolate mousse for an appetizer before the mains. One knows this because of the implicit codes Douglas says are at play in the British system of meals but by implication could be "deciphered" analogously in any system of meals in any human culture. And these are not just codes to impose order on chaos, though of course they do that. They are "coded and scripted set of actions that serve particular social and psychological functions" (Kripal et al. 2014), that is, rituals in the weak sense that serve to create and maintain the social boundaries of family, culture, ethnicity, and class. Table etiquette, which likewise varies from culture to culture (e.g., Euro-American eating with forks, knives, and spoons; Indian and Arab etiquette of eating with one's hands; East Asian etiquette eating with chopsticks), performs similar, complementary functions. This becomes quite clear, sometimes awkwardly, for guests at meals in the home of people whose culture and accompanying table etiquette are quite different from their own (Visser 1991; Harvey 2013).

Types of Eating Rituals: A Formal Classification

In addition to differentiating eating rituals by their social functions, or better, the degree of their practitioners' intentionality and awareness of them as rituals with world-making, group-defining social functions, eating rituals may also be classified according to their form. Though the list of types of eating rituals to follow reiterates some of the rituals used as examples in the discussion above of rituals in the strong and weak senses, and cannot be claimed to be exhaustive, it nevertheless provides a good overview of the most generally recognizable forms of eating rituals. They are

1. **Orders of meals**: both the "courses" within them (e.g., appetizer, main course, dessert; drinks, before, during, and after the main course) and where they fit in the

day, e.g., breakfast, lunch, dinner, in between meal snacks, high and low teas, happy hours for drinks, etc.) with variations from culture to culture

2. **Seasonally cued meal rituals** (harvest festival meals like Jewish Sukkot or American Thanksgiving, Halloween trick or treating; Christmas dinners; the Jewish Passover Seder or Persian New Year's day Nowruz festive meals in the spring; 4th of July picnics in the summer, evening Muslim "break fasts" *iftar* meals during the month of Ramadan; or annual meals commemorating other sorts of historical events, like Scottish Robert Burns Day or African American Juneteenth meals)
3. **Meals occasioned by rites of passage**, like wedding banquets, birthday parties, *quinceañeras*, baby namings, or funerals
4. **Table etiquette rules** governing seating, table settings (what kinds of utensils if any and how they're arranged), what to wear, guest and host responsibilities, respect for social hierarchies and gender roles, appropriate postures and behaviors (like eating with your mouth shut, not burping or farting), etc. which of course also vary from culture to culture
5. **Dietary taboos**: prohibited or permitted foods as discussed above, which involve not only specifying from which plant, animal, and nonorganic sources foods may or may not be eaten but also how they are prepared (e.g., kosher meat must be salted and drained of blood; organic produce cannot be grown using certain pesticides or fertilizers), and official or semiofficial authorities who supervise their production and preparation and certify that the foods have met the required standards (e.g., the Jewish Orthodox Union, the US FDA, Muslim halal inspectors, etc.)
6. **"Scripted meals,"** that is, meals that involve the saying, singing, and/or reading of specific words accompanying the eating, which can range from improvised or prescribed food blessings, to reading and performing actual scripts like the Jewish Passover Haggadah, to suggested talking points, to shared song sheets, short readings brought or composed by the participants, to formal speeches

Particularly, notable literary representations of this are the speeches praising the god of Love in Plato's *Symposium* or General Löwenhielm's speech at the banquet in the movie *Babette's Feast* (Betzer et al. 2003, based on the short story by Isak Dinesen [1950/1993]; Brumberg-Kraus 2008). In short, since rituals are "scripted and repeated actions. . .usually performed in a culturally prescribed space and time and often by a religious specialist" (Kripal et al. 2014, p. 116), it makes sense to categorize eating rituals formally according to which sort of scripts and repeated actions they are comprised of (not to mention what "ingredients" and other "props" are used in them), where and on what occasions they are performed, who conducts them, and for whom.

Eating Rituals as Rituals of Relationship

Since eating rituals are fundamentally social activities – even when eating alone one follows the types of socially determined codes and patterned behaviors discussed above – they are inherently relational. In other words, eating rituals typically construct human relationships with the natural world, with other human beings, and with supernatural beings.

With Nature

It is not precisely accurate to say human beings construct relationships with "nature" through eating rituals, since in the ecology of things, humans are a part of nature, not apart from it. In this sense, Graham Harvey's (2013) definition of religion aptly applies to eating rituals as well. They are about respecting relationships between human and other than human persons – including other animals, plants, rivers, rocks, gods, mountains, celestial bodies, and so on. In terms of nature, humans, like other animals, are evolutionarily, cognitively "hard-wired" to recognize and distinguish between three main ways of relating to things in the environment in order to survive: Is it food? Is it a potential mate? Or is it a predator? Perhaps the taboos against eating other humans, having sex with animals or inanimate objects, or eating other animals that might see humans as food (not that any of these taboos are absolute given the variety of human practices) are rooted in these basic distinctions. Eating rituals, to the extent they maintain these categories, code and pattern relationships to fellow beings in the natural world as food, partner, or predator. That certainly puts Visser's (1991) observation with which this chapter opened in the proper light: table manners originated to curb our instincts to use our knives on our fellow diners rather than on our dinner. In any case, to have rituals designated for how to treat food implies that there are *different* rituals designated for how to treat potential mates, as well as for how to treat – that is, fight or flee from – potentially dangerous predators or rivals for resources. In other words, eating rituals are part of a whole system of rituals that are nothing less than "reenactments" of the myths that found and ground particular worlds to make those worlds "come into being" (Kripal et al. 2014, p. 116). Put differently, these ritual systems presume and imply "sacred stories" that cast all the denizens of the natural world in specific roles – relationships – vis-a-vis one another, which in effect constructs a cosmos, an ordered world of relationships between all that is. Most pertinently for conscious beings like humans, these ritual reenactments map out what is food, (and what isn't), who could be a mate (and who or what isn't), and who or what is out to get us (or isn't). Thus, in his aptly titled book *Food, Sex, and Strangers: Understanding Religion as Everyday Life,* Graham Harvey (2013) focuses on the world-making *rituals* of "religion" – understood as respecting *relations* between humans and other than human persons – by describing religions (or for a more neutral term, worldviews) as kinds of "cosmic etiquette" varying across cultures.

With Other Human Beings

Nevertheless, eating rituals are still quite concerned about relations with other people. Meals are basically social rituals that form and shape boundaries between people. Some meal rituals are rituals of inclusion (e.g., "family style" vs. serving people their meals on separate dishes; potlucks; the free vegetarian meals open to all served from the *langar*s [communal kitchens] in Sikh temples; anticipating or asking guests beforehand what their dietary constraints are and providing accordingly; inviting non-Jewish guests to Passover seders, non-Christian guests to Christmas dinners, etc.). Others are rituals of separation, such as when one's own food taboos prohibit them from eating in others' homes; arranging children's and adult tables; distinguishing head tables from other tables, like the faculty tables in British colleges; seating segregated by gender; rules for admission and membership for exclusive eating clubs; "no shoes, no shirts, no service"-type dress codes at restaurants; pricing menu items beyond the reach of most consumers at high-end restaurants; the rituals of first class, business class, and economy class seating and food service on airlines; segregation or exclusion of people from eating establishments because of their race, ethnicity, religion, or sexuality; restriction of certain parts of Biblical sacrifices to male hereditary priests and their families; etc. The practice of many elderly as well as young "unattached" adults to eat alone is also a kind of "ritual of separation," regardless if that is the eater's choice, or a matter of circumstance beyond the eater's control (e.g., loss of one's spouse or other significant other[s]) economics, social isolation because of where one lives, being socially ostracized as a pariah, etc.). Finally, the specific rules and responsibilities of host and guests are often codified in lists of meal rules, such as those enumerated in ancient Jewish rabbinic *derekh eretz* literature, Greek and Roman eating club rules parodied by the second-century CE writer Lucian, and this passage from the Gospel of Luke 14:7–14 (New Revised Standard Version) in the Christian New Testament attributed to Jesus:

> When he noticed how the guests chose the places of honor, he told them a parable. "When you are invited by someone to a wedding banquet, do not sit down at the place of honor, in case someone more distinguished than you has been invited by your host; and the host who invited both of you may come and say to you, 'Give this person your place,' and then in disgrace you would start to take the lowest place. But when you are invited, go and sit down at the lowest place, so that when your host comes, he may say to you, 'Friend, move up higher'; then you will be honored in the presence of all who sit at the table with you. For all who exalt themselves will be humbled, and those who humble themselves will be exalted." He said also to the one who had invited him, "When you give a luncheon or a dinner, do not invite your friends or your brothers or your relatives or rich neighbors, in case they may invite you in return, and you would be repaid. But when you give a banquet, invite the poor, the crippled, the lame, and the blind. And you will be blessed, because they cannot repay you, for you will be repaid at the resurrection of the righteous.

One could find similar rules for proper host and guest behavior in modern etiquette advice columns (e.g., Galanes 2012) or etiquette books (e.g., Post 1994; Martin 2005) in the appropriate sections.

With Supernatural Beings

Eating rituals that establish and maintain relationships with supernatural beings are of two types: those that involve the supernatural beings as companions, hosts, or guests at meals, or those in which the supernatural beings are themselves the food which is consumed, literally or figuratively. Supernatural beings may include God, the gods, deceased ancestors, nature spirits, ghosts, demons, in short, any other beings perceived as being somehow "more" than those ordinarily met in nature. That said, in most non-Christian or Biblically based, non-monotheistic religious or cultural traditions, such as the indigenous cultures of Native Americans, the Maori of New Zealand, or the Yoruba of Nigeria, or Shinto in Japan, these kinds of beings are not considered to be unnatural or apart from nature; they are simply other than *human* beings (Harvey 2013), though perhaps they may be *super*human (Kripal et al. 2014). The most well-known example of a ritual in which God, incarnate in his Son Jesus Christ, is food and drink to be consumed, is Christian communion, the Eucharist. But in many other traditions, there are gods who are foods, such as the *soma* consumed in the Hindu Rig Veda hymns, or the Aztec and Mayan corn (maize) god or goddess. Moreover, in some cultures, deceased ancestors may also be consumed (often as ground bones or burnt into powder mixed with other foods but sometimes in smellier, earthier, less refined forms), in what Visser (1991) calls endocannibalism, as part of mourning rituals.

Perhaps more typical are rituals that treat gods, ancestors, or other supernatural beings as hosts or guests at meals. Sacrifice rituals in which animal or plant food offerings are made to the gods in their temples or other shrines devoted to them, that is, shared with them in their "houses," have already been mentioned. These shrines may also be located in family homes, such as shrines in Hindu homes where images of deities are offered foods, bathed in clarified butter, and dressed (what Eck [1981] describes as "playing house with the gods"), or the idea in post-Biblical rabbinic Jewish traditions that the dinner table is a *mikdash me'at* – a "mini-temple" – where God can still be served through sharing food, in lieu of the sacrifices that can no longer be performed in the Jerusalem Temple destroyed in 70 CE. The Jewish tradition of separating *hallah*, a portion of dough set aside when making bread and burnt (for God), which has become the term for the braided or round egg breads typically served for Sabbath and holiday meals, is another way of sharing food with God even after the temple sacrifices are no longer possible (Brumberg-Kraus 2018). The traditions across cultures for verbally invoking the gods by name are ways of acknowledging them as the hosts of one's meals, such as the classical Greek and Roman invocations of the gods before meals, Christian grace, or Muslims uttering *bismillah* ("in the name of God") before eating or slaughtering animals for meat. The opening blessing before the Jewish grace after meals is literally called "the blessing of invitation" (*birkat ha-zimmun*), in which the meal participants explicitly acknowledge that it was from God's table they ate, "Blessed are You Our God, from Whose table we have eaten." The presence of dead ancestors may also be acknowledged as if they were guests at meals, whether formally, in home shrines especially in East Asian cultures where food is offered to them or when the yet unburied bodies of family members might be present in the homes where the living family members live (such is in the funeral practices of the Toraja in Indonesia [Montagnon et al. 1977/2001; Crystal 1974], or the roots of some Halloween traditions featured in Ray Bradbury's animated movie based on his novel *The Halloween Tree* [Kirschner et al. 1972/1993/2016]), or informally, in the conversations recalling deceased or otherwise absent family members that typically arise during family seasonal or rite-of-passage meal celebrations. Nature spirits too may be considered as guests welcome to partake of food consumed by humans, as the Indonesian Toraja who shared their rice harvest with rats, understood as the embodiment of such spirits. However, this could go awry, as when the rats consumed too much of the rice harvest, which some Toraja understood as retribution for the increasing adoption of Christianity in place of their traditional indigenous ways (Hollan 1988). In a sense, all acts of eating directly or indirectly involve some kind of violence between humans and other than human beings which threatens their fundamental "relationality" and must somehow address and repair the breaches that living in the world requires. (The reader is referred to the Handbook Section on Ethics). In Graham Harvey's view (informed especially by the modern Maori religious thinker T. P. Tawhai), the basic point of religions is to provide rituals to negotiate this necessary oscillation between acts of violence and reconciliation basic to our existence in the real world. As Harvey puts it, "[R]eligion occurs when people face their victims," – animal, vegetable, and mineral; natural and super-natural –

> fully cognisant that reciprocity is integral to relationality, and seek to enhance intimacy with others despite violence. Religious activity is undertaken when, *in ritual and etiquette*, in restraint and celebration, and in honouring mana and taboo, people seek permission and offer placation either for necessary but nonetheless wrongful acts of violence. (p. 116)

In other words, if indeed, "religion is etiquette in the real world" (Harvey, p. 199), then rituals of eating, which are all about structuring people's relationships to the real world, engage people in "religious," or at least religion-like behavior, whether conscious of it or not.

Eating Rituals Are More Than Just *Eating* Rituals

Since much of the violence related to eating usually has occurred long before the food has actually arrived at the table to eat – e.g., in the killing of animals for food, in the harvesting of produce out of the soil, or in the often inequitable economics of production and distribution of food – one must point out the importance of the rituals of food preparation when discussing the role of rituals in eating. The two main categories for food preparation rituals are (1) the rituals of acquiring foods and (2) the rituals of cooking foods. In the first, by whom and how are foods acquired? Grown oneself, bought in open markets, in grocery stores or chains, prepared at restaurants (fast food and more formal and/or expensive), ordered and delivered on-line, etc.? Is the food acquired by begging, either necessitated by the eater's poverty, or to make a symbolic point, that the eater is detached from material things and striving for them, as in the case of Theravada Buddhist and Jain monks, or the practice of the Jesus and earliest apostles as itinerant charismatic healers and preachers, to demonstrate their faith in God to supply their needs (albeit through the hospitality of their sympathizing communities). Gerd Theissen (1978) aptly calls this practice "charismatic begging." This also benefitted the ordinary Buddhists, Jains, and Christians who acquired merit or blessing for feeding their teachers. And each of these stages or options of food acquisition has its own set of patterned and repeated typical behaviors. Is it daily, weekly, less frequent, seasonal, or hunger impulse driven? Jewish Biblical and post-Biblical traditions are particularly notable for their extensive rules not only for eating food but also agricultural rules: how and when plants are to be harvested; how animals are to be raised, slaughtered, and apportioned between ordinary Israelites, priests, and their families, and God in the sacrificial system; which rules are to be practiced when the sacrificial system no longer exists after the destruction of the temple and exile of Jews from the land of Israel after 70 CE? (Brumberg-Kraus 2015). And one can find similar kinds of rule books for agriculture in other traditions (not to mention farmers' almanacs) as well as for sacrifices. As for rituals of shopping for foods, everyone who has themselves or knows others who observe the kinds of dietary restrictions discussed above is familiar with the rituals of checking labels for ingredients and/or appropriate certifications. Likewise, when dining out, there are the rituals of checking for problematic ingredients by asking if something is made with chicken stock, is gluten free, contains nuts, etc. And cooking food also has its own set of rituals, from following family customs and traditions for preparing certain dishes, to intentionally using inherited family heirloom cookware (e.g., a favorite pot or knife), to the religious rules governing the preparation of halal or kosher foods in the kitchen (like discarding eggs with bloodspots or using separate sets of dishes and cookware for dairy and meat preparations, to the conventions "inscribed" and also varying in time and place in the phrasing and order of instructions in cookbooks. And as in the rituals of food acquisition, so in food cooking, one can ask: Is it males or females, parents or children, professionals or nonprofessionals, members of particular social classes or from specific racial and ethnic backgrounds who are assigned or who have voluntarily taken on the tasks of cooking? Indeed, the significant decrease of people who do their own cooking at home from scratch in contemporary Western industrialized societies is itself a remarkable shift in the ritual practices of cooking. Michael Pollan, in his book *Cooked* (2013), intended to stem this trend, nevertheless acknowledges the views of some that pretty soon home cooking will be as rare or obsolete as making one's own clothes. Given this trend, the rarer occasions for home cooking tend to be ritualized – for seasonal holidays, like Thanksgiving, Christmas, Passover, or for birthdays. That said, the occasions for opting not to cook (that is, paying others to cook) by going out to dinner or arranging caterers to celebrate a birthday, wedding, anniversary, retirement, school graduations, etc., may also be understood as seasonal, life cycle, or otherwise patterned and predictable rituals.

Rituals and the Psychology of Taste

Whatever social constructing, world-building functions the rituals of eating and preparing food have, especially in negotiating people's complex relationships in and with the real world, they are able to do so because of the tremendous psychological power rituals have on the human experience of eating. First, certain emotions can be specifically associated with eating (Rozin 1999), namely, disgust (Rozin et al. 1997), "the emotion of elevation," (Haidt 2003) and gratitude (Algoe and Haidt 2009). According to Algoe and Haidt (2009), elevation is the emotion

> elicited by acts of charity, gratitude, fidelity, generosity, or any other strong display of virtue. It leads to distinctive physical feelings; a feeling of 'dilation' or opening in the chest, combined with the feeling that one has been uplifted or 'elevated' in some way. It gives rise to a specific motivation or action tendency: emulation, the desire 'of doing charitable and grateful acts also.'

While disgust for social vice (elevation's "opposite") is obviously associated with food preferences, in that bitter tasting foods tend to trigger the same disgust reflex (Rozin et al.), the connection between the "other-praising" emotions of elevation and gratitude to eating is a bit more complicated. The link is oxytocin, the so-called love hormone, which plays a role both in modulating preferences and satiation for the taste of sweetness (Leng and Sabatier 2017) and is released when people experience the emotions of elevation and gratitude (Algoe & Haidt). Without going too deeply into the chemistry, suffice it to say that when oxytocin is released in diners' brains during a meal either because of eating tasty sweets or because of their admiration for their company's behavior and/or their ritualized expressions of gratitude, the ensuing emotion of elevation may make the meal (ful)filling even without eating as much food as the diners may have initially craved. In other words, good company and the emotions that go with it may be as satisfying as eating the food itself. The right words and gestures at the meal, that is, rituals of eating, already discussed above, can prompt this emotional effect. Moreover, in their study, Vohs et al. (2013, p. 1715) demonstrate that rituals per se, defined as "symbolic activity that often includes repeated and unusual behaviors occurring in fixed, episodic sequences," can make food actually taste better. Finally, rituals can have the psychological effect of *changing* one's taste preferences, in what Prescott (2012) calls "evaluative conditioning." Though people may be "hard-wired" to like or dislike particular flavors – most children prefer sweet to bitter foods, and some people for genetic reasons cannot abide the taste of cilantro – none of this is written in stone. Human taste preferences are nearly infinitely malleable, depending upon situation and habituation. A case in point is that while many children do not like the bitter tastes of coffee or beer, acquiring a taste for them is somewhat incentivized by their association with adulthood. Practiced as rituals of adulthood, such acquired tastes exemplify evaluative conditioning. And the reverse can happen. A traumatic experience associated with a food once liked can turn one off to it from then on. Most of the taste preferences for celebratory seasonal foods, family dishes, or the familiar cuisines of one's own culture discussed above were acquired through the evaluative conditioning of regular habitual ritual practices. Indeed, it is the psychological effect of rituals of eating to associate "powerful, pervasive, and long-lasting moods and motivations" (Geertz 1973 pp. 90, 94) to specific foods, situations, places, and people that give these rituals in the strong sense their world-making power.

Conclusion

The role of ritual in eating is to make it meaningful to people – affectively, cognitively, socially, culturally, and, yes, religiously. However, the meaningfulness of eating rituals is not "religious" in the sense that they necessarily require or imply adherence to specific faith traditions or belief systems. Rather, the rituals involved in the daily and necessary acts of human eating are "religious" in the role they play in coding and "scripting" sets of actions that serve particular social and psychological functions, in reenacting myths that make worlds come into being, whether those who practice them are aware of it or not. In particular, because food is so "fundamental, fun, frightening, and far-reaching" (Rozin 1999), the rituals associated with it are nothing less than a kind of implicit or explicit "cosmic etiquette." Rituals of eating form the fundamental *relationships* people have with the human and other than human persons with whom *we* cohabit in the real world. Are they food, foes, or friends? Fellow diner or dinner? Rituals of eating are a subset of *all* the *rituals of respecting relationships* between human and other than human persons in the world. In other words, how should we behave with them appropriately? The first step toward this respect is to abandon the omniscient third person objective pose, a linguistic ritual of hyperseparation that as scholars we are somehow outside or above this network of relationships in nature (Harvey 2013).

Emotions of Eating and Drinking

18

Herbert L. Meiselman

Contents

Abstract

The study of emotions has grown in the last 20 years from both the health orientation and the commercial product development orientation. The field continues to discuss the definition of emotion and the theory of emotions, both of which have implications on how to measure emotions, which is the main focus of this chapter. Emotion is usually defined as a rapid reaction to a stimulus, which could be a food or drink. Longer-term feelings are usually called moods. Existing emotion lists, in many languages, help the researcher to determine whether their method (questionnaire) contains real emotion words. Emotion questionnaires include some traditional ones from earlier days of emotion research to newer questionnaires often developed in the commercial product-development context. These questionnaires have produced a large number of research studies on food and drink products. One of the biggest challenges of emotion research is doing emotion research cross-culturally. This is especially true with questionnaires that use words; often the original research was done in English or another western

language and then transported to another western country or to an Asian or other country. It is sometimes not clear whether the original emotion concept exists in the other country, and what words express that feeling – sometimes the emotion term does not clearly exist, and sometimes more than one word is used to express that feeling.

Introduction

Eating and drinking are behaviors surrounded with emotions. We experience emotions before we drink or eat, we experience emotions while eating and drinking, and we experience emotions after eating and drinking. Further, since we eat and drink multiple times every day, food and drink are major sources of emotions in our daily lives. Studying the connection between food, drink and emotions is both relatively old and relatively new. For many years, emotions have been studied as the precursor to eating, especially overeating and overdrinking. This is the more clinical side of food-emotion research, with an emphasis on health. For example, the health-oriented journal *Appetite* has had 1,066 papers dealing with "emotion," mainly since 2005, with a general increase after 2010, and the journal *Eating Behaviors* has had 400 papers, mainly since 2007 (numbers accurate as of August 2019). More recently emotions have been studied as a measure of how people react to food and beverage products. This is the more commercial food-emotion research, with an emphasis on product development and testing. The journal *Food Quality and Preference* shows 391 papers dealing with "emotion" mostly since 2010; the journal *Food Research International* shows 95 papers dealing with "emotion" mainly since 2015 (numbers accurate as of August 2019). There have been major increases in interest in emotion for both types of food related emotions – health oriented and product development oriented. The first book on the topic of emotion measurement was the book by Meiselman (2016); most earlier books dealt with emotion theory.

When combined together the study of emotions leading to (over)eating and the study of food products leading to emotions represent a large field of research worldwide in both academia and commercially (Macht 2008; Meiselman 2016).

Defining Emotions

Before examining the research on eating, drinking and emotions, it is appropriate to define some terms. The broadest term in this field is affect or affective behaviors or feelings. These terms refer to all subjective events which are valenced, meaning they can be positive or negative (Desmet 2008 in Schifferstein and Hekkert, Product Experience). Affective states is the broadest category, and they include emotions, attitudes, traits, and moods (Ferdenzi et al. 2013). *Thus, affective states and emotions are not synonyms*; "All emotions are affective, but not all affective conditions are emotions" (Clore et al. 1987).

The definitions of emotion and mood to follow are meant to assist the reader with the remainder of this chapter; however, it is important to point out that arguments continue within the field about the exact meaning of affect, emotion and mood, and also how to measure them (Coppin and Sander 2016; Barrett 2016). Copin and Sander (2016) summarize the situation by noting that “The topic of emotion rarely leaves individuals unemotional”(Coppin and Sander 2016). These authors further note, “The difficulty of defining emotion, and delineating its boundaries to other affective phenomena (e.g., mood, preference, attitude, passion, affect) is not the only challenge. . ..The issue of defining emotion is still a contemporary one (Russell 2012), and strongly impacts current models of emotion (Sander 2013).” Feldman Barrett (2016) summarizes the state of emotions the same way, “a perplexing situation: there are a *multitude* of emotion theories that vary a great deal from one another in almost every way imaginable; they disagree on the details of how an emotion should be defined,. . .” (Feldman Barrett 2016).

An emotion is an affective response to a stimulus (person, statement, thing, etc.). Usually the person can identify the stimulus that produced the emotion. They are of short duration, usually measured in seconds or minutes. Emotions have multiple components including a cognitive, a behavioral, and physiological components.

Mood is also an affective behavior, but one cannot identify a specific stimulus that led to the mood. Emotions develop quickly and last a short time; moods develop more slowly and can last a (very) long time. Moods can be described as more diffuse, less intense (Desmet 2008).

Why is it important to define emotions and to differentiate them from other affective states? Because if one wants to conduct research on emotions or to measure emotions, one needs to know where to draw the line on what to include, and what to exclude. The literature on emotions is filled with examples of supposed emotions that do not fit these definitions, and which are not found on emotion lists (see the section “Emotion Lists”). Part of the problem in getting general agreement on emotion definitions and emotion theory is the very wide practices of including/excluding emotions. This is especially true because emotion measurement takes place in a number of very different fields, including Clinical Psychology, Consumer Research and Marketing, Advertising, Hospitality, etc.

Emotion Lists

Emotion lists are very helpful in conducting research on emotions, and were reviewed by Jiang et al. (2014) and Grühn and Sharifian (2016). Emotion lists provide guidelines on what to include in emotion research and what to exclude or to at least question. Just as there are many views of emotion, there are many lists of emotions, so the recommended approach is to not depend on one list of emotions but to use several or many lists of emotions. The lists of emotions include word lists, picture/image files, face files, and motion picture files (Table 1). Grühn and Sharifian (2016) discuss each method in terms of the following criteria: ecological validity, temporal resolution (processing time), controllability (for the stimuli), complexity

Table 1 Sample lists of emotional stimuli by type of stimulus

Authors	List	Type and number	Ratings
Words			
Bradley and Lang (1999)	ANEW		Dimensional on 9-point SAMs • Valence, arousal, dominance
Whissel (2009)	DoA	8742 English words	Dimensional on 3-point bipolar scales • Pleasantness, activation, and imagery
Warriner et al. (2013)		13,915 English lemmas	Dimensional on 9-point bipolar scales • Valence, arousal, and dominance
Grühn (2016)	EMOTE-A	985 English adjectives	Dimensional on 7-point bipolar scales • Valence, arousal, emotionality, concreteness, imagery, familiarity, clarity of meaning, control, desirability, and likeableness
Grühn (2016)	EMOTE-N	1287 English nouns	Dimensional on 7-point bipolar scales • Valence, arousal, emotionality, concreteness, imagery, familiarity, and clarity of meaning Objective word characteristic: • Memorability
Images			
Lang et al. (2005)	IAPS	956 images	Dimensional on 9-point SAMs • Valence, arousal, dominance
Marchewska et al. (2013)	NAPS	1356 images	Dimensional on 9-point bipolar scales • Valence, arousal, and dominance
Grühn et al. (2015)	AID	7,232 images	Dimensional on 7-point SAMs • Valence and arousal
Faces			
Ekman and Friesen (1976)	POFA	110 images	Discrete facial expressions • Happiness, sadness, surprise, fear, disgust, anger
Minear and Park (2004)	PAL faces	1,142 images by 576 persons	Dimensional
Ebner et al. (2010)	FACES	2,052 images by 171 persons	• Discrete – Neutral, anger, disgust, happiness, fear, and sadness
Film clips			
Philippot (1993)		12 film clips	Discrete – 6 emotions • Amusement, anger, disgust, fear, neutral, and sadness
Gross and Levenson (1995)		16 film clips	Discrete – 16 emotion terms
Schaefer et al. (2010)		70 film clips	Dimensional • Arousal on 7-point bipolar scale • Positive and negative affect on subscales Discrete – 7 emotions

(continued)

Table 1 (continued)

Authors	List	Type and number	Ratings
			• Anger, fear, disgust, sadness, amusement, tenderness, neutral
Sharifian and Grühn (2015)	SEEMS	21 film clips	Dimensional on 7-point SAMs • Valence and arousal Discrete – 20 emotion terms

(of the stimuli), and emotional intensity. Word lists are lower for ecological validity, complexity and intensity, but higher for temporal resolution and controllability, whereas film clips show the reverse scores (higher for ecological validity, and emotional intensity, etc.)

When developing an emotion questionnaire including an emotion list, it is important to keep in mind that there are more negative emotion words than positive emotion words, but positive emotion words are more frequent in speech. Positive words tend to be shorter, while highly arousing words tend to be longer and less frequent.

Grühn and Sharifian (2016) point out that high frequency words are better remembered in recall tasks, but low frequency words are better recognized in recognition tasks.

Two helpful traditional lists of emotion words are the lists of Clore et al. (1987) and the list of Laros and Steenkamp (2005) who list 313 emotions drawn from the literature (173 negative, 140 positive). They provide a code to attach each emotion to those who have included it in their previous lists; thus, is a good summary list of work done before 2005. Ortony et al. (1987), Clore et al. (1987) developed their emotion lexicon starting with 585 “emotion” words, which was then reduced to 234 based on their criteria for defining emotions.

Laros and Steenkamp (Table 2):

Gmuer et al. (2015) argued that previous emotion lists were not based on linguistic analysis (Table 3).

Finally, as we observe more automated emotion research, using social media and other sources of words, we should mention the LIWC word list. The Linguistic Inquiry and Word Count (LIWC) (2001) used in on line research, contains 615 emotional/affective terms including 251 positive and 345 negative. The newer, revised LIWC (2015) contains 1393 affective words with 620 positive and 744 negative.

The reader should note that all of these lists contain more negative words than positive words, although positive words used with food might be more frequent. In fact, Gmuer et al. (2015) note that their Swiss convenience sample categorized 49 affective food terms as positive ($n = 34$) much more than negative (n-12 or neutral ($n = 3$), even though there were more negative affective terms in their overall list of 272 food-related terms.

Another approach to developing emotion lists is to get information from consumers, especially when one is interested in emotions relative to a specific product category (e.g., pasta or chicken). One can ask how consumers feel before they decide

Table 2 Emotion words

Negative emotion words	Positive emotion words

to have the food or after they eat the food. If one uses this approach you must use a large representative sample of consumers., not a small convenience sample. One could then check the terms developed against the lists above – if the words appear in the lists above, they are probably emotions; Of the words cannot be found on any lists of emotion, they are probably not emotions. Developing a new food questionnaire is a labor-intensive process. Which is why many researchers use an already published questionnaire, even when that might not be a perfect fit.

Methods for Measuring Emotions

Emotions can be measured in several ways. Lucas et al. (2009) list the methods and their strengths and weaknesses. *Self-reports of emotion* are captured by questionnaire or interview, and these methods might suffer from a number of biases including social desirability and extreme responding. Also respondents might be unwilling or unable to report their feelings, especially in certain cultures (add a ref. on cultures?). Instead of self-reports one can use *observer reports of emotion* which correlate moderately with self-reports. *Facial measurement* has been suggested as a measure of emotion for some time, including the Facial Action Coding System (FACS)(see below). The method is based on measurement of muscle activity, but when it is done by observers it might be subject to both personal and cultural bias. In addition, substantial training is required for data collection and the actual measurement is time consuming. In addition to facial measurement by trained observers, several automated methods are available, such as from Noldus (see below). There is some evidence that facial measurement distinguishes different positive affective states, but has trouble differentiating positive emotions. *Physiological measures*, especially those from the autonomic nervous system, are also used to measure emotions (see below). Once again, these measures tend to differentiate negative emotions but not positive ones. Finally, there are a number of *behavioral measures or emotion-sensitive tasks*, such as mood boards (see below). Interestingly, no one method has emerged as the preferred method; many studies of food use self-report questionnaire methods, but some use facial and physiological methods, and behavioral methods. This partly depends on the theoretical and practical orientation of the researchers, but also involves practical testing considerations like training time, testing time, budget, how fast one needs the results, the cooperation of the test subjects, and many other factors.

Self-Reports of Emotions

Emotion questionnaires are probably the most commonly used method for measuring emotions, because of practical considerations. They require little preparation, can be done almost anywhere (both on site and remotely), require no professional administration, and can be done inexpensively with small or very large numbers of respondents. In commercial work, they fit in easily to consumer testing, where the

consumer is usually being asked questions anyway. They have a major potential problem with various response biases so the administration of questionnaires needs to avoid these as much as possible with carefully worded instructions and comments during testing (see Jaeger and Cardello 2016). Obviously testing branded products within a company might lead to biased responses.

Emotion questionnaires have been designed for clinical applications aimed at the health perspective, and emotion questionnaires for food product applications aimed at the commercial perspective. The former questionnaires are often given before consuming food, based on the view that negative emotions lead to overeating in certain individuals (restrained eaters) (Macht 2008; Macht and Simons 2000). Since this type of research had been going on for some time, these questionnaires tend to include some of the traditional affect questionnaires. Examples of these questionnaires include the Positive and Negative Affect Schedule (PANAS) (Watson et al. 1988) and the Consumption Emotion Set (CES)(Richins 1997), Profile of Mood States (POMS) and Multiple Affect Adjective Checklist (MAACL).

The PANAS (Fig. 1) is one of the shortest and most frequently used of these emotion questionnaires; it also balances positive and negative emotions with 10 of each. However it has received criticism for its choice of words (e.g., see Diener et al. 2009). Nevertheless, it has been shown to be valid (i.e., representing two dimensions of affect) and reliable with no major differences among demographic subgroups (Crawford and Henry 2004). The PANAS is available in the 20-item original format or the enlarged 60 item PANAS-X (Watson and Clark 1994). The PANAS has been translated into many languages (see the Watson website?). Other traditional emotion questionnaires are the Profile of Mood States with 65 terms (POMS, McNair et al. 1971) and the Mood Affective Adjective Check List (MAACL) with 70 or 132 terms published by Zuckerman and Lubin in 1965 and the revised MAACL-R (Zuckerman and Lubin 1985). The POMS and MAACL have been used more in clinical research than food product research.

The Consumption Emotion Set (CES)(Richins 1997) provides a longer questionnaire; people can use the whole 47 item questionnaire or can select the terms they want to use for a specific food category or product. There are examples of the CES used in food and drink research; for example Edwards et al. (2013) showed a reduction in emotions from before a meal to after a meal in a student cafeteria environment.

Questionnaires concerning food products are usually given during eating or shortly after eating, in order to test how the product makes you feel. Traditionally, the impact of foods and beverages was tested with hedonic questions (how much do you like this product?); emotion measurement has been used along with liking, beginning in the period 2000–2010, based on the repeated finding that liking alone does not predict commercial success very well (Jiang et al. 2014). In fact, three different methods were described to consumer researchers at the 2008 Eurosense conference, whereas no commercial emotion methods had been presented at meetings before this (see EsSense Profile, GEOS, and Conceptual Profiling method below). Since the first arrival of emotion questionnaires for product testing, there have been a number of new methods proposed. The following is a list of the methods currently being used to study foods and beverages:

1. EsSense Profile®: The EsSense Profile® was introduced at Eurosense in 2008, and the resulting paper published by King and Meiselman (2010), who include examples of distinguishing emotions for different food categories, and for different food flavors of the same food category, which suggests that emotions can be

Worksheet 3.1 The Positive and Negative Affect Schedule (PANAS; Watson et al., 1988)

PANAS Questionnaire

This scale consists of a number of words that describe different feelings and emotions. Read each item and then list the number from the scale below next to each word. **Indicate to what extent you feel this way right now, that is, at the present moment *OR* indicate the extent you have felt this way over the past week (circle the instructions you followed when taking this measure)**

1	2	3	4	5
Very Slightly or Not at All	A Little	Moderately	Quite a Bit	Extremely

___________ 1. Interested	___________ 11. Irritable
___________ 2. Distressed	___________ 12. Alert
___________ 3. Excited	___________ 13. Ashamed
___________ 4. Upset	___________ 14. Inspired
___________ 5. Strong	___________ 15. Nervous
___________ 6. Guilty	___________ 16. Determined
___________ 7. Scared	___________ 17. Attentive
___________ 8. Hostile	___________ 18. Jittery
___________ 9. Enthusiastic	___________ 19. Active
___________ 10. Proud	___________ 20. Afraid

Fig. 1 (continued)

tied to product ingredients. Further research on the method was published by King, Meiselman and Carr in 2013 and King in 2016. The EsSense Profile® was designed at McCormick Co. Inc. (an international spice company) for general use with foods, with the advice to modify EsSense for application to specific food categories or food products. EsSense contains mainly positive emotion terms (39 terms, 4 negative) in line with the hedonic asymmetry (greater use of positive emotions vs negative emotions) reported by Desmet and Schifferstein (2008). The emotion terms are scaled on a 5-point scale. The issue of using more positive or negative terms is discussed below. A reduced form of the EsSense (EsSense25)

Scoring Instructions:
Positive Affect Score: Add the scores on items 1, 3, 5, 9, 10, 12, 14, 16, 17, and 19. Scores can range from 10 – 50, with higher scores representing higher levels of positive affect. Mean Scores: Momentary = 29.7 (*SD* = 7.9); Weekly = 33.3 (*SD = 7.2)*

Negative Affect Score: Add the scores on items 2, 4, 6, 7, 8, 11, 13, 15, 18, and 20. Scores can range from 10 – 50, with lower scores representing lower levels of negative affect. Mean Score: Momentary = 14.8 (*SD* = 5.4); Weekly = 17.4 (*SD* = 6.2)

Fig. 1 The Positive and Negative Affect Schedule (PANAS)

has been published (Nestrud et al. 2016 – see Fig. 2). The EsSense Profile® has probably been the most widely used emotion food questionnaire, but it has received criticism on several issues including the issue that emotions should be studied on specific food categories rather than with a general scale.

2. GEOS/ScentMove/UniGEOS: The GEOS and ultimately the more global UniGEOS were designed at Firmenich Company for use with odorous products including both perfumes and foods. The emphasis in development and testing was not on food products. GEOS (36 emotion terms) was presented at the same 2008 Eurosense meeting and published in 2009 (Chrea et al. 2009); ScentMove TM (18 emotions terms) in 2010 and UniGEOS (25 emotion terms) was published in 2013. These scales were reviewed by Porcherot et al. (2016) (Table 4).
3. Conceptual Profiling: Thomson and colleagues (from MMR) proposed the method of conceptual profiling for measuring emotions, emphasizing that questionnaires assume that the emotion experience is conscious and can be reported. Thus, Thomson proposed a way of determining emotions by looking for conceptual associations during the exposure to a food product. Thomson presented his approach at the same 2008 Eurosense meeting, and published his method in 2010 (Thomson 2010; Thomson et al. 2010). MMR's method of conceptual profiling (Thomson 2016) involves two main steps: first, the development of a specific lexicon (list of affective terms) for a product category, and then scaling of those terms using best-worst scaling. Best worst scaling takes more time that direct scaling, and that has been one criticism of the method. Developing a separate lexicon for each application for the method would also take time. Thomson has also provided a more general lexicon based on four European languages

EsSense profile	EsSense25	EsSense profile	EsSense25
Active	Active	Loving	Loving
Adventurous	Adventurous	Merry	
Affectionate		Mild	Mild
Aggressive	Aggressive	Nostalgic	Nostalgic
Bored	Bored	Peaceful	
Calm	Calm	Pleasant	Pleasant
Daring		Pleased	
Disgusted	Disgusted	Polite

Guilty	Guilty	Whole	
Happy	Happy	Wild	Wild
Interested	Interested	Worried	Worried
Joyful	Joyful		

Fig. 2 The EsSense Profile® (with 39 items) and the EsSense25 (with 25 items)

(Thomson and Crocker 2013). Ng et al. (2013) use conceptual profiling to demonstrate that intrinsic product characteristics are more related to emotions (and to liking), while extrinsic product characteristics such as packaging are more related to functional attributes.

4. Spinelli et al. (2014) developed a different questionnaire method, called EmoSemio, for measuring emotions emphasizing choosing words for a specific product category, and using full sentences rather than single emotion words. The EmoSemio list contained 23 items – lists for other product categories might have more or less. Spinelli et al. also emphasized that their questionnaire was developed in Italian for Italians and thus worked better than translating from another language which might use different words or use the same words differently. Sentences in EmoSemio can be simple (instead of the word "happy," EmoSemio says "It makes me happy."), or more complex (instead of the word "relaxed," EmoSemio says "It relaxes me, and makes me carefree."). The use of simple words ("happy") might be more clear or less clear; the complex sentences (like "It relaxes me, and makes me carefree.") might introduce different affective terms (are relaxed and carefree the same?). EmoSemio has contributed to the emotion questionnaire discussion by raising the issue of language and translation, and by proposing the use of phrases or sentences rather than words,

Table 4 Proposed universal Emotion and Odor Scale (UniGEOS) with nine affective categories and 25 affective terms in four languages. N is the number of geographic areas (out of the seven studied) in which the term appears

English	French	Chinese	Portuguese
1. Unpleasant feelings			
Disgusted ($N = 7$)	Dégoûté	厌恶的	Enojado
Irritated ($N = 6$)	Irrité	恼怒的	Irritado
Unpleasantly surprised ($N = 6$)	Désagréablement surpris	不愉快的意外惊喜	Desagradavelmente surpreso
2. Happiness/delight			
Happy ($N = 6$)	Heureux	幸福的	Feliz
Pleasantly surprised ($N = 5$)	Agréablement surpris	惊喜的	Agradavelmente surpreso
Well-being ($N = 3$)	Bien-être	安宁	Bem-estar
3. Sensuality/desire			
Desire ($N = 7$)	Désir	渴望	Desejo
Romantic ($N = 7$)	Romantique	浪漫的	Romântico
Sensual ($N = 6$)	Sensuel	肉欲的	Sensual
4. Energy			
Refreshed ($N = 7$)	Rafraîchi	恢复精神的	Refrescado
Energetic ($N = 6$)	Énergique	精力充沛的	Energético
Revitalized ($N = 5$)	Revitalisé	恢复生机的	Revitalizado
5. Soothing/peacefulness			
Relaxed ($N = 7$)	Relaxé	得到安宁的	Relaxado
Comforted ($N = 5$)	Réconforté	宽慰的	Confortado
Soothed ($N = 4$)	Apaisé	受安慰的	Sossegado
6. Hunger/thirst			
Mouth-watering ($N = 5$)	Salivant	令人垂涎欲滴的	Com água na boca
Thirsty ($N = 3$)	Assoiffé	口渴的	Sedento
Famished ($N = 2$)	Affamé	极饥饿的	Faminto
7. Interest			
Amusement ($N = 3$)	Amusement	娱乐	Diversão
Interesting ($N = 2$)	Captivant	有趣的	Interessante
Impressed ($N = 1$)	Impressionné	印象深刻的	Impressionado
8. Nostalgia			
Sad ($N = 3$)	Triste	伤心的	Triste
Melancholic ($N = 1$)	Mélancolique	忧郁的	Melancólico
Nostalgic ($N = 3$)	Nostalgique	怀旧的	Nostálgico
9. Spirituality			
Spiritual feeling ($N = 1$)	Sentiment spirituel	精神感觉	Sentimento espiritual

5. Since many product researchers also collect sensory and hedonic data in addition to emotion data, Schouteten et al. (2015) developed the EmoSensory®Wheel (also see Schouteten et al. 2017). The method uses product specific terms and a rate all that apply scaling approach. The Wheel is presented with a separate

9-point hedonic scale; the EsSense Profile TM is usually presented with a hedonic scale as well.

One of the key questions in emotion questionnaires is whether the emotion terms should be mainly positive, or equally positive and negative. Do negative emotions lead the respondent to use more negative emotions? Do more positive emotions do the same thing? Hwang and Matsumoto (2016) report many more negative facial expressions to products than with questionnaires.

Clinical research on eating disorders has tended to focus on negative emotions (Macht 2008; Leehr et al. 2015; Sultson et al. 2017). For example, in the recent development of the Positive-Negative Emotional Eating Scale, Sultson et al. used 7 positive emotion items and 12 negative emotion items. Evers et al. (2018) report from their meta-analysis of the literature that only restrained eaters exhibit increased eating following negative emotions (Evers et al. also present other recent meta-analyses of these data.). In their meta-analysis, Evers include 52 studies where negative emotions were induced drawn from 49 papers, and 13 studies where positive emotions were induced drawn from 12 papers – one can see that negative emotions dominate this clinical literature on emotions and eating. The authors conclude: “Compared to negative emotions, however, positive emotions have hardly been investigated in relation to its impact on eating behavior” (p. 204). Positive emotions are reported to produce a small increase in eating.

Another question in emotion questionnaires is whether the emotion terms are general or product category specific or product specific. There appears to be a place for both more general and more specific approaches; the more general approaches will probably have less discrimination between similar products but will be useful across a broad range of products, reducing research cost and time. The more specific approaches will probably produce sharper product differences, but will take more time and hence greater cost. Commercially, larger international companies often invest in their own methods, while smaller companies often use existing methods.

Yet another issue in questionnaires is their cross- cultural application and validity. This subject has received attention for some time, but the awareness of the challenges of applying emotions from one culture into another culture is increasing (Chentsova-Dutton and Lyons 2016). The typical problem is that emotion research is often conducted in the West, most often in the English language. Then researchers try to export that language to another country using a simple translation of the emotion terms. This has proved to be inadequate. Two questions have been raised: do the emotions from the first (English speaking) country exist in the target country? And if the emotions exist, are the same words appropriate for that feeling? Ogarkova (2016) has written about the problems of translation of emotion words. In addition, van Zyl (2016) provides evidence that culture does not mean the same as language. Comparing European and American Spanish speaking countries and Portuguese speaking countries, van Zyl and Meiselman observed greater similarity in use of emotion words between European countries than countries speaking the same language in Europe and America. In other words, Brazil was more similar to Mexico than to Portugal, and Spain was more similar to Portugal than to Mexico. The best advice seems to be that conducting emotion research cross culturally requires the use of a multilanguage team of language experts and emotion experts. Simple translation is usually not adequate.

An alternative to questionnaires to assess emotions is sentiment analysis (Mohammad 2016) which is aimed at any text including social media messages. Thus, this avoids many of the possible biases of emotion questionnaires, but it can only be applied to food names, not to actual food products. One can search for a product name (chocolate chip cookie) or a category (chocolate) or a brand and examine the valence of the affective words used. This has the disadvantage of not including a list of different emotions. It will be interesting to see how sentiment analysis develops in the years ahead, as an alternative to questionnaires for the study of food names. People might raise ethical questions about conducting research without consent.

Finally, those using a substitute stimulus for an actual product, for example a product name, must keep in mind that people often respond differently to a name and to an actual product (Cardello et al. 2012). This is probably based in the tendency to optimize the product when using a name; that is, consumers think of a good example of the name, not an average or even poor version.

Body Measures of Emotions

Body measures of emotion include the following: skeletal muscle movements, especially facial, vocalizations, postures, physiological responses mainly autonomic. Body measures of emotion are often called intrinsic measures, while self-reports are called extrinsic measures, and researchers sometimes express concerns with one or the other type of measure (e.g., see Koster and Mojet 2015).

For some time there has been a serious search for alternatives to self-reports of emotion, and many of these alternatives to self-reports have been body measures (Jiang et al. 2014). The attraction is obvious: self-reports are plagued with real biases, or the fear of biases. Body measures appear to be the bias-free alternatives; objective measures of emotion. But what if self-reports and body measures do not agree – which is valid?

While emotions displayed on the face have received a lot of the attention in body responses of emotions, Aviezer et al. (2012) demonstrated that body posture communicates emotion valence better than the face. There should be more work on body posture as a signal for emotion.

The evidence supporting vocalizations as a measure of emotion is weak at best; simple models linking speech frequency or intensity have not shown much promise, although research has examined more complex speech variables (Yang and Lugger 2010) as well as speech patterns of individuals. Yang and Lugger emphasize the implicit aspects of speech in trying to connect speech and emotions, rather than the linguistic content of the explicit aspects.

Facial Measurement: Both facial measurement and autonomic physiological activity have been used to measure emotions. Facial measurement has been used as a measure of emotion for some time (Hwang and Matsumoto 2016); facial measurement is achieved through observer judgments or through equipment which senses the facial muscles. Observer trained facial measurement is time-consuming and requires highly trained observers, which also takes time (can be 6 months of training).

Direct measurement of facial muscle activity can use the Facial Action Coding System (FACS) which measures 44 facial muscles. A faster version more specifically aimed at emotions is EMFACS. Hwang and Matsumoto emphasize that measuring facial muscle activity is not theory based, and can be used to measure facial muscle movement in any situation (conversation, eating, etc). They claim that seven emotions can be clearly recognized from facial muscles: anger, contempt, disgust, fear, happiness, sadness and surprise. Note that only one of these is positive, happiness. Hwang and Matsumoto argue that the relatively small number of emotions that can be coded is actually larger if one views these emotions as categories of emotion rather than specific emotions. For example, anger might include mad, enraged, annoyed and so on. However, some would argue that there are subtle differences among these words that might be of interest in some measurement situations. Hwang and Matsumoto (2016) present data from studies of personal and homecare products (not food) and found incongruence between self-reports and facial measures which often showed negative emotions. This leads one to question whether self-reports and facial measures are measuring the same thing – do they both measure emotion? Self-reports are direct reports of an experience; facial measures are observer reports of muscle movement, without reference to the experience.

Freitas-Magalhaes (2012) presents an interesting historical review of facial measurement, and lists the many methods which are available in addition to FACS:

Freitas-Magalhaes concludes that facial measurement of emotion faces two challenges: whether facial-emotion links are universal and whether they are culturally dependent. These arguments have been going on a long time (e.g., see Russell 1994) and a quick resolution is not likely.

One of the popular commercial systems for measuring facial muscles is FaceReader™. FaceReader™ automatically measures the following emotions: happy, sad, scared, disgusted, surprised, angry, neutral, contempt. Again notice that happy is the only positive emotion. FaceReader™ has been used in studies of foods. Danner et al. (2014) used a variety of measures of emotion in response to different juices. For FaceReader™, they observed that negative facial expression was stronger for disliked juices, but positive facial expression was not stronger for liked juices. This confirms other research that facial expression is a better measure for negative emotions than positive emotions, and for disliked products rather than liked products. De Wijk et al. (2012) used FaceReader ™ with children and young adults, and found that facial expressions only occurred to disliked foods., and they occurred very quickly, and might be easily missed. Wei He, working in deWijk's laboratory (He et al. 2014) studied pleasant and unpleasant food odors, and measured facial expressions and ANS responses. Unpleasant fish odor produced fewer neutral facial expressions and more disgusted and angry expressions. Interestingly the response time for the emotion "happy" was much longer than for the negative facial expressions. The results of these studies are a challenge in food research where most food products are liked by most people (hedonic asymmetry), thus limiting the applicability of facial measurement. Another practical implicit problem with facial measurement is the challenge of using it while eating and drinking when a fork or drinking glass might be in the way.

Autonomic Nervous System Measures

There is an obvious appeal to measuring emotions without asking leading questions, and without the person's knowledge of what you are trying to ascertain. Monitoring autonomic responses like heart rate holds the promise of measuring emotions without these complications. And researchers in affective behavior and physiology have been measuring autonomic responses for some time.

Kreibig (2010) provided a summary of 134 papers on autonomic recording for emotion research, noting that 34 were cardiovascular measures, 22 were respiratory measures, and 6 were electrodermal measures. This tells us what types of autonomic measures are being used in such research. Kreibig's review shows that increasing emotion does not always lead to increasing autonomic indicator – for example, contentment and happiness, both positive emotions, do not have the same physiological response. Further there are often different results among the studies. Kreibig notes that both liked stimuli and disliked stimuli might increase hear rate, as well as a number of other emotions (surprise, disgust etc).

De Wijk et al. (2012) found significant differences in finger temperature and in skin conductance for liked and disliked foods, but did not find significant differences for heart rate, the most commonly used autonomic measure. De Wijk et al. did not ask for emotional responses. Danner et al. (2014) also found differentiation of liked and disliked products with skin conductance and pulse amplitude, but not heart rate. In the study by He et al. (2014) on facial expressions and ANS responses to pleasant and unpleasant food odors, unpleasant fish odor produced higher heart rates and skin conductance responses, and lower skin temperature. Heart rate differentiated between odors after 400 ms, much faster than skin conductance and skin temperature (Table 5).

Summary

Emotion measurement has been applied to eating and drinking for some time, first from a clinical perspective and more recently from a commercial, product development perspective. This work has grappled with several problems in the emotion measurement area: the definition of emotions, the relative importance of positive and negative emotions, the use of self-report or bodily measures, and the cross-cultural differences which might exist. The field is now seeing a great deal of research and application, and there will probably be some progress on these issues over the next decade.

Table 5. Associations between ANK patterns and specific emotions based on Kreibig (2010) (From de Wijk et al. 2012)

	Anger	Anxiety	Disgust contamination	Disgust mutilation	Embarrassment	Fear	Fear imminent throat	Sadness crying	Sadness non – crying	Sadness Anticipatory	Sadness acute	Affection	Amusement	Contentment	Happiness	Joy	Anticipated pleasure visual	Anticipated pleasure imagery	Pride	Relieve	Surprise	Suspense
Heartrate	↑	↑	↑–	↓	↑	↑	↓	↑	↓	↑	↓	↓	↓ ↑	↓	↑	↑	↓	↑	↓ ↑	↑ –	↑	(↓)
Fingertemp	↓	↓	↓ ↑	↓ ↑		↓		↓	↓	↓ ↑	↓		C		↑		(↑)				↓ ↑	
SCR	↑	↑	↑	↑		↑	↑				↓		↑	–			↑			↓

The Developmental Perspective

Infant Appetite: From Cries to Cues and Responsive Feeding

19

Marion M. Hetherington

Contents

Abstract

Infants are adept at communicating hunger, appetite, and satiation. While one cannot really "know" what infants are attempting to communicate, it can be assumed that crying after some hours of food deprivation relates to hunger, that decreased interest in feeding relates to satiation, and that aversive facial expressions in response to a new food reflect dislike. So at the very least, it can be said that infants express fundamental needs as well as their likes and dislikes of specific foods. For infant communication to be effective, caregivers should be able to understand infant cues, and for this to happen reliably, communication cues should be easily discernible, replicable, and responsive to changes in need state (Hetherington, Physiol Behav 176:117–124, 2017). For example, appetite signals should decline as the meal progresses, and expressions of liking and wanting should depend, in part, on the foods offered. For responsive feeding to take place then, caregivers must be able to recognize and respond to infant appetite cues and so provide appropriate nourishment

and care to their infants. In this chapter progression from milk to solid food feeding and the infant's ability to self-regulate energy intake will be considered. The facial expressions and overt behaviors infants use to communicate with caregivers about their interest and willingness to eat will be characterized. Finally, sensitivity to the ways in which infants communicate hunger, appetite, and satiation will be discussed.

Costly and Cute: The Helpless Newborn Human

Human newborns are uniquely helpless after birth, compared to other primates. They are entirely dependent on caregivers and require an inordinate amount of attention. The human neonate has been described as "costly and cute" (Trevathen and Rosenberg 2016); the costs refer to the dedicated labor and financial burden involved in raising a child. Fortunately costs are balanced by the attractiveness of the newborn and their capacity to captivate the attention of carers. The early dependency of babies favors processes of learning and socialization and reinforces the central importance of parenting in supporting healthy development.

The newborn is proficient at signalling hunger to their mothers via the hunger cry (Gilbert and Robb 1996; Zeskind et al. 1985). The hunger cry is the culmination of a series of behaviors from agitation, mouthing, and discomfort to a distress call. Research on infant cries indicates that adults listening to cries are able to distinguish the hunger cry from the pain cry through perceived and physical acoustic differences (Zeskind et al. 1985). Over the first year of life, the hunger cry changes in acoustic characteristics with an increase in fundamental frequency which signals the transition from reflexive to intentional crying (Gilbert and Robb 1996). As motor skills develop, infants become more adept at communicating hunger, appetite, and satiation in diverse ways. To be effective, however, communication between the infant and the caregiver is dependent upon the sensitivity of the receiver to recognize, interpret, and respond to these signals (Hetherington 2017). The World Health Organization defines responsive parenting as "prompt, contingent and appropriate interaction with the child," and responsiveness is associated with better health outcomes and psychosocial and cognitive development (WHO 2006). Therefore, how infants communicate their energy needs and the ways in which parents respond to them are key to healthy growth and well-being.

Before Mother's Milk

Babies are born as "univores" securing all their nutrient and energy needs from a single source, namely, milk. At around 6 m of age, infants are introduced to solid foods as energy, and nutrient requirements can no longer be met by exclusive breastfeeding (WHO https://www.who.int/maternal_child_adolescent/documents/9241593431/en/). The solid foods "complement" nutrition and energy provided by milk, thus the term "complementary feeding" rather than weaning, since infants can be fed breast milk long after 6 m. The transition from univore to omnivore has been described as the omnivore's dilemma (Rozin 1976). The dilemma arises from the potential hazards faced by the human infant when accepting novel foods. It is at once necessary, but potentially challenging. Given that milk is sweet to taste, it is said that infants are "hard-wired" to prefer sweet substances as an adaptive mechanism to secure a safe source of energy. To accept foods with different basic tastes, the infant must experience novel odors, tastes, and textures. This transition is enabled by both innate preferences and the capacity to learn, through mere exposure and learned safety which foods are acceptable.

Interestingly, and long before this transition, babies experience flavor in utero. Studies with animal and human participants demonstrate the role of fetal learning in odor and taste preference acquisition. Fetal learning occurs when flavors derived from the maternal diet are experienced via amniotic fluid. For example, Hepper (1988) demonstrated fetal learning in an animal model by feeding pregnant rats garlic or no garlic during pregnancy and then presenting garlic or onion in petri dishes to their 12-day-old pups. As a measure of preference, the time spent by the pups over each stimulus was recorded as well as the total amount of time spent on each side of the cage containing the stimulus. Pups born to dams fed garlic preferred garlic over onion and offspring of the control group showed no preference for either stimulus. This finding was replicated in cross-fostered pups. Therefore, odor learning occurs in utero suggesting a biologically adaptive behavior which favors positive associations with components of the maternal diet, perhaps to enhance kin recognition (Hepper 1996) and possibly to guide the developing pup to a safe, familiar food source.

In the human equivalent of these studies, head and mouth movements are used to indicate preference for odors in babies. For example, Soussignan et al. (1997) investigated the response of 3-day-old babies to artificial (vanillin, butyric acid, formula milks) and biological (breast milk, amniotic fluid) odors using recordings of behavioral (facial and oral movements) and autonomic (respiration, differential skin temperature) events. In these studies nose wrinkling and the "grimace" facial expression were interpreted as disgust for an aversive odor (butyric acid) relative to a positive odor (vanillin). These responses may reflect biological utility in guiding babies away from odors that may indicate that a food is rancid (butyric acid) and potentially harmful (Soussignan et al. 1997).

Marlier and Schaal (2005) video-recorded babies' responses to breast milk or formula using mouthing and head orientation in a choice paradigm. Human milk produced more frequent mouthing and greater head orientation than formula even in babies who had been formula fed. Evidently, the attractiveness of human milk containing many different aromatic compounds familiar to infants via in utero experience was preferred over formula which tends to be bland and of uniform flavor.

Overall, these studies indicate that during the early postnatal period, young animals, including humans, can express preference toward familiar odors (experienced in utero). The ways in which likes and dislikes are communicated in early life are through a series of behaviors including oral activation like mouthing, orientation or place preference, and facial expressions.

A Shared Love of Sweetness and Dislike of Bitterness

Facial expressions in response to different basic tastes have been well characterized in newborn babies in the elegant studies conducted by Steiner (1977). In these studies, likes and dislikes to pure tastants were recorded following delivery of the substance via pipette to newborns. The subsequent, specific facial response to water, sweet, sour, and bitter tastes were assessed to determine affective quality of the tastes. Steiner observed distinctive tongue protrusions and "smile" responses to sweet, lip pursing to sour, and the characteristic "gape" to bitter tastes. These facial responses have been observed in nonhuman primates, and a collaboration between Kent Berridge and Jacob Steiner resulted in mapping "sensory typical" and affective responses to basic tastes across different mammalian species (Steiner et al. 2001). These authors proposed that human hedonic and aversive reactions are directly related to the taste reactivity patterns of other animals. For example, in both the rat and primate, there is a shared tongue protrusion in response to sucrose in solution (representing the sweet taste) and shared "gape" in response to quinine in solution (representing the bitter taste). These responses are thought to be functional, in that the tongue protrusion extends exposure time and coverage over the tongue of the sweet solution which is liked and the gape allows ejection of the disliked, bitter-tasting fluid from the mouth. Sweetness generally signals a safe source of energy, and bitterness signals potential toxicity, and so neonatal affective responses are adaptive.

In addition to facial expressions in response to foods which signal likes and dislikes, human infants also have a diverse repertoire of more obvious and overt acceptance and rejection behaviors which occur in advance of the substance being tasted. For example, an obvious set of "approach/acceptance" behaviors indicating appetite and "wanting" is the extent to which the infant gazes at the food in anticipation of eating, leans forward to accept food when offered, and then opens their mouth in readiness to eat. Then the avidity with which solids or liquids are consumed provides further evidence of appetite. Once the food has been consumed, the infant may then begin to show a slowed rate of eating and a series of overt avoidance/rejection behaviors such as looking away from the food, gazing at other objects in the environment, closing the mouth, arching the back, or turning the head away (see Hetherington et al. 2016; Nekitsing et al. 2016; McNally et al. 2019).

In summary, infants signal their preference for sweetness and dislike of bitterness through facial expressions. Beyond these basic responses which appear to be hard-wired and phylogenetically old (shared with other species), human infants signal acceptance and rejection as they experience new foods during their transition from univore to omnivore, from consuming sweet-tasting milk to a broad range of complex solid foods.

Self-Regulation

Infants who are exclusively breastfed have already experienced a wide variety of flavors from the maternal diet and are therefore more willing to accept novel foods such as vegetables during complementary feeding (Sullivan and Birch 1994). Breastfed babies regulate energy intake to match energy requirements, showing self-regulation. For example, in a well-controlled, prospective study of exclusively breastfed babies in a developed country, energy intakes from breast milk matched energy requirements producing normal growth trajectories (Nielsen et al. 2011). In this study, volume of milk ingested, energy intake, and milk energy content were measured using the doubly labelled water method. This technique of providing mothers with a dose of doubly labelled water then sampling urine is the gold standard method for assessing energy requirements. In this study, when infants were re-tested, between 15 weeks and 25 weeks, milk intake increased significantly and matched energy requirement to sustain normal growth.

In another study where breastfed babies were randomized to complementary feeding at 4 months or exclusive breastfeeding for 6 months, the researchers found no difference in total energy intakes or body composition at 6 m (Wells et al. 2012). Here, the stable isotope method was again used to determine precisely how much energy requirement was achieved through milk, and then energy intake from solid foods was determined using weighed intakes. The infants randomly assigned to complementary foods at age 4 m consumed significantly less breast milk at age 6 m compared to the babies exclusively breastfed. Both groups showed the same rate of growth and had similar energy intakes. Therefore, these studies provide evidence of self-regulation during the first 6 m of life in breastfed babies.

In formula-fed babies, the capacity to regulate energy intake has also been studied, and given that the content of formula can be manipulated, this permits investigation of self-regulation related to systematic changes in energy density and macronutrient content on total energy and nutrient intakes.

Fomon and colleagues (1971) gave one group of infants a lower energy density (ED) formula (54 kcal/100 ml) or higher energy density formula (100 kcal/100 ml). The babies assigned to the lower ED version consumed significantly more formula but did not manage to match the energy intake of the higher ED formula group, so gained less weight. More recently, Timby et al. (2014) randomized infants to receive a lower protein, lower ED experimental formula (60 kcal/100 ml), or standard formula (66 kcal/100 ml). Infants receiving the experimental formula consumed a significantly greater volume to match the energy intake of the standard formula.

In a study of energy compensation, Brugaillères et al. (2019) provided carrot puree with or without added oil to increase energy density of the puree to 11-month-old infants; then they repeated the study at 15 m. They found that at 11 m infants compensated at a test meal offered 25 min after the puree by 52%, but by 15 m this depreciated to −14%. These data suggest that self-regulation may decline with age and that infants need to have multiple exposures to low energy density foods with added energy in order to learn about their postingestive consequences. This study illustrates the potential role of learning in infant feeding.

In summary, both breastfed and formula-fed babies show evidence of self-regulation. However, with complementary feeding and the introduction of energy dense, complex foods, infants appear to compensate for energy loads less well with maturity. Therefore, there is a significant role for learning in the early years as infants associate the sensory characteristics of different foods with their post-ingestive consequences.

Nutritional Wisdom and the Role of Learning

As infants move away from milk as their only source of nourishment, they are offered a range of solid foods to ensure appropriate nutrition. As mentioned, infants have a positive, unlearned acceptance of sweetness, but they have an aversive, innate rejection response to bitterness. This implies that infants must acquire a liking for bitter tastes through experience, if they are to accept bitter tastes. The role of learning, therefore, is crucial in the transition from univore to omnivore. In the classic observations made by Dr. Clara Davis in the late 1920s and 1930s, she demonstrated the capacity of infants to select a diet from an array of raw and cooked foods to sustain healthy growth (Davis 1928, 1939). The small number of infants she followed generated a huge data set as all meals were recorded for up to 6 years (Strauss 2006). The infants were given solid foods on a tray, and they could select whatever they wanted. Nurses who were present to ensure the safety of the infant were instructed not to guide the infant's choice. Overall, the infants selected a range of around ten foods per day and achieved a balanced diet, which ensured their health and well-being. One infant reversed symptoms of early-stage vitamin D deficiency (rickets) through selection of cod liver oil. The meal patterns of these infants during complementary feeding provide evidence of "nutritional wisdom," namely, when offered a variety of wholesome foods, infants choose well – they did not simply select their preferred sweet foods but consumed a number of foods, and in some cases the infant preferentially consumed more of the cooked version of the food compared to the uncooked (see Table 1). Although infants have an innate preference

Table 1 An example of food intake in an 18-month-old infant from Dr. Clara Davis (1939) and her study of "nutritional wisdom"; note the difference in the weight of raw and cooked apple and oats, indicating that the cooked versions were preferred

7 a.m. breakfast	5 p.m. supper
60 cc milk	230 cc milk (Grade A)
26 g raw apple	50 g fish
62 g cooked apple	1 cooked egg
100 cc orange juice	20 g raw tomatoes
0 67 g cooked wheat	150 g banana
0 15 g cooked barley	100 g orange segments
0 16 g cooked liver	**10 g raw oats**
0 50 g cooked sweetbreads	**56 g cooked oats**

for sweet, they nonetheless acquire a liking for a variety of foods covering all the basic tastes in order to attain adequate nutrient intakes, and sufficient energy to match requirements. Of course, this “experiment” demonstrates nutritional wisdom under very constrained circumstances, and it is not clear given the modern food environment of highly palatable, energy dense, nutrient-poor foods that infants would also select as wisely. These early studies by Davis reinforce the importance of learning that the infant’s appetite is influenced by the food environment presented and that given a range of foods, infants select well and not only their most preferred item.

Vegetables as a First Food

At the time of complementary feeding, when infants make the transition from univore to omnivore, they are uniquely willing to try new flavors (Harris 2008). A number of researchers have used vegetables as a first food during complementary feeding. In part this is because intakes of vegetables tend to be below recommendations globally and establishing liking for these foods in early life may provide the foundation for preferences later on (Barends et al. 2013; Hetherington et al. 2015; Remy et al. 2013). To test whether early exposure to vegetables as a first food enhances acceptance of vegetables, infants were randomly assigned to a control group receiving no prior vegetable experience or an intervention involving a step-by-step introduction of novel vegetable purees over 24 days. In the first 12 days of complementary feeding, vegetables were added to milk and then to cereal for the next 12 days (Hetherington et al. 2015). Acceptance was measured using intake, ratings of liking by mothers and researchers, as well as filmed facial and behavioral responses to pureed vegetables offered on days 25 and 26 (carrot on d25 and green bean in d26). Video recordings were coded using the Feeding Infants: Behaviour and Facial Expression Coding System (FIBFECS; Hetherington et al. 2016) with six acceptance/rejection behaviors (turns head away, arches back, crying/fussing, pushes spoon away, leans forward, and rate of acceptance; see Fig. 1) and seven facial expression items (brow lowered, inner brow raised, squinting, nose wrinkling, lip corners down, upper lip raised, and gaping). Examples used in the training from the coding system are provided in Fig. 1.

In this same study, infants were offered nine consecutive spoonfuls of vegetable puree, and behaviors and facial expressions were assessed per spoonful. When offered vegetable puree, the infants from the intervention group showed a greater duration, pace, and consumption of each vegetable than the infants from the control group. Investigator ratings (but not maternal ratings) of liking were sensitive to group assignment with higher ratings for vegetables in the intervention compared to the control group. Overt acceptance and rejection behaviors (reflecting wanting) differed by group assignment. Infants with prior vegetable exposure showed fewer rejection behaviors and more acceptance behaviors than those in the control group. Facial expressions related to aversion did not differ by group

Cue	Baseline	Response
Gape		Turn head away (THA)		
Pushes spoon away (PSA)		
Leans forward (LF) ready to eat		
Opens mouth in anticipation of food acceptance		

Fig. 1 Facial expressions and overt behaviours filmed at baseline and in response to vegetables offered during weaning

but did differ by vegetable. Thus, more frequent aversive facial reactions were observed in response to the green bean than to carrot. This may reflect the natural sweetness of the carrot which is accepted more easily than the green bean which is less sweet.

In summary, vegetables offered as a first food tend to be well accepted, and there has been a consensus statement promoting vegetables as a food to offer during complementary feeding in order to encourage preference development for vegetables (Chambers et al. 2016). Infants exposed to vegetables at complementary feeding added to milk then to cereal show evidence of liking and wanting for these foods as a function of learning. Mothers may misattribute facial expressions as disgust or dislike, but these may simply be surprise, and it may take many exposures (between five and ten) before children accept bitter-tasting, green vegetables.

Recognizing Infant Appetite Cues in the Transition to Solids

So far, we know that infants are capable of signalling appetite, that they acquire liking for foods through experience, and that they are capable of self-regulation to meet energy needs. How then do infants signal interest in food, readiness to progress to solid foods, and sensations of hunger, appetite, and satiety? The types of cues which infants use at various stages of development are summarized in Table 2 (adapted from Pérez-Escamilla et al. 2017).

Mothers have been interviewed to investigate how they know when to introduce solid foods (e.g., Anderson et al. 2001). In this study, readiness was signalled in terms of visual interest in foods eaten by family members. Hunger cues were described in relation to babies' characteristics (e.g., age, weight), their overt behavior (e.g., rapid rate of milk consumption, agitation, "chewing" their hands), and external factors such as time of day and time since last feed. Mothers reported being able to identify a "hungry cry," and they reported satiation cues in terms of expressions of contentment, especially infants appearing more settled after a feed.

Hodges et al. (2008) investigated cues which prompted mothers to initiate and end feeding. Like Anderson et al. (2001), the authors found mothers used both infant behaviors and external cues (e.g., time) to identify hunger. Typical hunger cues in this study were crying, fussing, and licking the lips, and these were reported across several age groups (3, 6, and 12 months). Common satiation cues included pulling away, spitting food out, and refusing food. The prominence, intensity, and specificity of infant cues guided decisions about initiating and ending feeds, and mothers found cues easier to interpret with increasing infant age.

Hodges et al. (2013) went on to develop a tool to characterize and code responsive feeding called The Responsiveness to Child Feeding Cues Scale (RCFCS). This tool has 20 types of hunger cue and 28 types of satiation cue which can be recorded during meals. Hunger and satiation cues are further categorized as "early" (e.g., increased alertness), "active" (e.g., excitatory movements), and "late" (e.g., fussing and crying) in order to reflect changes in cue intensity. The authors found that mothers were typically more responsive to hunger than satiation cues. However, better responsiveness to satiation was predicted by maternal characteristics such as healthy BMI, longer breastfeeding duration, and higher educational level.

In their study of the changes in feeding cues expressed over time, Hodges et al. (2016) observed mother-infant pairs during mealtimes at infant ages 3, 6, 9, 12, and

Table 2 Hunger, Appetite, and Satiation cues by approximate stage of development; adapted from the Feeding Guidelines for Infants and Toddlers, Perez-Escamilla et al (2017)

Age	Hunger	Appetite	Satiation
0–6 months	Agitation, mouthing, sucks on fist, fussing, distress cry	Orienting/mouthing, rapid sucking, then slows down	Rate of sucking slows and stops, seals lips together, ejects nipple, sleeps
4–6 months	Fussing, crying, agitation, shows excited arm and hand gestures	Visual interest in foods offered, licking lips, opens mouth in readiness to eat, leans forward to receive food, feeds avidly then slows down	Rate of sucking slows, rate of food acceptance slows then stops, gaze aversion
5–9 months	Reaches for food, points to food	Visual interest in food offered, leans forward to accept food, eats avidly then slows	Eating slows, pushes food away, turns head away, twists body away, gaze aversion, increased exploratory gaze, plays with food or utensils
8–11 months	Reaches for food, points to food, gets excited in the presence of food	Gazes at food, interest in food offered, self-feeds, eats avidly then slows	Eating slows, pushes food away, turns head away, twists body away, gaze aversion, increase in exploratory gaze, plays with food or utensils, gets restless to leave table
10–12 months	Uses sounds and language to verbalize interest in eating	Gazes at food, self-feeds, gestures for more food, eating rate initially rapid then slows	Eating slows, shakes head to indicate "no more," gets restless to leave table
12–24 months	Combines gesture and vocalization to express need to eat	Gazes at food, self-feeds, eating rate initially rapid then slows	Uses specific utterances such as "all done" and "get down," plays with food or utensils

18 months in the home. They used RCFCS at each time point and noticed that fullness cues became more diverse and less subtle over time. For instance, in the first two observations (3 m and 6 m), disinterest, falling asleep, and decreased muscle tone and activity signalled fullness, but during the later observations, pushing or pulling away and communicating "no" verbally became more apparent. In relation to appetite, postural attention and reaching for food increased after 6 months. As the infant develops, their motor and language skills enable them to assert interest or disinterest in eating.

Similarly, a study by Skinner et al. (1998) used pictures of hunger cues, and mothers were asked at what age these were displayed by their baby. The authors reported that cues of readiness to eat (e.g., opening the mouth as the spoon approached) appeared at a younger age than satiation behaviors (e.g., closing the mouth to reject food) (4.4–5.7 months vs. 5.8–7.5, respectively). Food dislikes were communicated via facial expressions and by body movements, such as turning the head or the body away from food or throwing food away. These signals of food dislike appeared by 8 m of age, and strong indications of food likes and dislikes increased in frequency with age. Overall, mothers reported that their infant's ability to communicate improved in scale and scope over time in tandem with the mother's improved skill in interpreting this communication (Skinner et al. 1998).

Visual interest in food items during a meal followed by disinterest has been noted in a number of studies as an indicator of appetite and satiation. For example, gaze aversion, when infants look away from the caregiver as food is offered, is identified as a potent disengagement cue (Sumner and Spitz 1994), and visual attentiveness to the caregiver at the start of a meal is regarded as an indicator of infant feeding responsiveness (Hodges et al. 2013).

Recent evidence from the Leeds laboratory has demonstrated that shifts in gaze may reflect changes in interest in food during a meal (McNally et al. 2019). In this study, 20 mother-infant pairs were filmed consuming a solid meal on two separate occasions. Infants were aged between 6 m and 18 m (mean age 11.7 months $\pm$3.40). All infants had been breastfed at birth for at least a few days, average breastfeeding duration was 24 weeks, and solids had been introduced at around 22 weeks. Gazing at food was most frequent during the initiation of eating and then declined during the first course. At the same time, exploratory gaze involving intent gazing at feeding utensils, food remnants, or other objects while touching or manipulating them increased during the first course. Interestingly, when a second course was presented to the infants, gazing at food resumed in the early stage of intake and then declined over time, perhaps signalling sensory-specific satiety (McNally et al. 2019).

Mothers' perceptions of infant feeding cues in the first 2 years of life generally reveal that hunger cues are easier to perceive than satiation cues and that feeding cues are easier to interpret as children grow older (McNally et al. 2016). It is likely that with developmental maturity, infants become more adept at communicating hunger, appetite, and satiation. However, caregivers must also learn to recognize and respond to these cues over time.

In summary, during milk feeding, the first form of communication about hunger status is through hand to mouth, agitation, orienting toward the breast/bottle, and culminating in the "hunger" cry. As infants develop, infants signal interest in solid foods through visual interest in family foods, fussing, agitation, and licking their lips. Appetite is signalled by mouth opening in response to food, eagerness to accept foods offered, the rate at which food is accepted, and gazing at food. Satiation is initially signalled through disinterest and sleep and later signalled through avoidance cues such as slower rate of acceptance of food offered, gaze aversion, turning the head away, pushing food or spoon away, and twisting the body away from food offered. As children progress to solid foods, the approach and avoidance behaviors develop further in scale and scope. With maturity, infants begin to use language to signal enjoyment of food and to indicate likes/dislikes. The urgency and survival value of communicating hunger is simple, strong, and dramatic, taking precedence over other needs. Cues to signal fullness appear later than hunger cues and responsiveness to these may depend on characteristics of the mother including breastfeeding duration, BMI, and education. Gazing at food appears to reflect interest in eating (appetite), and this wanes during the course of a meal. Therefore, there are a number of cues used by infants to signal their underlying need state which change as the infant is fed; and it is up to caregivers to notice these subtle changes in cue communication.

Responsive Feeding: Cue Recognition and the Role of Feeding Method

The extent to which mothers and other carers identify, recognize, and respond to infant feeding cues will determine whether infants are fed *responsively*. The ways in which parents feed their children and their understanding of their infant's appetite cues influence the early entrainment of appetite control (Disantis et al. 2011; Hurley et al. 2011). For example, DiSantis et al. (2011) proposed that "responsive" mothers are sensitive to hunger and satiation cues and respond appropriately, while discordant responses to infant cues such as pressuring to eat or overriding the cues of satiation might increase overfeeding and risk of obesity. Similarly, Worobey et al. (2009) found that mothers with lower sensitivity to feeding cues at 6 months had infants who gained more weight between 6 and 12 months than mothers with a higher level of sensitivity. Also, restrictive and indulgent feeding practices were associated with a high BMI in infants and young children (Hurley et al. 2011), and the use of assertive prompts to eat and intrusiveness during the meal predicted higher adiposity in toddlers (Lumeng et al. 2012). Taken together this evidence indicates that parents may override infant signals of hunger, appetite, and satiation and superimpose their own expectations about when eating begins, how much to feed, and when eating ends.

Mothers who breastfeed might be more responsive to infant feeding cues than mothers who formula feed assuming that mothers who breastfeed situate control of the timing and volume of milk feeds with their baby. When mothers feed formula or breast milk via a bottle, they are more able to judge the volume consumed, and the temptation to encourage babies to finish the bottle is possible. It has been found that more intensive bottle feeding (breast milk or formula) results in a greater risk of overconsumption (Li et al. 2008, 2010) and, therefore, it is not merely the source of the milk supply but also the delivery method which matters for weight regulation. Feeding from a bottle (breast milk or formula) is also associated with a lower ability to self-regulate intake than feeding directly from the breast (Arenz et al. 2004).

In order to understand better the potential differences in mealtime interactions based on prior milk feeding experience, we conducted a series of investigations in the UK and Israel on the same cohort of infants from the milk feeding stage to solid food introduction to 24 m (Shloim et al. 2014, 2015, 2017, 2018). Milk feeding was filmed in 27 mothers (13 breastfeeding; 14 formula feeding), and infant appetite cues were recorded when the infants were aged between 3 and 22 weeks. Engagement (interest in the feed) and disengagement (signalling disinterest) cues during the feed were recorded at the beginning, middle, and end of the meal. Examples of engagement cues included sucking sounds, mutual gaze, and opening the mouth in readiness to feed, whereas examples of disengagement cues included pushing away or back arching. Over time, engagement cues tended to decrease, and disengagement cues tended to increase, reflecting the transition from interest in milk to disinterest and satiation. Breastfed infants tended to display both types of cue more frequently than formula-fed babies, and they opened their mouth indicating readiness to eat at the beginning of the feed compared to formula-fed infants (Shloim et al. 2017). This suggests that breastfed babies were more active participants in the feed and signalled more to the mother their appetite and satiation status.

Mothers from the same cohort were then filmed during mealtimes on four further occasions postpartum (2–6 m, 8–12 m, 14–18 m, and 20–24 m). Feeding behaviors were coded using the Simple Feeding Element Scale (Shloim et al. 2015). In the first measurement postpartum, mealtime interactions indicated that women who breastfed (rather than bottle fed or fed solids) presented fewer distractions during the meal, provided a more ideal feeding environment and fed more responsively (Shloim et al. 2017). In the subsequent measurements, infants were more likely to communicate potent engagement cues such as babbling, mutual gaze, and looking at mother with developmental maturity, whereas disengagement cues remained stable over time. Interestingly, disengagement cues such as fussing and tray pounding were most likely to occur at the end of the meal signalling disinterest in eating (Shloim et al. 2018).

Interventions to encourage more responsive feeding in bottle-fed babies have been conducted by Ventura and her colleagues (Ventura and Golen 2015; Ventura and Hernandez 2018). In these studies, mothers were given clear bottles or opaque, weighted bottles from which to feed their infants. The opaque, weighted bottles resulted in mothers feeding infants less formula, feeding them at a slower rate, and displaying more sensitivity to the infant's satiation cues compared to using the standard, clear bottle (Ventura and Hernandez 2018). This simple manipulation appeared to direct mothers away from crude volume control toward reading their infants better. Crucially, there was a strong moderating effect of the clarity with which infants expressed satiation cues. Thus, infants who were rated as displaying more obvious satiation cues were fed less in the opaque condition than the clear condition, whereas lower clarity of cues resulted in equivalent amounts of milk fed to babies in each bottle condition. This illustrates the importance of infant proficiency in expressing cues as well as maternal sensitivity to these cues.

In summary, developmental maturity ensures that infants express more diverse and assertive means of communicating hunger, appetite, and satiation; however, responsiveness to these cues may be influenced by features of the mother such as her BMI and the ways in which she feeds her baby (via breast or bottle). There is evidence that breastfeeding mothers are more responsive to their infants, and in part, this could be due to the communication proficiency shown by breastfed babies (Shloim et al. 2017). Finally, the bidirectional nature of the mealtime interaction means that more proficient communication of appetite and satiation by the infant may also result in more responsive feeding by mothers, and responsive feeding in turn encourages greater proficiency in expressing appetite and satiation cues.

Conclusions

Infants make the transition from univore to omnivore and, in so doing, demonstrate a diverse range of ways to communicate to caregivers their needs. They become more adept at conveying appetite, interest in food, liking, wanting, and satiation through a range of behaviors. Babies are capable of self-regulation demonstrated during milk and early solid food feeding, but the ability to compensate for additional energy in the short-term declines with age. Therefore, caregiver responsivity to infant communication is central to facilitating self-regulation. A number of research tools have been developed and tested to identify the communication cues used by infants. Some coding systems can be applied to detect liking and wanting first foods offered around the time of complementary feeding (Hetherington et al. 2016; Nekitsing et al. 2016). Other tools such as the RCFCS permit a sensitive analysis of the ways caregivers recognize and respond to child feeding cues (Hodges et al. 2013). Mealtime interactions reveal the bidirectional and reciprocal nature of communication between infants and their caregivers, and targeted interventions designed to promote responsive feeding have shown that parents' ability to respond to their infant is modifiable. In summary, human infants are highly dependent on their caregiver to provide sufficient energy for survival; they are capable of self-regulation but need the caregiver to respond promptly and appropriately. Recording mealtime interactions offers the researcher a means to identify the bidirectional nature of responsive feeding which is based on caregivers being able to recognize and respond to infant communication. Characterizing infant cues and encouraging caregivers to engage in responsive feeding may provide an opportunity to intervene to promote self-regulation, healthy eating, and growth. However, infants also vary in their proficiency to communicate energy needs and eating traits such as fussiness may contribute to difficult mealtime interactions. Understanding both the caregiver's ability to recognize cues and the infant's ability to convey their needs is crucial to effective communication of hunger, appetite, and satiation.

Eating and Drinking in Childhood

Contents

Abstract

This chapter describes the development of eating and drinking in typically developing children up to the end of school age. Together with physiological and cognitive development, children's eating behavior undergoes major evolutions. During the early period when eating is essential to sustain growth, children eat easily and at the onset of complementary feeding discover the foods of their future diet which are marked by distinct tastes, flavors, and textures from the milk they had received before. Then they undergo a period when they may become picky and/or neophobic, which may last until school age. For this reason, eating and drinking will first be described in infancy, before the onset of food neophobia (from birth to 2–3 years), during the preschool years (from 2–3 years to 6 years), and right after this period, in school-aged children (from 7 years until 11 years). The mysteries of (pre)adolescent eating and drinking will not be covered in this chapter. Then, within each section, the following aspects will be covered: sensory capacities, likes and dislikes, attitudes and thinking, and role of the environment, including the family environment.

Introduction

How to cover such a complex topic as eating in childhood in one chapter? It is a challenge, because eating and drinking in childhood are nearly as complex as in adulthood, if not more, given the developmental aspect specific to childhood! Infants are born with sucking abilities and within a year from birth will transition from their mother's breast to the family table. What a journey through eating and drinking! First, concerning childhood, it may be relevant to refer to "drinking and eating" rather than to "eating and drinking," because children start their journey through the consumption of foods and drinks by first consuming a unique liquid substance, (breast) milk. It is only by about the first half of the first year that foods other than milk start being consumed. This corresponds to the recommendation of the World Health Organization regarding the ideal age for introduction to complementary foods (WHO World Health Organization 2003). This recommendation is universal because according to the WHO, human milk is the most adapted food for all newborns, but this is all the more true in parts of the world where access to potable water (which is needed for the preparation of infant formula as a substitute for breast milk) is not granted. However, because some women have working activities outside the households in many countries, a transition to other foods than breast milk may be necessary before the age of 6 months, which may have led pediatric societies throughout the world to suggest the introduction to complementary foods as of the age of 4 months (as observed for the European Society for Paediatric Gastroenterology, Hepatology, and Nutrition (Fewtrell et al. 2017), the Chinese Ministry of Health, and the Japanese Ministry of Health (in (Inoue and Binns 2014)), to name a few examples). The WHO recommendation is related to the protective effect of breastfeeding against infections and, as suggested more recently, to the positive (but unwanted) association between the initiation of complementary feeding before 4 months and the development of overweight and obesity (English et al. 2019). Introduction of complementary foods about the first half of the first year is also related to the developing feeding skills of the infant, which strongly evolve during the course of the first year (Fewtrell et al. 2017; Nicklaus et al. 2015). When the oral cavity increases in size, when lips and the tongue are able to retain food in the mouth, when coordinated lateral then rotatory movements of the jaws are developing, only then is the infant able to process foods other than liquids in the mouth (Nicklaus et al. 2015). These tremendous developmental features happen in a relatively short period, which constitute a "window of opportunity" to learn about food (Nicklaus 2016b). Therefore, during childhood, "eating and drinking" first mean drinking and progressively mean eating at the family table where children will ultimately eat like their parents, if they are provided with the opportunity to learn about "adult" foods.

"Eating and drinking" in childhood must also be considered in relation to the various functions of eating and drinking. In childhood as later during adulthood, "drinking and eating" first serve the primary function of covering nutritional needs for maintaining body functions, with the specific nutritional need to cover healthy growth. Second, "drinking and eating" deliver pleasure, through the presence of the mother (importance of her physical contact as shown in skin-to-skin practice, of her body warmth, of her voice, her smell, etc.) (Schaal 1988), through the positive reinforcement related to the cessation of the painful feelings related to hunger, to the satisfaction related to satiation and the ingestion of calories, and through the pleasurable sensory properties of foods that are either immediately pleasant to the child or learned through experience with foods. Third, "drinking and eating" contribute to socialization; and for children it is essential to learn to eat like their siblings, in order to develop social competencies that will enable their integration to social activities encompassing eating, such as schooling. Finally, because drinking and eating are so embedded into our daily lives, they also contribute to define one's identity, and the food choices that we make daily carry important symbolic values toward others. This is true also in children, and many of children's reactions to parental feeding strategies can also be interpreted in relation to defining their own identity.

In order to describe the main features of eating and drinking in childhood, this chapter is organized in different sections related to the main stages related to eating in this particular age range. One important dimension to account for regarding eating in children is the development of a phase during which children exhibit strong neophobic reactions (i.e., reluctance to eat and try new foods) and may come to reject foods that were previously eaten. This phase generally starts by the end of the second year, when marked signs of food neophobia/fussiness/pickiness become the norm (and may concern at least three children out of four), and fades away by about 8 years of age (Dovey et al. 2008; Nicklaus and Monnery-Patris 2018; Rioux in press; Taylor et al. 2015). For this reason, eating and drinking will first be described in infancy, before the onset of food neophobia (from birth to 2–3 years), during the preschool years (from 2–3 years to 6 years), and right after this period, in school-aged children (from 7 years until 11 years). The mysteries of (pre)adolescent eating and drinking will not be covered in this chapter. Then, within each section, several aspects related to eating will be described. First, sensory capacities will be exposed, because at an early stage in life, sensory-motor inputs play a particularly important role in determining food choice decision-making. Then, likes and dislikes will be explained, which develop in relation to dietary experience. Third, attitudes and thinking abilities will be described, since cognitive abilities strongly evolve across childhood. Finally the role of the environment in shaping eating and drinking will be explained, focusing in particular on the role of the social environment (including family environment), which changes drastically across development.

This chapter focuses on the development of eating behavior of typically developing children and does not cover the potential specific needs of children with atypical development, whether it stems from physiological or psychological impairment. Furthermore, most of the studies used to document this chapter were conducted in

Western Europe or in the USA. While one may reasonably assume that these pieces of evidence relate to fundamental learning mechanisms, in relation to physiological and psychosocial factors, it may be questioned whether the phenomena described in this chapter hold true in all parts of the world. More specifically, many factors that strongly relate to the development of eating and drinking are so variable across the globe (food availability (in relation to climate variations), cooking habits, culture and prejudices about infant and child feeding, socioeconomic development, parental feeding practices, parental feeding and parenting style, exposure to food commercial, etc.) that their independent or combined influences on all aspects of children's development of eating and drinking are not known with precision. Whenever possible, examples from non-Western countries will be exposed.

Infancy: Drinking and Eating Before the Onset of Food Neophobia: The Golden Age

Sensory abilities. Infants are born with the capacity to taste and smell drinks and foods (Lipchock et al. 2011). While it is difficult, if not impossible, to compare infants and adults sensitivities to tastes and smells in line with strong differences in applicable methods, several studies indicate that infants display finely tuned abilities to differentiate flavors of foods and drinks, which can be inferred from their preferences. For instance, they can distinguish the smell of milk from that of water, the smell of breast milk from that of formula milk, and the smell of their mother's milk from the smell of another lactating woman (Marlier et al. 1998). They can also demonstrate a preference for an odor that was experienced in utero, which also reveals the transnatal continuity in terms of food flavor learning (Schaal 2005). They can differentiate and prefer the odor of vanilla compared to the odor of butyric acid (Soussignan et al. 1997). Concerning taste perceptions, newborns are able to display a variety of facial expressions and behavioral responses when they are exposed to the different primary tastes (sweet, salty, sour, bitter, and umami) (Lipchock et al. 2011). Later in development during infancy, infants still show contrasted preferences across the primary tastes, but preference for all tastes do not evolve in the same way: for instance, the preference for salty taste increases sharply during the first year (Schwartz et al. 2017). Regarding manipulation of food textures, infants are born with very limited oral skills that only enable sucking during the first months (Nicklaus et al. 2015). However, they can develop control over sucking during the first months and can refrain from drinking a formula milk that they do not like, as was shown in the case of hydrolyzed protein formula (generally prescribed in case of allergy to cow milk proteins). Such formulas have a strong flavor (bitter, sour, in relation to the hydrolysis of the formula into smaller peptides), which children start rejecting around the age of 3.5 months (Trabulsi and Mennella 2012). Their abilities to develop more sophisticated oral control over food gradually evolve during the first years of life, but it is only when final denture is in place that chewing efficiency of children reaches adult maturity (Nicklaus et al. 2015). This happens during preadolescence.

Food likes and dislikes. In relation with these finely tuned and developing sensory abilities, infants exhibit a marked development in terms of food likes and dislikes. From birth on, their preferences are strongly dependent upon their food and flavor experience (Nicklaus 2016a; Schaal 2016; Trabulsi and Mennella 2012). This may be interpreted as an adaptation mechanism to enable the chemosensory guidance toward foods that are safe to eat within a given environment. This conclusion may appear as very broad, but several pieces of evidence can support it. At birth, preference for an odor can be guided by prenatal exposure to the same odor present in a food consumed by mother: this was shown concerning the consumption of food containing the anise flavor (Schaal et al. 2000). At the start of complementary feeding, children's preference for food flavor can be related to prior learning, during pregnancy as shown regarding exposure to carrot flavor (Mennella et al. 2001) or to green vegetable flavor (Wagner et al. 2019) or to prior learning during lactation as shown regarding exposure to carrot flavor (Mennella et al. 2001), to caraway flavor (Hausner et al. 2010; Wagner et al. 2019), or to green vegetable flavor (Wagner et al. 2019). The exposure to the flavor of garlic during pregnancy was even shown to influence children's preference for garlic flavor in a potato gratin up to adolescence (Hepper et al. 2013). The exposure to vanilla flavor in the context of milk feeding was shown to influence adult's preference for vanilla flavor in a ketchup (Haller et al. 1999), revealing the long-term influence of such an early sensory imprinting on food preference. Epidemiological studies also point to the association between breastfeeding and further acceptance of fruit and vegetables (Burnier et al. 2011; de Lauzon-Guillain et al. 2013; Skinner et al. 2002).

Preferences for foods at the onset of complementary feeding can be modulated by milk feeding experience, in relation to the milk composition independently from the maternal food consumption, in the context of breast milk (Schwartz et al. 2013) or formula feeding (Beauchamp and Mennella 2011). After the initiation of complementary feeding (introduction of foods other than milk to the child's diet), children can process foods which have a soft texture (like infant cereals or purees foods) but are still limited in their ability to process hard/chewy foods (Demonteil et al. 2019), but in terms of flavors, they tend to accept a wide variety of foods (Lange et al. 2013). Notably, the liking of a food (judged from parental reports) can differ as a function of food taste, and infants may like more foods that have a saltier taste (Schwartz et al. 2011), in relation with the development of salt taste preference (Schwartz et al. 2017). This is not a good news because the consumption of sodium is advised against at this stage of life, in relation to kidney immature functioning.

The beginning of complementary feeding itself is fundamental period for children for learning about foods. Many experiments conducted during this period show that repeated exposures help children to like a variety of foods (Sullivan and Birch 1994), even foods they did not like right away (Maier et al. 2007). The diversity or variety of foods fed during this period is also strongly supporting the development of likes for unknown foods. Studies in this area showed that the introduction of three different types of vegetables (or fruits) at the very beginning of complementary feeding instead of one type only is associated with a higher acceptance of a new food right after this period (Gerrish and Mennella 2001; Maier et al. 2008; Mallan et al. 2016;

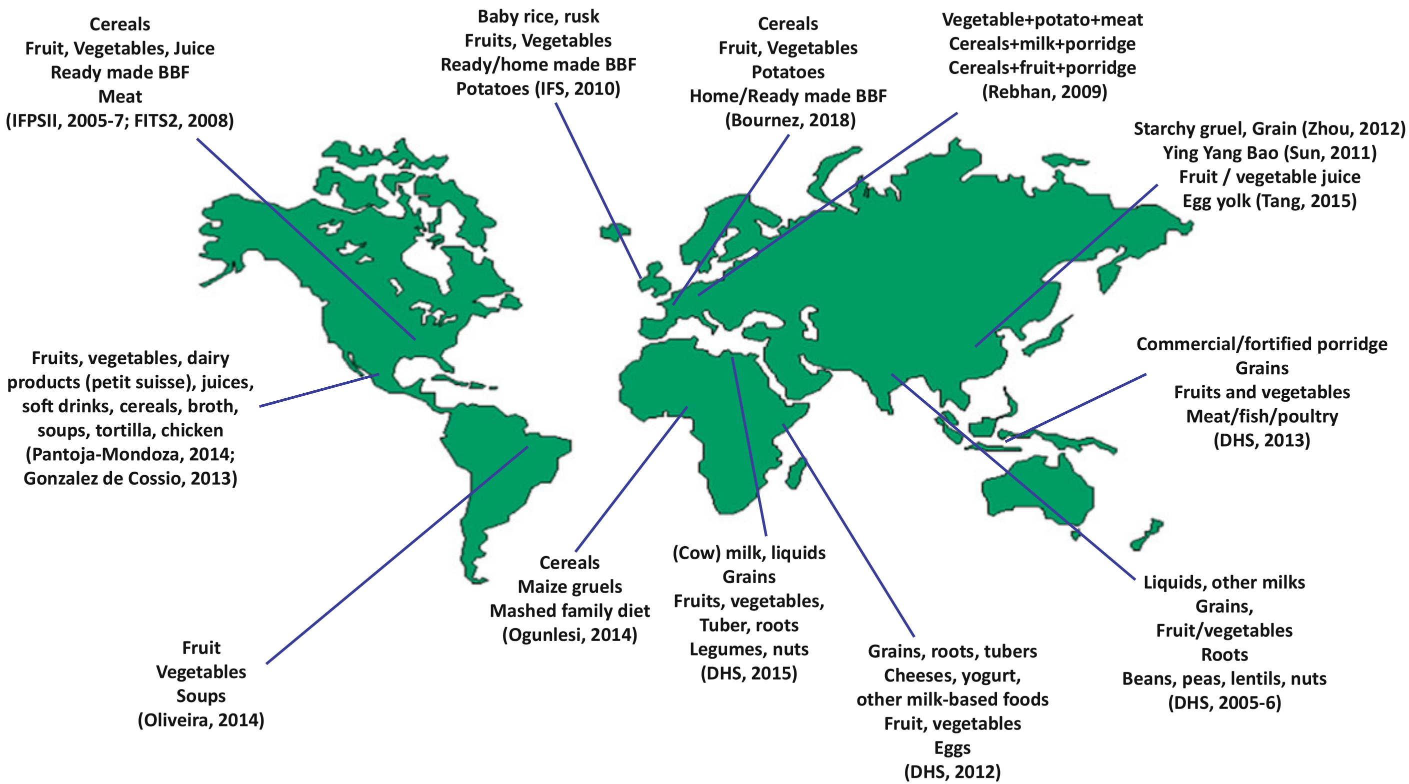

Fig. 1 Mapping of the first foods offered across the world. BBF: ready-prepared baby foods. (Sources: the USA (Grummer-Strawn et al. 2008; Siega-Riz et al. 2010), the UK (McAndrew et al. 2012), France (Bournez et al. 2018), Germany (Rebhan et al. 2009), China (Sun et al. 2011; Tang et al. 2015; Zhou et al. 2012),

Mennella et al. 2008), which demonstrated lasting effects on intake of familiar or novel vegetables up until the age of 6 years (Maier-Nöth et al. 2016). The effect of the introduction of a variety of foods on the development of food preference may depend on the age of children: a study conducted in the UK showed an effect of the introduction to a variety of vegetables on acceptance of a new vegetable in infants introduced to complementary foods after 6 months, but not before 6 months (Coulthard et al. 2014). A study conducted in three cultural contexts (the UK, Greece, and Portugal) where feeding practices are different (high vegetable variety at the beginning of complementary feeding in Portugal but low in Greece and the UK) showed that the effect of an imposed pattern of vegetable variety introduction has more effect on children's acceptance of a new vegetable in countries where parents were not culturally inclined to provide a high variety of vegetables (e.g., in the UK and Greece) than in a country where an introduction of a high variety of vegetables is the norm (e.g., in Portugal) (Fildes et al. 2015).

Having a look about the first complementary foods that are fed around the world is useful to understand how early feeding practices relate to cultural eating habits, as represented in Fig. 1. The types of foods fed in a given culture are generally related to the food availability in this country, to the existence of core foods in the diet (e.g., tortilla in Mexico, legumes and nuts in India, tuber and roots in Egypt). Some regularities can also be observed, like the use of local or commercial cereals or grains and the introduction of vegetal products, like fruit, vegetable, roots, and tuber, while the diet is still rich in milk.

Altogether, this period appears as fundamental for learning about food likes. Beyond the repeated exposure mechanism for learning (or mere exposure), forms of Pavlovian conditioning may also modify children's behavior toward foods (as far as intake or liking are concerned). Preference for an unknown flavor (the conditioned stimulus) may be conditioned by a liked flavor (the unconditioned stimulus, e.g., the sweet taste) in the case of flavor-flavor learning or by the presence of nutrients (the unconditioned stimulus being calories) in the case of flavor-nutrient learning. This has been studied in infants, but the actual contributions of these mechanisms are still controversial (Yeomans 2012). Flavor-flavor learning (with sugar as the unconditioned stimulus) does not produce significant effect on learning to like a new vegetable, but the association of the flavor of a food to calories from lipids may in fact be associated with conditioned satiation (Caton et al. 2014; Remy et al. 2013), revealing the importance of energy density in conditioning food intake. More studies are needed to better understand learning mechanisms for a range of foods with a range of flavor additions, or of energy densities, in order to understand which flavor intensity and which energy density would be associated with the highest increase in liking an intake, especially for foods which are not liked right away by children such as vegetables.

Fig. 1 (continued) Indonesia (Statistics Indonesia (Badan Pusat Statistik-BPS) et al. 2013), India (International Institute for Population Sciences (IIPS), Macro International, & 2007 2007), Ethiopia (Central Statistical Agency [Ethiopia] and ICF International 2012), Egypt (Ministry of Health and Population [Egypt] et al. 2015), Nigeria (Ogunlesi et al. 2014), Brazil (Oliveira et al. 2014), Mexico (Gonzalez de Cossio et al. 2013; Pantoja-Mendoza et al. 2014))

Attitudes and thinking. Although children are mostly in a preverbal stage during this early period before the onset of food neophobia, they start developing representations about foods, either related to whether foods are edible or not (Fallon et al. 1984) or whether foods "smell good or bad" (Wagner et al. 2013). By the beginning of the second year of life, when infants watch people eating different foods, they expect agreement in food likes, revealing a social agreement model, in which infants expect a generalization of food preferences among people eating the same foods, especially if they share the same language (Liberman et al. 2016).

Role of the environment. The previous observation drives to underline the power of the social environment in the shaping of children's eating behavior (Savage et al. 2007). The younger the children, the less autonomous they are in terms of drinking and eating; meaning, they need to receive social support to drink and eat properly. This is strongly shaping what and how much children eat (Shutts et al. 2013). For instance, research has shown that infants aged between 7 and 14 weeks drink more formula in the presence of social interactions, revealing the power of social reinforcement at a very early stage (Lumeng et al. 2007). The mechanisms behind social eating are multiple: when infants are old enough, eating together enables sharing the same foods, which provides an opportunity for the repeated exposures learning mechanism to take place. Moreover, this provides a context for visual imitation. Eating together is also accompanied by conversations at the meal table, which may have the power to define likes and dislikes even at a very early stage of food discoveries (Wiggins 2019). Altogether, social eating in early childhood is a context for "emotional pervasion": language may help develop knowledge and social norms about what is "good for children" to eat which could sustain the pleasure from eating specific foods related to their sensory properties (i.e., children's perceptions of whether the food is "good to them" to eat). During this very early stage in life (as also later in life!), pleasure from eating is partly constructed by interactions with others and socially produced (Marty et al. 2018a).

The Preschool Age: A Neophobic Phase, Source of Family Tensions

Sensory capacities and cognitive development. At around the end of the second year of life, children start demonstrating strong neophobic reactions, when presented with unknown foods (Dovey et al. 2008; Nicklaus and Monnery-Patris 2018; Taylor et al. 2015). They may also demonstrate rejection reactions when offered foods they previously ate without problem. This type of neophobic behavior is a source of questioning for parents and researchers alike. Very often, this neophobic temperament is associated with a low consumption of fruit and vegetables. Some researchers suggested that this type of eating behavior could be related to a specific sensitivity to flavors, as measured by a psychometric scale evaluating "sensory sensitivity" through parental report in children aged 2–5 years old (Coulthard and Blissett 2009). Further work helped to refine this observation based on children's behavioral observations while tasting or smelling actual food tastants or odorants, showing that a higher reactivity to food smells but not to food tastes was associated with a higher neophobia score (Monnery-Patris et al. 2015). Beyond this sensory-based interpretation of the development of neophobic behavior in children, other aspects of cognitive development could account for this evolution. It has been proposed that neophobic behaviors could be adaptive to prevent the child from ingesting noxious foods once the child becomes autonomous and mobile enough to reach for foods (or objects) from the environment, without the supervision of parents or caregivers (Nicklaus and Monnery-Patris 2018). Cognitively speaking, food neophobia also seems to parallel the development of categorization abilities in children (Lafraire et al. 2016). The use of the "no" frequently associated with neophobic reactions (or rejection of some food items) can also be interpreted in relation to the emerging awareness by children of their distinction from their parents (especially their mother). They are learning during this phase to manipulate a new power, which has strong consequences on their social environment.

Food likes and dislikes. Studies conducted right at the beginning of the neophobic period show that by 2 or 3 years of age, children have established firms likes and dislikes (Nicklaus et al. 2005b) and start making less varied food choices despite the increase in their absolute nutritional needs probably in relation to their likes and dislikes (Nicklaus et al. 2005c), and their patterns of likes/dislikes are quite stable throughout childhood and adolescence (Nicklaus et al. 2004, 2005a). For instance, these studies show that the children who chose vegetables most frequently at 2–3 years were also those who consumed a higher variety of vegetables up to the age of 22 years. Thus, most likes and dislikes could be formed at an early stage during childhood and could be relatively stable through childhood. This does not preclude learning at all ages during childhood, as shown in many studies with older children, or even adults. Given the high plasticity of the affective system controlling the food system, food preferences may also find their origin in early dietary exposure. For instance, preschool-aged children may prefer more sour beverages if they had been exposed to a specific formula milk with distinct taste properties, such as extensively hydrolyzed cow milk protein formula, which may taste bitter or sour (Mennella and Beauchamp 2002). Thus, variations in flavor preferences during the preschool period may find their origin in early dietary exposures during the first years of life.

The immediate consequence of food neophobia is the fact that food or beverage likes and dislikes during this period are strongly influenced by the degree of familiarity of the child with the food or beverage. Repeated exposures may help overcome neophobic reactions, if foods are actually tasted and not only visually exposed to children (Birch et al. 1987), but the effect of repeated exposures seems to attenuate as children grow in age (Caton et al. 2014). In this study, repeated exposures to a new vegetable (artichoke) were associated with a high food consumption and to a high increase in consumption after exposure in children in their first year, but these effects were attenuated in children in their second or third year. This suggests a lower flexibility in terms of learning to like a new food as children grow into preschool age. Because of repeated exposures which still appear as a robust mechanism for learning, children learn to like the specific features of a food they are exposed to. For instance, children who had been exposed to salty or sweet tofu learn to prefer the version they had been exposed to, but not the other versions (Sullivan and Birch 1990). Although the repeated exposure mechanism is theoretically well described, reviews on its effects show small effect sizes when looking at the evolution of specific food acceptance, such as vegetables (Appleton et al. 2018). Other strategies to enhance children's vegetable acceptance, such as parental education, are not more successful (Hodder et al. 2018).

Attitudes and thinking. During the preschool stage, children start developing an abstract reasoning about foods (Michela and Contento 1986; Roedder 1999); executive functions develop, as well as brand representations (McAlister and Cornwell 2010). The emergence of more developed mental representations about foods may also be associated with side effects: for instance, children learn to associate "good for health" with "bad taste," for instance, when they are asked to eat vegetables, which taste bad to them, because "they are good for them." This may create unwanted expectations in such a way that a given product (a sweet beverage, in this study) labeled as "good for health" is less liked by children than when it has no label (Wardle and Huon 2000). Similarly, foods that are said by caregivers to "make you strong" are less eaten than foods with no label (Maimaran and Fishbach 2014). Would such unwanted expectations about the relationship between "good for you" and "bad taste" be observed in non-Western cultures? This is, to the best of our knowledge, not documented; but it is likely that any type of contradiction between information provided related to a food and individual preference is likely to produce a decrease in liking, as shown also in adults. So at this early stage in life, it appears clearly that health-oriented arguments are not a good strategy to encourage the consumption of a given food. Indeed in many studies, applying such strategies in the family context to encourage the consumption of foods is generally associated with a lower willingness to taste such foods, but in such studies it is difficult to tear apart cause and consequences. It may very well be that parents use more bribing strategies to make children taste a food when they know that their child has previously shown rejection reactions to this food and/or when they consider that this food has a specific nutritional interest (e.g., vegetable). But if these foods with specific interest are also foods which generally taste bad to children (e.g., vegetable), the application to bribing strategies may be critical in generating negative expectations about the food, resulting in a negative spiral likely to create (unwanted) educational tensions at the family table.

Role of the environment including parental feeding practices. As suggested above, another important consequence of the emergence of a peak of neophobic reactions in children is the feeding strategies adopted by parents to encourage their children to eat the rejected foods. Because neophobic reactions are often observed in reaction to the presentation of foods such as vegetables and fruit, and because most parents are aware of the health values and of the importance of consumption of such foods to maintain a healthy status, often the strategies employed by parents are applied to the same types of foods (Savage et al. 2007). (Of note, this observation cannot be generalized across the full socioeconomic gradient, since some research studies have clearly shown that in families with a lower socioeconomic status, the foods preferentially fed to children are unhealthy, indulgent foods that are perceived to be the only affordable option by parents (Fielding-Singh and Wang 2017).) Research has long shown that such strategies, such as coercion, bribing, or forcing, can have counterproductive effect by generating a negative context around eating, which acts as an unconditioned stimulus to condition rejection of the food (Savage et al. 2007). In some circumstances, rewarding the consumption of a target food with a small, nonfood reward could have a positive effect (Cooke et al. 2011). However, it is now considered that repeated exposures alone, without reward, should be the best way to promote the development of liking for a given food, even if its effects are of small amplitude (Appleton et al. 2018; Hodder et al. 2018). On the contrary, parents may also wish to restrict access for foods which are either specifically liked by children or considered "unhealthy." In this case again, the application of restriction may increase the desire to eat the "forbidden" food (Fisher and Birch 1999; Jansen et al. 2008).

During the preschool period, children start attending daycare, or preschool, depending on each country's schooling organization. This creates the condition for socialization effects to take place, and research indeed shows that social modeling has a strong effect on willingness to taste unknown foods. For instance, children are more willing to taste unfamiliar foods if adults are also eating the food (Addessi et al. 2005; Harper and Sanders 1975), if peers declare that they like the food (Greenhalgh et al. 2009; Hendy 2002), and if peers may even be more influential than adults (Frazier et al. 2012; Hendy and Raudenbush 2000). Research also showed the influence of the presence of other children on the level of food consumption: preschool children ate more pizza in groups of nine than in groups of three individuals (Lumeng and Hillman 2007). At this age children become sensitive to portion size, meaning that they eat more when larger food portions are presented to them (Reale et al. 2019).

School Age: A Curious, Autonomous Eater Still Framed by Parental Practices

When approaching school age, reasoning and reading abilities increase which facilitate the conduct of studies with children; hence many studies have focused on this age range.

Sensory capacities. While it becomes easier to study sensory perceptions as children grow older (Nicklaus 2015), the most relevant knowledge related to development of sensory aspects of eating relates to sensory preferences in children, not to perceptions. Studies show that children aged 6–12 years old find sweeter variants of beverages less sweet than teenagers or adults but prefer them (Zandstra and de Graaf 1998) and that preadolescents have a more marked preference for very sweet solutions than adults (Desor et al. 1975). When the kids were followed up to early adulthood, their preferred level of sweet taste was lower than when they were preteens, revealing a change in affective tone for very sweet products (Desor and Beauchamp 1987). Rejection of bitterness of common substances (urea, caffeine, tetralone) is observed in school-age children and is indeed applied in practice by the addition of bitter substances (tetralone or Bitrex©) to home care products to deter their consumption by children (Mennella et al. 2003). The taste of a food may influence how much children can like it. For instance, children can get to like a sweet orangeade after eight exposures, but not a sour orangeade (Liem and de Graaf 2004). Sensitivity to bitterness may strongly influence liking for bitter foods: children who are more sensitive to PROP or 6-*n*-propylthiouracyl more frequently refuse vegetables, which may taste bitter, than nonsensitive children. This was confirmed for spinach (Turnbull and Matisoo-Smith 2002) and broccoli (Keller et al. 2002), but the association is not systematically observed (Anliker et al. 1991). Similarly, children who like sourness (boys, in that study) may also like sour fruits more than children who don't like sourness (Liem et al. 2006). Saltiness may also influence how much children like and consume foods but has a minor influence compared to level of hunger, which is the n° 1 factor to explain level of food intake (Bouhlal et al. 2013).

Likes and dislikes. The influence of hunger on food choices leads to considering the importance of energy density in driving children food preferences and energy intake control. It was indeed shown, in sweet-flavored beverages which were caloric or not (based on use of sucrose or sucralose, a nonnutritive sweetener), that energy density seems to condition more stable flavor preferences than sweetness alone (Remy et al. 2014). Furthermore, this study shows that energy density is not detected on the short term after consumption (i.e., within 1 hour post consumption of a new beverage) but is learned through repeated exposures. This suggests the importance of providing foods with a constant flavor-energy density association, in order to facilitate appropriate food intake control in children and adaptive flavor preference learning. However, it is very likely that by school age, children have already developed their main food repertoire and developed marked food likes and dislikes which may strongly influence their food choices. They have extensive knowledge about meal structure, type of foods likely to be offered at a given meal (Birch et al. 1984). This implicit knowledge can guide children in making choices to optimize liking level through a competitive range of foods which may vary in terms of healthiness (Marty et al. 2018b).

Attitudes and thinking. As underlined previously, cognitive abilities evolve strongly with age, and this has been especially studied in the context of understanding the effect of cognitive cues on food decision-making, for instance, in the context of food advertisement and marketing (Story and French 2004). Credence cues as those used in (food) advertisement are likely to influence choice behavior. Before the age of 7/8 years, children tend to view ads as entertaining and informative, which makes them very vulnerable to ads (McAlister and Cornwell 2010; Michela and Contento 1986; Roedder 1999). After this age, children begin to understand the persuasive intent of ads but can still be persuaded by the emotive message of ads. Credence cues from representations and expectations, which are likely to modulate experiences pleasure (Fernqvist and Ekelund 2014). In children as in adults, brands have a positive effect on liking, which may be modulated by socioeconomic status (Sosa and Hough 2006). Thus, the presence of licensed characters has a positive effect on liking, as revealed also in preschool children (Roberto et al. 2010). The use of such characters may be more influential than the application of cognitive information about nutritional content to alter children's evaluations of foods, which may be effective in health-concerned children only (Engell et al. 1998).

The emergence of mental representations about foods makes it possible to consider the manipulation of these representations to modify food choices, if one admits the connection between intentions and actions. In other words, it may be possible to orientate children's food choices by making choice option more or less salient in children's mind, by manipulating cues in the environment that are likely to "prime" mental representation of these foods (Chambaron et al. 2015; Gaillet et al. 2013). Following on this idea, one study attempted to prime mental representations of healthy versus unhealthy foods in children by using olfactory primes (respectively, a pear odor to prime "healthy foods" and a pound cake odor to prime "unhealthy foods") and evaluated whether the presence of these olfactory primes would be associated with different choices for healthy versus unhealthy foods and whether the effect of the olfactory primes on food choices would be different in children with or without overweight (Marty et al. 2017a). In children with obesity, the fruity odor increased the likelihood of a fruit to be chosen compared to the no-odor condition, while the fatty-sweet odor had no effect on food choice. In children without obesity, both the fruity and the fatty-sweet odors decreased the likelihood to choose a fruit compared to the no-odor condition. The different patterns of results obtained in both groups of children suggest differences in the mental representations activated by non-attentively perceived olfactory cues based on weight status. This suggests important differences in attitudes toward eating associated with weight status, which were either pre-existing the development of overweight or resulting from the overweight status. Thus, the development of obesity with age is not only associated with physiological and psychological adverse effects but also to modifications of mental representation of foods which are likely to alter food choices in everyday situation.

Attitudes toward eating can also evolve because of the development of individual relationships with foods and eating (independently from weight status). Affective attitudes toward foods develop in parallel to cognitive attitudes and could be influential in determining food choices. For instance, children's attitudes were defined as nutritionally oriented versus hedonically oriented and evaluated with a direct task or an indirect task (Monnery-Patris et al. 2016). With development, the direct task (food categorization) showed a significant increase in nutrition-driven categorizations with school level, but the indirect task showed an increase in hedonically oriented attitudes, in relation to the children learning culinary scripts in his/her environment. This reveals that with development, children increase their nutrition knowledge (and are able to report so accordingly) but when asked less directly also reveal an increasing dominance of affective-based relationship to food. To note, a complementary study looking at food choices and their associations with affective or cognitive attitudes showed that children with high nutritionally oriented attitudes (whether they were studied directly or indirectly) made a *lower* number of healthy food choices when they were offered the possibility to choose among snack foods of differing healthiness values (Marty et al. 2017c). This observation that nutritionally oriented attitudes were not associated with a higher choice of healthy foods may suggest that on the contrary, hedonically orientated attitudes could help children make healthy food choices when healthy versus unhealthy choices are equally likely or in other words that pleasure of eating could be favorable to healthier choices in some circumstances.

This method to study attitudes also revealed differences among children according to weight status (Marty et al. 2017b). There was no difference in nutritionally oriented attitudes with the indirect task, but with the direct task, children with overweight or obesity revealed more nutritionally oriented attitudes than normal-weight children. This could be related to the tentative management of their overweight by their caregivers, which could drive them to declare more attention toward the nutritional aspect of eating.

Role of the environment. These few examples illustrate how children's representation about foods can be modified with development, in relation to the immersion in the social milieu in which children live. As noted by P. Fielding-Singh, "whereas low-SES parents use food to buffer against deprivation, high-SES parents provision foods to fulfill classed values around health and parenting" (Fielding-Singh 2017). Children incorporate social norms about which foods are relevant to eat in which situation, and they can adjust the food choices they make to various social situations (Marty et al. 2018b). Clearly, even at this early age, food choice decisions increase in complexity as they can be influenced by pleasure, interactions with parents, sibling, social norms, marketing messages, etc. (Lapierre et al. 2017). Mapping the role of the environment in this context becomes more difficult because it becomes almost as complex as in adults. In children as in adults, the environment in which choices are made can influence food choice. This aspect of the choice environment was explored to evaluate the effect of nudging strategies on food choices. Nudges (e.g., "any aspect of the choice architecture that alters people's behavior in a predictable way (1) without forbidding any options or (2) significantly changing their economic incentives" Thaler & Sunstein 2008, in (Cadario and Chandon 2019)) intend to make foods more or less salient, in order to facilitate or hinder food choice. Nudges applied to encourage healthy eating have proven as successful to increase healthy food choices in children as in adults (Cadario and Chandon 2019). However, modification of the food offer is not always sufficient to promote healthy eating. Providing more choice between different types of vegetables to children was seen as a means to increase their consumption and liking, because this could increase self-efficacy and feelings of autonomy (Zeinstra et al. 2010). However, in this study, the provision of more choice options was appreciated by children but did not result in an increase in vegetable liking or consumption.

Other nudging studies prime the social norms around the food consumption in order to encourage healthy eating. One study, for instance, delivered information to children suggesting that other children had eaten a large amount of carrots, no carrots, or control information (Sharps and Robinson 2015). Children ate more carrots when they believed that other children had eaten a large amount of carrots, compared to all other conditions. This example shows that perceived social norms can influence healthy eating in children. This is not always pushing children toward healthier food choices. For instance, when children are asked to choose foods for a birthday party among a selection of healthy versus unhealthy foods, they are much more likely to choose unhealthy options than when make food choice for a nutrition class (Marty et al. 2018b)!

During school age, children are given more and more autonomy regarding food purchasing, and their buying strategy develop (Hartmann et al. 2017). They buy the brand they like rather than the brands they know, and they become price-sensitive. This may open ways to encourage healthy eating by applying price increase for energy-dense, unhealthy foods. However, the long-term consequences of such strategies on mental representations of healthy versus unhealthy foods are unknown. Clearly, more research is needed to understand the effect of the environment (including social media) on twenty-first century's children's eating and drinking behavior and the conditions under which healthy and sustainable food choices are made.

Conclusions

In conclusion, drinking and eating in childhood bear a special significance considering that eating behavior is learned and that most of this learning process takes place during the early years, forming enduring memories, for the best or for the worst. Thus, early drinking and eating experience may program both food preferences and the health status of the adult. However, in relation to the importance of sensory inputs for children, and of pleasure from eating, childhood is also a period when pleasure plays a prominent role in orienting food choices. When growing into school age, children's food choices can be modulated by attitudes and social norms and start to recompose because of the internalization of social norms related to eating and drinking.

Food Neophobia in Childhood

21

Camille Rioux

Contents

Abstract

Food neophobia is defined as the reluctance to eat new foods. It has been presented as one of the main obstacles to improving children's intake of fruits and vegetables. Hence, it is essential to uncover the factors that influence the development or expression of food neophobia in childhood, in order to promote the adoption of healthy eating behaviors early in life. To date, research on neophobia has revealed a large range of factors influencing this disposition:

both individual factors (e.g., genetic influences and temperament traits) and environmental factors (e.g., early food experiences and feeding practices). Various strategies can efficiently decrease children's food neophobia expression, such as taste and visual exposure to new foods. Further studies could systematically evaluate the effectiveness of such interventions, as well as investigate the mechanisms behind positive effects.

Introduction

Children's low consumption of fruits and vegetables is a common source of concern for parents who are worried about their child's dietary diversity and quality (DeCosta et al. 2017). Food neophobia, defined as the reluctance to eat new foods, has been presented as one of the main obstacles to improving children's intake of fruits and vegetables (Cole et al. 2017; Dovey et al. 2008; Lafraire et al. 2016). The impact of food neophobia extends well beyond childhood, since dietary habits acquired during childhood largely determine dietary patterns in adulthood (Nicklaus et al. 2005). It is therefore essential to understand the mechanisms underpinning food neophobia in childhood, in order to promote the adoption of healthy eating behaviors early in life. This chapter aims to examine the question of food neophobia in typically developing children (adults and those children who have been diagnosed with a pediatric disorder such as avoidant/restrictive food intake disorder(ARFID) are out of the scope of the present chapter). The chapter starts by discussing how to characterize food neophobia and a general approach to its measurement. The second part provides an overview of the factors influencing food neophobia. Then, an evaluation of the effectiveness of different interventions aimed at reducing food neophobia is presented, highlighting on interventions based on food exposure, and further opportunities for research and interventions are explored.

Characterization and Measurement of Food Neophobia

Definition

Food neophobia is defined as the reluctance to eat new foods or the fear of new foods (Pliner and Hobden 1992). Food neophobia can be considered as a true phobia (Maratos and Sharpe 2018): it is associated with typical physiological fear responses, such as galvanic skin response (i.e., changes in sweat skin activity) and an increase in pulse or respiration rhythm. Additionally, food neophobia in children is often associated with an increased anxiety or even disgust over new foods, as well as with attentional biases toward new foods. All three components (anxiety, disgust, or attentional biases) are often found in phobias (see Maratos and Sharpe 2018 for a review of food neophobia as a true phobia). This fear of new food is assumed to serve a protective function for omnivorous species (i.e., species that do not eat just one type of food) in potentially hostile food environments (Pliner and Hobden 1992; Rozin 1979). Rozin (1979) described food neophobia as an efficient adaptive strategy for children to avoid the risk of ingesting new (and thus potentially poisonous) food items, once they are mobile enough to reach for, and consume food available in their proximal environment. Some authors have suggested that this view explains why plant-based foods such as fruits and vegetables are the privileged targets of food neophobia as plants often contain secondary compounds that can be toxic to human and no visual features reliably signal which plants may contain these toxic compounds (Cashdan 1998; Wertz and Wynn 2014; Włodarczyk et al. 2018).

The notion of *novelty* plays a central role in the definition of food neophobia. This notion has to be broad since a rejected new food can be (i) a food item the child has never encountered before or (ii) a food that has been encountered before but, due to variations in color, shape, preparation, etc., is not currently recognized by the child. This means that *new* foods can include items previously accepted by the child, well known from the caregivers' perspective, and frequently consumed in the cultural area the child belongs to (e.g., a tomato for most European children). In other words, it is from the child's perspective that the notion of novelty has to be analyzed. A new food item can be *genuinely new* (e.g., a dragon fruit for most European children) or *perceived as new* (e.g., a tomato cut into cubes instead of slices). Some authors have suggested that this view also explains why fruits and vegetables are the privileged targets of food neophobia as they are more likely to exhibit changes in color, shape, or preparation between servings than other foods (e.g., starchy foods) and therefore can be more easily perceived as new by children, even though they have been encountered in other forms before (Harris 2018).

In both cases (genuinely new food or food perceived as new) the presented food is not subsumed under a known category (e.g., the category *tomato*), and properties of the food cannot be inferred (such as the property *edible* if the presented food would be categorized as a tomato). Categorization is a fundamental cognitive process that allows us to organize objects into groups that share common characteristics (Murphy 2002). One main use of categories is to make predictions about new items (e.g., tomatoes are edible; therefore if a new item is categorized as a tomato, one can infer that this new item is edible) (Murphy 2002). Accordingly, some researchers suggest that food neophobia is closely intertwined with the development of categorization abilities in the food domain, abilities that largely improve around 2–3 years of age as children become more mobile (Harris 2018; Lafraire et al. 2016; Nicklaus and Monnery-Patris 2018; Rioux et al. 2016; Rioux et al. 2017b). More precisely, Rioux and colleagues recently found a robust association between food neophobia and food categorization abilities in 2- to 6-year-old children (Rioux et al. 2016; Rioux et al. 2017b). Categorical judgments are mainly made based on visual cues as neophobic reaction results in new foods being rejected on mere sight, even before being tasted or swallowed (Cashdan 1998; Harris 2018; Dovey et al. 2008; Lafraire et al. 2016). Vision is indeed the main sensory component predicting whether a child would try a new food (Nicklaus and Monnery-Patris 2018).

Trait Neophobia Versus State Neophobia

Food neophobia is most often conceptualized as a personality trait, a continuum along which children (and more generally individuals) can be located in terms of their stable and persistent propensity to avoid new foods (Alley 2018; Dovey et al. 2008; Pliner and Hobden 1992). Indeed, as listed below, food neophobia exhibits most of the characteristics known as supporting the definition of a personality trait:

(a) *Heritability*. For instance, comparing food neophobia between monozygotic twins (sharing all their genes) and dizygotic twins (sharing on average half their genes), researchers found that food neophobia is highly heritable (see section "Genetic Influences" below).
(b) *Linked to biological mechanisms (*e.g., *neurochemical*, *neuroanatomical)*. A handful of studies have revealed implication of neural mechanisms in food neophobia (Klarer et al. 2014).
(c) *Early ontogenetic appearance*. Food neophobia appears in the first few years of life and is fully expressed by preschool age (see section "Developmental Trend and Gender Differences" below).
(d) *Counterparts exist in nonhuman primates as well as in certain other social mammals*. Neophobic behaviors are commonly observed among omnivorous species, such as capuchin monkeys or rats (Rozin 1979).
(e) *Generation of important individual differences*. Pliner and Hobden (1992) developed a scale to assess the level of individual food neophobia and found a great inter-individual variation in respondents' answers: some respondents obtained low scores and could be defined as neophilic, while others obtained high scores and could be defined as neophobic.

Nevertheless, food neophobia does not seem to exhibit one important characteristic of a personality trait: to be relatively enduring and predictive of conceptually coherent outcomes. Indeed, while neophobia is thought to be relatively stable during early childhood, most researchers agree that, in late childhood, the expression of food neophobia decreases (see section "Developmental Trend and Gender Differences" below). Additionally, food neophobia is only partially predictive of coherent behavioral outcomes, since most studies found only medium correlations between neophobia and willingness to try new foods. A recent review of instruments developed to measure food neophobia (Damsbo-Svendsen et al. 2017) revealed that the highest correlation between neophobia and willingness to try new foods found in the literature was 0.47. The lowest correlation was 0.11 (correlation coefficients range from −1 to 1. These two end points mean that two constructs are perfectly negatively/positively correlated, while a coefficient of 0 means that the two constructs are not at all correlated). This led some authors to rather address neophobia as a state (Alley 2018), a transitory negative emotion (in the case of neophobia, fear), elicited by the idea of ingesting a specific food, in a specific context. In this view, the expression of food neophobia can be unstable, age-dependent, and modulated by context modalities such as food properties, individual's mood, or social modeling (Alley 2018).

To reconcile the distinction between food neophobia as a trait or as a state, the concept of disposition is enlightening (Mumford 1998). Dispositions are seen as genuine and functional properties ascribed to objects, kind, or persons (e.g., the disposition *fragile* for a glass). To each dispositional property corresponds a typical manifestation (e.g., *shatter when struck* for a fragile glass), explained by a physical/biological state or mechanism (possibly unknown). Importantly, to possess a disposition is not to be in a particular state but to be liable to be in a particular state when certain circumstances are met (e.g., *if* the fragile glass is struck, it shatters). Neophobia could then be viewed as a disposition. Only when neophobic children are presented with new foods, they will present rejection behaviors. The circumstances are met when a food is genuinely new or perceived as new. As children develop and get older, fewer things are new for them, thus the circumstances that trigger food rejection behaviors occur more and more rarely, potentially explaining the non-stability of neophobia during the lifespan.

Measurement of Food Neophobia in Childhood

Questionnaires

Methodologically speaking, it appears that when neophobia is conceptualized as a trait, questionnaires are used (Alley 2018). This is due in large part to ease and rapidity of administering such measures (Alley 2018). The first researchers to develop a food neophobia scale were Pliner and Hobden (1992), who designed the Food Neophobia Scale (FNS). This questionnaire asks adult participants to indicate the extent to which they agree, or not, with statements about consumption of new foods, such as "If I don't know what is in a food, I won't try it" (see Fig. 1). Originally devised to score adults' neophobia, the FNS was rapidly adapted to measure children's neophobia (e.g., "If my child does not know what is in a food, she/he won't try it," Children Food Neophobia Scale (CFNS); Pliner 1994). This scale has been widely used to measure food neophobia in childhood and successfully

Fig. 1 Items of the original Food Neophobia Scale. (Retrieved from Pliner 1994)

I am constantly sampling new and different foods
I don't trust new foods.
If I don't know what is in a food, I won't try it.
I like foods from different countries.
Ethnic food looks too weird to eat.
At dinner parties, I will try a new food.
I am afraid to eat things I have never had before.
I am very particular about the foods I will eat.
I will eat almost anything.
I like to try new ethnic restaurants.

adapted (e.g., the Fruits and Vegetables Neophobia Instrument (FVNI), the Food Neophobia Test Tool (FNTT), the Questionnaire pour Enfant de Neophobie Alimentaire (QENA); see Damsbo-Svendsen et al. 2017 for a recent review on tools to measure food neophobia). It has also been translated into several languages, for instance, French, Spanish, Chinese, Swedish, and Italian (Damsbo-Svendsen et al. 2017).

Both auto-assessment scales (i.e., children respond for themselves) and hetero-assessment scales (i.e., caregivers respond for their children) are used. Hetero-assessment scales are commonly used with children younger than 5–6 year olds (Alley 2018). It is important to have in mind that hetero-assessment scales give only approximation of children's own food behaviors. There are potential social desirability biases (i.e., parents may present a better image of their children or themselves), or parents may sometimes project their own behaviors onto those of their children (Alley 2018). In fact, caregivers' reports of their children's neophobia only moderately correlate with children's reports of their own neophobia (e.g., $r = 0.3$ in Pliner 1994). Both auto-assessment scales and hetero-assessment scales also have the potential pitfall of memory errors (Alley 2018). Additionally, recent reviews (Alley 2018; Damsbo-Svendsen et al. 2017; de Lauzon-Guillain et al. 2012) pointed out that several existing scales measuring children's food neophobia are not completely reliable, potentially leading to deceptive conclusions. For instance, the widely used FNS/CFNS failed to validate construct validity and/or temporal reliability (de Lauzon-Guillain et al. 2012). This means that they can measure something else than neophobia (failure to validate construct validity) and provide different outcomes if completed several times (failure to validate temporal reliability). This urges caution of the choice of the scale selected to measure food neophobia in children.

Willingness to Try New Food Tasks

Rather than asking people about consumption of new food in general, one can attempt to determine actual consumption of specific new foods (Alley 2018). There are some clear advantages to using direct consumption measures. When faced with a request to actually select or eat new food items, young children might provide better information on the attractiveness of particular new food items, than when expected to deal with a purely verbally based assessment, as the actual presence of food is believed to trigger the emotional response. This strategy is actually often used when food neophobia is considered as a state. However, there are a multitude of factors that shape an individual's food choices and vary across time and situation (such as hunger level) and make it difficult to create a test that purely reflects variation in food neophobia (Alley 2018). These measures of food neophobia are thus better treated as a mean to test the construct validity of questionnaires (Alley 2018; Damsbo-Svendsen et al. 2017).

The most common task used is the "Willingness to Try New Food" task (WTNF), in which children are presented with new foods and are asked to try them. The first WTNF task was developed by Pliner and Hobden (1992). It consists of participants ranking six a priori new foods from five categories (salads, dips, crackers, vegetables, and snacks) in order of their willingness to taste them (in a fictitious subsequent tasting session). Pliner and Hobden's food task has been widely used and largely adapted (Alley 2018; Damsbo-Svendsen et al. 2017). Some authors use pictures of foods instead of actual foods, while others use real foods. Some authors add familiar foods to the task and compare the number of familiar foods tasted to the number of new foods tasted. Further, in some WTNF, children have to taste the foods, while on the original task, they just had to indicate which foods they were willing to taste (see Damsbo-Svendsen et al. 2017 for a review of WTNF tasks). Usually, the willingness to try new foods is moderately to highly correlated with scores on food neophobia scales.

Developmental Trend and Gender Differences

Most researchers agree that neophobic behaviors appear at around 2 years of age, when children become more mobile and could find themselves outside parental guidance (see Dovey et al. (2008) and Lafraire et al. (2016) for reviews on the developmental pattern of food neophobia). A few recent studies have also discovered precursors of food neophobia in infancy, though after weaning (Harris 2018; Moding and Stifter 2018). There is however a contention in the literature as to whether neophobic behaviors increase progressively thereafter or remain stable during early childhood. On the one hand, some authors found that 5-year-old children tend to be more neophobic than their younger counterparts. On the other hand, other authors did not find any correlation between food neophobia and age within the 2- to 6-year-old age range (see Lafraire et al. 2016 for a review; see Table 1). Longitudinal studies on food neophobia are scarce and are needed to investigate further its developmental trend. Nevertheless, there is a relative consensus that in late childhood/beginning of adolescence, the expression of food neophobia decreases, until it reaches a relatively stable expression in adulthood (Dovey et al. 2008). Actually, the mere fact that fewer things are new for an adult or an adolescent than for a child automatically reduces the expression of food neophobia (Cooke and Wardle 2005).

Concerning potential gender differences, most studies investigating food neophobia during childhood did not find gender differences (see Dovey et al. 2008 for a review). Though some studies have found differences in both directions (i.e., girls being more neophobic than boys and vice versa, see Dovey et al. 2008), however, overall there is still limited evidence for a robust association between food neophobia and gender (Dovey et al. 2008).

Food Neophobia and Its Association with Diet Quality and Weight Status

Food neophobia has been shown to affect children's diet and food preferences. The food items that are rejected the most are certainly fruits and vegetables (see Kral

Table 1 Summary of studies relating food neophobia to age during early childhood

Publication	Population	Measurement instrument	Correlation with age
Addessi et al. (2005)	2–5 years, the USA	WTNF task	No association
Barends et al. (2014)	12–23 months, the Netherlands	WTNF task	Positive
Cashdan (1994)	1–10 years, the USA	Questions on reaction to novel food	Positive
Cooke et al. (2003)	2–6 years, the UK	CFNS	No association
Koivisto-Hurti & Sjoden Koivisto-Hursti and Sjöden (1996)	2–9 years, Sweden	CFNS	No association
Monnery-Patris et al. (2015)	20–22 months	Children's Eating Difficulties Questionnaire (Rigal et al. 2012)	No association

(2018), Cole et al. (2017), and Nicklaus and Monnery-Patris (2018) for reviews on food neophobia and its association with diet quality and weight status). Numerous studies have indeed uncovered negative associations between food neophobia and intake of fruits and vegetables (Cole et al. 2017; Nicklaus and Monnery-Patris 2018, see Table 2). This often goes along with a negative association between food neophobia and liking for these food products (Henriques et al. 2009; Laureati et al. 2015). Besides fruits and vegetables, the intake of other food groups such as meat and protein are also negatively impacted by food neophobia (Kral 2018). Therefore, food neophobia in children is associated with decreased dietary variety and quality (Kral 2018) along with a possible lack of essential micronutrients and fibers that are necessary for a normal and healthy child development (Dovey et al. 2008; Lafraire et al. 2016).

Regarding weight status, studies that have systematically examined the relationship between food neophobia and BMI scores are scarce and have produced mixed results. Some studies found no association between BMI and food neophobia, but others found that neophobic children tend to be overweight, as they seem to eat few fruits and vegetables and high quantities of discretionary foods (Cole et al. 2017). Overall there is limited evidence to date for a robust association between food neophobia and BMI scores in children and adolescents (Kral 2018).

Food Neophobia and Its Relationship with Food Pickiness

Food neophobia is often associated with food pickiness, another type of food rejection (neophobic children are often also picky and vice versa) (Dovey et al. 2008). While food neophobia is well defined, the definition of food pickiness is more imprecise and a matter of contention. Generally, it is defined as the rejection of new

Table 2 Summary of studies relating food neophobia to dietary intake outcomes. (Adapted from Nicklaus and Monnery-Patris, 2018)

Publication	Population	Measurement instrument	Dietary intake outcomes in neophobic children
Cooke et al. (2003)	2–6 years, the UK	CFNS (only six items)	Lower consumption of fruits, vegetables, meat, and egg
Cooke et al. (2006)	4–5 years, the UK	CFNS (only six items)	Lower consumption of fruits, vegetables, meat, and egg
Galloway et al. (2003)	7 years, the USA	CFNS	Lower consumption of vegetables
Helland et al. (2017)	2–3 years, Finland	CFNS	Lower consumption of fruits, vegetables, and fish
Maiz and Balluerka (2016)	8–16 years	CFNS	Lower consumption of fruits, vegetables, and fish. Higher consumption of sweets and candy
Nicklaus et al. (2005)	4–22 years	CFNS	Lower consumption of all food groups
Perry et al. (2015)	24 months	CFNS	Lower consumption of fruits and vegetables. Higher consumption of discretionary foods

and previously accepted foods, along with the rejection of certain textures that are rejected after the tasting step (i.e., foods are tasted but not swallowed) (Dovey et al. 2008; Lafraire et al. 2016; Rioux et al. 2017a). Rioux and colleagues have recently suggested that theoretically speaking, food neophobia and pickiness may capture a similar kind of fear for new and potentially toxic foods. Indeed, as with food neophobia, pickiness presents at least one signature feature of a phobia, that is to say an increased disgust over food items in general (Rioux et al. 2017a). Moreover, texture rejection, an important component of food pickiness, can prevent children from the ingestion of decayed foods that can potentially become toxic foods (as texture can inform of the decay of a food). Additionally, the authors suggested that what is thought to be rejection of familiar foods is probably rejection of foods perceived as new for children (see section "Definition"). Nevertheless, neophobia and pickiness appear to be two behaviorally distinct kinds of food rejection (Dovey et al. 2008; Lafraire et al. 2016; Rioux et al. 2017a). Although the motivation for rejection may be the same, caregivers appear to distinguish food neophobia from pickiness: distinguishing rejection due to texture (pickiness) from rejection due to sight (neophobia) and rejection after the tasting step (pickiness) from rejection before the tasting step (neophobia).

Typology of Factors Influencing Food Neophobia

Extensive research on food neophobia has revealed a large range of factors influencing this disposition in childhood. They can be broadly divided into two categories reviewed below: intrinsic/individual factors and extrinsic/social or environmental factors (see Fig. 2).

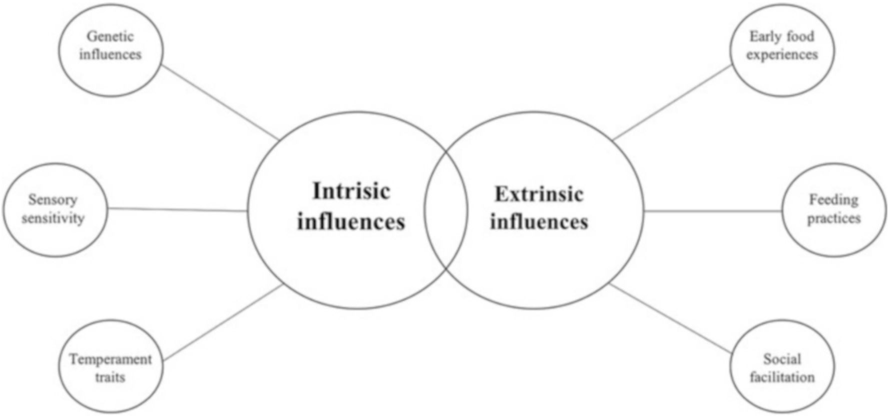

Fig. 2 Typology of factors influencing food neophobia (Adapted from Lafraire et al. 2016)

Intrinsic Influences on Food Neophobia

Genetic Influences

There is evidence that points to genetic influences underlying food neophobia. Studies to establish the contribution of genetic factors to food neophobia are of one main type: twin studies (see Cooke 2018 for a review). Twin studies compare similarity between monozygotic twins who share 100% of their genes and dizygotic twins who share 50% of their genes. These studies produce robust estimates of the contribution of genes on food neophobia (e.g., Cooke et al. 2007) and generally revealed that food neophobia is highly heritable (from 58% to 78% of the variance of food neophobia could be explain by genetic factors; Cooke 2018).

The Role of Sensory Sensitivity

The anticipated sensory characteristics of foods (e.g., smell, texture, etc.) are recognized as a key determinant of decisions about whether to accept or reject a food (Farrow and Coulthard 2018; Wadhera and Capaldi-Phillips 2014), and evidence suggests that there is individual variety in how children perceive and evaluate sensory information, influencing food neophobia. Indeed, it has been shown that sensorily hypersensitive children are more likely to be more neophobic – hypersensitive children are more able to identify subtle changes in the sensory properties of stimuli, such as changes in smell, for instance (Blissett and Fogel 2013; Farrow and Coulthard 2018). Monnery-Patris et al. (2015) have explored smell and taste sensitivity in children by asking them to taste different solutions representing basic tastes, such as sweet or salty, and sniff different solutions representing pleasant or unpleasant odors and found that food neophobia in toddlers was correlated with smell sensitivity, but not taste sensitivity. It has also been shown that neophobic children sniff new food from a further distance compared to their non-neophobic counterparts (Farrow and Coulthard 2018). Other studies have also revealed an association between tactile sensitivity and food neophobia (Smith et al. 2005). For instance, it has been shown that tactile defensiveness (overreactions to the experiences of touch or withdrawal responses to some typically inoffensive tactile stimuli perceived as offensive) is associated with high food neophobia (Smith et al. 2005). Together these findings indicate that neophobic children may experience exaggerated reactivity to olfactory and tactile food cues. It is interesting to note that these cues can be perceived before the food stimuli is tasted or swallowed, which is consistent with the claim that food neophobia serves a protective function (Rozin 1979).

Relationship Between Food Neophobia and Temperament Traits

Temperament traits are defined as individual differences in emotional and behavioral reactivity that are relatively stable (Nicklaus and Monnery-Patris 2018). Several temperament traits have been found to be associated with food neophobia (see Lafraire et al. 2016 and Nicklaus and Monnery-Patris 2018 for reviews). It is assumed, for instance, that food neophobia is associated with increased anxiety in children (Lafraire et al. 2016; Nicklaus and Monnery-Patris 2018). More precisely, it has been shown that girls with food neophobia are more anxious than their non-neophobic counterparts. Sensation-seeking has also been found to be negatively associated with food neophobia (Nicklaus and Monnery-Patris 2018). Children who are greater sensation-seekers, that is to say, requiring a lot of stimulation to reach the appropriate level of awakening, tend to be less neophobic. Some researchers have also proposed that food neophobia could be a direct consequence of one specific dimension of temperament: approach/withdrawal (Moding and Stifter 2018). This dimension characterizes individual differences in responses to new stimuli, such as toys, people, or situations. Children who are low in approach tend to show negative affect toward new stimuli and withdraw from them (Moding and Stifter 2018). In their longitudinal study, Moding and Stifter (2018) showed that children with low approach tendencies at 18 months had higher levels of food neophobia at 4.5 years of age. This set of studies raises the question of the selectivity of neophobia and suggests that food neophobic children are likely to present neophobic behavior in other domains as well (as revealed, for instance, in Moding and Stifter 2018).

Extrinsic Influences on Food Neophobia

Early Food Experiences and Feeding Practices

Several studies have proposed that children’s immediate environment is important in shaping their food neophobia (prenatal food experiences and feeding practices). Regarding prenatal and early experiences, evidence suggests that children are more willing to taste new flavors if they have experienced them through amniotic fluid (Cooke 2018; Mennella et al. 2001). Indeed, infants show less negative facial expressions to carrots when introduced to the diet if their mother had drunk carrot juice during the third trimester of pregnancy (Mennella et al. 2001). Regarding the influence of children’s post-birth environment, certain feeding practices significantly affect food neophobia expression (Cooke 2018; Lafraire et al. 2016). For instance, commonly used parental feeding strategies such as food rewards, or pressure to eat, increase the expression of children's food neophobia (DeCosta et al. 2017; Nicklaus and Monnery-Patris 2018; Lafraire et al. 2016). On the other hand, breast-feeding and offering children a high variety of vegetables at weaning seem to have a positive impact on food neophobia (Cooke 2018; Nicklaus and Monnery-Patris 2018). It is nevertheless important to note that most studies on food neophobia are not longitudinal (children are not followed during several months or years and are instead seen only once); therefore it is difficult to know the causality of the effects (is it because a child is neophobic that caregivers use more negative feeding practices or the inverse?).

Social Facilitation

Another far and wide studied extrinsic factor influencing food neophobia is social facilitation (Lafraire et al. 2016; Nicklaus and Monnery-Patris 2018), defined as an increase in the probability of performing a class of behavior in the presence of conspecifics performing the same class of behavior at the same time (see Herman 2015 and ▶ Chap. 14, "Social Influences on Eating" by Higgs this volume, for a review of the food social facilitation effect). Put differently, social facilitation means that when a child eats in the presence of others eating food, her behavior is socially facilitated toward food intake. It has been shown, for instance, that toddlers are more willing to taste a new food if they see an adult eat it first (Addessi et al. 2005). Adults can serve as models for food acceptance, e.g., an encouraging teacher or a friendly visitor in a classroom can foster food acceptance in young children. However social facilitation with peers (i.e., other children) seems more effective (Lafraire et al. 2016). Social facilitation is enhanced when models are familiar to children (Harper and Sanders 1975) and are "prosocial" (i.e., nice and helping) (Hamlin and Wynn 2012). Nevertheless, questions remain on what aspects of modeling are actually effective on children's food acceptance: the act of consuming the food, facial expressions or verbal messages that are associated with parental or peer consumption, or a combination of these factors (Blissett and Fogel 2013).

Interventions to Overcome Food Neophobia

Various reviews of existing interventions show that certain strategies efficiently decrease children's food neophobia (Appleton et al. 2016; DeCosta et al. 2017; Keller 2014; Knai et al. 2006). These interventions can generally be divided into two main types: interventions focusing on the eating context and interventions focusing on the food itself (see Appleton et al. (2016) and DeCosta et al. (2017) for reviews). The interventions focusing on the eating context usually manipulate extrinsic factors known to influence neophobia, mentioned in the section above (see, for instance, Laureati et al. 2014, for an intervention in schools using peer social facilitation to decrease neophobia). Therefore, these interventions will not be further developed in this chapter (see DeCosta et al. (2017), for a review of the interventions focusing on the eating context).

Regarding the interventions based on the food itself, three types of interventions are widely used to decrease food neophobia: flavor-flavor learning, flavor-nutrient learning, and mere exposure (Appleton et al. 2016). Ninety percent of the interventions based on the food adopted at least one of these methods (Appleton et al. 2016). Flavor-flavor learning (FFL) and flavor-nutrient learning (FNL) are two strategies based on conditioning: an association between a neutral conditioned stimulus and a positive unconditioned one will trigger a positive attitude toward the conditioned stimulus, even when the unconditioned stimulus is latter removed. The principle of FFL is that the pairing of a target food (often a new vegetable), with a taste that is already liked (e.g., a sweet or salty taste), should trigger positive attitude toward the target food. The principle of FNL is that the pairing of a target food, with a food with high-energy density (e.g., enriched in fat), should trigger positive attitude toward the target food. Both FFL and FNL have been shown to positively enhance new fruit or vegetable acceptance in children (Appleton et al. 2016; Caton et al. 2013; Nicklaus and Monnery-Patris 2018). For instance, Caton et al. (2013) found that infants accepted more plain artichoke puree at posttest, compared to baseline, when they had been offered ten times artichoke puree enriched in fat (FNL strategy). The third type of strategies used is mere exposure (also named repeated exposure). According to the mere exposure theory (ME), the exposure to one instance of a given food stimulus is sufficient to trigger a more positive attitude toward a subsequent instance of that particular stimulus, because it increases its familiarity (Zajonc 1968). There is considerable support for the success of such ME on food acceptance in controlled experimental settings, as well as in more ecological settings like home or school environments (see Cooke 2007 for a review). For instance, some researchers asked caregivers to expose their 5- to 7-year-old children to bell peppers (an a priori new vegetable) for eight consecutive days and found that, compared to a control group, children in the exposure group ate significantly more bell peppers at posttest than at baseline (Cooke 2007).

Despite the apparent efficiency of these three strategies (FFL, FNL, ME), it has been argued that conditions within studies are often confounded and that, in many studies that purported to measure conditioning effects (FFL and FNL interventions), exposure was actually not controlled for (Appleton et al. 2016). In fact, studies comparing directly these three strategies often found no advantage of conditioning (FFL and FNL) over mere exposure (ME) (Caton et al. 2013; Nicklaus and Monnery-Patris 2018). For instance, Caton et al. (2013) found that infants who had been exposed to plain artichoke puree (ME condition) accepted plain artichoke puree as easily at posttest, as children who had been exposed to sweetened puree (FFL condition) or puree enriched in fat (FNL condition). As mere exposure interventions are easier to implement and seem to be as effective as FFL/FNL interventions, ME appears to be the simplest choice to enhance positive attitude toward fruits and vegetables and to decrease food neophobia (Appleton et al. 2016). It is nevertheless important to note that many exposure studies have failed to adopt an appropriate control group against which to compare the intervention group's changes in food attitudes (Appleton et al. 2016; Dazeley et al. 2012). For future investigations of ME, it is important that control groups are closely matched to experimental groups in terms of demographics but also in terms of the food tested at baseline and posttest (equivalence in familiarity, liking, energy density, food category, etc.).

Taste Exposure

In the food domain, an exposure can occur in different modalities (taste, sight, smell, etc.). The majority of studies on ME have only investigated whether taste exposure will be efficient to decrease food neophobia (see Cooke (2007) and Dazeley et al. (2012) for reviews). This central interest in taste exposure may be due to the seminal study of Birch et al. (1987). The authors directly compared the effect of visual and taste exposure on preschoolers liking for new fruits. They found that visual exposure led to an increase in liking for the appearance of the new fruits, while taste exposure led to an increase in liking for both the appearance and taste of the new fruits (Birch et al. 1987). Subsequent research on ME focused on taste exposure as it was thought to be necessary to enhance consumption of new foods like fruits and vegetables. Nevertheless, it could be argued that visual exposure would not likely directly influence taste preferences but can influence instead willingness to taste exposed foods (Dazeley et al. 2012).

While the benefits of repeated taste exposure are evident (Cooke 2007), these strategies may be difficult to implement outside the laboratory since 10–15 taste exposures to a new food item may be needed for its successful acceptance in preschool-aged children (Cooke 2007). This is a number greater than most parents are willing or able to provide (Dazeley et al. 2012). This number may even increase for highly neophobic children (de Wild et al. 2017) that yet need the most this kind of intervention.

Visual Exposure

Because neophobic reactions result in foods being rejected on mere sight, before being tasted (Cashdan 1998; Dovey et al. 2008; Lafraire et al. 2016), it is reasonable to suppose that *visual* exposure could be as efficient to reduce food rejections than *taste* exposure. Indeed, according to some authors, a child will taste a food (e.g., a tomato) only if it visually matches him/her prototypical food representations in mind (e.g., the red and round tomato) (Dovey et al. 2008; Lafraire et al. 2016). Additionally, while after weaning infants are normally familiarized with the taste of several vegetables (through pureed baby foods), they often are not familiarized with the visual aspect of the whole vegetables. Furthermore, interventions seeking to enhance positive attitudes toward fruits and vegetables through taste exposure also increase the visual familiarity of the target. In studies that offer children repeated taste exposures, the food is both seen and tasted at each session, and it is difficult to isolate the effect of taste exposure alone (Dazeley et al. 2012). It is therefore plausible that the effectiveness of taste exposure interventions is partly due to a greater visual familiarity with the target food (Dazeley et al. 2012). Finally, from a practical point of view, it could also be less effort for caregivers to provide visual exposures to food (e.g., through picture books), especially if it occurs outside mealtimes that carry the stress associated with ensuring that the child is consuming a healthy diet (Dazeley et al. 2012).

There is actually an encouraging body of evidence to support research into the impact of visual exposure on children food neophobia (see Dazeley et al. 2012 for a review). For example, some authors provided 2- to 6-year-old children with picture books about leeks or carrots. They showed that toddlers consumed more of the vegetable they had seen in their picture book (carrot or leek), compared to a matched control vegetable. Importantly, some authors found similar changes in new vegetable acceptance for highly neophobic children and non-neophobic children (Rioux et al. 2018). This suggests that visual exposure might be employed successfully with children for whom taste exposure has been showed to be less efficient (de Wild et al. 2017). Furthermore, Osborne and Forestell (2012), one of the few authors which directly compared visual and taste exposure since Birch et al. (1987), found that visual exposure was as efficient as taste exposure to enhance willingness to taste new fruits in 4- to 8-year-old children. Interventions that use a more direct contact with unfamiliar food and enable children to play with it (so as children are not just passively exposed to pictures) also show promising results (Coulthard and Ahmed 2017; *Sapere Method*, Nicklaus and Monnery-Patris 2018). For instance, Coulthard and Ahmed (2017) found that children who played a game of bingo with real fruits and vegetables consume more of a new fruit than children who played the same game with picture stimuli. Additionally, they found that children who played the bingo game with pictures ate more of a new fruit after the session than children who simply viewed and sorted the same pictures (Coulthard and Ahmed 2017). The potential for visual exposure to enhance children's willingness to taste new foods therefore deserves further exploration, especially to investigate whether it produces long-term effects. Indeed, there is a dearth of research evidence supporting long-term changes in children's diets after taking part in exposure interventions (Appleton et al. 2016; Knai et al. 2006).

The Mechanisms Behind Mere Exposure

While a large body of research has investigated the potential effect of mere exposure, there is no consensus on its mechanistic explanation. It is yet important to understand the mechanisms behind such a strategy if we want to create the most possible effective interventions to decrease neophobia. One of the mechanisms by which exposure is assumed to engender a positive attitude toward a stimulus is thought to be "learned safety" (Cooke 2007): repeated ingestion of an unfamiliar food without negative post-ingestion consequences (e.g., nausea, illness) will lead to increased acceptance of this food (Cooke 2007). Nevertheless, the recent evidence that mere visual exposure could also enhance the acceptance of unfamiliar food items casts doubt on whether the "learned safety" hypothesis entirely explains the positive effect of exposure. There is an alternative explanation, which embodies a cognitive approach to the mere exposure effect (Aldridge et al. 2009; Lafraire et al. 2016). By increasing the amount of experience an individual has with any stimulus, repeated exposure increases the ease and speed with which the stimulus is categorized (Aldridge et al. 2009): when a food item is first presented to a child, it is organized into categories relating to its characteristics (Murphy 2002). Knowledge gained through this first encounter allows for easier and faster categorization, when subsequently presented with the same or a similar food item (Aldridge et al. 2009). This gained ease in categorization is then hypothesized to lead to a positive attitude toward the stimulus. A recent study partly supports this hypothesis. Using a sorting task involving pictures of fruits and vegetables to assess categorization performances, Rioux et al. (2018) showed that categorization performance was associated with food neophobia disposition. Moreover, in the same study, the authors found that a visual exposure intervention (table mats with pictures of new vegetables were displayed on school canteen tables for several days) was more efficient for those children with good categorization performance (Rioux et al. 2018). Efficiency of the intervention was measured via Willingness to Try New Vegetable tasks proposed at baseline and after the intervention (see section "Willingness to Try New Food Tasks"). Therefore, it seems that an ease in categorization indeed leads to more positive attitude toward exposed stimuli. Nevertheless, it remains to be seen if visual exposure intervention actually increases food categorization performances. There are few hints to think it could be the case. For instance, it has been recently shown that a short exposure to few animals through a class trip to a zoo enhances animal category-based induction performances (Badger and Shapiro 2019).

Summary and Further Directions

Children moving into the second year of life have to make quite complex decisions about the foods they will eat and accept. Food neophobia, reviewed in the present chapter, is one of the strategies infants and children employ to deal with this complex problem of food selection. There has been considerable research on the topic, but some questions remain. First, there is a lack of cross-cultural studies to investigate the influence of culture on children's food neophobia. Most studies on the topic have been conducted in Western and rich countries (Nicklaus and Monnery-Patris 2018). It will be valuable to investigate whether food neophobia is universally observed and especially investigate children's neophobia in rural communities practicing more traditional subsistence. This investigation will first require to have tools to measure neophobia validated in several cultures (not merely translated), which is rarely done. Second, longitudinal studies on food neophobia are scarce and are much needed if we want to have a clear picture of its developmental pattern. The evidence provided by the rare longitudinal studies reveals that precursors of food neophobia are already present in infancy and contrasts with the common picture that neophobia arises as toddler become mobile (Dovey et al. 2008). Third, further studies could systematically evaluate the effectiveness of interventions aimed at decreasing food neophobia, investigate the mechanisms behind positive effects, and test for long-term effects (Appleton et al. 2016). Systematic comparison between interventions can prove difficult because a wide variety of outcome measures are used to assess efficacy (e.g., trait neophobia, willingness to try exposed foods, food consumption in grams) but is of interest to identify those of greatest benefit.

Eating in the Elderly

22

Claire Sulmont-Rossé

Contents

Abstract

Although having a good diet is recognized to be important for successful aging, malnutrition is one of the highest threats to the health, autonomy, and well-being of older adults. Several medical associations and public policies have proposed dietary guidelines directed at elderly people to ensure a healthy nutritional status and prevent the onset of disease. However, several studies have demonstrated the inadequacy of food intake in the elderly population. A decline in energy and protein intake is frequently observed with aging, in particular for the very old and/ or dependent people. The aging process, even when it takes place normally, is associated with several changes likely to have an impact on food intake and the nutritional status of the elderly people such as impairment in appetite regulation, oral health, and chemosensory perception. Beyond these changes, the life of an

elderly individual is marked by “breaking points” which may have a social origin (e.g., retirement, widowhood, fall in income) or a medical origin (e.g., onset of a disease, dementia). These breaking points are likely to disrupt their lifestyle habits and in particular their eating habits, leading to new eating habits, which are sometimes inappropriate and at the origin of unbalanced diet. In the context of an aging population, it is therefore crucial to combine meal interventions and food development with nutritional strategies to stimulate appetite and sustain food intake in the older individuals, in order to support active and healthy aging.

Introduction

Aging is a universal, natural, and physiological mechanism which is imposed upon somebody without choice. During this period, a healthy human being is affected by impairments which can weaken him. Functional deficiencies and cognitive capacities progressively decrease during aging, inducing a vulnerable status which increases the risk of disease and dependence. But at what age does one become an “elderly” people? For the professionals in marketing, the consumer becomes a senior at the age of 50 years old, while for the public authorities, the person is considered a senior between 60 and 65 years old (the access age to certain social financial supports) (Ogereau 2019). In the labor market, the average age of retirement is 64 for the men and 61 for the women (OECD 2017). Finally, for health professionals, the old age begins over 70 with the onset of chronic diseases (Jaul and Barron 2017).

All over the world, the proportion of elderly people in the population is growing quickly. According to data form World Population Prospects, the number of persons aged 65 or over is expected to more than double by 2050, rising from 612 million in 2015 to 1.5 billion in 2050 (United Nation 2017). In 2018, there are an estimated 681 million people aged 65 or over in the world, comprising 9% of the global population. Currently, Europe has the greatest percentage of population aged 65 or over (18%), but rapid aging will occur in other parts of the world as well, so that by 2050, all regions of the world except Africa will have nearly a fifth or more of their population at age 65 and above (28% in Europe; 23% in Northern America; 19% in Latin America; 18% in Asia and Oceania; 6% in Africa). Increase in life expectancy also leads to an increase of the “very old,” namely, people aged 80 or over. The number of 80 and over is expected to increase from 126 million in 2015 to 202 million in 2030 and 425 million in 2050. These “very old” people are also the ones who present the poorest health and accumulate the severest disabilities.

In the context of an aging population, one of the major societal concerns of countries is to allow everyone to “age successfully.” Allowing people to “age successfully” means enabling people to carry through their projects at every phase of their lives by coming to terms with physical and social changes. It means allowing people to maintain their self-esteem and to adapt to their environment (including food-related) with regard to their preserved abilities. Successful aging also means allowing the elderly person to benefit from relevant support when difficulties arise with accomplishing certain activities (including food purchasing, meal cooking, and feeding one's self). Although having a "good diet" is recognized to be important for successful aging, malnutrition is one of the highest threats to the health, autonomy, and well-being of older adults (di Francesco et al. 2007; Leslie 2011). Malnutrition corresponds to a deficiency in nutritional intake, in terms of calories and/or nutrients, and is associated with numerous adverse outcomes: it increases the incidence of falls, fractures, disease, and hospitalization, it causes or worsens a state of frailty and disability, and it affects the quality of life of elderly people (Corti et al. 1994; Wallace et al. 1995; Rasheed and Woods 2013). Poor nutrition is not simply a result of disease states but often precedes and predisposes elderly people to disease (Ferry et al. 2007).

Several medical guidelines and public policies specify the nutritional needs of elderly people and make nutritional recommendations to allow elderly people to achieve a healthy nutritional status (World Health Organization (WHO) and Tufts University School of Nutrition and Policy 2002). There are also nutritional recommendations aimed at preventing specific diseases (Bauer et al. 2013; Rizzoli et al. 2014; Mohajeri et al. 2015). However, several studies have demonstrated the inadequacy of nutrient intake in the elderly population (Roman-Vinas et al. 2011; Mensink et al. 2013). Consequently, the present chapter will first describe the impact of aging on food intake, both from a qualitative (i.e., dietary pattern) and quantitative (i.e., nutrient intake). In a second section, the determinants of eating behavior in the elderly people will be reviewed. Finally, some possible levers to improve elderly people's compliance with dietary recommendations will be discussed.

Impact of Aging on Eating Behavior

Qualitative Aspects: Aging and Dietary Pattern

Most of the food dietary guidelines directed to elderly people are close to those intended for an adult population: emphasizing the consumption of fruits, vegetables, and whole grains while reducing the consumption of sodium, saturated fat, and added sugar. However, the guidelines published by the World Health Organization also included recommendations to answer specific changes observed in the older people (World Health Organization (WHO) and Tufts University School of Nutrition and Policy 2002). Two recommendations may be linked to a decline in food intake and diet variety in old age: "Select nutrient-dense foods such as fish, lean meat, liver, eggs, soy products" and "Eat several (5–6) small non-fatty meals. This pattern appears to be associated with greater food variety and lower body fat and blood glucose and lipid levels, especially if larger meals are eaten early in the day." One recommendation echoes the decline in thirst regulation with aging, "Avoid dehydration by regularly consuming, especially in warm climates, fluids and foods with a high water content," and one recommendation is related to the suggestion that diet high in long-chain polyunsaturated fatty acids may protect people from cognitive decline and dementia (Sydenham et al. 2012): "Where refined fats are necessary for cooking, select from a variety of liquid oils, including those high in ω-3 and ω-9 fats." Interestingly, some recommendations included in the WHO's dietary guidelines are related to meal commensality: "Transfer as much as possible of one's food culture, health knowledge and related skills to one's children, grandchildren and the wider community"; "Enjoy food and eating in the company of others."

Comparison of young* versus *old people. Three large cross-sectional studies have observed a tendency for higher consumption for healthy foods and lower consumption for unhealthy foods in the older respondents compared to the young ones. In the USA, the National Health and Nutrition Examination Survey (NHANES III) showed that older adults tended to consume more vegetables and fruits but less sweet and fat foods than younger adults (1988–1991, $n = 8696$, 16 to +80 years old, 24-h recall; Drewnowski and Shultz 2001). In the French INCA 3 study, a higher consumption rate of fruit, vegetables, meat, and fish was observed for people aged 65–79 compared to people aged 18–44. Conversely, a higher consumption rate of sweet foods was observed for the former compared to the latter (2014–2015, $n = 2121$, 18–79 years old, 24-h recall; ANSES 2017). Finally, in the French Nutrinet-Santé cohort study, it was observed that consumption frequency for cooked vegetables, raw fruits, and fish increased with age, while it decreased for meat and sweet desserts (2016, $n = 32{,}696$; 20–79 years old, food frequency questionnaire; Sulmont-Rossé et al. 2017). In a longitudinal study, Plessz et al. (2015) explore the evolution of vegetable consumption over 20 years among a sample of 15,681 French participants aged 40–49 years at the beginning of the follow-up. The authors observed that the probability of consuming vegetable everyday increased with aging, both for women and men.

Aging* versus *cohort effect. However, one should be cautious before concluding that aging is accompanied by an increase in healthy eating. Indeed, the studies mentioned above are all but one cross-sectional and thus do not allow for deciphering between a true aging effect or a cohort effect. In France, the BDF survey ("Enquête des ménages") was conducted every 5 years from 1979 to 2000 in a representative sample of the French population by the French National Institute of Statistics and Economic Studies (INSEE). Data were analyzed by the CREDOC (Centre de Recherche pour l'Etude et l'Observation des Conditions de Vie). In data analysis, people were stratified by age cohort (e.g., people born from 1956 to 1947). The compilation of data collected from 1979 to 2000 shows that overall, the old cohorts (people born from 1936 to 1917) purchase on average more fresh fruits and vegetables than the young cohorts (people born from 1976 to 1957). However, results show an increase of fruit and vegetable purchase in the young cohorts from 1979 to 2000 but a decrease in the old cohorts (Fig. 1). In other words, young people increased their fruit and vegetable purchase from 1979 to 2000, while old people decreased it, but overall, young people tended to purchase less vegetables and fruits than old people (in 2000, the purchase rate of the cohort [1976–1967] was still lower than the one of the cohort [1916–1907]) (Recours et al. 2005; Hébel and Recours 2007).

Dietary patterns in the elderly population. Some studies have explored the evolution of food choice in an elderly sample and have reported a trend toward fewer healthy food choices in the "older elderly" subjects compared to the "young

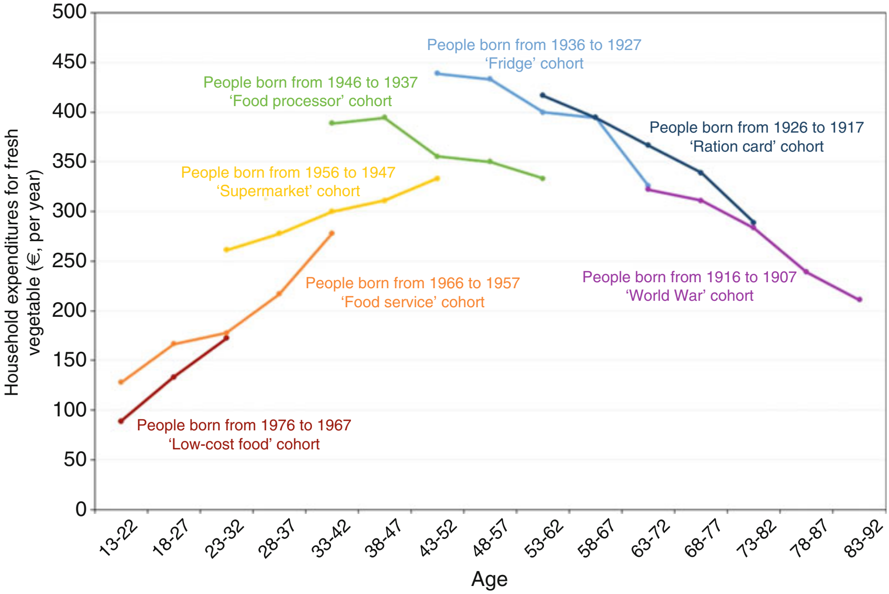

Fig. 1 Impact of age and cohort on the household expenditures for fresh vegetables in France. (From Recours et al. 2005; data source: survey BDF 1979, 1984, 1989, 1995, 2000, INSEE)

elderly" subjects. For instance, in a sub-population of elderly subjects, older subjects ate meat, fish, cereals, raw vegetables, and pulses less regularly ($n = 9250$ community-dwelling aged 65 years and over in France; Larrieu et al. (2004)). Barnia et al. (2005) and Power et al. (2014) reported that older elderly subjects consumed more sweet and fat foods than younger elderly subjects (64–74 years) ($n = 99{,}744$ French adults aged 60 years and over for Barnia et al.; $n = 208$ community-dwelling Irish adults aged over 64 for Power et al). However, Appleton et al. (2009) observed that a higher consumption of vegetables was associated with higher age in adults aged 65 or over. These discrepancies between the studies may be linked to the fact that food choices are characterized by a large inter-individual variability within the elderly population. Several studies have highlighted various dietary patterns in the older age, including "healthy" pattern (fruit, vegetable, fish), "western" pattern (meat, pastry), "traditional" pattern (bread, potatoes, milk, vegetable, butter, stock), or "snacking" pattern (frequent snacks, crackers, biscuits) (Schroll et al. 1996; Corrêa-Leite et al. 2003; Samieri et al. 2008; Bedard et al. 2015; Andreeva et al. 2016; Gazan et al. 2016; Thortpe et al. 2016).

It should be noted that all the studies mentioned in these sections were conducted in Western countries (USA, Europe, Australia). There is a crucial need to explored change with ageing in other parts of the world that will also be affected by aging population (Asia, Latin America). Furthermore, these studies mainly recruited "community-dwelling" elderly, namely, elderly people living at home, and some have included health variables in their survey (e.g., Samieri et al. 2008; Andreeva et al. 2016). However, the living status (at home versus in institution) and the health status are not always specified in these publications (e.g., Bedard et al. 2015; Thorpe et al. 2016). Consequently, there is a need for a better characterization of elderly samples in future studies (age mean, age range, living status, health status, dependency grade, frailty, etc.) in order to better decipher between changes in healthy aging versus changes occurring with the onset of frailty, disease, or dependence.

Quantitative Aspects: Aging and Nutritional Intake

Contrary to common beliefs, nutritional needs decrease little with age and are sometimes even higher than the needs of younger subjects. With regard to caloric intake, a joint report from the Food and Agriculture Organization and the World Health Organization recommend a daily allowance of 2450 kcal/day for men and 2000 kcal/day for women (FAO and WHO 2001). The European Food Safety Authority (EFSA 2013) recommends a daily allowance of 2000–2600 kcal for people aged 30–39, from 2000 to 2500 kcal for people aged 50–59, and from 1800 to 2300 kcal for people aged 70–79. With regard to protein intake, recent works carried out by the consortium PROT-AGE (Bauer et al. 2013) and by EPSEN (Deutz et al. 2014) show that older people need to ingest more protein than younger people to stay healthy, to maintain their abilities and to fight infections. Among others, it was demonstrated that a higher amino-acid bolus is required to stimulate muscle protein synthesis in the elderly compared to younger individuals (Cuthbertson et al. 2005; Walrand et al. 2011). As a result, the daily protein intake should be 1–1.2 g protein per kg of body weight per day for a healthy person over 60 versus 0.8–1 g per kg of body weight in younger subjects.

Comparison of young* versus *old people. Despite these recommendations, several studies have reported lower energy, macro- and micro-nutrient intake in the elderly compared to younger population. In the USA, the NHANES III survey showed that energy intake for men ranged from a high of 3100 kcal/day at age 20–29 year to 1900 kcal/day at age 70–79 years. For women, the corresponding range was 1900–1400 kcal/day (Briefel et al. 1995). A French survey (Etude Nationale Nutrition Santé – IVS 2006) revealed that energy intake declined from 2400 at age 18–29 years to 2000 kcal/day at 55–74 years for men and from 1700 to 1500 kcal/day for women. In the French INCA 3 study, the energy intake was equal to 2196 kcal/day for people aged 18–44, 2108 kcal/day for people aged 45–64, and 1913 kcal/day for people aged 65–79 (ANSES 2017). Similarly, lower protein intake in the elderly was observed compared to young adults (Campbell et al. 1994; Rousset et al. 2003). Lower food intake is also associated with decline in the intake of most micronutrients. Age is associated with declining consumption of calcium, iron, zinc, B vitamins, and E vitamins with some variations between men and women (Drewnowski and Shultz 2001). According to the IVS survey, 68% of men and 88% of women aged 55–74 years did not meet the recommended dietary allowances for calcium (IVS 2006).

The small old eater. In addition to the dietary patterns described previously, several authors observed a "small eater" pattern in their elderly samples (Schroll et al. 1996; Corrêa-Leite et al. 2003; Samieri et al. 2008; Gazan et al. 2016; Thortpe et al. 2016). These patterns were characterized by a low consumption for most food items and were associated with a caloric intake below the recommendations (~ 1380 kcal/day for women and ~ 1800 kcal/day form men). Across these studies, the prevalence of small eaters in the elderly population is far from being negligible, ranging from 23% (Gazan et al. 2016) to 55% (Thortpe et al. 2016). A meta-analysis conducted by Ter Borg et al. (2015) on 46 studies revealed that 10–12% of community-dwelling older adults do not meet the daily allowance for protein. The situation worsens in old age and dependent seniors. In the longitudinal Survey in Europe on Nutrition and the Elderly: a Concerted Action (SENECA), 247 Danish and Dutch people aged 70–75 were first surveyed in 1988/1989 and re-examined 4–5 years later, in 1993. Results showed a significant decline in energy intake for both genders over the 4 years of follow-up (Schroll 1997). Lesser et al. (2008) reported that energy intake was considerably lower than recommended in very old seniors in the Eastern/Baltic European country. Recently, Sulmont-Rossé and Van Wymelbeke (2019) weighed all foods and beverages consumed by 88 French elderly people living in geriatric long-term care facilities for 24 h. The results showed that the average caloric intake was 1693 kcal/day for men and 1364 kcal/day for women, below recommended daily allowance. With regard to proteins, the average intake was 63 g/day for an average weight of 74 kg in men and 55 g/day for an average weight of 61 kg in women. Based on these results, only 13% and 20% of the participants met their caloric requirements and protein, respectively. Furthermore, 60% and 40% of participants consumed respectively less than 2/3 of their caloric and protein needs.

To sum-up this first section, seniors tend to make healthier food choice than cohorts of younger adults. However, a decline in energy and protein intake was observed with aging which may weaken the nutritional status of the elderly and predispose them to associated pathologies (sarcopenia, malnutrition). This drop in food intake worsens with the increase in age and the onset of dependence, which requires us to pay particular attention to the food diet of very old, frail, or institutionalized elderly people.

Determinants of Eating Behavior in the Elderly

In the elderly population as in younger populations, eating is a complex behavior driven by many determinants and their interaction (Köster 2009; Brug et al. 2017). In the present chapter, a choice was made to focus on determinants specific to old age. However, this list should not be considered as exhaustive, and for several determinants, the scientific literature is scarce and inconclusive. In fact, eating behavior in the elderly has received much less attention than eating behavior in children for instance (in Google©, the research "children eating behavior∗r" raised 256 million results compared to 44 million for elderly; June 2019). It is expected that this chapter will evolved in the future with growing interest in the elderly because of an aging population.

Determinants Related to Aging Process

The aging process, even when it takes place normally, is associated with many changes likely to have an impact on food intake and the nutritional status of the elderly (Morley 2001).

Hunger and satiety. From a physiological point of view, aging is accompanied by gastro-intestinal changes such as a slowdown in gastric emptying, an increase in baseline levels of anorexigenic hormones which induce satiety, and a decrease in levels of orexigenic hormones with stimulate appetite (Clarkston et al. 1997; Hays and Roberts 2006). These modifications may contribute to dysregulation of hunger and thirst in the elderly (Rolls 1993; Hetherington 1998). Roberts et al. (1994) reported that following 21 days of food deprivation, younger subjects increased their food intake to compensate for underfeeding whereas the older subjects did not. Conversely, younger subjects decreased their food intake following overfeeding, whereas the older subjects did not. Similarly, Phillips et al. (1984) reported that after a 24-h water deprivation, elderly subjects failed to rehydrate, whereas young subjects did so successfully. A meta-analysis conducted by Giezenaar et al. (2016) on 59 studies showed that after overnight fasting, hunger and energy intake were, respectively, 25% and 16–20% lower in older compared with younger adults. Looking at short-term regulation, it was demonstrated that after ingesting a fixed amount of a food or a drink, elderly subjects were less accurate to adjust their subsequent intake according to the energy content of the preload compared to younger subjects (Longbottom and Hetherington 1995; Rolls et al. 1995). Finally, Rolls and McDermott (1991) showed that elderly subjects did not show sensory-specific satiety, while such an effect was observed in younger age groups: elderly subjects did not show a decrease in desire to eat for the food that they have just eaten compared with uneaten foods.

Oral health. Many studies have shown that aging can be accompanied by significant changes in the oral health and one of the most obvious changes is tooth loss. According to a German National Survey (Micheelis and Schiffner 2006), the most frequently lost teeth are the molars followed by the maxillary premolar and front teeth. In this survey, young adults had 25 $\pm$ 4 remaining teeth while the elderly had 14 $\pm$ 10 remaining teeth. Despite the fact that the prevalence of edentulism has been dropping for the past decades, it remains higher in older adults than in young adults (Wu et al. 2012). Aging is also associated with a decrease in muscle mass (Melton et al. 2000) and in occlusal strength (Bakke et al. 1990). However, while older people adapt relatively well to decline in muscle strength by increasing chewing time, masticatory efficiency significantly decreases with tooth loss (Kohyama et al. 2003; Ikebe et al. 2011). According to Steele et al. (1997), the conservation of at least 21 natural teeth well distributed in the mouth is necessary to maintain a proper masticatory function. The systematic literature review of

Kiesswetter et al. (2018) highlighted a significant impact of dental status on eating behavior in the elderly, with lower intake of hard-to-chew foods (e.g., raw fruit and vegetable, meat, nuts) in elderly people (65+ years) suffering from dental impairments compared to those with a good dental status. In parallel, aging is often accompanied by a decrease in salivary flow: Vandenberghe-Descamps et al. (2016) observed a 38% reduction of salivary flow in individuals aged 70 and over compared to individuals aged 20–55 years. In some studies, hyposalivation was associated with a lack of appetite in hospitalized and independently living elderly people and a reduction in the consumption of vegetable, fish, and shellfish. However, the impact of hyposalivation on eating behavior remains too little explored in the scientific literature to draw definitive conclusions (see Muñoz-González et al. 2018 for a review).

Chemosensory perception. It is also well-known that aging is accompanied by a deterioration in the acuity of taste and smell perception. For olfaction, the literature showed an increase of odor detection thresholds in older people, a decrease in perceived odor intensity of supra-threshold concentration and a decrease in the ability to distinguish between odors (see Sulmont-Rossé et al. 2015 for a review). For gustation, the literature review of Methven et al. (2012) showed that older adults display higher detection thresholds in more than 70% of the studies. Perceived taste intensity at supra-threshold levels was found to be significantly lower for older adults in 64% of studies (see also Mojet et al. 2001, 2003). Some authors have observed that a decrease in chemosensory capacity was associated with a lower appetite (de Jong et al. 1999), a lower interest in food-related activities (e.g., enjoying cooking; Duffy et al. 1995), or a lower diet variety (Kremer et al. 2014). However, the role of chemosensory function on food intake in the elderly remains unclear and poorly documented compared to masticatory function (Kiesswetter et al. 2018).

Determinants Related to Aging Trajectory

Beyond changes related to the aging process, the life of elderly people is marked by “breaking points” likely to disrupt their lifestyle habits and in particular their eating habits (Falk et al. 1996; Cardon 2010). These breaking points may have a social origin (e.g., retirement, widowhood, fall in income) or a medical origin (e.g., onset of a disease, dementia). These changes are progressively crystallized in the form of new eating habits, which are sometimes inappropriate and at the origin of unbalanced diet (Ferry et al. 2005; Huffman 2002; Caradec 2008).

Social ruptures. Retirement is a major transition in the life course, and several studies showed that households substantially reduce food expenditures upon retirement (see Allais et al. 2018 for a review). Looking at the impact of retirement on eating behavior, a Finnish cross-sectional study showed an increase of healthy food habits in women from 55–60 to 60–67 years, and this increase was higher in retired employees compared to their continuously employed counterparts (Helldán et al. 2011). However, Allais et al. (2018) found a drop in quantities purchased for several food items, with positive health effects attributable to decrease in the consumption of sugary- and salty-fat foods, but also potentially negative health consequences due to lower intake of meat and fish (see also Baer et al. 2018). Widowhood is a painful but also common life event in the old age. It was shown that widowhood modifies the eating habits of the remaining person with the disappearance of homemade dishes and an increase of ready-to-eat or frozen dishes (Donkin et al. 1998; Shahar et al. 2001; Cardon 2010) as well as a decrease in diet variety (Quandt et al. 2000; Vinther et al. 2016) and in energy intake (Heuberger and Wong 2014). Rosenbloom and Whittington (1993) interviewed 50 recently widowed (within 2 years) people 60 and over and 50 married subjects of similar age. Their results indicated a decline in meal enjoyment and appetite as well as lower diet quality in the widowed subjects than in the married subjects. Vesnaver et al. (2016) attributed these changes in meal preparation and food choice to the loss of meal commensality. In fact, eating alone has been associated with lower caloric intake (Locher et al. 2005) and lower food variety (Kimura et al. 2012). Inadequate money and physical disabilities affecting food shopping or cooking are other social factors identified as affecting food choices and nutritional intake in the elderly (van der Pols-Vijlbrief et al. 2017).

Disease and drugs. Several diseases may have a negative impact on appetite and food intake and lead to an unintentional weight loss in elderly patients (e.g., cancer, depression, gastrointestinal disease, cancers, cardiovascular disease, nutritional disorders, respiratory disease, chronic infection; Berry and Marcus 2000). Furthermore, numerous drugs are known to cause appetite loss (iatrogenic anorexia; Morley 1997), to alter taste and smell perception (Schiffman 1991; Doty and Bromley 2004), or to elicit oral (mycosis, xerostomia; Ghezzi and Ship 2000) and digestive (nausea, vomiting, constipation; Carr-Lopez and Phillips 1996) troubles. These side effects take an additional toll on the physiological aging of sensory, food oral processing, and digestive functions and consequently worsen the negative impact of aging on appetite and eating behavior.

Dysphagia. Once ready to be swallowed, a food bolus is pulled toward the pharynx by the tongue movements (oral phase) and propels into the pharynx (pharyngeal phase). During the pharyngeal phase, the soft palate rises and the epiglottis lowers to block the airways. Finally, the bolus is driven by peristalsis in the esophagus to the stomach (esophageal phase). Alterations in chewing and salivation may result in large food particles and a poorly cohesive food bolus which can lead to swallowing disorders. However, aging can be accompanied by a delay in triggering the pharyngeal swallowing reflex, a decrease in peristaltic forces and a failure to close the airways or to open the upper sphincter, in particular in people with neurological pathologies or stroke (Britton 2016). Swallowing disorders can range from simple discomfort to an increasing risk of aspiration (misdirection of food bolus into the respiratory tract), which may cause aspiration pneumonia or even death by suffocation (Ebihara et al. 2016). Prevalence of dysphagia is estimated at between 8% and 15% in elderly people living at home and 30–40% in patients living in institutions (Puisieux et al. 2009). It has been reported to affect 8–80% of stroke patients and 11–81% of Parkinson patients (Takizawa et al. 2016). In order to prevent the risk of aspiration, dysphagic patients are often served with “texture-modified foods" in the form of chopped, blended, or pureed foods. Obviously, the setting-up of this specific diet has serious consequences on eating behavior. Beyond the decline in diet variety (e.g., more cooked foods and less raw fruits and vegetables), it leads to a decrease in appetite and food intake as texture-modified foods are often unattractive and unpalatable (Rofes et al. 2011). In fact, several studies have shown that dysphagia is associated with a significant increase in the risk of malnutrition (Serra-Prat et al. 2012).

Dementia. Food refusal is a common trouble in elderly people suffering from neurodegenerative troubles (see Berry and Marcus 2000 for a review). Alzheimer's disease is often associated with feeding difficulties and changes in eating behavior which may cause a decrease in food intake (Cullen et al. 1997; Wasson et al. 2001; Correia et al. 2010). Ikeda et al. (2002) observed that 58% of Alzheimer patients showed at least one symptom among the following: swallowing difficulty (e.g., coughs or chokes when swallowing, takes a long time to swallow food or liquids), change in appetite (e.g., loss or increase of appetite), change in food preference (e.g., prefers sweet foods more than before), disorders of oral behavior (e.g., tends to overfill mouth, eats non-edible foodstuffs), feeding difficulties (e.g., eats with hands, takes a long time to eat). Distraction from eating, frequent table-leaving events, and refusal to eat because of inability to recognize an object as food were other eating disorders frequently reported in Alzheimer patients living in long-term care facilities (Norberg and Athlin 1989).

Dependence. The onset of functional or cognitive disabilities may lead elderly people to require help for achieving daily tasks, including tasks related to eating (food purchase, meal cooking, and even support during mealtime). Cardon and Gojard (2009) proposed the term "culinary dependence" to describe situations in which "elderly people are unable to obtain and/or prepare food for their meals and are forced to delegate these tasks to others." There are several degrees of culinary dependence, ranging from the help provided by a family or professional helper to meals-on-wheels services and, finally, long-term care facilities. Whether voluntary or not, admission to a nursing home is a major turning event in the life of an elderly person, as it modifies his/her habits and physical and social environment. The elderly person must adapt to rules set by the establishment, notably with regard to food. In fact, multiple aspects of life in a nursing home are governed more by necessity than by personal choice (Mallon, 2004). Table placing, dinner guests, menus, and mealtimes depend less on the free choices of residents and more on organizational constraints of the nursing home. Furthermore, eating in nursing home implies a redefinition of the meal, from the point of view of the nursing staff who are subjected to specific constraints connected to hygiene and nutritional frame but also from the point of view of the residents who are subjected to the changes of practices and to the redefinition of commensality. Corbeau (2001) wrote that the symbolic dimension of a meal, a strong element in feeding behavior, is highly damaged in institution settings: "The opacity of the food sector at hospital makes hardly easy the incorporation of signs and reassuring symbols which may allow finding his cultural matrix and habits." This may disengage an elderly individual from his/her diet, which in turn may have a negative impact on appetite and food intake. Gustafsson et al. (2003)

reported that older women suffering from stroke, rheumatoid, arthritis, or Parkinson's disease "valued their independence and feared dependence when declining ability threatened performance of food-related work."

Levers to Stimulate Appetite and Sustain Food Intake in the Elderly

As discussed in the previous sections, aging is often accompanied by a decline in appetite and food intake which may predispose the elderly to nutritional risk. Beyond nutritional interventions which consist in providing the elderly with nutritional education, nutritional supplementation, or even parenteral and enteral nutrition in acute cases, some studies have tested various strategies to stimulate appetite and increase food intake in the elderly, in particular in the institutionalized elderly. These strategies can be divided among two main axes: improving meal context and improving pleasure elicited by food.

Improving Meal Context

Several authors have stressed the importance of meal context on the appetite and food intake of older adults, in particular in long-term care settings (Nijs et al. 2009; Nieuwenhuizen et al. 2010; Philpin 2011). However, as pointed out by the systematic literature review of Abbott et al. (2013), studies remain too few to provide definitive conclusions on the effectiveness of meal context to improve eating behavior in the elderly.

Looking at ***the social context of a meal***, one of the very rare studies conducted at home assessed the impact of an intervention combining dietary advice and meal commensality in community-dwelling older adults living alone (<70 years old) (McHugh et al. 2016). The intervention consisted in providing the participants with a guidebook on nutrition and culinary skills, and participants received a weekly visit from a trained volunteer who prepared and shared a meal with them. Results showed a significant improvement for food enjoyment in the intervention group compared to a control group, but no effect on energy intake. In a nursing home, Charras and Frémontier (2010) observed a positive impact on body weight of having shared mealtimes between caregivers and older people with Alzheimer-type dementia.

Looking at ***the physical context of a meal***, Gibbons and Henry (2005) observed that energy intake was 8% higher when elderly subjects ate in a training restaurant (improved environment) than in a standard environment (staff canteen). In older patients suffering from dementia, an increase of food intake was associated with the improvement of room lighting and table setting contrast (Brush et al. 2002), with the diffusion of music in the dining room (Ragneskog et al. 1996; Thomas and Smith 2009), with the diffusion of a food odor before the meal (Sulmont-Rossé and Van Wymelbeke 2019) and with the enhancement of the color contrast of tableware

(Dunne et al. 2004). However, Divert et al. (2015) failed to observe any increase in meal enjoyment or food intake when institutionalized elderly people were allowed to choose decorative objects (e.g., table cloth, table ware, flowers) to put on their dining table or to choose the music to be played during the meal.

Finally, looking at ***the service***, Shatenstein and Ferland (2000) observed that changing from a centralized food delivery system to decentralized bulk food portioning led to an increase of energy intake (+24%) in residents with dementia. However, Cluskey and Dunton (1999) and Divert et al. (2015) showed that providing institutionalized elderly people with small portions led to a decline in food intake despite older people often complaining that portion sizes are too big in nursing homes.

Finally, seven studies assessed large-scale changes which mainly aimed at shifting the dining room from an institutional appearance to more home-like setting (Table 1). Five of these studies reported that an improvement in the context of the meal could have a positive impact on food intake (Elmståhl et al. 1987; Desai et al. 2007; Nijs et al. 2006; Kremer et al. 2012) and/or body weight (Mathey et al. 2001a; Nijs et al. 2006). Kenkmann et al. (2010) observed no impact of a 1-year intervention on weight, despite a slight (but not significant) reduction in weight loss in intervention homes compared to control homes. In these studies, the context of meal in nursing homes was improved "as a whole," by improving several dimensions related to the food (e.g., choice, variety), to the service (e.g., buffet style, second helping), to the people (e.g., promoting autonomy, social interaction), to the staff (e.g., staff sits down at tables with residents), and/or to the situation (e.g., table dressing, attractive dining room). As a result, even though some of these studies showed that improving meal context had a positive effect on food intake, such "holistic" changes are difficult to implement in the field because they are difficult to reconcile with the constraints of nursing homes in terms of cost and personnel.

Improving Pleasure Elicited by Food

In order to compensate for the decline in olfactory and gustatory capacities with aging, several authors have proposed to enhance the flavor of food, namely, to deliberately add an aroma or a taste compound in the food. For instance, Bellisle et al. (1991) tested the impact of adding monosodium glutamate (compound responsible for the umami taste) in two soups, rice, and mashed potatoes. The results showed an increase in food intake for one soup (+7%) and for the mashed potatoes (+17%) compared to meals with standard foods. Similarly, Mathey et al. (2001a) enhanced the flavor of the protein dishes served to elderly people living in nursing home. After 16 weeks of intervention, the authors observed a slight increase in weight (+ 1 kg) in people eating enhanced dishes compared to residents who continued to eat standard dishes (control group). However, when Essed et al. (2007) replicated this study under the same conditions, this positive impact of flavor enhancement was no longer observed. In fact, when one is looking at the different

Table 1 Impact of improved meal context on eating behavior in institutionalized elderly people: literature review

Study	Control condition	Intervention condition	Population[a]	Design[b]	Duration	Outcome	Effects[c]
Elmstahl et al. (1987)	Trays	**Decor 40s**	Older people ($M = 80$)	Within-subject	4 months	Food intake	+
	Hospital decor	Bulk portioning service	Living in long-term care units	($n = 16$)		Body weight	**0**
		Residents could help themselves					
		Improved dining room decor					
Mathey et al. (2001b)	Trays	**Refined ambiance**	Older people ($M = 82$)	Between-subject randomized trial	1 year	Food intake	(+)
	Limited staff	Meal served in dishes on the table	Living in nursing home	Control group ($n = 10$)		Body weight	+
		Assistance by the staff		Test group ($n = 12$)		Quality of life	+
		One nurse for two patients					
		Improved table dressing, music					
Remsburg et al. (2001)	Trays	**Buffet-style dining program**	Older people ($M = 80$)	Between-subject randomized trial	3 months	Body weight	**0**
	No choice	Choice, second helping	Living in long-term care units	Control group ($n = 20$)			
		Assistance by the staff		Test group ($n = 20$)			
		Improved table dressing, music					
Desai et al. (2007)	Trays	**Home-like setting**	Older people ($M = 88$)	Between-subject	9–12 months	Food intake	+
	Institutional appearance	Bulk portioning service	Living in dementia units	Control group ($n = 23$)		Body weight	**0**
		Cafeteria style with waitress service		Test group ($n = 26$)			
		Improved dining room decor					

Nijs et al. (2006)	Trays	**Family ambiance**	Older people ($M = 77$)	Between-subject randomized trial	6 months	Food intake	+
	Choice of menu	Choice	Living in nursing home	Control group ($n = 83$)			
	15 days in advance	Meal served in dishes on the table		Test group ($n = 95$)		Body weight	+
		Personnel sat with residents				Quality of life	+
		Improved table dressing					
Kenkmann et al. (2010)	Crowed room	**Restaurant atmosphere**	Older people ($M \approx 87$)	Between-subject	1 year	Body weight	**0**
	Single sitting	Choice (more options, at mealtime)	Living in nursing home	Control group ($n = 48$)		Meal enjoyment	**0**
		Display of food		Test group ($n = 57$)			
		Fewer tables, several sittings					
		Improved table dressing					
Kremer et al. (2012)		**"Delicious green table"**	Older people ($M \approx 78.5$)	Between-subject	8 weeks	Energy intake	**0**
		Organic food, choice, appetizer	Living in nursing home	Control group ($n = 40$)		Food intake	+
		Residents could help themselves		Test group ($n = 28$)		Meal enjoyment	+
		Improved table dressing					
		Countryside decor

studies on this topic, it appears that flavor enhancement seldom improved food intake in the elderly (Table 2).

Some authors have studied the impact of sauces or condiments on food intake in institutions. For example, Appleton (2009) found that adding sauce to the main course increased energy intake, but this gain result from an increase in sauce intake, not in main dish intake. In contrast, Divert et al. (2015) showed that providing condiments on the meal tables (e.g., butter, tomato sauce, lemon, parsley, mayonnaise) had a positive impact on food intake in institutionalized elderly people.

Finally, Sulmont-Rossé et al. (2018a, b) tested the feasibility and effectiveness of improving the sensory quality of food according to sensory expectation and food preference of elderly people. This study focussed on three types of dishes: a ready-to-eat dish from the French familial cuisine (veal stew), a texture-modified food (pureed beef-carrot), and a fortified food (high-protein and high-energy dense vanilla custard). In a first stage, independent-living and institutionalized elderly people were asked to taste the market products and to suggest how the sensory characteristics could be improved (appearance, flavor, texture, etc.). On the basis of these results, different variants were developed for each dish. In a second step, a second panel of independent-living and institutionalized elderly people rated their liking for each variant. Finally, in a third step, a consumption test was carried out in a nursing home to compare the initial market variant and the variant that was the most appreciated in the previous step. The results showed that improving food sensory properties according to elderly people's expectations led to an increase of food intake (+6%). Furthermore, the results also showed that the variants improved on several sensory dimensions (texture, taste, aroma) were preferred to the variants improved on only one dimension. This argues in favor of a multidimensional approach when developing food for the elderly population (see also Kremer et al. 2014).

Conclusion

In view of the major challenge posed by malnutrition among the elderly population in terms of quality of life and public health, it is crucial to develop meal interventions and food products that promote appetite and sustain food intake in the older adults, in combination with nutritional strategies. However, to be effective, such research should take into account the capacities and the expectations of the elderly people. The last word comes from a man over 70 years old who has lost his sense of smell. To the question "Do you still enjoy eating, even if you have less sense of smell?" This person answered very spontaneously: "Oh yes! Oh yes, YES, YES! Eating is almost the only pleasure we have left!."

Introduction

At the beginning of the twentieth century, while tensions in Europe intensified, began a politico-philosophical inquiry into "the psychology of the people" as it relates to the question of national belonging. Culture and collective mores were found to be at the heart of what constitutes the "consciousness of being a people" (Fouillée 1903). As French and German conceptions of nationality came to a head over the status of Alsace-Lorraine, certain German writers attempted to pinpoint what it meant to be French, or to possess a French soul, a French spirit, and French taste. In *Dieu est-il Français?* (1929), journalist Friedrich Sieburg (1991) wrote the alimentary customs, the importance placed on local specialties, on the culinary arts, on wine, and on menus as the embodiment of French culture. At the same time, novelist Ernst Robert Curtius (1932) defined what made France and what set it apart from Germany, paying particular attention to the kinds of social and intellectual democracy through which the country developed its idea of civilization and articulated its cultural identity:

> It is universal not only in the sense that it unites the nation and humanity, and that within the nation it includes all classes, but also because it covers the whole of existence (. . .) We may indeed assert that in France civilization begins with food. Gastronomy is part of civilization. (p. 39)

Gastronomy, which includes processes ranging from "farm to fork," and of which the culinary arts are but one component (Csergo 2016b), has thus become, through a synthesis of the diversity of cultural heritages, one of the most emblematic representations of French culture. A model during the sixteenth and seventeenth centuries, French gastronomy triumphed in the eighteenth century, continued to exert a hegemony during the nineteenth century, and saw a weakening of its dominant position at the close of the twentieth century. In response to this more recent change in status, France has developed strategies designed to maintain influence and preeminence. To trace this history is to trace a cultural history in which the culinary arts were constituted in France as a form of political, economic, and social government, as well as diplomatic device.

An Assertion of a *manière française* at Table

Medieval recipe books describe a culture of cooking and dining common to all European elites. Characterized by a taste for spice, acidity, and the associations of both sweet and salt and sweet and sour, cookery of Middle Ages nonetheless saw the expression of certain national tastes and the use of ingredients or cooking methods specific to each country (Rambourg 2005).

It is in the sixteenth century that the idea of "*une manière française*" at table asserted itself, this in line with the growing sense of belonging to the nation. Beginning in the Middle Ages (Beaune 1985), this construct of "belonging" was reinforced in the sixteenth century as a unifying response to the bloody territorial and religious conflicts that had divided the kingdom. It is rooted in the monarchy's pursuit of centralization: the political and cultural assimilation of the provinces by the nation. The institution of French as the administrative language by Francois I (1494–1547) is but one example. This last policy helped to foster the scholarly discovery of the provinces, their natural features, their inhabitants and their histories, and their resources, the sum of which not only generated a certain degree of local patriotism (Yardeni 2005) but also contributed to the wealth of the entire kingdom. As such, alongside landscapes, remarkable buildings, industries, and markets, a decisive place was given to agricultural production and to the way the people fed themselves, but also to the princely cultures of banquets, the pageantry of the table, and dishes prepared and served the *manière française* at table (Du Chesne 1620, pp. 409–410). Thus, distinguished from those of other peoples, the table became a site of expression of the cultural community being forged. Meanwhile, the kingdom's superiority in various domains, particularly in that of cooking and the culture of feasts, was affirmed. The expression of such a feeling of superiority can be attributed to a cultural context in which the will to express the love and pride of a nation under construction and the return to fashion of an ancient form of rhetoric, that of epideictic oratory, converged. This public statement of positive and persuasive judgment in favor of a given object had the effect of producing, and sharing, common values. Estimation, consideration, and appreciation, which in the Middle Ages had been reserved for God alone (*löenge de Dieu*), were transferred to the nation: to the genius of its soil and to the divine profligacy of its productions. The territory of France, its *terrouer* in old French, becomes the *Jardin des Délices* (Alquié, 1670), a unique place where one finds both spiritual and sensual pleasure, a "Paradise Regained." We might find in this phenomenon the origins of how *terroir* came to express in France the "nous national," or "ce qui nous unit" (Droit 2015).

The affirmation of the superiority of France's agricultural products and of its table is also very much a matter of economic design. After years of conflict and devastation, Henri IV (1553–1610) made use of the peace that followed to establish reconstruction policies, which were rooted in the dominant mercantilist theories of the period. Mercantilism is an economic practice first developed in England in the sixteenth century, which seeks the greatness of the developing state the financial means necessary for its political and war action; it consists of bringing gold into the coffers of the state by ensuring a positive trade balance. In view of augmenting a state's powers, mercantilism grants the sovereign the financial means to take political action and/or make war. In other words, a state's power is measured by the abundance of its wealth in gold and silver. In the absence of precious metal mines, this abundance can only come from a positive trade balance. Plowing and grazing were recognized as France's main riches, since they nourished its people and helped it to avoid the need for imports while favoring exports (Serres 1600). The idea of regional agricultural specialization (Montchrestien 1615) supports this point of view. Colbert, Louis XIV's minister of Finance, would take this tack. For instance, to reduce the commercial power of Holland, he favored the French production of cooked pressed cheeses, encouraging the farmers of the North to create counterfeit Netherlands cheeses whose importation he had prohibited.

Thus, praise of the nation for its agricultural and alimentary wealth as well as the *manière française* at table served mercantilism, which itself brought an economic dimension to the political and cultural connections being made for the purpose of uniting the people of France. Mercantilism was a factor in strengthening the consciousness of national unity through the protection it offered to the country and its subjects by way of the sovereign.

The defense of the language and recognition of the nation's history, its culture, and the national economy were closely associated. The culture of the table was an essential component, of which agricultural production constituted the base, the *terroir*, the values.

Birth and Codification of a French Cuisine and Table

During the seventeenth century, a French style of cooking and "art of the table" was codified for better assertion and dissemination. European elites were fascinated by it, just as they were fascinated by Versailles and the French taste that found expression there.

Under the reign of Louis XIV (1638–1715), absolutism and centralization reached their peak. The superiority and grandeur of France were now embodied in the *Gloire du Roi*, through which the process of building a national cultural identity continued. This *Gloire* is based upon a "government of minds" (Lavisse 1978), that is to say, absolutism means exercising political control over all fields of knowledge, including the arts, with the aim of promoting a French style that symbolizes the power of the state and attempting to eclipse the reigning Roman model. The academic system was at the heart of the matter: *l'Académie française* (1635), created for the purpose of perfecting and universalizing the French language, *l'Académie de peinture et de sculpture* (1648) and *l'Académie d'architecture* (1671), and the sometimes transitory académics schools of dance (1662), of opera (1671), of music (1672), of performance (1674), all of which were used to set up and support a doctrine of official taste *à la française*, now a mark of distinction. The industrial arts and crafts (tapestry, lace, glassware, mirrors) were organized around the same objective, through state-owned industries. The ornamental and leisure arts, described by Kant (1985) as satisfying only the senses but not the mind, did not benefit from institutional structures, but nonetheless experienced the same forms of academization and codification. Such is the case with the art of cooking and the art of the table.

Brought to the fore by royal command and playing a central and ceremonial part in the staging of the monarchy, these arts were not granted academic bodies, but nevertheless they were academized: they were ordered into bodies of rules and doctrines, which, as for the major arts, subscribe to an ideal of taste. As the rules of gardens *à la française* were defined, so were those of *cuisine à la française*. In 1651, La Varenne's *le Cuisinier François* identified these rules. This text marked the beginning of a revolution that became known in the eighteenth century as "new French cuisine." It broke with the medieval culinary tradition still in force in many European courts, as well as with the Italian-centered Renaissance. This "French" cuisine offered new flavor profiles and thoughtful food combinations, new skills, and the use of indigenous resources. It saw a decline in the use of spices in an attempt to preserve a food product's natural taste. It was also characterized by more precise cook times, the separation of sweet and savory, and sweet and sour, as well as the use of fat and butter (La Varenne 1983). These characteristics remain the basis of French cuisine.

La Varenne's cookbook was followed by a series of texts, all of which set out to order and to structure a French style of the table in terms of vegetable production (Bonnefons 1651), pastry (An. 1653), confectionery (An. 1650), food service and the ways of butchering and carving meat (LSR 1674), the dishes or courses served, as well as the aesthetics of the table settings and linens. All of these books, supported by illustrations, cemented this style to better teach a growing canon of living *à la française* to the trades at work in the townhouses of Paris (Gady 2008). Equipped with kitchens and reception rooms, pantries, and dining rooms (Lestienne 2017), such townhouses testify to the importance accorded by an enriched bourgeoisie – which had acquired, through the purchase of offices, the honors of serving the state and with all the social obligations this newly acquired status entailed – to the art of receiving at table.

Praise for France's prodigality, for the abundance and quality of its products, was now being extended to its cuisine. The author of *Délices de la France* (1670), Savinien d'Alquié, described France as distinguishing itself by the perfection of its cuisine ("we have the best Cooks in the world" (pp. 233–234)) and of its service *à la française*, in vogue throughout Europe (p. 147).

This culture, he wrote, was spreading throughout urban society: "profusion and profligacy reign in the refreshments and feasts that the least bourgeois, and even the least artisan, offers his friends" (pp. 233–234). This trend continued throughout the eighteenth century. Through the emergence of a bourgeois kitchen and table, itself modeled on a simplified court table (Takats 2011), came a national kitchen and table. Hence, the codes, established at Versailles, passed on to a new social layer to acquire wealth, were then diffused to the rest of the social body while also becoming a cultural reference among European elites.

A Common Culture that is the "Making of France"

The revolutionary decade, which saw the rise of the Republic, did not break with this model but rather strengthened it. In 1798, Louis-Sébastien Mercier wrote that during the horrors of the revolution, Adéphagie (the goddess of gluttony) had lost none of her empire, "within striking distance of the guillotine and the large cemeteries filled with victims" (1990, p. 455).

Aron (1975) showed how, throughout the nineteenth century, gastronomy was strengthened by the new bourgeoisie who, coming to power, identified with this mode of expression. He traced the "social requalification" of the table, carried out by gastronomes like Berchoux, Brillat-Savarin, and, above all, Grimod de la Reynière, identified as the first to transmit the aristocratic mores of the table (Grimod de la Reynière 1978). The spectacularization of food and the rituals of the table found a new home in restaurants, which began to appear as cooks and *maitre d'hotels* sought to work outside of aristocratic homes. The restaurant became the new and public space for the culinary arts. The establishment founded by Chef Beauvilliers in 1782 became one of the most elegant and reputable places in Paris.

In line with its own values, the new political regime, the Republic, continued to build upon and to transmit this culture of the table which, once again, found itself at the heart of a nation under construction and central to the national community's sense of belonging. Praise for France's culinary prowess now extended to its diverse territories and the people who lived in them, whose common past was traced through their everyday lives (Grell 2000). Indeed, when the Revolution ordered a review of France's economic and social status, it also produced a review of the nation's wealth in the form of its customs, its monuments, and its natural resources. Agricultural specialties and eating habits were viewed as proof of France's diversity as well as what tied it together, united as it was by a continuity, a past, and a future. For quite apart from other regional particularities, local food cultures were not considered a hindrance to the construction of a republican unity. In conjunction with the practices of Ile-de-France elites, these would undergo a process of "nationalization," integrated into a cultural ensemble that would become French gastronomy. As such, gastronomy is (always) an instrument of national harmony. To educate its citizens, the Republic would design "patriotic gardens" wherein each section was named after a memorable event, a historical personality, a building, or a food specialty (Deleyre 1793, pp. 25–26). A few years later, in 1807, Grimod de la Reynière evokes this educational tool and arranged for the production of a particular kind of national map:

> (...) Featuring the gourmet productions that made our cities famous (...) Thus, instead of the steeple of Amiens, we distinguish at this place a duck pie; at Nérac, a terrine of red partridges; a duck liver in Toulouse (...). (2012, p. 622)

This first food-centered map of France, published by Gassicourt (1809), presents specialties, noteworthy as much for their taste as for the memories they both carry and impart. That the Republic and its territory could be learned through its local food specialties is indicative of the status that food continued to hold in the imaginary, and in the symbolic representations, of the nation. Written into the history of the Earth (and of the people who occupy it), foods came to be seen as monuments, as reminders of a common past, constituting a group identity. Like castles and cathedrals, they were regarded as a form of cultural heritage (Csergo 2011). This pedagogy of France by way of gourmet specialty would be popular throughout the nineteenth century: children's books, popular poetry, school textbooks of the Third Republic, as well as countless vignettes and prints would form the tools that taught the nation (Csergo 1999) through the consumption of its incomparable gastronomic wealth. It would also maintain a lasting fusion of France's sensitive identity (Sansot 1985) with its political and civic identities.

Beyond the food products, it is the cuisine that, in the twentieth century, would be subject to the same process of social and regional synthesis. In an attempt to create hallmarks of the nation's new identity, the first publications on regional cuisine were published. Interestingly, these books represent areas with contestable borders: Geneva, former free republic, occupied by and annexed to France (An. 1798); Alsace, a pivotal site where French and German conceptions of nationality would meet (Spoerlin 1811); and the South, where Michelet had not yet encountered "the true France" (Durand 1830). At the end of the century, almost all regions would have their repertoires of recipes and food products but also their local stories of food customs (Csergo 1999), many of which are still in print.

The early twentieth century saw the first compilations celebrating France's culinary wealth, in all its social and regional components. *L'Art du bien manger* (Dumonteil and Richardin 1901) demonstrates this process of integrating regional cuisines into the national cuisine. This monument raised in honor of French cuisine is a synthesis of "renowned dishes of great restaurants," of "local cuisine," of "recipes from the old French kitchen," and of "the bourgeois kitchen and the housewife's kitchen" as well as "simple and easy recipes." In 1913, *Les Bons Plats de France* (Pampille, alias Marthe Allard-Daudet, 2008) was the first to associate French cuisine with the immutable identity of a *terroir*, the highest expression of the soil and the rural territory that produced it. This would also make gastronomy a touchstone for the reactionary and nationalist right. In 1933, *le Trésor gastronomique de France* (Croze and Curnonsky 1933) concludes this review of alimentary and culinary production that had begun in the eighteenth century. Cuisine has thus played a significant role in mapping out and memorializing the nation. It has been a key vector in the work of linking *petites patries*, or local homelands, to *la grande patrie*, or nation (Thiesse 1997) and has rendered the table an embodiment of France; they are both one and yet divisible. The attachment of the French to their gastronomy, whatever their social and regional origins, their religious or philosophical convictions, is a sign of this policy's success. This is what led Zeldin (1977) to describe gastronomy as a French passion.

The Hegemony of a Cultural Model for an Economic Dimension

The table, with the cultural value it had accrued and the reputation it has acquired, would contribute to France's cultural hegemony in Europe, and in the world, until the end of the twentieth century. *Gloire du Roi* having become *Gloire du peuple*, gastronomy would figure in various forms of international exchange, sustaining France's economy by way of its territories.

As an instrument of government foreign policy, gastronomy deployed the power of the nation through diplomatic action, strengthening strategic decisions abroad, helping to form alliances, managing conflicts, but also influencing public opinion, creating a "desire for France."

All sovereigns since François I gave primacy to culinary diplomacy exercised state to state in the form of official receptions and banquets. During the reign of Louis XIV, culinary diplomacy rose on an unprecedented scale. Through the pomp, refinement, ceremony, aesthetics, and general excellence of the royal table on display at Versailles, France did more than stage an absolute monarchy in all its grandeur. It also pushed foreign embassies to take on or emulate aspects of the French cultural identity, thus confirming and ensuring the nation's influence and preeminence. The reign of the French model would outlive a succession of political regimes – from a monarchy to a republic to an empire – all of which would draw from its prestige. This culinary diplomacy even fueled a national mythology. The current government still refers to the "diplomatico-gastronomic masterpieces" made during the Congress of Vienna (1814–1815), to the sumptuous receptions put on by Talleyrand, who had been made *Amphitryon* of the Napoleonic regime and to whom legend attributes the following aphorism: "a diplomat's best assistant is his cook." Indeed, it was the cooks who were the main ambassadors of the French table. The excellence of their art was practiced in all European courts and beyond. The greatest of them served kings, princes, and foreign embassies. Among them were Vincent La Chapelle, who wrote his *Modern Cook* in English (1733); Alexis Soyer, whose work held such influence in Victorian England; Antonin Carême, styled as "king of cooks and cook of kings," prodigy of culinary architecture and decoration; as well as Jules Gouffé and Urbain Dubois, held similar sway during the nineteenth century and Auguste Escoffier and Prosper Montagné in the early twentieth century, quickly translated as they were into English (Laudan 1996). All of these cooks actively participated in establishing the French model and maintaining its preeminence.

Meanwhile, the industrial revolution and the advent of liberal capitalism altered the geo-economic balance in the world, increasing competition between countries. The so-called "modernist" nations, namely, Germany and the United States, brought their industrial foods to market, which the French denounced as food "imposture." Nonetheless, their low cost rendered such products a serious threat to French food production. France thus undertook to defend its share of the export market. Beyond culinary diplomacy, France began developing a broader diplomatic project, with the aim of influencing attitudes and ensuring markets for terroir products, for cooking, for wine and spirits, and for the decorative arts of the table. That politicians and mayors of major cities, like Edouard Herriot in Lyon (Csergo 2008) or Gaston Gérard in Dijon (Laferté 2002), set out to give their respective cities a gastronomic status was both beneficial to the development of the surrounding territories as well as to France as a whole. Their gastronomic crusades were part of a patriotic mission: to defend the national economy along with the French identity.

Promotional activities were carried out at international fairs and exhibitions in view of acquiring and maintaining export markets. The main objective was to conquer the American market, then dominated by Germany. Ally and the world's largest economic power, the United States, offered a market that appealed to French ambitions given the commercial blockade imposed on Germany and Austria during the First World War. France saw an opportunity to "capture American gold." In 1915, at the height of war, France introduced the "Palais de la France" to the San Francisco International Exhibition, which boasted lavish banquets. A look at trade with the United States reveals that French food products hold a certain "seductive charm" for Americans. Their symbolic meaning, great style, and an art of living tinged with elitism and aristocracy – now become cultural and commercial brands – appealed to newly wealthy Americans with a fondness for conspicuous consumption. Beyond individual food products, trade began to move toward the pleasures of the table "*à la française*" repackaged as luxury goods, recalling a golden age of royal splendor (Csergo 2016b). Champagne, fine wines, liqueurs and spirits, cured or potted meats, haute cuisine, and tableware, with their artisanal excellence contrasted with the mass-produced goods offered by an American industry convinced only of the most functional aims of the act of eating. These distinctions would influence France's commercial export strategies.

Well before the reign of gastrodiplomacy, France sought to guarantee the long-term export of the best and most expensive products to the United States and thus launched operations intended to influence consumers, to create and maintain a desire for French gastronomy. Meals displaying French-style splendor were given in the sumptuous dining halls of luxury *Palace*-hotels and in transatlantic ships, whose kitchens were staffed by Escoffier's disciples. Further, Gastro-diplomatic delegations, composed of renowned winemakers and chefs, were sent to the United States to train the social elite and restaurateurs in the French model of the table. Banquets became showcases of products – wines, fine china, gold and silver plate, and crystal glassware – as well as savoir-faire related to cooking, eating, and drinking. Emphasis was placed on the learning of grape varietals, the temperature of consumption of different wines, and the pairing of dishes with wines, this last a notion that already fascinated Americans. This promotional work in the area of export development is indissociable from efforts to conquer the tourism market. The challenge that this growing industry set for itself was to attract tourists, among them wealthy Americans, to bring "foreign gold" into France and by extension preventing competing powers from similarly enriching themselves. The project was fueled by a theory, fashionable at the time that tourism, which consists of selling goods and services to a foreigner on, in this case French soil, is the equivalent of serving an "export market from within." The idea that France's appeal was based on its cultural resources (its history, landscapes, monuments, local traditions), all of which coalesce in the art of eating well. The following statement, attributed to paragon of American success, John D. Rockefeller, supports this understanding of what constitutes resources: “The French have a great industry but they do not realize it. It is their art of dining and their eating practices.” In Paris, in the towns and villages of France, in restaurants and inns, be they refined and reserved for the elite or more commonplace and rustic, the table, the diversity of the products that adorned it, and the hospitality that accompanied it became tourist attractions. The consumption that these practices and products generated operated as levers of economic development. It was also a matter of setting French culinary style apart from the influence of tasteless, non-specific international cuisine, which began to appeal to – and be expected by – a growing number of international tourists, to protect the treasure that is French alimentary art “in the same way that monuments are protected,” and to cultivate the charm of a provincial welcome and to make restaurant owners aware of the advantages of using local products, local wines, and recovering local dishes. During the 1920s, a culinographer, Curnonsky, evoked in this regard the *Sainte Alliance du tourisme et de la gastronomie* (Csergo 2007). Around the same time, tourist guides, newspapers, and magazines specializing in tourism and gastronomy, designed to give travelers the desire to taste France, began to multiply: inviting readers to crisscross the country by train, by bicycle, or by car, to taste the local specialties in the best way, i.e., in situ, sauerkraut in Alsace, “foie gras” in the Périgord, and lobster by the sea. Gourmet maps were produced for visitors so that they might easily locate local specialties, consuming them on the spot or taking them home. Such maps helped to shape the regional gastronomic and culinary stereotypes that would take hold.

To the iconic depictions of Versailles or Chartres, those of castles and abbeys, the beaches of Normandy and the Côte d’Azur, were then added local products and dishes and the art of living at table. National identity, made up of its regional components, thus joined the tourism project, itself an instrument of defense and promotion of what was becoming a fixed identity. This perspective on tourist-related communication continues to dominate.

Preeminence Under Threat

From the sixteenth century onward, France built a persuasive praise (*éloge*) followed by storytelling (Denning 2004) concerning the identity and excellence of its table culture. It thus ensured and maintained the hegemony of a model that would last through the 1960s, during which its dominant position would be reaffirmed by the *nouvelle* nouvelle cuisine, promoted by the great chefs and by Gault et Millau, publishers of le *Dix commandements* (1973).

However, from the 1990s onward, this preeminence began to waver. The new globalization and the financialization of gastronomy favored the emergence, if not the visibility, of other culinary models. Given the economic stakes in this sector, these models represented [serious] competition, even at a moment when Michelin-starred French chefs were opening restaurants in the United States or in Japan. As “world food” came to the fore, France denounced the option of

American-style expansion and the "miscegenation of anything and everything, where every culinary culture in the world delivers its simplest and least refined foods" (Lazareff 1998, p. 61). Fast food, ethnic restaurants, casual dining, pizza, or Tex-Mex were nonetheless popular in France, as in the rest of the world. Regrettably, Gault listed fewer French restaurants in Paris than foreign restaurants. Other threats, even more worrying, made their appearance: the increased competition with Californian, Australian, and Chilean wines; Italian cuisine surpassing French cuisine in international polls; the growing popularity of Japanese and Thai cuisines; and chefs from other countries, like Ferran Adria and Marco Pierre White, whose innovations earned Michelin stars. The crisis culminated with 3-starred chef Pierre Gagnaire's declaration of bankruptcy: with some saying that international competition had had the better of the French kitchen.

While this competition calls the French model into question, its elitist and prestigious heritage with its formalisms and rigidities, its intimidating and discriminatory doctrines, in May 1996, an appeal to "save the French cuisine threatened by globalization" was launched. Signed, notably, by Ducasse, Robuchon, Blanc and Loiseau. Against "Japanese-Californian" cuisine and "unbridled creativity," this tricolor crusade, based on the values of terroir and regional traditions, set out to defend the "French identity" in cooking. In response to this discourse described as d'*archéo or archaic.* and *pétainiste. During the German occupation, Petain set up an authoritarian regime that glorified attachment to the land, as the embodiment of an immutable national identity.* (Noce 1998). Other chefs *Bras, Chibois, Gagnaire, Lorain, Passard, Roellinger, Troisgros and Veyrat*, signed a counter appeal, inviting a rethinking of French cuisine through cultural mixing.

While this crisis led some American observers to announce the decline of the hegemony of the French model (Gopnik 1997), in 2003 a vast French-bashing offensive was launched. This followed France's condemnation – in the form of a speech at the United Nations – of the American Iraqi Freedom project. In retaliation, the United States attacked French food products: wines were dumped down in the gutter, or, along with cheeses and foie gras, they were removed from the menus of many restaurants. California then voted to ban the sale of foie gras (2004). *On January 5, 2015, the United States Court overturned this provision, saying it interfered with commercial law*; and two members of the House of Representatives sought to rename French fries, Freedom fries. But in reality, the roots of this diplomatic culinary war run deep. They reveal trade tensions that lasted several years. Indeed, in the logic that led to cultural exception (Gagné 2005), and with the intention of setting limits on the rules put in place by the World Trade Organization (WTO) that tend to favor the all-powerful American trade and the standardization of productions and goods, including cultural ones, France defended a UN strategy of cultural diversity. This would lead in 2001 to the Universal Declaration on Cultural Diversity and in 2005 the Convention on the Protection and Promotion of the Diversity of Cultural Expressions. Reproaching the Convention for its lack of clear definition as to what constitutes "cultural expressions" and denouncing the implicit protectionism of the market, the United States refused, and still refuses, to ratify it. Food markets are at the heart of the argument, as evidenced by the article published in 2005 about the position taken by

Bill Clinton's former secretary of agriculture, Dan Glickman: "All countries that negotiate Trade agreements will therefore find that there is always a cultural point of view in coffee, banana, cotton or cheese" ("La Convention sur la diversité culturelle inquiète Hollywood,", *Le Monde*, 2005.10.22, https://www.lemonde.fr/culture/article/2005/10/22/laconvention-sur-la-diversite-culturelle-inquiete-hollywood_702423_3246.html, consulted 2014.06.17).

Two years later, *Time* devoted an article to "The Death of French Culture" (Morrison 2007) and, in 2009, French cuisine, whose attachment to elitism and tradition was similarly decried. Michael Steinberger wrote, for France, "Food had always been a tool of French statecraft; now, though, it was a source of humiliation." (2009, p. 10). At the same time, an increasingly internationalized Michelin was accused of favoring French restaurants: the reign of the red guide, undisputed since the 1930s, was strongly shaken, especially when Sanderens (in 2005) and Roellinger (in 2007), each rejected their three stars. Competing ranking systems like the *San Pellegrino World's 50 Best Restaurants* began to appear, and great French establishments were ignored. Other international awards followed, and the French were, if not absent, at least ranked last or nearly. The resulting anxiety over these developments led the French government, in partnership with the daily newspaper, *Le Monde*, to launch a survey on the state of French taste in the world (Le Monde 2009). Its conclusions underline that, while French cuisine remains a reference, French chefs have lost their influence and no longer practice in the upper echelons. That is, they have ceased cooking for heads of state and other persons of influence.

There is, it must be noted, a broad and continued interest in the notion of *terroir*, over which France claimed a certain exclusivity. Following European regulations, North America also sought to recognize and regulate local products (Black 2007). And with support from UNESCO and the World Trade Organizations, came a "*terroir*isation" of the world. The food tourism market was thus flooded with competition. With the development of the cultural tourism doctrine, the UNWTO (2003) encouraged all countries to undertake heritage and tourism valuations of their local products and culinary traditions. From then on, the initiatives multiplied – the creation of wine or cheese routes, food festivals, cooking competitions and farm visits – and new culinary tourist destinations emerged, like Peru, named the "best gastronomic destination in the world" since 2013 by the World Travel Awards (Csergo 2016a).

Thus, the new globalization has changed the geopolitics of gastronomy in the world. The status quo, the influencers and influencees, and the markets have been reshuffled, and all threaten France's historical position; its preeminence as a country of good food, good products, and good wines; and its image as a gastronomic nation.

For the Survival of a Model and the Maintenance of Preeminence: Cultural Heritage and Gastrodiplomacy

It is in this context that France undertook not only to defend its cultural model of the table but also to regain a preeminence that, if not lost, was at least being disputed. To this end, the state developed a communication plan with two main components: cultural heritage and gastrodiplomacy.

The first counteroffensives were launched on the cultural heritage front, both at national and international levels. In 2006, at the national level, foie gras, the product and the feeding process it necessitates, was designated as a "cultural and gastronomic heritage of France" – this as a means of protecting a market threatened by animal rights lobbies and of illustrating the "heritage and the link to the soil that characterize the originality of the French food model (Code rural, art. L654-27-1 du 5 janvier 2006 – art. 74.)." In 2014, wines and spirits from local traditions had their turn to receive the "cultural heritage, gastronomic and protected landscapes of France" label (Code rural, art. L665–6, Loi n° 2014–1170 du 13 octobre 2014-art. 22). This recognition would allow them to bypass laws prohibiting the advertisement of foreign alcoholic beverages, to which they are subject [outside of France] (Code de la Santé publique, art. L3323-3-1, Loi n° 2016–41 du 26 janvier 2016-art. 13). Finally, the French Inventory of Intangible Cultural Heritage, launched in 2009, increased its inscriptions relating to food production "savoir-faire."

At the international level, France took advantage of the UNESCO Conventions, including inscribing the landscapes of its major wine regions among those "Cultural Landscapes" of the 1972 World Heritage Convention. To date, the Jurisdiction of Saint-Émilion is registered; the Loire Valley between Sully-sur-Loire and Chalonnes; Coteaux Houses and Champagne Cellars; Climates of the Burgundy vineyards. In 2008, the French President himself petitioned the Convention for the Safeguarding of Intangible Cultural Heritage (ICH-2003) for its recognition of French gastronomy. Justifying his position, he said: "We have the best gastronomy in the word." The project, which caught the attention of other countries wanting to position themselves accordingly, culminated in 2010 with the inscription of the "French gastronomic meal." On line: https://ich.unesco.org/en/d%C3%A9cisions/5.COM/6.14, consulted 2019.03.04. This inscription received unanimous praise in France, in particular by the French Prime Minister, as a tool for promoting the table, the cuisine, and the products that adorn it on an international scene.

Building on this recognition, the French government opened a second front, launching a vast international relations and soft power offensive (Nye 2004). Beyond the more traditional form of culinary diplomacy at work in the form of pomp and ceremony in the dining establishments of the Republic, France was now to practice "gastrodiplomacy" on the world stage. Appearing in 2002 (Food as ambassador 2002), the term "gastrodiplomacy" refers to a country's self-promotion via its kitchen, its network of chefs, entrepreneurs, and other actors in that sector that, like ambassadors, work to ensure French gastronomy's influence abroad. This tactic is supposed to attract investors and develop commercial and tourist markets (CCI 2014).

In 2012, Secretary of State Hilary Clinton launched the Diplomatic Culinary Partnership Initiative aimed at increasing the role of cuisine in American diplomacy, and in it France recognized the form of public relations that it had initiated as early as the seventeenth century. Gastronomic promotion, which had heretofore been relegated to an undersecretary in charge of trade and craft, was now within the purview of the Minister of Foreign Affairs himself, who could offer the initiative all the authority and prestige of his office.

By virtue of the new state's branding strategy, France as company was now invited to promote its cultural identity, now a trademark (Aronczyk 2008). Gastronomy, therefore, has found itself at the cross-section of a number of diplomatic, trade, and tourist-based initiatives. In 2012, the Minister inaugurated the state's commitment to the strategy during an official visit to the United States for a meeting at the United Nations headquarters; there, he launched the *Taste of France*, an operation set up to defend French gastronomic heritage, foie gras, *appellations contrôlés*, and French wines, this on American soil. Henceforth, chefs and winemakers are to accompany official delegations abroad, not only to serve at receptions but to promote business. French embassies around the world are required to carry out a campaign designed to seduce invited leaders. At his sumptuous official residence on the Quai d'Orsay, the Minister himself greets the annual arrival of the updated Michelin Guide, or the *Meilleurs Ouvriers de France*, with fanfare, receiving three-starred chefs or the best cheesemakers and bakers at his table, with an eye to, for instance, inscribing the French baguette on UNESCO's Intangible Cultural Heritage list. Beyond [the celebratory dinners], and with the aim of counteracting the loss of French gastronomic influence abroad, it is to those three-starred chefs who have acquired the status of international businessmen – particularly those with connections to the United States – that the Minister turns. He is seeking expert opinion on those public policies that might best foster France's products, its cuisine, its culture, and gastronomic heritage (Ducasse et al. 2014). To minimize the impact of ranking systems from the English-speaking world so that the French model might again recover its influence and prestige, the nation supports the production and promotion of *La Liste des listes* (the List of lists). Developed from a compilation of 200 gastronomic guides, mostly of French origin, and online review sites, this List, which has no international impact, nevertheless reassures the French gastro-diplomatic sphere by showing that French chefs are still among the best. Finally, in terms of events, Chef Alain Ducasse is entrusted with the task of overseeing *Good France-Gout de France*, offered up as a counteroffensive to French bashing and as an assertion of French dominance in the kitchen. Presented as the perfect illustration of UNESCO's classification of the French gastronomic meal, this operation, inaugurated the evening of March 19, 2015, takes its cue from Escoffier's Epicurean dinners circa 1912. In hundreds of cities across five continents, French gastronomic dinners are given in both French ambassadors' residences and in restaurants. In the first edition, the high point was the dinner given at Versailles, in the symbolic *Gallery of Great Battles*, which retraces the historic victories won by the French army. Here, a meal dreamed up by 6 three-starred chefs was served to 650 guests, including all the ambassadors of the world stationed in Paris.

Conclusion

In the early nineteenth century, as gastronomic discourse took hold, Utopian Charles Fourier wrote:

> One day, we will see (. . .) empires have their armies battle it out by means of gastronomy, to determine the most perfect of even the simplest dishes (. . .) and a nation's renown will be settled by its *soufflé omelette*. (1973, p. 339)

Time seems to have proved him right, as this battle has effectively begun. In building a sense of belonging to the nation and modeling and imposing its cultural prestige, France has long benefitted from the hegemonic model of its table. Now, faced with the ambitions of other countries making a claim for their own gastronomy, France deploys state communication strategies to maintain for – or reclaim on behalf of – its products, its cuisine, and its etiquette, a certain luster. For this purpose, political actors, advised by communications experts, imagine new concepts, such as la *Vallée mondiale de la gastronomie*, and new facilities, like *les Cités internationales de la gastronomie*. Official events that bring French cuisine and its art of the table to the fore make use of such sites as l' l'Élysée, Versailles, le Louvre, la Sorbonne, and les châteaux de la Loire. These national monuments serve as a gilded backdrop for chefs who themselves wear the garb of those who, during the *Ancien Régime* and *Empire*, cooked in contribution to the nation's greatness. In the absence of evaluations, it is difficult, however, to judge the reach of such initiatives. Though originally modeled on the French court, the culture of the table evolved continuously between the sixteenth and nineteenth centuries, gradually integrating the entire social body: bourgeois or peasant, Parisian or provincial, professional or familial, and refined or extremely simple, the table and its cuisine acquired various forms of excellence. Participating in the affirmation of a French culture, these literally and figuratively fed a shared imaginary around which the French model persisted. But as this prestige, having faltered, has hit a crisis point, gastrodiplomacy and nation branding have been used as rhetorical tools for staging a kind of contrived alimentary splendor that speaks to a glorious, monarchical past. In a France subject to the standardizing effects of agribusiness, where "*bien manger*" is increasingly inaccessible, such stereotypes in fact threaten the foundations upon which the French gastronomic model was historically built. It could have the effect of not, in fact, perpetuating a living, appealing, popular culture but rather of ensuring the survival of a weakened, insincere model that precludes any chance of reconquest.

Meals and Snacks in Southeast and East Asia

24

Uyen Thuy Xuan Phan

Contents

Abstract

The concept of *meal* and *snack* has recently been the topic of interest of a body of various studies in the food choice domain. Food and drink are consumed as meal or snack. *Meal* and *snack* have a dynamic nature that is influenced by different aspects, especially culture. Culturally, the East and the West are considered to have a very profound influence on the eating and drinking of their people. This chapter explores the multicolored food culture of the East by investigating what people in East and Southeast Asia consume as *meal* and *snack*, how *meal* and *snack* are prepared and constituted, and in which manner those eating contexts happen. Besides, geography, ethnicity, and climate of those Asian subregions are also introduced. The chapter used various sources of information from public census data to research articles as well as unpublished data and prestigious education websites.

Introduction

According to Holcombe (2011), the concept of Asia was developed by the ancient Greeks only to distinguish this continent to Europe, its counterpart on the same largest landmass on earth, the Eurasia. Nowadays, with about 60% of the world's population (approx. 4.5 billion) (United Nation 2017) and the largest GDP in the world's production, the term Asia means much more than "not European." Asia should be looked at from the human geography point of view rather than physical geography as this continent is the world's most heterogeneous in culture, language, environment, climate, economics, and even history of civilization. The development of Asia has a strong bond with the development of four regions: East Asia, South Asia, Southeast Asia, and West Asia (aka the Middle East). Among these four regions, East and Southeast Asia signify the concept of Asia more than the other two as the physical characteristics of the peoples residing there are significantly different from the people from South Asia (in which India is a representative) and West Asia.

Southeast and East Asia: A Brief Introduction to Geography, Ethnicity, and Economy

East Asia constitutes China, Hong Kong, Taiwan, Macau, Japan, Mongolia, North Korea, and South Korea. These countries and territories are different in geographical characteristics, i.e., continental (China, Mongolia), insular (Japan, Hong Kong, Taiwan, Macau), and peninsula (North Korea, South Korea). Southeast Asia (SEA) consists of countries that are south of China, east of India and North of Australia. SEA consists of two geographic regions: the Mainland Southeast Asia (or Indochina) and Maritime Southeast Asia (or the Malay Archipelago). The Mainland section consists of Cambodia, Laos, Myanmar, Thailand, and Vietnam. The Maritime region houses Brunei, East Timor, Indonesia, Malaysia, the Philippines, and Singapore (Southeast Asia 2015). However, there used to be a variation in the classification of Vietnam as an East or Southeast Asian nation. According to Holcombe (2011), as Vietnam occupies a transitional zone that straddles both East and Southeast Asia and with a historical tie with China, Vietnam used to be labeled "Little China." Even now, Vietnam is often seen belonging to the Sinosphere, which indicates the cultural influence of China on Vietnamese culture. This aspect will be discussed further in the section "The Vietnamese Meals and Snacks" about Vietnamese food culture (see section "The Vietnamese Meals and Snacks").

The ethnicity of East Asia consists of three major ethnic groups, the Han, Yamato, and Joseon (Koreans), and a number of minorities such as the Zhuang, Hui, Tibetan, Mongol, Bai, Ainu, and so on. The Han occupies the majority of the China's population, approximately 1.22 billion (about 91.6%) in 2010. The other 55 minorities comprise the remaining 8.4% (about 111 million) of the total population, with the Zhuang ranked among the minorities (Poston et al. 2015). The Yamato is the dominant ethnic group in Japan, taking up more than 90% of the country's total population (127.5 billion) (United Nation 2017). Besides, Japan also has two primary minority groups, i.e., the Ainu and Ryukyuan people. These three major ethnic groups occupy 98.5% of the Japan's population. Korea is mainly populated by a Joseon or Korean peoples. This ethnic group is very homogeneous and is residing in both North and South Korea. In Southeast Asia, the Austroasiatic peoples share the Mainland with Tai peoples while predominating the Maritime region. However, there has been a large wave of labor migration among the SEA countries (Kaur 2015). The formation of ASEAN and Mekong subregion has created the corridors for many laborers to migrate from Indonesia, the Philippines, and Thailand to Malaysia, Singapore, and Brunei or from Myanmar, Cambodia, and Laos to Thailand. Such movement has strong impact on the economic development as well as creates an intercultural complexity for the area including the diversity of regional foods and drinks.

The climate of East and Southeast Asian countries are influenced by the huge Asian monsoon circulation system. The Asian monsoon is divided into two subsystems, the South Asian (or Indian) and the East Asian monsoon systems (Yihui and Chan 2005). The latter system is also divided into the East Asian summer and winter monsoon. Much of the rainfall in the regions occurs during the summer monsoon season, usually between April and September, resulting in an intensive agriculture with two to three crops per year. Rice, the main crop in the regions, heavily relies on the yearly summer monsoon as many Southeast Asian countries do not have large irrigation systems surrounding lakes and rivers and wells or aquifers are often shallow (www.nationalgeographic.org/encyclopedia/). The winter monsoon does not have so pivotal influence in Southeast and East Asia's economy as its summer equivalent does. This season lasts from October to April, and sometimes is associated with droughts.

East and Southeast Asia, together, are the world's most populous and economically dynamic places. The diversity of ethnicities in the regions, both indigenous and migrating, has developed a multicolor food culture with unique flavors that are often identified as "Asian flavor."

Asian Flavor Signature

According to Kittler et al. (2011), food has a symbolic function of cultural identity. The old proverbial saying "you are what you eat" expresses the powerful influence of what one eats on who one is. A Southeast Asian person, thus, should not be mistaken with a European in that respect, given the profound differences between Southeast Asian cuisine and its European counterpart. As the concept of Asia is signified mainly by East and Southeast Asia (Holcombe 2011), the Asian flavor identity discussed in this section is derived from the cuisines of these subregions only.

Common ingredients in East and Southeast Asian cuisines include rice, ginger, garlic, green onion, sesame seeds, soy sauce, and tofu (Van Esterik 2008).

Depending on specific cuisine, other spices and condiments will be included. Red pepper powder in Korean foods or dried spices such as cloves, nutmeg, and cinnamon in Malaysian dishes are two examples. Besides, flavor paste such as mixture of chili, garlic, shallots, salt, and sugar is the authentic feature of many Southeast Asian cuisines such as Thai and Vietnamese. Asian foods are known for its use of a vast array of green and aromatics herbs and vegetables, either for cooking or garnishing or side dishes to go with noodles - lemongrass, basil, Chinese coriander, cilantro, mint, chives, dill to name a few. Coconut can be considered the most used fruit in SEA cuisines, as toppings or flavorings in dishes such as curries, stews, hot pot, and desserts. Different from European or Western diet, meat is not the central focus of Asian foods (Nam et al. 2010). Many of Asian meat-based dishes use only a small quantity of pork, beef, or chicken.

Fermentation is the popular food preservation method in these subregions. Fermented dishes such as *kimchi*, fish sauce, shrimp paste, and *prahok* are the vital parts of many cuisines in the regions such as Korea, Thailand, Vietnam, Cambodia, and Laos. The use of fermented fish products are the distinguishing element between East and Southeast Asian cuisines. To SEA people, fermented fish products are considered the "taste of home country" (Van Esterik 2008) and thus can partly relieve the nostalgia of the immigrants.

East Asian cuisines are found not to use ingredients that share flavor compounds (Ahn et al. 2011). The authors investigate the authenticity of the ingredients used in North American and East Asian cuisines and found that North American food heavily relies on dairy products, eggs, and wheat, while East Asian cuisine is dominated by plant derivatives like soy sauce, sesame oil, and rice and ginger. Adding these four ingredients to a dish can automatically make it taste "Oriental."

The Chinese Meals and Snacks

Located in a large area with a vast landscape of grassland, mountains, desserts, lakes, and rivers and more than 14,000 km of coastline coping with a population of 1.41 billion and diverse ethnicities, China is famous with a multi-featured food culture that satisfies the eyes and tongues of both gourmets and regular diners. Overall, Chinese cuisine can be separated as Southern and Northern cuisines, which dated back to the seventh century B.C. (Nam et al. 2010). The Southern Chinese dishes lay stress on freshness and tenderness, while the Northern counterparts are heavier in using fat and garlic due to the cold weather. Chinese dishes are also known for the ingenious use of medicinal herbs and spices for prevention and cure of diseases (see Li et al. 2004). Stir-frying is the most notable food preparation method in Chinese cooking. Thus, *wok* (a round-bottomed pan) has become an integral part of Chinese signature in the world cuisine. There are a body of various Chinese restaurants bearing the word *wok* such as China wok, Golden wok, Famous wok, Best wok, Great wok, and King's wok to name a few.

Regional cuisines play a key role in Chinese food culture. The Eight Great Traditions, including Anhui, Zhejiang, Jiangsu (east), Sichuan, Hunan (west), Cantonese, Fujian (south), and Shandong (north), have contributed their own unique features, flavors, materials, and cooking methods to shape the current Chinese cuisine (Nam et al. 2010). Anhui cuisine is known for its simplicity with wild herbs and simple cooking technique. Zhejiang cuisine has its fame in fresh and mild flavor with mellow fragrance and not greasy. Jiangsu dishes make use of a wide variety of seafood and fresh herbs and vegetable, emphasizing natural aromatics. Thus, Jiangsu foods are not overwhelmed with strong spices such as garlic and chili. Sichuan cuisine is the real opposite to Jiangsu's with the dominant use of hot and spicy (somewhat numbing) seasonings as dried chili pepper, Sichuan pepper, broad bean chili paste, etc. Sichuan hot pot, Kung Pao chicken, and Mapo tofu are some Sichuan's most famous and well-received dishes in the world. Hunan cuisine is often compared to its Sichuan counterpart for being hot and spicy. However, Hunan dishes are usually spicier by pure chili content and less oily. Cantonese cuisine, together with Sichuan's, has traveled the most thanks to the economically importance of Hong Kong and the Pearl River Delta region in the 1980s and 1990s and the migration of workforce from Sichuan Province and Chongqing Municipality (Klein 2009). Cantonese foods are restricted in the use of spices and condiments to promote the freshness and quality of the main ingredients. Fujian or Hokkien cuisine stresses the umami taste and often is light but subtly flavorful. The common cooking methods are boiling, steaming, stewing, and braising. Last but not least, the Shandong cuisine completes the eight major cuisines of China with an emphasis on seafood (sea cucumber is a favorite), onion, and soup (clear and milky). Shandong dishes are typically fried, making it crisp, tender, and greasy.

China has a long historical tradition of agricultural practice, and main staple foods are plant-based foods. Rice (*fan*) and side dishes (*cai*) of vegetables are always the main components of every Chinese meal (Klein 2009). This is considered the elementary structure of a Chinese traditional meal. Plain rice is typically steamed or boiled and served separately from the side dishes. In addition to vegetables, there has been an increase in the consumption of meat and meat products, fish and seafood, milk and eggs, fat, and alcohol since 1990s (Klein 2009; Nam et al. 2010). The scarce consumption of meat can be accounted for religious practice of Buddhism and Taoism in the country.

Culinary art is the unique feature of Chinese cuisine. In China, food is also for psychological satisfaction. Chinese foods are artistic and sensitive (Sun et al. 2004). There are several fundamentals in the constitution of a Chinese *meal*. The first one is the pivotal role of rice (饭:*fan*). A Chinese meal is constructed around rice. The word *fan* (饭)can also be translated to *meal* when it is combined with words indicating time of the day such as *zaofan* (早饭:morning meal or breakfast), *wufan* (午饭:midday meal or "lunch"), and *wanfan* (晚饭:evening meal or "dinner"). According to Klein (2009), a proper balance between *fan* and *cai* is the factor distinguishing a Chinese *meal* from a *snack* (*xiao chi* or small eating). The second fundamental is in the food preparation method, in which careful attention is paid to the application of "adequate" heat as well as chopping and cutting the materials to acquire eye-catching appearance. Another specialty of Chinese food is the combination of key spices that create the so-called Chinese flavor to the dish. These normally are ginger, soy sauce, and onion (Nam et al. 2010; Klein 2009).

A Chinese meal is built around social relationship and hierarchy. Family members sit around a table for regular meal. The seating is arranged around the highest honorable person in the family that could be the grandpa or the father depending on whether it is an extended or nuclear family. The underlings are taught to serve food to the elders first, and the meal does not start until the elders begin. Having meal together is a way the Chinese as well as other East and Southeast Asian peoples strengthen kinship and community relationship. In Chinese culture, people usually treat others to meal to make friend or enhance established relationship. Rice is served in a common bowl and so do side dishes. Diners take foods from those sharing bowl by their own chopsticks. Serving spoon or fork or chopsticks are sometimes provided for hygiene reason, though this manner is usually not a common practice at family meal across China (Ma 2015).

The pattern of having three meals a day is also popular in China. However, this pattern is more preferred in urban than rural areas, where people tend to eat two meals a day. According to Ma (2015), the Chinese people eat breakfast around 6:00 AM to 8:00 AM and later on weekends. Residents of big cities such as Shanghai or Beijing do not have breakfast regularly for reasons such as limited time or losing weight. This breakfast skipping trend is also widespread in the world. Chinese breakfast foods are often light and simple such as dumplings, congee, soymilk, steamed buns, or noodles. Lunch normally takes place between 11:00 AM and 1:00 PM. Lunch can be eaten at home, in office, or in fast-food restaurants. In contrast, Chinese dinner is more abundant in foods, commonly two to four dishes and one soup (Ma 2015).

Chinese food culture is also famous with an assortment of *xiaochi* (snack foods) which are the important category of street food. The traditional *xiaochi* are made of grains and beans. Kimura (2012) has named a number of favorite Beijing *xiaochi* including *doufu nao* (unmolded hot soft tofu covered with a sauce), *dou jiang* (soy milk), *youtiao* (deep-fried, twisted bread sticks), *baozi* (steamed buns), *zhima shaobing* (hard bun with sesame), and *douzhir* (supernatant of fermented mung bean milk). *Xiaochi* are sold in markets and street food stands. They have become specialties for dining out in many cities across China. *Xiaochi* foods are traditionally consumed in between meals, as snacks, when diners are visiting markets or temples. *Xiaoye*, the midnight snack, is also formed by *xiaochi* food items. In addition to three main meals, the Chinese do consume snacks and have a flavorful collection of traditional *xiaochi* to snack on throughout the day.

The Japanese Meals and Snacks

The geography and climate of Japan play an essential role in shaping the Japanese food culture. Japan is a multi-island nation whose majority landscape is mountain and is surrounded by the sea. The Japanese cuisine, thus, greatly reflects those two resources, and the Japanese refer to their food as “the delights or treasures of the seas and the mountains” (Ashkenazi and Jacob 2003). Wide valleys and its rivers are also important parts of Japan’s landscapes that provide a vast array of freshwater produces to the Japanese cuisine. Japan enjoys a temperate climate with four distinct seasons: cold temperate winter from December to February, warm-but-not-too-hot spring from March to May, hot and humid summer from June to August, and cooler autumn from September to November. Overall, the country is cold in the north, temperate in the central, and subtropical in the south. The average annual rainfall is high across the country, especially in between summer and autumn. The climate of Japan is also influenced by the monsoon circulation. This is especially crucial for the growth of rice, the most important staple crop in Japan. Rice, of course, is one essential element of a Japanese meal. This is clearly displayed in the word the Japanese use to indicate *meal*, *gohan* (ご飯), which literally translated as "rice." Thus, breakfast is called *asagohan*, lunch *hirugohan*, and dinner *bangohan*. This construction of meal label is very coherent with that of the Chinese meal label discussed in section "The Chinese Meals and Snacks". Three meals a day is also a common food pattern in Japan.

Unlike Western breakfast, Japanese traditional breakfast has all elements of a complete meal, comprising of steamed rice garnished with nori; miso soup, a protein (salted grilled salmon, for instance); and various side dishes such as pickled vegetables (Kittler and Sucher 2001). However, to the Japanese, breakfast is not supposed to be heavy, and thus breakfast foods are often light and not oily. Western-style breakfast has recently emerged in Japan due to its convenience and less time consuming as compared to the traditional style. Cereal and milk, yogurt, toast, butter, eggs, and sausages are some common Western-style breakfast foods in a Japanese household. Many Japanese people have lunch away from home during the week-days, and thus Japanese lunch is lighter and simpler. *Bento*, boxed lunch, has become a unique feature of Japanese food culture. *Bento* can be either homemade or purchased from convenience store or specialty shop and comes in a huge variety (Koh 2003; Ashkenazi and Jacob 2003). *Bento* is also highly appreciated for many other occasions such as picnics or even between acts in the theater. The stay at homes also prefer a light meal such as a bowl of noodles or rice with leftovers from previous night. Dinner tends to be more elaborate and complex as it is the main meal of the day for many Japanese people after a long working day. Evening meal often includes rice, soup, a protein (meat or seafood), side dishes of vegetables, and pickles (Koh 2003). This adheres to the *ichijûsansai* structure (one soup, three dishes) with the unquestioned presence of rice. If missing one of these elements, particularly rice, the eating is considered incomplete or a *snack* before a main *meal*. According to Ashkenazi and Jacob (2003), the three *ichijûsansai* dishes are one of raw fish (*sashimi*), a food cooked in a sauce (*nimono*), and a grilled or roasted dish (*yakimono*). Murakami et al. (2019), using the data from the 2012 National Health and Nutrition Survey in Japan (NHNSJ), has identified various meal-specific dietary patterns, as follows:

– Breakfast (four patterns): "Rice/vegetable/fish/pulse/seasoning," "bread/dairy/fruit/sugar," "meat/egg/fat," and "tea/coffee"
– Lunch (four patterns): "Bread/dairy," "noodle/seasoning," "meat/fat," and "vegetable/pulse/potato/sugar"

– Dinner (four patterns): “Meat/vegetable/seasoning,” “noodle/alcoholic beverage,” “fish/sugar/alcoholic beverage,” and “other grains/fat”

Those patterns confirm the increase of meat consumption in Japanese diet, which used to consume more fish than meat (Nam et al. 2010). In other word, Japanese diets have become more westernized.

The Japanese also enjoy snacks. Murakami et al. (2019) indicated that on average snacks contributed to 8% of the total energy intake of the Japanese participants in the 2012 NHNSJ. Working people often pause for a midmorning snack that can be a quick bowl of noodles or a cup of tea with a rice cracker (Ashkenazi and Jacob 2003). Western-style snacks such as cookies, cakes, or ice cream are also available. *Oyatsu (*お八つ), whose meaning can be either a snack at 3:00 PM or a snack between meals (wiktionary.org/お八つ#Japanese), is included in Japanese diet. Street food vendors or fast-food restaurants are some of the possible places for a Japanese to have a quick bite (Traphagan and Brown 2002).

Korean Traditional Meal

Korean food culture has been developed in close relationship with its long agricultural history and the urge of food preservation due to a monsoonal climate with a hot summer and a harsh winter (Chung et al. 2016a; Kim et al. 2016b). Fermentation has historically become the ideal choice for food preservation in Korea due to the limited production of cooking oil (Kim et al. 2016b). Various fermented dishes made of fish, vegetables, and beans have been the authentic feature of Korean cuisine. Fermented soy products, *jang*, including *kanjang* (soy sauce), *doenjang* (soybean paste), and *gochujang* (hot fermented chili paste) as well as *kimchi* (fermented cabbage and radish are the most two common), are some examples of the popularity of fermented dishes in Korean diet.

Korean food can be commonly defined as “food made with traditional Korean ingredients or agricultural products” or more precisely as “foods made with ingredients or agricultural products that have been traditionally used in Korea, or with similar ingredients or agricultural products, use authentic or other similar cooking methods, have historical and cultural characteristics, and have developed and passed on through people’s lives” (Chung et al. 2016a). The latter definition is praised for its reflection of consistency, patience, consideration, beauty, and appreciation for art (Kim et al. 2016b). K-diet has been defined in the Seoul Declaration of Korean diet (Kwon 2016) as quoted below:

– composed of Bap (cooked rice) and Kuk (soup), and various Banchan (side dishes) with one serving called *bapsang*
– kimchi is always served at every meal
– includes proportionally high consumption of vegetables, moderate to high consumption of legumes and fish and low consumption of red meat
– banchan is mostly seasoned with various jang, medicinal herbs, and sesame or perilla oil

The Declaration also characterized the K-diet as having various recipes based on rice and grains, more fermented foods, scarced deep-fat fried cooking, more meals from seasonal produce, various local cuisine, and more home-cooked meal. In Korean perception, food, revealed from the ten most renowned Korean paintings, is a symbol of power, health supplements and medicine, feelings and affections, and medium to communicate with gods (Chung et al. 2016a).

Korean meals, thus, are typically constructed around that *bap/kuk/banchan* combination. The Koreans also eat three meals a day as the Chinese and Japanese do. Breakfast, however, is a bit lighter than lunch and dinner and/or with fewer *banchan*. Rice, soup, *kimchi*, and any number of *banchan* would make the first meal of the day complete. In addition to the traditional meal type (*bapsang*), the Koreans also like noodles with broth and meat or vegetables at lunch time (Kittler and Sucher 2001). Dinner is considered the main meal of the day and faithfully adheres to the *bap/kuk/banchan* principle. Korean people have a tradition of eating meat, dated back to the invasion time of the Mongolians in the thirteenth century (Nam et al. 2010). Pork, beef, and chicken are the main meat ingredients of the Korean cuisine. Meat is prepared by various cooking methods including roasting, grilling, stewing, steaming, or boiling in soup. Meat is often marinated with *Doenjang* for flavor enhancement. Various meat-based dishes have become an essential part of the *banchan* category. Table 1 presents some of the featured dishes of the Korean *bapsang*.

Home-cooked meal (*jipbap*) would be the most preferred as the Korean people greatly value family relationship, and in their opinion, food represents a mother's love (*umma-sonmat)*. The Koreans also pay much attention to the visual appeal of the food beside flavor. Korean foods are found to possess various aesthetic qualities such as the aesthetics of harmonization and convergence, of waiting and patience, of beauty with various colors, and of refinement (Chung et al. 2016b). *Bibimbap* (a one-bowl rice dish with mixed vegetables and gochujang), *tangpyungchae* (mixture of *chungpo-muk*, beef meat, and vegetables), *seok-ggakdugi* (a food made with white radishes that are boiled for ease of consumption for the elderly), and cherry *pyun* (a traditional Korean snack (*hangwha*) made from a mix of sifted cherries, honey, and starch that is boiled down and hardened) are some examples of such qualities (Chung et al. 2016b). Thus, a Korean meal is a good example of food with both beautiful appearance and authentic taste.

The Vietnamese Meals and Snacks

Vietnam is located on the Indochina Peninsula. It borders China to the north, Cambodia and Laos to the west, the Gulf to Tonkin to the east, and South China Sea to the south (Walther et al. 2015). The country mainland area has an S shape, stretching from latitude 23°23′ north to 8°27′ north (Vietnam Government Portal, http://www.chinhphu.vn). In 2018, the population of Vietnam is more than 94.6 million (General Statistics Office of Vietnam, http://www.gso.gov.vn). The average temperature in Vietnam ranges from 21 °C to 27 °C and gradually increases

Table 1 Some featured dishes of a Korean meal

Category	Name of dish	Description	Source
Rice (*bap*)	*Ssalbap*	White rice, brown rice, black rice	Kim et al. (2016b)
Soup (*kuk*)	*Doenjangkuk*	A soup made with vegetables and *doenjang*	Kim et al. (2016b)
	Miyokkuk	Sea mustard soup	Kim et al. (2016b)
	Soegogimukuk	A beef and radish soup	Kim et al. (2016b)
Side dishes (*banchan*)	*Kimchi*	Fermented vegetables (commonly cabbage or radish) with a variety of seasonings such as red pepper powder, garlic, spring onion, ginger, and salted seafood	Jang et al. (2015); Park et al. (2014)
	Namul	Vegetable side dishes that are either steamed, stir-fried, or marinated and seasoned with sesame oil, salt, vinegar, garlic, green onion, dried chili peppers, and soy sauce	Kim et al. (2016b)
	Bulgogi	A barbecued beef, where beef is sliced and marinated in soy sauce and spices and then cooked on a grill	Nam et al. (2010)
	Samgyeopsal	Grilled pork belly which is unseasoned	Nam et al. (2010)
	Ssam	Loose leaf lettuce, *Perilla* leaf, crown daisy	Kim et al. (2016b)
Sauce (*jang*)	*Doenjang*	A fermented soybean paste traditionally manufactured from *meju*, which is fermented rectangular shape molded from crushed cooked soybean	Park et al. (2003)
	Gochujang	A red pepper paste made from *meju*, rice powder, salt, and red pepper powder	Shin and Jeong (2015); Kwon et al. (2015); Kim et al. (2016a)

from north to south. Average annual rainfall is from 1,500 to 2,000 mm. Air humidity is less than 80%. Because of monsoon influences and terrain complexity, Vietnam is often hit by severe weather such as typhoons, floods, and droughts.

The territory of Vietnam is geographically divided into three distinct regions, i.e., North, Central, and South. Each region has its own unique characteristics in biodiversity, culture, ethnicity, and climate. These characteristics have defined those three regional cuisines. The Northern Vietnamese cuisine focuses on the elegance and delicacy of foods that are often mild, subtle, less spicy, less fatty, and less sweet than the other two regional cuisines. *Pho*, the world renowned beef noodle soup, is the representative of this type of cuisine. The Central cuisine is not so delicate as its Northern counterpart. It is characterized by bold, salty, and spicy flavor. As food resources are scarce due to a severe climate, brining is commonly used for food preservation, and thus dried salted seafood products have become an important part of daily meal in this subregion. Besides, fermented fish products are also popular such as *mam ruoc* (fermented shrimp paste). Salt, *củ nén* (*Allium* genus), peanut, galangal, black pepper, and chili are the typical spices in Central cuisine. The Southern cuisine is distinguished from the other two cuisines by its sweet flavor. Tamarind, lemongrass, and coconut (usually coconut water) are common ingredients (Helmisaari 2015). Southern Vietnamese cuisine pays much attention to the flavor not visual appeal of the dishes.

Vietnamese cuisine, overall, follows the two principles of yin-yang (*am duong*) and five elements (*ngu vi*). Yin-yang principle is shown in the way food ingredients are combined, i.e., "cold" ingredients require "hot" spices and vice versa. Duck meat (cold) has to be cooked/eaten with ginger/ginger sauce (hot), or spicy foods (hot) have to go with sour and sweet tastes (cold). The generating interaction between the five elements which include metal, wood, water, fire, and earth is employed via the harmonious combination of at least five ingredients in one dish. The five ingredients of minced pork (protein, earth; fat, fire), rice vermicelli (starch: wood), salt (metal), and onion (water) in *nem rán* (deep-fried spring roll) are good example of this principle. Duong et al. (2014), by interviewing 100 foreign tourists, reported that tourists perceived Vietnamese foods as delicious foods, diversified in ingredients combination, made of distinctive ingredients, made of fresh ingredients, good for health, and visually appealing.

Vietnam is the most Sinicized country in the Southeast Asia as it has significant historical ties with China (Holcombe 2011). Vietnamese cuisine, consequently, is substantially influenced by Chinese cuisine. The essential role of rice and side "with rice" dishes in the constitution of a Vietnamese meal is the firm evidence. Some characteristics of a Vietnamese meal can be pointed out as below (Van Esterik 2008; Helmisaari 2015).

- Rice is served from a communal pot with people taking individual serving on separate bowls.
- Rice is eaten with a variety of side dishes including fish, vegetables, soup, sauces, and condiments.
- *Nuoc mam* (fish sauce) is a basic ingredient and iconic condiment present at all meals.
- Use of fresh herbs and leafy vegetables such as mint, basil, cilantro, and coriander stands out.
- Pork is the main meat as it is consumed by over 98% of the Vietnamese household.
- Chopsticks are daily used.

A recent study by Phan and Chambers (2018) investigated the inter-regional differences among the people of the North, the Central, and the South of Vietnam in their food patterns and their motives of not choosing certain foods for meals and snacks. The findings from a total of 836 participants (278 North, 213 Central, 345 South) show that rice is more likely to be eaten for breakfast in the North and the Central than in the South where rice noodle soups are the most popular breakfast food. There is no difference in preference for lunch foods among the three regions. For dinner, the Central people do not eat fast foods (pizza, burger) as often as people in the other two regions do.

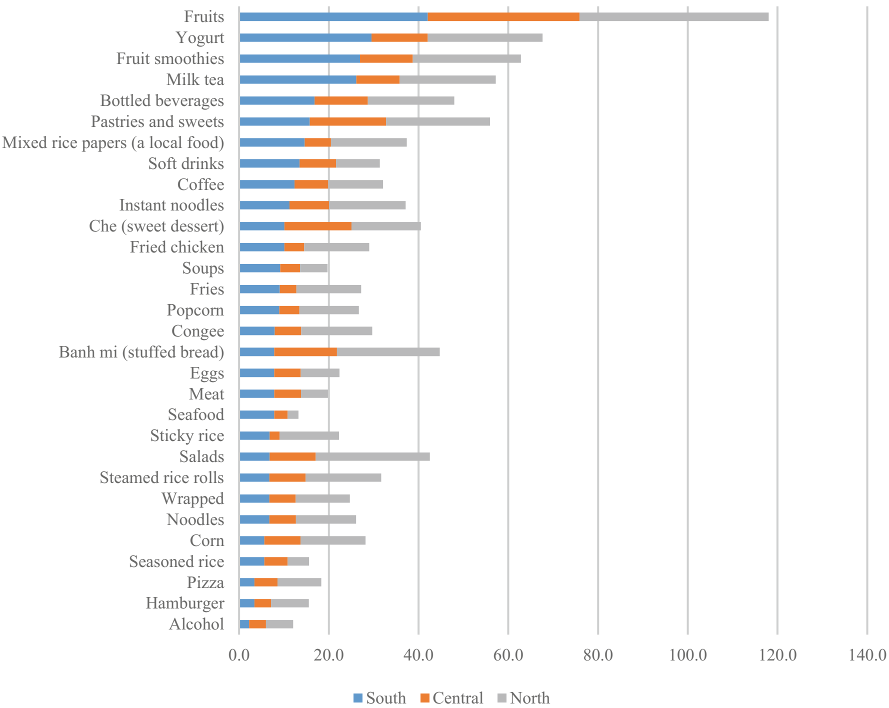

Fig. 1 Consumption likelihood of 31 snack food categories as reported by 310 respondents from the North (85), Central (136), and South (89) of Vietnam. (Phan and Chambers 2018)

Various snack foods can be found in Vietnam, from North to South. In the North, snacks are affectionately referred to as "*quà vặt*," in which *quà* literally means gift and *vặt* can be understood as small, extra eating. Thus snacks are equivalent to treats. Figure 1 presents the likelihood a food can be chosen for snacking by a Vietnamese who is from either North, Central, or South of Vietnam. Fruits, yogurt, fruit smoothies, milk tea, bottled beverages, pastries and sweets, *banh mi* (Vietnamese stuffed bread), and salads (various styles, often seasoned with fish sauce) are the snack categories that many Vietnamese people would choose for their extra eatings. This shows the diversity of Vietnamese snacks, including both sweet and savory dishes, as long as the dish does not contain rice. This somehow reconfirms the "meal-making" function of rice in Vietnamese food culture as the word *meal* in Vietnamese, *bữa cơm*, contains the word rice (*cơm*).

Thai Cuisine and Thai Meal Constitution

Thailand is the only Southeast Asian country that has never been colonized and thus it enjoys the freedom of adopting ingredients and dishes from other countries (Seubsman et al. 2009; Van Esterik 2008). Indian foods, such as curries, introduced by the Khmer in the fifteenth century (Sunanta 2005); chili by the Portuguese in the sixteenth century; herbs, fruits, and stir-fried dishes by the Chinese (Seubsman et al. 2009); and Western cuisine in the seventeenth century (Sunanta 2005) are important examples. Similar to other Southeast Asian cuisines, Thai foods are known for containing lots of fresh herbs and spices such as citrus, basil, cilantro, ginger, galangal, turmeric, garlic, shallots, pepper, and chilies. Fish sauce is also an authentic feature of Thai foods. Thai fish sauce is usually made from fermented shrimp or squid or oyster (Nam et al. 2010) which is different from Vietnamese fish sauce, which is made from fermented fish like anchovies. The regular uses of galangal, kaffir leaves, holy basil, and ginger and the combination of sweet, sour, salty, bitter, and spicy (Zevnik 2016) have created the distinctive Thai flavor that helps distinguish Thai cuisine from other Southeast Asian cuisines such as Vietnamese or Cambodian ones.

Thai meal is often comprised of a number of dishes that are different in color and flavor. Some principles of taste combination can be pointed out as sweet and sour, hot and spicy, and salted or bland (Seubsman et al. 2009). An early work reported that a proper Thai meal is constructed around rice (*khaw*) and also follows the constitution of rice and "with rice" (*kab khaw*) side dishes (Walker 1996). "No meal is complete without rice" was one of the attitudes the Thai participants in that early study stated. A more recent study has confirmed the essential role of rice and vegetables in a Thai daily meal (Papier et al. 2017). Fish and seafood are preferred source of protein. Meat plays a minor role in Thai meals because cows and buffalos used to be the mainstays of farm and village life (Mortero 2005). Thai meal also practices the five elements principle via the combination of ingredients. Besides, the aesthetics of elegance is another feature of Thai meal. This can be observed from various royal dishes.

Thai people has a unique dining etiquette as food must not be eaten fast, and the mouth should be closed while chewing. Soup must be eaten by spoon. Thai people use fork and spoon for all foods except noodles (primarily eaten using chopsticks) (Nam et al. 2010). Fork is set on the left-hand side of the rice plate, and spoon is on the right-hand side. The tradition of using fork and spoon dates from to the nineteenth century in the reign of King Rama III. Thai people generally share meal with family and friends to reinforce their relationship (Thanasabkasem 2014).

Thai people often consume one-dish meal for breakfast and sometimes Western-style breakfast and coffee. In addition to the three-meal pattern, between-meal snacks are common in Thai diets. Nutrition transition has been found in Thai diet as reported by Kosulwat (2002) or Kelly et al. (2013). Papier et al. (2017) recently explored four dietary patterns for both Thai men and women, including healthy transitional (soy milk, beans, and milk), fatty Western (fatty meat and deep-fried and Western foods), highly processed (fruit with added sugar, processed fruits), and traditional (fermented fish and soybean, glutinous rice, bamboo shoots, and chili dipping sauce). Among those, traditional diets are characterized by "high sugar, starch availability, and lower dietary diversity" and so are highly processed.

Thai food preparation methods are passed down from generation to generation. Following methods are those playing essential role in the designation of Thai food (Thanasabkasem 2014).

- *Tam*: Pounding food with mortar and pestle
- *Yum*: Combining cooked meat with vegetables, fresh herbs, and seasoning with salad dressing
- *Gaeng*: Cooking meat and vegetables in water or coconut milk
- *Tom*: Boiling
- *Yang*: Grilling or roasting over low or medium heat (charcoal is often used)
- *Larb*: Mincing or grounding pork or poultry and seasoning with herbs and toasted rice
- *Tom* Yum: Making spicy soup by using lemongrass, kaffir lime, and chilies and seasoned with lime juice and fish sauce
- *Ping*: Grilling over medium fire until done, resulting in crispy surface

The following statement by Thompson (2002) has beautifully and precisely described Thai cuisine: "Thai is not an instant cuisine. . ., it expects time and effort to be spent and it requires honed skills, but it rewards with sensational tastes."

Conclusions

Southeast and East Asian cuisines represent not only the food cultures but also the geographic, social economic, historic, climatic, and ethnic characteristics of the regions. Southeast and East Asian food cultures have interrelationship with each other, especially there has been a strong Chinese influence on the food cultures of the majority of Southeast Asian countries. Due to this Sinicization, meals in East and Southeast Asia share a common feature in its strong bond with rice. However, each cuisine has managed to develop unique flavor codes via the remarkable harmonization and combination of various ingredients, especially herbs and spices, condiments, and sauces. This very fine practice is the key of success for anyone who would like to create the so-called Asian flavor.

25 Meals in Western Eating and Drinking

Mari Niva and Johanna Mäkelä

Contents

Abstract

Meals are a way of organizing eating into events that have a particular structure and form, and they play an indisputable and even self-evident role within the rhythms and routines of everyday life. In late modern societies, concern about the fate of meals has arisen in both public and academic discourse. It has been suggested that eating is characterized today by individualization, destructuration, and informalization and that communal meals are increasingly being replaced by snacks and solitary eating. This chapter focuses on meals in today's affluent societies and reflects on why meals are considered important, how meals are defined, and what material elements and social dimensions they contain. It looks at how societal and cultural changes and ecological concerns may influence the organization and future of meals, and it suggests that the content of meals will change in response to the need to diminish the ecological burden of food production and consumption. In particular, plant-based options will at least partly need to replace meat and other animal-based foods. However, there is no reason to expect that the meal as a social institution will break down. Despite the fact that

not all meals are characterized by conviviality and companionship, they continue to serve as a significant arena of human sociability and togetherness. Sharing food is, after all, an essential part of being human.

Introduction: Why Do Meals Matter?

Meals are considered to be a profound element of human sociality, and they are important in our lives in numerous ways, both practically and symbolically. In the *practical sense*, food is fundamental in keeping us alive and going, and what is eaten at meals is significant for both short- and long-term health and wellbeing. Procuring food, planning and preparing meals, eating, and cleaning up afterward take up a significant portion of our waking hours, and meals both shape and are shaped by the schedules and rhythms of daily life. Meals punctuate our days and separate weekdays from weekends and the everyday from the feast. Buying food demands financial resources, and, for those with small incomes, finding the money to obtain food that is both liked and nutritionally adequate may be a constant struggle and cause of distress (Holm et al. 2018).

In the *symbolic sense*, meals signify diners' positions in their social networks and reflect their cultural and culinary capital as well as their ideas about what is good and proper eating. The characteristics of the foods that are eaten and the social organization of a meal, such as how and by whom it is cooked and with whom and at what level of formality it is enjoyed, are all loaded with symbolic meaning. It is difficult to find any "occasion for significant human interaction" in which food does not play a role; a celebration or other important gathering without eating together would be most exceptional (Lalonde 1992, p. 71). And as Mary Douglas (1972) has noted, the ways in which people orchestrate their eating into meals reflect the forms of social relationships of which they are the core. Sharing a meal with somebody is a sign of belonging to a particular community. Food communicates who people are within their communities and social relations, and both the symbolic meanings and practical organization of meals may differ according to the diners' social positions (Bourdieu 1979/1984).

Contemporary ideas about good eating are informed by a range of food-related discourses on such topics as healthiness, family communion, commensality, good taste (in both the sensorial and sociocultural meanings of the word), expectations of the preferences of diners, know-how and skills in cooking, and, increasingly today, concerns about what is sustainable in terms of eating. The cook and the person eating are now expected to take a stand not only on the "private virtues" implied by the consumption of food, such as taste, price, convenience, and nutritional value, but also on the "public virtues" relating to the wider society, such as ethics, justice, and ecological impact (Micheletti 2003; Niva and Jallinoja 2018). Such expectations broaden the scope of what good meals and eating are about and make new demands on consumers and meal providers to eat in socially and environmentally responsible ways.

The current discourse on food and eating often centers on food choice, a term adopted in both popular discourses and in many disciplines. Individualistic in its tone (see Murcott 1998), food choice is used as a general denominator of what people choose to eat and the individual characteristics, motivations, and attitudes influencing their choices. From the perspective of everyday life, however, where most eating takes place in the context of meals, one might ask whether it would be more useful in studies of eating to think of meals rather than food choices as the analytical unit of investigation. In his reflection on how meals influence food choices, David Marshall (1993) concludes that not only acceptability but also *appropriateness* to purpose is essential when people consider what food to eat. Appropriateness refers to the context in which the food is to be consumed and embraces the type of eating event (breakfast, lunch, dinner, or snack), the social company, and the formality of the eating event (on the application of the concept of appropriateness in consumer and sensory sciences, see Giacalone 2019). The food has to fit within the "meal system" (Marshall 1993, p. 280) of the household and accord with various often implicit rules concerning what, how, and when it is appropriate to eat. In this way, appropriateness determines what is chosen as food. Similarly, in a later chapter, Marshall (2005) contends that the meanings of food reside more in the routines, conventions, and rituals of meals than in the foods that are eaten at them. In this sense, food choice can be seen as subordinate to how meals are socially organized and regulated in the routines and habits of everyday life (see also Warde 2016; Murcott 2019).

There are strong social norms around meals. As noted in the Introduction, one of the more important norms relates to commensality (Fischler 2011), i.e., eating at the same table with other people and sharing food with them. Numerous studies have shown that commensality is regarded as an essential part of eating and of what is considered to be a "proper" meal (e.g., Mäkelä 2009; Charles and Kerr 1986). For instance, Sobal and Nelson (2003, p. 188) emphasize the significance of commensality by rephrasing the saying "you are what you eat" to "you are who you eat with." Social psychologists use the concept of "social facilitation" to describe the tendency of people to adapt to other people's eating in social situations (Higgs et al. 2019). For instance, people often adjust what and how much they eat to the behavior of significant others present in the situation. The commensal units and circles (Sobal and Nelson 2003) in which people operate reflect social relationships in family life, work, and society at large. The most important commensal unit is the family, followed by groups of people getting together for lunch or coffee at work. Commensal circle refers to a wider network of people who could, in principle, take part in a meal, with the family still at the core of the circle.

Due to the strong connotation of eating together as a sign of family communion, family meals have been described as the "archetype" of commensality, with the combination of food and family creating an idealized "symbolic icon" (Sobal et al. 2002, pp. 391–392). Families are seen to reaffirm their cohesion by eating together, and those failing to do so are dismissed as failed families. So powerful is the social norm of family eating that food providers, particularly in middle-class families, tend to praise commensal eating as the ideal although that does not necessarily mean that they are able to eat family meals regularly (Backett-Milburn et al. 2010) or that meal provision is something that parents actually enjoy. Kinser's (2017) study shows that, even though mothers work hard to cook and share meals with their families, they may have decidedly mixed emotions about the obligation and responsibility to do so. The participants in Kinser's focus groups provided meals at the expense of their own needs and interests and struggled to arrange family meals for "the health of it, and . . . for the *status* of it" (p. 38). Overall, their accounts of family meal provision were characterized by notions of work, burden, battle, fighting, and control. As the quotation shows, the mothers were well aware of not only the claimed benefits but also the social value and normative expectations of family meals.

Such everyday struggles are forgotten, however, when the ideal of the family meal is celebrated in both public discourse and in numerous nutritional, psychological, and social scientific studies that demonstrate the multiple benefits to children of regular family dinners. Adolescents who frequently eat a family meal have lower odds of cigarette smoking, alcohol use, and drug experimentation even when controlling for family structure and parental education and employment (Mure et al. 2014). Brown et al. (2019) show that adolescents who feel loved by their parents and like to spend time with them are more likely to eat family meals than others. Studies also show that adolescents and young adults themselves value family meals (e.g., Hunt et al. 2011), so it is no wonder that parents see it as their responsibility to provide the shared experiences of eating with their children. School meals are also expected to be commensal events that enhance the school community and lead to better academic performance, improved behavior, and more energetic children (Elliott and Hore 2016).

Shared meals are lauded not only by families with children but also by newlyweds and cohabiting couples. Marshall and Anderson (2002, p. 193) found that, for young Scottish couples, a shared dinner was an important part of living together and spending time with one's partner and that "eating properly" was a metaphor of family life. Similarly, according to Sobal et al. (2002), eating together is a major spousal obligation through which newlywed couples in the US negotiate their "food lives" (Sobal et al. 2002, p. 384) so as to enjoy commensal meals within "doing marriage" (Sobal et al. 2002, p. 391) and strengthening their conjugal ties. "Proper meals" involve eating with a "proper person" (Sobal et al. 2002, p. 391); for newlyweds, that is self-evidently the spouse.

Such is the power of the ideal of shared meals that eating alone is frowned upon. A lonely diner is pitied, and people are assumed to prefer eating in company if they have the opportunity to do so. Indeed, a person declining the company of others at a meal is regarded as strange because people are expected to share their food (Fischler 2011). It has been found, however, that older people who live alone may actually enjoy eating alone, deciding by themselves when and what to eat, and not having to worry about other people's preferences. Eating in solitude may thus symbolize control, independence, and competence (Thomas and Emond 2017). At the same time, a growing body of literature focuses on "solo dining," understood as eating alone in the public sphere (e.g., Lahad and May 2017). Some solo diners may dine alone because they are travelling alone while others may take great pleasure in going out for a solitary meal to enjoy the taste of food and the dining experience without having to socialize (beyond discussing the food with the restaurant staff).

An important element of commensality has been the idea of sharing the same food, but this ideal has not always been fulfilled in practice. Historically, there is evidence of privileging men's nutritional needs over those of women, with women obliged to settle for inferior food compared to men (Murcott 2019). Research in Britain in the 1980s showed that, in unemployed families with tight budgets, women would do without meat and fish so that their husbands and children could eat adequately (Charles and Kerr 1986). Interestingly, the variation in foods eaten at a shared meal today is often based on individual choices and dietary restrictions rather than differences in family members' autonomy and power relations. Allergies, chronic illnesses, and the increasing popularity of, for instance, vegetarian and vegan diets pose challenges to the ideal of a meal as an event for eating and enjoying the same food (on veganism, see the chapters in this book's section on ethics of eating; on vegan diets and family conflicts, see, e.g., Roth 2005).

What Is a Meal?

Contemporary Western eating can usefully be described as an "eating system" (Mäkelä et al. 1999; see also Gronow and Holm 2019). This system includes three dimensions: eating pattern (the rhythm and the number of eating events as well as the alternations of hot and cold eating events), meal format (the composition of the main course and the sequence of the whole meal), and the social organization of eating (where and with whom people eat and who did the cooking). In a similar vein, Yates and Warde (2015, p. 300) define the cultural complex of a meal as comprising the foods and dishes that are served, the patterning of the eating events (i.e., the structure of the sequential episodes), the format of the event (i.e., the organization of dishes in parallel and in series), the preparation and provisioning of the meal, and finally, the social occasion of the event. Lalonde (1992, p. 70) has suggested four interpretations of a meal: It can be thought of as "timely repast," as an object with a particular structure, as "scripted" action with certain objectives, or as a socially meaningful event.

The roots of exploring meals as a vital part of people's everyday lives can be traced to British meal research in the 1970s and 1980s. Scholars such as anthropologist Mary Douglas (1972/1997; see also Douglas and Nicod 1974) and sociologist Anne Murcott (1982) explored British working class and Welsh middle-class meals to characterize the grammar of a "decent" and "proper" meal in the British context. In their classic article, Douglas and Nicod (1974) describe the structural and taste characteristics of the meals using the binary pairs of salty/sweet, hot/cold, and liquid/dry. In addition, they found that the classifications of meals were based on their abundance, complexity, and ceremonial aspects. According to Douglas and Nicod, the British working-class meal model comprises many distinct, complementary, and often contradictory classifications.

Douglas and Nicod (1974) also devised a meal system that consists of three meal types. The first is a major meal or the main meal (A), the second is a minor meal or the second meal (B), and the third category consists of even less significant meals, or third meals (C) (Douglas and Nicod 1974). They found that the meal categorized as a main meal in Britain was based on the elements of a staple (potato), a center (meat, fish, or egg), trimmings (vegetables), and dressing (gravy). Anne Murcott (1982) pursued the same approach in her work on proper meals in South Wales. Not surprisingly, she found that a proper meal possessed the same structure that Douglas and Nicod had found: It consisted of one meat-based course, two vegetables, and gravy, which tied the ingredients on the plate into a proper meal. Indeed, a proper meal was a plateful of ingredients that were carefully chosen to represent a particular element of a meal.

The British meal research tradition has been very influential worldwide but especially in the Nordic countries (see, e.g., Gronow and Holm 2019). In the late 1980s, Marianne Ekström (1990) applied the idea of a grammar of meals in her study of Swedish meals. She concluded that a cooked (i.e., proper) meal consists of four components. The main ingredient was usually meat or fish, the first trimming was the starchy element (e.g., potatoes), and the second trimming comprised vegetables. Finally, extra trimmings could be vegetables or condiments. Later in the 1990s, a research project on Nordic meal patterns (Kjærnes 2001) defined a proper meal in the Nordic countries as a plateful of food consisting of at least three elements: a center (C), a staple (S), and vegetables (V) or, instead of vegetables, bread (B). In addition, a proper meal might include trimmings, such as sauces, condiments, or pickles (see Mäkelä 2001). A study in 2012 found that dinners in the Nordic countries are still typically one-course meals with relatively simple structures (see Holm et al. 2019 in this collection). This Nordic meal model contrasts with, for instance, Italian or French traditions favoring meals with several courses (Poulain 2017).

As the above examples of meal research suggest, eating events are largely organized around meals, be they minor, such as breakfast, or major, such as lunch during the day and dinner in the evening. These are concepts that people in developed countries know so well that they are essentially self-evident (e.g., Marshall 1993). When talking about breakfast, for instance, people generally assume that others can infer not only that they mean a morning meal but also that it includes certain culturally specific but recognizable elements. Bread is an example of a breakfast item identifiable across Europe whereas bacon, eggs, and beans would be associated with an English breakfast and a croissant with a French one. Similarly, lunch in the contemporary vocabulary refers to a meal that is typically larger than breakfast and takes place later in the day, around noon or somewhat later. Lunch may be hot or cold, depending on national and cultural traditions and institutional arrangements relating to work and school life (e.g., Holm et al. 2019). Dinner is assumed to be the major meal of the day, often with a culturally specific established structure varying from one-course to several-course meals. As with lunch, typical dinner times vary from country to country, and there are also in-country variations. In the Nordic countries, for instance, hot dinner usually takes place between 4:00 and 8:00 pm (Holm et al. 2015) with nationally varying peak times (Bøker Lund and Gronow 2014). Thus, even though Western food cultures seem to share the “idea” of breakfast, lunch, and dinner as meal events taking place at certain times of the day, their structures and practices vary somewhat.

A snack, which is generally considered to be not a meal but a separate, more unstructured type of eating event (see Marshall 1993, 2005; Warde and Yates 2017), is a more arbitrary concept. A snack can take place at any time between meals, and there are typically no strict rules about its content or where it should be consumed. We may note that this distinction between meals and snacks is itself a token of the social and cultural significance of meals. However, as Warde and Yates (2017) have noted, meals and snacks should not be understood as diametrically opposed to each other but rather as different types of eating events. The increasing consumption of snacks is often somewhat disapprovingly referred to as “grazing” (e.g., Fischler 2011), but the fact that the number of eating events per day is slightly increasing (Bøker Lund and Gronow 2014; Poulain 2017) suggests that snacks are becoming more important in contemporary eating.

Changing Meals

Meal patterns are culturally specific and change in time. Although the discourse on meals during the past few decades has fretted over the individualization and destructuration of meals (see Mäkelä 2009; Gronow and Holm 2019), research has shown that individually varying mealtimes were not uncommon in earlier centuries and decades. In eighteenth- and nineteenth-century France, the number of daily meals and mealtimes varied according to the diners’ social positions, and not all family members necessarily ate together (Flandrin 1996). In nineteenth century Britain, upper-class children never ate with their parents, and, unlike their parents, they were served a very limited variety of foods (Murcott 1997). The names of meals at various times of the day have changed too; in France, what was formerly termed *dîner* (dinner) is now known as *déjeuner* (lunch) (Flandrin 1996). Similar changes have taken place in other countries. In the USA, industrialization and the emergence of (male) professions in cities in the late 1800s gradually led to a shift from eating a large meal at midday to eating the main meal in the evening (Erby 2017). In Finland, breakfast in the 1920s was still a full, hot meal similar to lunch and dinner. Breakfast evolved from a hot meal to a coffee-with-bread eating event only when working days were shortened by legislation to eight hours and coffee became affordable to the working class (Prättälä et al. 1993). In 1950s Britain, over 40% of the population had a hot weekday breakfast (typically bacon and eggs) whereas only 6% did the same in 2012 (Yates and Warde 2015).

Erby (2017) suggests that, in the USA, the idealization of the family meal started in the mid-1800s, when industrialization, market capitalism, and individualism began to influence the dynamics of family life. While men increasingly worked in paid labor outside the home, women, at least in the more affluent households, stayed home and were expected to focus on the domestic realm. It was their task to provide meals, which now acquired new meanings as tokens of caring for the children and the husband (so that he could enjoy the homely atmosphere and gather strength at home both during the midday break and after a hard day’s work). The American family meal was born out of this romanticizing of the home as a “wellspring of virtue and love" (Erby 2017, p. 674). At the same time, attention was now paid to table manners, moderation in eating, and the foods served at meals. In the middle-class domestic ideal, family meals were an arena for practicing self-restraint and proper behavior.

As these and other examples show, industrialization, economic development, and changes in working schedules outside the home have primarily been responsible for large-scale societal changes in mealtimes and the social organization of meals over the past 200 years (Flandrin 1996; Prättälä et al. 1993). Similarly, in affluent contemporary societies, what people eat and when and with whom they take their meals are to a large extent demarcated by the increasing share of single households and non-nuclear families, the urban way of life, the working hours of adults, the school schedules and extracurricular activities of children, and the commodified and commercialized organization of the food supply (see, e.g., Gronow and Holm 2019; Murcott 2019). The organization of meals can thus be seen as an indicator of how, in a given society, everyday life is configured around paid work, household work, school, and leisure – at least for the majority who participate in work or educational institutions.

In the past few decades, both popular and academic discourse has raised concerns about a general destructuration and invidualization of eating, including the "demise" of meals, particularly shared meals, which have allegedly been substituted by "grazing" and snacking (Fischler 2011). In the social sciences, one of the more widely cited proponents of this view is the French sociologist and anthropologist Claude Fischler, whose concept of "gastroanomy" (Fischler 1988) has gained wide popularity in discussions about the decline of meals. However, as Anne Murcott (2019) has pointed out, there is more evidence of a century-long concern about the decline in family meals than of such a decline's having actually taken place. She has also noted that the middle-class family has come to represent the ideal family, and it is against this ideal that many commentators worry about the decline of family meals (Murcott 1997). Similarly, Andersen and Hedegaard Larsen (2015) note that the myth of the vanishing family meal emerged from the idealization of times past and serves the interests of those who wish to criticize modern "unhealthy and unsociable" ways of eating (Andersen and Hedegaard Larsen 2015, p. 287). Furthermore, it should be noted that the meanings of concepts such as "meal" and "family" are changing over time and vary in diverse cultural contexts.

As social scientists have pointed out, the celebration of commensal and family meals rarely acknowledges that commensality does not always equal conviviality. Meals also involve power struggles over what, how much, and when to eat and over the gendered division of responsibility in providing meals; they are occasions when the potentially tense relationships in a family become evident (e.g., Andersen and Hedegaard Larsen 2015; Murcott 1986, 2019; Roth 2005). Andersen and Hedegaard Larsen (2015) argue that the family meal should be seen "as a symptom of a happy family rather than its cause or as a solution for making families (more) happy" (p. 289). The celebration of shared meals, particularly family meals, has also been challenged by feminist studies. Research into how households manage food provision has shown that family foodways are, to a great extent, still dictated by patriarchal values that strongly moralize mothering practices that deviate from the norms of good and caring mothering, including self-prepared meals enjoyed with the whole family (Kinser 2017).

Conceptualizations of the elements of meals and proper meals are also changing. For instance, in Britain, the "meat and two veg" ideal still exists, but it is increasingly reserved for special occasions, and raw ingredients are often mixed with ready-prepared convenience foods in home cooking (Gatley et al. 2014). Since the 1950s, midday meals in Britain have become much simpler, evolving from typically hot meals to sandwich-based meals. Evening meals still exhibit a staple-and-center structure, but more pastas (probably with mixed ingredients) as well as pizzas and burgers are eaten than in earlier decades, particularly among younger people (Yates and Warde 2015). In the Nordic countries, it appears that, from the late 1990s to the early 2010s, dinners have increasingly become one-course meals, "platefuls," that include more components than before. Nordic dinners are still dominated by meat dishes, but vegetarian dishes are becoming somewhat more popular (Holm et al. 2015). At the same time, particularly on weekends, restaurants and cafés offer meals that combine the conventional meals, and new names for such "hybrids" are emerging. The most common is probably "brunch", a portmanteau of breakfast and lunch. Terms describing the combination of lunch and dinner have also recently emerged, including lunner, linner, or lupper. Such examples show that meals are not a static system but continually evolve, not only in what is eaten but also in how different meals are imaginatively combined in new constellations.

Another challenge to meals comes from concerns about the sustainability of our current foodways. This relates particularly to the position of meat and other animal-based foods in contemporary meals. As noted above, meat has a central position in Western meals and is ascribed many positive meanings (Latvala et al. 2012). Questioning its status may lead to increasing tensions in families if some family members would like to reduce the share of animal-based foodstuffs in family meals while others would not. As Roth (2005) has noted, a family member who adopts a vegetarian diet in a meat-eating family challenges the family foodways and threatens the family's homeostasis by redefining the meanings of meat and turning upside down the hierarchy of various foodstuffs in the family's meal system. The vegetarian may be interpreted as questioning the entire family system by refusing to eat meat, which signifies maleness, power, strength, and, typically, male dominance in families. The family meal may then become an arena of contention because, by refusing food that other family members would happily eat, the vegetarian challenges the family identity and puts into question his or her membership in the unit. In such a situation, the power relations within the family are renegotiated, and families use diverse strategies to reconstruct family cohesion. According to Roth (2005), because families know that vegetarianism is (often) not only about abstaining from meat but also about embracing an ideology that resists the dominant culture's values, institutions, and practices, they may dismiss vegetarianism as "just a phase," pressure the vegetarian to eat meat, challenge the moral justification of vegetarianism, or force the vegetarian to develop strategies of conflict avoidance, such as agreeing to eat meat occasionally or to refrain from discussing moral justifications of vegetarianism.

Social scientists in the 1980s and increasingly thereafter have noted that meal patterns in Western countries are changing due to various societal changes, particularly women's increasing participation in working life, the availability of alternatives to meals cooked from scratch, increasing incomes, the declining share of food expenditure in the total consumption expenditure of households, and the increasing number of restaurants and cafés that offer alternatives to home meals (see, e.g., Gronow and Holm 2019; Murcott 1997, 2019; Yates and Warde 2015; Warde 1997, 2016). We are undoubtedly seeing a trend towards less formal eating, "lighter" meals (i.e., having simpler structures), snacking, and less ritualistic meals (Marshall 2005; Gronow and Holm 2019), but this does not necessarily mean that meals as a social institution are threatened. As shown above, the organization of meals was not stable in earlier decades either. When society changes, patterns of meals and eating change too. The position of the meal as a central social institution structuring everyday life (Mäkelä 2009) and as a "lived experience" (Lalonde 1992, p. 75), does not seem seriously threatened, although the number of meals eaten alone may increase with the growing number of single households.

As Marshall (1993) has noted, "Different meals are marked by the time at which they occur, the frequency with which they occur, people who are present at the meal, the number of participants, the nature of the food served, the food combinations, the purpose of the event and the time spent on the food preparation, consumption and the duration of the meal" (p. 284). When one or more of these characteristics and their relations evolve over time, meals change too, but it seems that Marshall's proposition that "meals have become the things that occur between snacks" (1993, p. 286) holds true only in the literal sense that meals and snacks necessarily alternate during the day. People in Western countries still eat meals, major and minor, and little evidence suggests that snacks risk their cultural and social significance. However, Marshall rightly notes that meals are becoming less formal and that what were previously classified as "minor meals," i.e., cold meals and meals with fewer elements, are becoming more common.

Conclusion: The Future of Meals

What does the future of meals look like? Are shared meals challenged or even on their way to vanishing, as assumed in much contemporary writing? Is eating going to based more and more on whims, personal tastes, genetic predispositions, nutrigenetic diets, and laboratory-grown ingredients that scarcely resemble the plants or animals from whose cells they are produced? Are the demands of sustainability or the need to adapt to climate change and declining biodiversity going to restrict our diets in profound ways?

These large questions surround the discourses on meals and eating patterns in the late 2010s, and the answers will depend on political decisions; cultural, societal, technological, and economic developments; and changes in the biosphere and our living environment now and in the coming decades. The current patterns of eating are challenged by health, ethical and ecological concerns, and the necessary changes are going to affect the content of future meals.

However, our analysis suggests that there is no reason to expect that the position of the meal as such in Western patterns of eating is at risk, simply because meals have such a strong grip on the sequential arrangements of everyday life. In addition, individualism and commensality are likely to coexist in the future (Mäkelä 2009; Gronow and Holm 2019). Even though food and its origins may change, the role of meals as the essential social glue between people probably remains unchallenged because sharing food seems to be an essential part of humanity.

What will probably change is the food on our plates and how we organize our eating in a way that entails as little ecological burden as possible. This will mean reducing the share of animal produce in meals and replacing it with plant-based options as well as making greater efforts to avoid wasting food. One of the authors of this chapter noted in 2009 that "the heated discussion on climate change pushes forward increasing awareness of sustainability of both the production and consumption of food" (Mäkelä 2009, p. 46). In the 10 years since that remark was made, the question of climate change has become more pressing than ever (Willett et al. 2019). Solving it by changing patterns of eating may be easier said than done, however, due to the deeply ingrained nature of our routines and habits of eating as well as the failure (so far) of policy-makers to adopt serious measures to alter animal-based agricultural practices. Meat and dairy products are part and parcel of Western meals, and changing that will require a profound change in what is produced on farms; manufactured in the food industry; sold in grocery stores, cafés, and restaurants; and prepared in homes and in public food provision. The same goes for addressing food waste; all actors in the food system need to reduce the amount of wasted food, which will not happen without a reordering of the system of food provision. The reasons for food's being waste are very practical. No one in the food system wants to waste food, but the objectives, practices, and unexpected events in the flow of business and everyday life generate excess and, consequently, waste (see, e.g., Evans 2012; Murcott 2019). The focus in efforts to reduce waste should, therefore, be on those practical circumstances rather than on educational campaigns and blaming consumers.

Anne Murcott (1986, p. 79) has pointed out that, to the same degree that "we are what we eat," it may be argued that "we eat what we are." Our social identities are inextricably tied to what, where, how, and when we eat. The need to look at food from the perspective of sustainability gives Murcott's notion extra strength by linking our "eating identity" to the global ecological and social challenges of our time. If we eat what we are, then sustainable eating should become a part of our social identities just as "we are what we eat" is understood to encourage people to eat healthily. But it must be added that what we eat is not a purely voluntary, autonomous choice; that choice is made amidst a myriad of cultural norms and meanings, social relations, institutional arrangements, and political regulations, and it should go without saying that this is particularly true for the many surviving on meagre incomes who struggle every day to feed and care for themselves and their families.

"We eat what we are" must be understood as pertaining not only to individuals as diners, consumers, and parents but also to everyone in our roles as citizens, farmers, educators, lobbyists, government officials, politicians, or employees in the food system. What we eat in our future meals will depend on all of these as well as on the economic costs associated with the transition to more sustainable diets.

Packaging of Food and Drink in Japan

26

Katarzyna J. Cwiertka

Contents

Abstract

This chapter outlines the trajectory of change that the packaging of food and drink in Japan underwent between the late nineteenth century and the present day. It argues that three developments lie at the root of this transformation: the Westernization of Japanese diet, the growing reliance on mass-produced (semi) processed food, and the shifting landscape of the food retailing. In addition, the impacts of the environmental legislation and the growing labor shortage are also signalled.

The chapter begins with an overview of the contemporary state of affairs and later zooms deeper into the issues that the author considers of particular importance for the understanding of the historical shifts. They include the rise of paper and plastic into the position of the dominant packaging materials in Japan and the decline of glass, despite its spectacular growth during the first half of the twentieth century. The chapter further discusses the "packaging revolution" of the 1960s and the growing market for gifts that contain food and drink and how

the gift-giving practices in Japan affected innovation within the packaging industry.

Along with providing insights into the history of the Japanese packaging sector, this chapter contributes to the understanding of the culinary transformation of Japan in the course of the twentieth century.

Introduction

In her book *Wrapping Culture* (1995), Joy Hendry turns our attention to the practice of "wrapping," an aspect that fascinates foreign visitors to Japan, as well as recipients of Japanese gifts, meticulously wrapped in multiple layers. Hendry explains in the introduction that indeed the idea for the book began with the interest in the wrapping of presents, but the author applied the concept of wrapping in a much broader context, including exploring polite language as the wrapping of thoughts and intentions, garments as body wrappings, and constructions and gardens as wrapping of space.

Hendry begins her analysis with the description of what she calls "mundane wrapping," which includes such items as supermarket vegetables in plastic bags, individually wrapped biscuits and cakes, and seasonal gifts of vacuum-packed cured meats in elegant satin-lined cardboard boxes (1995, pp. 8–10). She is quite right in pointing out the meticulous attention to detail in terms of hygiene, convenience, and esthetics that constituted a characteristic feature of Japanese wrapping culture at the time of the Bubble Economy of the second half of the 1980s and years that followed. Yet, her book is misleading by implying a connection between the long-standing features of Japanese society with the contemporary packaging conventions.

Hendry is not the only one who has fallen into the trap of taken-for-granted continuity between the contemporary landscape of the Japanese packaging scene and pre-modern packaging practices (Japan Package Design Association 1976; Saito 1999). Yet, as the exhibition "Packaging Design from Japan: Too Pretty to Throw Away" (Machotka and Cwiertka 2016) made compellingly clear, this perception was fuelled by the appeal of retro branding, which had been a dominant trend in Japan since the 1980s (Nikkei Design 2012, p. 2). Retro designs, which can broadly be defined as consciously derivative of lifestyles, trends, or art forms from the historical past, add a cache of exclusivity and nostalgia to the commodities they adorn. In addition, by manufacturing a connection with an imagined past, they offer soothing relief from the uncertainties of modern life characterized by discontinuous and chaotic change.

This perception of continuity between pre-modern and contemporary Japanese designs is further sustained by the notion of timelessness of the "Japanese spirit," presented as being rooted in Japanese objects regardless of the period in which they are made. This concept is commonly exploited in exhibitions and other activities sponsored by the Japanese government with the purpose of global promotion of Japanese culture (Machotka and Cwiertka 2016, pp. 14–16). However, as this chapter will demonstrate, exploration of the historical trajectory of contemporary packaging practices invites quite a different interpretation, at least as far as the packaging of food and drink is concerned.

As elsewhere, the twentieth-century developments in food production and retailing one by one revolutionized the existing packaging conventions in Japan. The root of dramatic changes that took place in the packaging domain lay in the culinary transformation that swept Japan since the late nineteenth century. Three aspects in particular proved influential in this respect: the Westernization of Japanese diet, the growing reliance on mass-produced (semi)processed food, and the shifting landscape of the food retailing (Cwiertka 2006). Local neighborhood stores that had long remained the preferred location for shopping for ordinary ingredients have since the 1990s been replaced by supermarket and convenience store chains. The complex retail networks required increasingly sophisticated packaging solutions, leaving the ever fewer food items – fresh or processed – unpacked.

Japanese Packaging Industry Today

Without a doubt, the most important transformation that the routines and procedures related to packaging underwent in Japan during the last century is a shift from the multi-use to single-use, disposable containers. Wooden crates, boxes, barrels, wicker baskets and mats, wrapping cloth, and ceramic containers of different shapes and sizes were ubiquitous in pre-modern Japan, as was the case in the rest of the world (Nihon Hōsō Gijutsu Kyōkai 1978, pp. 5–7). While packaging solutions intended for a single use had not been entirely lacking in the past – straw, bamboo sheaths, and different types of leaves – they were utilizing material at hand, not especially manufactured with the packaging objective in mind. In contrast, today, a myriad of containers routinely discarded immediately after their content has been emptied are all products of sophisticated industry with a high degree of specialization.

A register of Japanese packaging businesses lists several hundred companies, divided into 81 categories (Nippō Ai Bii 2009). Each is dedicated to a particular aspect of the packaging process. There are firms concerned solely with the fabrication of packaging materials, from paper, cardboard, glass, and metals to different varieties of plastic. Other companies focus on the production of containers – jars, bottles, tubes, boxes, trays, etc. Labels are often designed and produced by yet other ventures. Finally, the machinery required for the manufacturing of all those components, as well as automated packaging robots, is a separate business altogether. This means that even a relatively straightforward product, such as a bottle of mayonnaise or a milk carton, is the result of the joint efforts of a manufacturer of plastic and paperboard, which is used by another firm to produce the bottle and carton itself. Certain products may also require a label, if it is not already printed on the container, which is then filled with the product – milk or mayonnaise, respectively – utilizing specialized machines and packaged again in boxes or crates for transport. Needless to say, those boxes are also manufactured by specialized firms. The packaging design, which is entrusted to marketing and branding professionals, must be integrated in terms of cost and schedule into the logistics of the entire process.

In 2013, the value of the Japanese packaging industry amounted to 6.05 trillion yen, which was more than the Japanese agriculture, fisheries, and forestry production taken together and slightly less than Japan's defense budget (Nihon Hōsō Gijutsu Kyōkai 2014, p. 3). Currently, Japan is the third largest single national packaging market in the world, following the United States and China (World Packaging Organization 2008, p. 4). In terms of per capita expenditure on packaging, Japan is possibly the front-runner, although the complexities of global trade make such a comparison problematic.

It needs to be pointed out that these statistics do not cover exclusively the food and beverage sector but are also utilized by the healthcare, cosmetics, and other consumer markets. While we may presume that the manufacturers of packaging in Japan keep detailed accounts of their customers and thus are in the position to calculate the share of the food and beverage industry in the overall use of packaging, this information is proprietary. The data provided by Transparency Market Research (TMR) for plastic packaging, available since 2005, is an exception. It reveals that the share of food and drink packaging in Japan has remained relatively stable in terms of both quantities and value, at around 65%. This is in line with the global data on packaging regardless of the material, released by the World Packaging Organisation. It indicates that food and beverage industry represents the lion share – over 50% – of the end-use market for packaging (World Packaging Organisation 2008, pp. 37–40).

Paper and Plastic

The two dominant packaging materials in Japan today are paper (in all its forms, including cardboard and cartons) and various types of plastic. In 2015 they represented, respectively, 40.80% and 31.3% of the total value of packaging on the market (Nihon Hōsō Gijutsu Kyōkai 2015). Paper and plastic are used separately or in combination with one another, as is the case with paperboard coated or laminated with LDPE (low-density polyethylene), which is widely utilized in fruit juice and milk cartons.

Plastic has infiltrated the Japanese packaging market at a phenomenal speed. In terms of quantity (expressed in weight), its share more than doubled during the last three decades of the twentieth century, from around 9% in the 1970s to around 19% in the early 2000s. Since plastic is relatively light compared to other packaging materials, its success becomes even more apparent from the perspective of value. Comprising just 4.6% of the total value of Japanese packaging industry in 1958, by 2005 it skyrocketed to 30% of the total value of packaging in Japan. In terms of quantity, paper and paperboard have accounted for more than 50% of the total production of the Japanese packaging industry since the 1950s and exceeded 60% in the year 2000. It is important to note that this increase in share was not caused by the use of increasing quantities of paper and paperboard; rather, it is due to the ubiquitous replacement of metal and glass packaging with plastic, which, as a lighter material than metal and glass, results in lighter overall packaging. Consequently, the same quantity of paper and paperboard will constitute a larger percentage of this smaller whole. In contrast to the quantities, the share of paper and paperboard packaging in terms of value decreased from around 50% in the early 1960s to around 42% in the early 1990s, where it has remained ever since (Nihon Hōsō Gijutsu Kyōkai 1972, 2015).

Domestic production of plastic began in Japan in 1955 with polyethylene (PE), followed by polyethyleentereftalaat (PET) and polystyrene (PS) in 1959 and polypropylene (PP) in 1960. These new substances were soon to become the material of choice in the packaging of food. One of the first commodities that utilized this new material was *miso* (fermented soybean paste), a rather ordinary ingredient in the Japanese kitchen that had been used on a daily basis for centuries. It had customarily been manufactured at home or bought directly from local merchants. As was the case with other everyday commodities, such as tofu, soy sauce and sake, customers brought their own containers to take the purchased article home. Miso packed in a polyethylene bag, at the time still imported, went on sale in 1954 (Minakuchi 2010, pp. 162–163).

In contrast to plastic, paper has been manufactured in Japan for centuries but only emerged into a mainstream packaging material after the mechanized papermaking technologies were introduced from Europe in 1874 (Ōji Seishi 2009, p. 21). *Washi* ("Japanese paper") refers to handmade papermaking conducted primarily as off-season winter work for farmers (Hughes 1978; Barrett 1983). Next to the publishing industry, different types of *washi* were utilized throughout the early-modern period in the manufacture of a wide variety of objects, ranging from sliding screens/doors and lanterns to fans, umbrellas, and even clothing. However, paper was still relatively costly, and those objects were by no means intended for a single use. The notable exception were fireworks and toilet paper (known as *otoshigami* and *chirigami*). The latter was a by-product in the paper manufacture, made from the outer dark bark and fiber residue that would otherwise be discarded (Hughes 1978, p. 173, 176).

At the time when the technology for the manufacture of "Western paper" (*yōshi*) was introduced in Japan, the paper industry had been thriving on both sides of the Atlantic to an extent that the 1860s was heralded by the contemporary "The Age of Paper" (Hunter 1978, pp. 386–388). The skyrocketing popularity of paper was caused primarily by the nineteenth-century innovations that transformed papermaking into a mechanized industry relying on wood pulp, instead of cotton and linen rags which had traditionally been used (Magee 1997). A dramatic rise in the productive capacity of paper mills caused a steep decline in paper prices, which, ultimately, was one of the factors that prompted the proliferation of paper in the food packaging industry. In addition, the development of mechanical processes to mass-produce paperboard cartons, in the final two decades of the nineteenth century, contributed to the further popularization of this form of packaging (Tweede 2012).

Although Western-style paper quickly gained ground in the newspaper business (Ōji Seishi 2009, pp. 28–29), and old newspapers evolved into a handy wrapping material at food stalls, it took several decades before the Japanese food packaging sector embraced cardboard boxes on a mass scale. The notable exception were caramel candies retailed in a pocket-size, yellow carton box. Launched in 1914 by the pioneering Western-style confectioner Morinaga, the product was the first turned into one of the most iconic merchandizes of the century and is still available today. Morinaga Milk Caramels – a box resembling a pack of cigarettes, containing 20 candies wrapped individually with wax paper – became a sensation, primarily due to the portable packaging, which could be easily carried to cinemas, picnics, zoos, and hiking trips (Mitsuda 2017, p. 72). The success of Milk Caramels positioned Morinaga as the leading producer of Western-style confectionery in Japan, and the company soon diversified into mass production of chocolate, biscuits, and candy.

Commercial success of pioneering producers of Western-style confectionery notwithstanding paper and paperboard did not develop into a mainstream food packaging medium before the dawn of the postwar "economic miracle" (1955–1973), a name given to this time span due to a spectacular increase of the GNP, with the average growth of real per capita consumption of 7.51% per year (Horioka 1993). The rising levels of personal consumption went hand in hand with the growing veneration of the American way of life, of which mass-produced food packed in colorful boxes was one of the most representative features. The 1960s witnessed a launch of a great variety of Western-style confectionery, such as Fujiya's Milky, Glico's Bisco, Morinaga's Chocolate Balls, and Meiji's Almond Chocolate, to mention only the most iconic brands. In addition, domestic production of paperboard drink cartons began in 1962, introduced 6 years earlier by the Swedish firm Tetra Pak. Milk companies saw potential for replacing glass bottles to restructure and extend distribution, and the shift was also encouraged by the Ministry for Agriculture, Forestry and Fisheries, which aimed at propagating milk consumption. By the mid-1990s, cartons comprised about 85% of milk containers and 39% of fruit juice containers (Penna 2002, p. 99).

During the high-growth period, paper also came to be extensively utilized in the packaging of souvenirs (*omiyage*), which are closely related to the rise of mass tourism. The origin of the custom of bringing a gift from a trip is centuries old, but the habit was considerably transformed by the proliferation of railway. Today, an ideal *omiyage* should contain a specialty food from the area one is visiting, and packaging design is one of the most essential elements of the branding strategies of their producers. These gifts are customarily distributed among relatives, neighbors, and colleagues; sweet and savory snacks (*kashi*) are particularly popular because they can be shared with others (Cwiertka with Yasuhara 2020, pp. 79–87). It is estimated that between the 1960s and the 1990s, the number of Japanese who travelled for pleasure – and thus purchased multiple *omiyage* items – increased fourfold (Kim 2011, pp. 202–204). Although the manner in which gifts are presented, including the way they are wrapped, has traditionally been of great importance in Japan, elaborate packaging of *omiyage* has since the 1970s attracted repeated criticism of being wasteful.

Yet, the biggest contribution to the phenomenal expansion of the use of paper in the Japanese packaging industry over the decades are corrugated containers (*danbōru*). They remain the largest volume paperboard product in Japan and are the vanguards of the packaging revolution that took place since the 1950s. The replacement of wooden crates/boxes, usually laid with straw, which had served as the main vehicle in the transportation of goods for centuries by cardboard boxes began as a by-product of the military procurement boom inspired by the Korean War (1950–1953). As a territory since 1945 occupied by the Allied Powers, Japan was developed into the base of logistical supports for all the troops fighting in Korea under UN Command. Japan Logistical Command (JLC) in Yokohama functioned as a requisitioning agency for all goods for Korea, from munitions and petrol to boots and ice cream. Moreover, goods shipped from San Francisco customarily arrived in Japanese rather than Korean ports and were stored in depots throughout Japan. In addition, the Procurement Section of the JLC purchased a wide variety of items from local merchants and producers in Japan (Cwiertka 2013).

Corrugated boxes were at the time the designated packaging containers in the US military, which meant that all the supplies ordered by the Procurement Agency had to fulfill these requirements. Under a strict guidance of the packaging professionals dispatched from the United States, and vigilant assistance of the Ministry of International Trade and Industry, seminars were held all over the country to familiarize Japanese businesses with the American packaging requirements (Nihon Hōsō Gijutsu Kyōkai 1978, pp. 83–84).

Largely owing to corrugated boxes, the use of paperboard in Japan expanded from 0.18 in 1950 to 12.52 million tonnes by the end of the century (Penna 2002, p. 96). Along with the supplies procured by the US military, *danbōru* soon began to be used in the domestic transport of fruit and vegetables and later the ever diversifying products of the food-processing industry.

The Packaging Revolution

Elaborate packaging of food and drink, referred to by Hendry as "mundane wrapping," has only become emblematic of Japanese consumer culture during the final decades of the twentieth century. It was, in the first place, conditioned by the postwar economic growth, which, in turn, initiated the shifting of the landscape of the Japanese retailing in the direction of self-service. The very first supermarket opened in Japan in December 1953, and by the end of the decade, over a thousand such self-service stores were in operation across the country. However, their growth remained slow. During the 1980s, the market share of supermarkets within the Japanese retail industry had barely surpassed 35% (Kensei 1997, p. 3). In fact, the expansion of large stores was intentionally hindered by the Ministry of Economy, Trade and Industry, motivated by protecting the livelihood of small retailers. The policy was revised in 1990s, and by the end of the century, the Large-Scale Retail Stores Law was repealed altogether (Grier 2000/2001). Today, supermarkets and convenience store's chains account for over 85% of food retail sales (Aoki 2018).

Along with those legislative measures, the shifting consumption patterns were also a factor at play in the proliferation of supermarkets. They emerged as the primary destination to find innovative products, such as processed and frozen food, and their production grew from 5,000 t in 1960 to 562,000 t in 1980 (Yano Tsuneta Kinenkai 2000, p. 294). By the mid-1990s, less than one-third of the food consumed by an average Japanese person was in the form of fresh foodstuff cooked at home (Ishikawa 2002, p. 170).

Thus, between the 1970s and the 1990s, the packaging conventions of food and drink in Japan were undergoing transformation under the influence of three concurrent developments, on top of the abovementioned shifts in retailing. To begin with, the share of processed food in the Japanese diet grew rapidly. All these products requiring appropriate packaging in the face of the retail network became increasingly complex and in self-service stores the new normal. As the competition between brands increased, producers increasingly used the packaging of their products rather than its content to differentiate themselves. These circumstances prompted a wave of innovations within the packaging industry, in terms of design and functionality.

The launch of ready-to-eat curry in a retort pouch, marketed in 1968 under the name Bon Curry, is a case in point. Within 5 years of its introduction, the product was selling 100 million packets a year, and it remains popular today (Arita 2008). Curry on rice, a British import that began to gain popularity in Japan around the turn of the twentieth century, had by the 1960s acquired a status of a national dish that was primarily enjoyed while dining out (Cwiertka 2006, pp. 8, 48–49). Thus, it was not the dish itself but rather the novelty and convenience of the packaging that were responsible for the product's success – Bon Curry was ready to eat after simmering the pouch in boiling water for 3 min. The pouch was constructed from a flexible metal-plastic laminate that was able to withstand the thermal processing used for sterilization – a process very similar to canning. The product was developed jointly by three Japanese companies: the food-processing business Ōtsuka Foods, the canning giant Tōyō Seikan, and the manufacturer of automatic packaging and filling machines Tōyō Jidōki. The technology utilized was quite new, having only been applied commercially in the United Kingdom and the United States a year earlier (Matsuoka 2010, pp. 141–142). The cutting-edge character of this packaging was confirmed by the fact that in 1969, a year after the launch of Bon Curry, a number of foods in retort pouches were selected by NASA for the Apollo 11 moon orbit mission. Until that point only dehydrated and freeze-dried foods were used by cosmonauts (Hefnawy 2010, p. 173).

Bon Curry was not an isolated case but rather an indicator of the growing sophistication of the Japanese packaging industry. Following the success of 1966 Tokyo Pack, the very first international packaging fair organized in the capital, Japan took up a leadership role in the global packaging business by initiating the establishment, in 1967, of the Asian Packaging Federation and, the following year, the World Packaging Organisation (Nihon Hōsō Gijutsu Kyōkai 1978, pp. 58–59). During the 1970s, the first signs of the transformation in the Japanese packaging industry could be observed, from a latecomer catching up with the technology developed in Europe and North America to creating its own innovative solutions for packaging problems. In 1976 Mitsubishi Gas Chemicals Co. Ltd.

marketed the first oxygen scavengers, also known as oxygen absorbers (Coles et al. 2003, p. 285). The first patent dates from 1938 in Great Britain, which used iron, zinc, or manganese to scavenge oxygen from canned foods. Further experiments were conducted by the US Army with the purpose of utilizing the technology in military rations, but the Japanese were the first to release it commercially (Cooksey 2010).

A great variety of oxygen scavenging systems are available on the market today, but little sachets containing iron sulfite are most commonly used worldwide. They help to extend shelf life of foods by decreasing the level of oxygen in the package. All sealed packages, even those closed hermetically, can permit the entry of air, which contains oxygen. Oxidative reactions – microbiological, enzymatic, or biochemical – are the primary factor in deteriorating foods, affecting their color, flavor, and texture. In the case of biochemical deterioration, the higher the temperature and the higher the moisture concentration, the more rapid this reaction is (Brody et al. 1995, pp. 5–6). Thus extracting oxygen is critical to prevent the loss of quality in packaged foods, particularly in hot and humid climates like that of Japanese summers.

Japan was not only the birthplace of commercial oxygen scavengers but also used to be their largest consumer. For example, during the 1990s approximately 2 billion oxygen scavengers were used across Japan annually, compared to 100 million in the United States (Brody et al. 1995, p. 15, 17). The estimates for the global oxygen scavenger market in 2001 were 12 billion units in Japan, 500 million in the United States, and 300 million in Western Europe (Souza Cruz et al. 2012). The hot and humid climate, along with the custom of exchanging perishable food gifts (see below), may be considered the primary factors driving the use of oxygen scavengers in Japan. Although the most current data suggest that the rest of the world has in the meantime managed to catch up with the Japanese market, they can be definitely marked as evidence of the rising Japanese leadership in the packaging innovation.

Packaging Embellishments

Gifts represent a major form of consumption in Japan and an important segment of the Japanese economy. A great deal of shopping activity in Japan is not for oneself but to buy gifts for others. Yano Research Institute valued all the gifts exchanged during the year 2016 at 10,206 trillion yen, which corresponds to 77% of total supermarket sales in that year (Cwiertka with Yasuhara 2020, pp. 77–78). Food and drink constitute the most important category of gifts. Consumable gifts are devoid of personal connotations and leave no trace in the house, which are reportedly the reasons behind this preference. This holds true not only for the mentioned-earlier *omiyage* but also for presents exchanged during the two traditional gift-giving seasons – the year-end *oseibo* and midsummer *ochūgen* (Machotka and Cwiertka 2016). These occasions signify gratitude to those whom people feel indebted including relatives, neighbors, teachers, and superiors in professional organizations.

What distinguishes gifted food and drink from ordinary commodities one would purchase for one's own consumption is the exclusive packaging design and an additional layer of wrapping paper, which envelops the already neatly packed content. Confectionery belongs to the most favored gift items, including high-end chocolates, a variety of Western-style cookies and cakes, as well as traditional Japanese-style confections (*wagashi*). Today, each individual *wagashi* is customarily wrapped and often placed on a plastic tray with tiny compartments for each one of them. Not infrequently, the tray is again sealed in plastic, with an oxygen scavenger sachet included for extra protection. The tray then may be inserted into a paperboard box, which in turn is wrapped in a sheet of wrapping paper. The design of this outside layer of packaging often utilizes decorative patterns that in the past used to adorn silk fabric, lacquer boxes, and other art objects. This gives the packaging an aura of sophistication and tradition (Machotka and Cwiertka 2016).

A variety of confections that comprise the *wagashi* category is enormous. Many are proud descendents of exquisite delicacies crafted centuries ago for Kyoto aristocracy and later for a slightly less genteel clientele of merchants, artisans, and entertainers (Nakayama 2001, p. 73). A characteristic feature of the business has always been its local character. Professional confectioners operated in the vicinities of their workshops and delivered their creations in wooden or lacquerware boxes (*seirō*), often with the shop's logo prominently visible on the outside (Nihon Hōsō Gijutsu Kyōkai 1978, p. 293). Contrary to the presumptions that contemporary conventions might impose on the past, *wagashi* were never individually wrapped. In fact, in his study of the early twentieth-century challenges faced by the *wagashi* sector, Tatsuya Mitsuda highlights the allegedly unhygienic conditions in which Japanese-style sweets were manufactured and sold (2017, pp. 62–63). For example, only 1 out of 20 *wagashi* workshops that operated on the fashionable Ginza street in Tokyo is reported to have passed the hygiene inspection executed in 1934 by the metropolitan police. Particularly illuminating historical evidence used in Mitsuda's study is a report by a contemporary from his study trip to North America, published in 1909 in *Jitsugyō Shōnen* (Industrious Youth), a new magazine targeted at aspiring businessmen (Satō 2016). The article remarks that in contrast to the practice of handing over the sweets to the customers in bags made from old newspapers and magazines, which was customary in Japan at the time, in the United States, customers are presented with their purchase in "beautiful boxes, wrapped up in beautiful paper, and tied up so that they could be easily carried" (Mori 1909, p. 6).

Such accounts are valuable because they directly contradict the taken-for-granted assumptions of continuity between the past and the present packaging conventions in Japan that had been discussed at the beginning of this chapter. No, the contemporary sensibility toward the hygiene and esthetics of food packaging is not an uninterrupted continuation of centuries-old tradition. The nowadays common practice of "individual packaging" (*kohōsō*) of food items that are already packed in a larger container, which results in multiple layers of packaging, was one of the big trends of the 1980s. This is clearly indicated by the statistical information of the value of *kohōsō* packaging machines. In 2009 their value was twice as high as in the 1980s, despite the fact that production had declined since 1992 (Minakuchi 2012, p. 12).

Individual wrapping of *wagashi*, at the time still by hand, emerged in the early 1950s, when cellophane, parchment paper, and glassine paper – all used for decades as wrapping material in Europe and North America – started to be utilized for this purpose (Nihon Hōsō Gijutsu Kyōkai 1978, p. 294). It is unclear what considerations have prompted this new practice, but we might surmise that due to growing demand, the sites of production of *wagashi* shifted from local stores that manufactured them on the spot to larger-scale workshops from where they now had to be transported. This, in turn, required more careful packaging than was the case before. Although concerns about overpackaging were voiced during the 1970s, which for the first time prompted consideration for the waste of resources (see the next section), the practice continued undisturbed.

Glass

Among all the categories of materials differentiated in the Japanese packaging statistics today, glass ranks lowest in terms of value (Nihon Hōsō Gijutsu Kyōkai 2014, p. 428). Owing primarily to their weight, which directly affects shipping costs, glass containers have been successively pushed away from the packaging market by aluminum cans, PET bottles, and laminated cartons and pouches. Despite this decline, the importance of glass in Japan's packaging history cannot be overlooked. Glass containers of different sizes and shapes had been employed for decades in the retailing of beer, sake, lemonade, and other liquids. Glass also played a role in the creation of many historical icons, commodities that in a split second reflect the spirit of the time (Heisei Botoru Kurabu 2017).

Like paper, the technology of glass manufacture arrived in Japan via two different channels: first from Ancient China and several centuries later from Europe. By the eighteenth century, a cottage industry of glassmaking developed in various parts of Japan, but the quantities and quality were low. In 1889, Shinagawa Glassworks began industrial production of beer bottles, still using the mouth-blowing method. Over 70 local companies that had ventured into beer brewing during the 1860s and 1870s utilized bottles imported from abroad. The consolidation of the industry in the early twentieth century left only six beer brewers on the market, of which Dai Nippon Beer and Kirin Beer companies were the largest (Alexander 2018, pp. 36–37). The two giants co-funded the first automatic bottle-making factories, which began production in 1916 (Jōkō and Ogawa 1995, p. 30).

Along with beer, glass bottles found an array of other applications in Japan's food and beverage retail sector. In 1909, the Ajinomoto flavor enhancer – chemically extracted monosodium glutamate in granulated form – went on sale in a slender glass bottle that looked like it might hold perfume. Suzuki Chemical Company, which marketed the product, appealed to the bourgeois housewives and their newly found sense of self as culinary professional and guardian of her family's well-being. The year 1931 marked the arrival of the product in a salt-shake-style bottle for use at the dining table, rather than in the kitchen, which symbolized Ajinomoto's acceptance as a daily necessity for the middle-class urban families (Sand 2005). Although the shape of the bottle has changed over the years, it can still be found today on every supermarket shelf (Heisei Botoru Kurabu 2017, pp. 50–51).

Regardless of its impact, the Ajinomoto shaker is not the most iconic glass container of twentieth-century Japan. This distinction should, in my view, go to none other than the *isshōbin*, the 1.8 l bottle. Traditionally, soy sauce and sake – the two essential liquids in Japanese daily life – had been kept in wooden barrels/kegs (*taru*) and ceramic bottles (*tokkuri*). When purchasing these two commodities, customers usually brought their own containers, into which the liquids were poured from barrels using a funnel and wooden measuring boxes (*masu*) of 1 *gō* (0.18 l), 5 *gō* (0.9 l), or 1 *shō* (1.8 l). *Gō* and *shō* are the units of volume belonging to the Japanese system of measurements used until the mid-twentieth century, when the metric system was legally adopted.

The sale of sake in glass bottles is said to have begun in 1886, primarily in anticipation of the prospects of foreign exports. Around the turn of the twentieth century, several brands – including Sawanotsuru, Hakutsuru, and Yamatodamashii – launched the *isshōbin* bottle. Other makers soon followed, joined a decade later by soy sauce brewers (Yamamoto 1990, pp. 137–144; Heisei Botoru Kurabu 2017, pp. 52–53). A total of 1.8 lbottles were by then manufactured in Osaka by Tokunaga Glass factory using the fully automated bottle-making machines developed and patented by the cutting-edge American glassware manufacturer Hartford-Empire. They gradually replaced ceramic bottles as the mainstream sake container. In the mid-1960s, sake was retailed exclusively in glass bottles, of which the majority were *isshōbin* (Dainakkusu 2018, p. 1).

With the successive Westernization of Japanese lifestyle since the 1960s, whisky and beer, and later wine, have swiftly replaced sake as Japan's "national drink" (*kokukshu*). The share of sake in the total domestic consumption of alcoholic beverages dropped from 80% during the 1930s to less than 7% today (Stegewers 2017, p. 143). This shift does not only affect the commercial future of the sake industry but also threatens the fate of *isshōbin*. With the growing popularity of smaller bottles and cup-size containers, along with the increasing use of laminated cartoon as packaging of cheaper types of sake, the 1.8 l bottle is truly on the verge of extinction.

Conclusion: The Future Challenges

In October 1973, the Arab members of the Organization of Petroleum Exporting Countries (OPEC) placed an embargo on the export of oil to countries supporting Israel in the Yom Kippur War. The embargo lasted until March of the following year and prompted a phenomenon, commonly referred to as "Oil Shock," which brought about far-reaching economic and political consequences worldwide, also for Japan. The Japanese economy fell into a recession, and the crisis reinforces the realization that resources and energy that the country needed for development were not infinite and that the culture of disposability, which had been constructed in the previous decades following the American example, had to be reconsidered. These circumstances were instrumental in initiating movements toward effective utilization of resources through recycling (Siniawer 2018, pp. 94–96, 122–129).

It took another two decades for the post-Oil Shock sentiments to be translated into national legislative action. The year 1995, which marked the enactment of the Law for the Promotion of Sorted Collection and Recycling of Containers and Packaging (usually abbreviated as Containers and Packaging Recycling Law), can be considered a turning point in this respect. The law established a system in which glass containers, PET bottles, and paper cartons are collected from households by municipalities and retailers and are then delivered to the Japan Containers and Packaging Recycling Association (JCPRA) for recycling. The manufacturers of these products are obliged to pay an annual fee to the JCPRA, which contracts recycling companies to process and recycle the waste. A 2000 amendment expanded the law to include non-PET plastic packaging and non-carton paper packaging as well (Tompkins 2019, p. 16).

The effects of this legislation are clearly visible in the statistics, which indicate a steady decline in waste generation in Japan starting in the early 2000s (Waste: Municipal waste 2019). The commitment toward recycling, outlined by the government as the main solution to solve environmental problems related to waste, has since the 1990s exerted an ever-increasing impact on the industry. This can clearly be observed through the pages of *Hōsō Times* (Packaging Times), a weekly newspaper targeted at packaging professionals, which has been published continuously since 1966. The journal now frequently reports on the topics related to energy and resources conservation, the search for alternatives for plastic, and other environmentally relevant issues. These aspects are likely to remain at the center of the industry's future concerns. However, there is an additional challenge that the Japanese packaging industry is facing at the moment: the shortage of human labor.

According to the data of the Cabinet Office, the percentage of elderly in Japan (defined as people aged 65 and older) is now the highest in the world, reaching 27.7% in 2017. In terms of labor force, this translates into approximately two working-age people supporting one elderly person (Annual Report on the Ageing Society 2018, p. 5). What makes these statistics particularly striking is a high pace of change that has led to current situation. The share of elderly in Japan used to be classified as "lower rank" until the 1980s and as a "medium rank" during the 1990s; the number of working-age people supporting 1 elderly declined dramatically from 7.4 in 1980 to 4.4 in 1995 and further to 3 in 2005.

In what way are these developments related to the packaging of food and drink in Japan? The answer to this question is provided by the front page of the recent edition of *Hōsō Times* (11 March 2019), which featured detailed statistics related to the packaging machinery produced in Japan between 1985 and 2018. The value of those machines has more than doubled over the course of this time span, and during the 2018 the sector registered a growth of 10%, compared to the previous year. This was a third consecutive year in which the reported growth was 10% higher.

In the analysis of those figures, provided by the journal, two major factors have been outlined – the growing interest in the Japanese packaging machinery by overseas importers on the one hand and the tenacious shortage of labor that inflames the domestic demand. Thus, a growing investment in automation has increasingly influenced the Japanese packaging industry and is very likely to expand even further in the future.

Consumer Research For Wine

27

Larry Lockshin and Armando Maria Corsi

Contents

Abstract

Wine is complex alcoholic beverage composed of a wide array of sensory and product attributes. Therefore, while wine is an interesting product to research consumer preferences for, there are a series of academic and practical challenges one needs to take into account.

The purpose of this chapter is threefold. First, the chapter explains the reasons why wine is considered a complex product. Second, the chapter illustrates the various quantitative techniques one can use to investigate consumer preferences toward different wines, showing the main advantages and disadvantages of each technique and some notable examples of research conducted with each of these techniques. Third, the chapter provides some practical advice in order to conduct

research for wine in an appropriate manner. In particular, the chapter explains what the researcher should keep in mind to set up the objectives of the research and how to apply these to the research approach. The chapter then continues by providing some indications of the costs one should keep in mind based on the approach one intends to use and the advantages and disadvantages of conducting research in-house versus outsourcing it to a research firm.

Introduction

Most people reading this chapter would be familiar with some aspects of consumer research especially in the food area, so why is it necessary to discuss consumer wine research specifically? There are three reasons why wine is a unique consumer product, and each of these affects how research should be conducted:

1. Wine is an *alcoholic beverage*, which brings a range of testing and tasting restrictions into play.
2. Wine is a *very complex product* composed of a large number of product attributes used by consumers in making their purchases.
3. Wine is composed of a *complex array of sensory attributes*, in addition to the product attributes.

Conducting useful research on wine, whether academically or commercially based, has a number of issues, which this chapter will explore. The first section covers the specific aspects of conducting research on an alcoholic beverage as well as the basics of the complexity of wine as consumer research product. The next section focuses on the quantitative research methods adapted to the complex system of product attributes exhibited by wine, including combining the extrinsic (packaging and label) attributes with the intrinsic (sensory) attributes in preference research. The final section explores some of the practical aspects of conducting consumer research on wine.

Why Wine Is Different as a Consumer Research Product

Wine as an Alcoholic Beverage

Research on any alcoholic beverage brings with it both ethical and legal responsibilities for the researcher. Researchers should clearly present the research as being alcohol-based and set forward considerations the potential respondents should agree to before participation. Some respondents, such as pregnant women or those taking medication that is antagonistic to alcohol, should be cautioned about participation and recommended to not to participate. Research by Mueller et al. (2009) showed that some respondents began to reach the legal limit for alcohol in the bloodstream (0.05 g /100 ml in most jurisdictions) after approximately

180 ml of consumption (6 $\times$ 30 ml samples), with females generally having the highest readings. Even those with lower blood alcohol readings stated the task became more difficult after the first six samples and the standard deviations within each subject increased as well, showing that the usefulness of the data can also be compromised with too many or large samples. When conducting consumer wine research, no more than six samples (30 ml) should be given to any respondent. Smaller samples can be used, but it's important for respondents to be able to re-taste each sample. Also, it is an important ethical consideration to have the means to measure the blood alcohol for all respondents and make sure it is below the legal limit in the jurisdiction where the research is conducted before allowing them to leave the testing facility.

Wine as a Complex Product of Extrinsic Attributes

The second important aspect to understand when conducting consumer research with wine is the complexity of the product (Hall and Lockshin 2000). Wine is one of the few products where the location of production plays a part in both the identification and preference for the specific product as well as influencing the sensory characteristics (Lockshin et al. 2000). There are dozens of wine-producing countries, hundreds of regions, hundreds of different grape varieties, and over 100,000 wine brands sold in the world. Because of these complexities, it is impossible to compare all options available to a consumer when conducting research. Researchers must decide which aspects are most important and focus solely on these in any one project.

There are a number of studies of consumer wine choice behavior (too many to list here), but a recent review of research in this area by Lockshin and Corsi (2012) confirms that previously tasting the wine and its price, brand name, grape variety, origin, any medal/award, an attractive label, and recommendations by others are the main factors consumers consider in choosing a wine. Lockshin and Cohen (2011) showed that the importance given to these attributes varied across the 11 countries in their study. This means that wine researchers need to use the most relevant attributes based on the country where the research is occurring or where the product will be sold.

Wine as a Complex Sensory Product

Food and beverages in general often have complex sensory profiles across visual, oral, olfactory, taste, and even aural dimensions. Each of these dimensions can be manipulated to some degree, more so for processed versus fresh products.

Wine is both an agricultural and processed product. The flavor profile for the grapes that become wine is a function of both its genetics (mainly grape variety but also clonal selections) and where and how it is grown. Grapes are one of the most sensitive plants in reacting to changes in their environment. A Cabernet Sauvignon grape, for example, grown in a warmer area will have a different profile from one grown in a cooler area.

Wine flavor is the result of all the factors from the grapes plus the outcome from a large number of decisions made in processing the grapes into wine. These range from the time and date of picking, through temperature of the fermentation, the use or not of cultured yeast, additions of acid or other adjustments, filtration, aging in oak or not, and even the type of container the wine is sold in, including the type of closure.

Consumer sensory research on wine is often used to measure preferences based on manipulations of some of the production factors in the vineyard and/or in the winery. Just like the many aspects of the extrinsic product features, testing changes in the intrinsic factors must be carried out carefully with only a few factors changed, while most remain the same. This is to ensure accurately measuring the results of a known change and being able to attribute preferences to a specific manipulation. Because wine is such a complex solution, changes in multiple variables will often have interaction effects that will be hard to attribute to a specific change in process.

Methods for Measuring Consumer Preference in Wine

The investigation of consumer preferences toward wine using quantitative techniques can be done using one of two types of data. One can ask people what they would do if they were to face a particular scenario, or one can look at what people have actually done. In the first case, one would refer to the use of Stated Preferences (SP), while in the latter one would refer to the use of Revealed Preferences (RP). One can group several techniques under these two large families of preferences. Below are brief explanations of the techniques used most often when analyzing consumer preferences toward wine, highlighting the advantages and disadvantages associated with each of them.

Stated Preferences

Rating-Based Models

Rating-based models have respondents rate each alternative, product, or construct statement on either a metric or a semantic scale. These scales are easy to present to respondents and are not expensive to collect, and they can be gathered through mail surveys or self-administered questionnaires online and hence do not cause linear dependency problems, which are inherent in ranking scales. Rating tasks require less time to respond to than ranking ones, and they give more information on consumer preferences, together with preference ordering of the options proposed. Rating scales form the basis of a widely known modelling approach: structural equation modelling (SEM) (Kline 2015).

However, rating scales present several drawbacks. First of all, the quality of data can decrease because respondents do not put much attention on the actual statement they are requested to judge. It is recommended that a quality control question (e.g., please select "strongly disagree") is included among the statements respondents are presented with. One doesn't need to do it for every construct, but having 2–3 quality control questions throughout the questionnaire will improve the quality of the dataset by eliminating those who respond wrongly.

Second, cultural differences influence the way people rate items. When one wants to compare data collected in different cultural settings, one risks having biased estimates of respondents' behavior. For example, it has been shown that some countries such as Italy or the USA use the extremes of the scales more than Japanese, Australian, or French people (Usunier et al. 2005; Lee et al. 2007). In some countries, one risks having a higher rating than in others, although the importance people place on the same item is identical. Good translations or lexical equivalence is also necessary for unbiased cross-cultural research.

Third, the spatial position of the "strongly agree" Likert scale rating influences choice. Friedman et al. (1994) demonstrated that people express higher agreement when this rating is located in the left-hand side of the questionnaire compared to the right-hand side.

A vast number of papers use rating-based models in wine consumer research, making it impossible to select a few one could consider exemplar for the application of these models. Instead, it is recommend to read the papers of Hein et al. (2008) and Mueller et al. (2009), as they provide comparisons between the use of rating-based models and other common acceptance and preference methods.

Ranking Tasks

A step above in terms of preference validity is provided by ranking tasks. When using ranking tasks, the researcher fixes an origin within which respondents give a judgment to each alternative from the "most preferred" to the "least preferred." Ranking techniques provide the most appropriate conceptual mapping to people's values. Ranking scales offer an advantage even in comparison to basic discrete choice experiment (DCE) tasks, as people may express their preferences not only on the most preferred alternative but also on all the options proposed to the respondent. The limitations of ranking techniques are as follows: (a) they are often difficult for respondents, as they demand considerable cognitive sophistication and concentration; (b) they are time-consuming and may therefore be more expensive to administer; (c) they are difficult to conduct through telephone surveys; and (d) the set of ranked items is often linearly dependent; hence, it is not always possible to employ conventional statistical techniques in the analysis of the latent content of ranked preference data.

Some notable applications of ranking tasks in wine consumer research are Quandt (2006), Balinski and Laraki (2013), and Cao and Stokes (2017).

Pick-Any Method

The pick-any method, also known in the literature as the check-all-that-apply (CATA) technique, is a technique where consumers are presented with a list of terms and are asked to select *all* that apply to the objects under investigation (e.g., wines, brands, regions of origin, etc.) (Ares and Jaeger 2015). The method was first developed in the branding literature (Bogomolova and Romaniuk 2010; Nenycz-Thiel and Romaniuk 2009), but it has been applied to other research fields, such as tourism (Bowe et al. 2013), sensory analysis (Ares and Jaeger 2013), and wine (Sjostrom et al. 2016). When using the pick-any method, researchers can establish what terms are perceived to be more strongly connected with the objects under investigation, allowing the discovery of which objects are perceived to be competing more closely.

The pick-any method improves the method of paired comparison in two significant ways. First, the pick-any method extends the comparison from just two alternatives to multiple alternatives across the list of terms the researchers intend to investigate. Secondly, the pick-any method is a "free response" measure, because respondents are free to link each term to one, none, or all the objects under investigation (Driesener and Romaniuk 2006). This reduces the discomfort respondents might encounter in selecting choices they would not make if they had the freedom to do so (Dhar and Simonson 2003).

There are two main ways in which one can analyze pick-any data. The first is numerical, while the second is graphical. A paper by Corsi et al. (2011) explains the formula for the numerical calculation. The more graphical approach consists of the application of correspondence analysis (CA) to the data. This multivariate statistical technique is conceptually similar to principal component analysis (PCA), but instead of using continuous variables, it is applicable to categorical data. As in PCA, the output of CA is a set of coordinates onto the *i* dimensions of a CA plot for each of the items included in the analysis. For ease of interpretation, the plot is often reduced to two dimensions. However, different to PCA, where each axis can be defined by the factor scores each original variable loaded onto, the axes in CA have no other meaning than a bidimensional representation of the associations between the items displayed in the plot (Beh 2004).

The main limitation of the pick-any/CATA method is that the binary-response format does not make it possible to measure the intensity to which a respondent attaches an item to the object under investigation (Meyners et al. 2016). For this reason, the rate-all-that-apply (RATA) technique has been developed (Ares et al. 2014). The main difference between CATA and RATA is that with RATA, the respondent is also required to rate the intensity to which they attach an item to the object under investigation, generally using a 3- or 5-point scale (Ares et al. 2014). However, it should be noted that subsequent studies (Vidal et al. 2015) didn't find any clear superiority of one technique over the other.

Some notable applications of the pick-any method in wine consumer research are Remaud and Lockshin (2009), Vidal et al. (2015), Sjostrom et al. (2016), and Corsi et al. (2017).

Discrete Choice Experiments (DCEs)

Discrete choice experiments (DCEs) are a quantitative technique, which allows the elicitation of respondents' preferences through the combination of selected product features (e.g., country of origin, region of origin, price, label style, etc.) into sets of competing alternatives (e.g., bottles of wine with different features). The product features to be included in a DCE are usually a combination of previous literature and qualitative pretesting, such as interviews or focus groups. The alternatives are allocated into choice sets using an experimental design. In the most basic form, respondents are asked to select the alternative they would buy/prefer for each of the choice sets they are presented with.

DCEs are based on random utility theory (RUT), the sound and well-tested behavioral theory of decision-making and choice behavior (Louviere et al. 2000). RUT assumes that the choice between the alternatives is driven by an underlying, latent construct called “utility.” This can be broken down into two components: a systematic and a stochastic component. The higher the “utility” associated with a product feature, and its relative levels, the more critical that feature is for the choice of a product. The most basic model for the estimation of utilities is the multinomial logit model (MNL), but many more complex and elaborate models have been developed over the years.

Some notable applications of DCEs in wine consumer research are Corsi et al. (2012), Jarvis et al. (2010), Lockshin et al. (2006), and Williamson et al. (2016).

It is worth noting that there have also been attempts to combine DCEs with sensory testing Mueller et al. (2010b). The attempt is commendable, because this research was probably among the closest to mimic real purchasing: taking the product from the shelf, tasting it, and making (or not) a repurchase decision. Results showed that price was a very positive driver of informed liking, but liking didn’t relate to the sales volume or to the choices respondents made in the DCE. Instead, the choices respondents made in the first DCE were strongly correlated with the choices they made in the second DCE, which was also combined with a tasting, confirming the anecdotal evidence that repurchase decisions are a combination of the extrinsic product characteristics plus intrinsic sensory attributes.

Another promising development of DCEs is represented by hybrid choice models (Kim et al. 2014). Their main advantage to traditional DCE is their ability to include attitudinal variables into the estimation model. One problem that traditional DCEs pose is that while they provide a very accurate estimate of consumers’ preferences, they lack the ability to incorporate anything that is related to the personality, attitudes, beliefs, values, etc. of the respondent, despite the fact that these might actually help the researchers understand why respondents have a certain preference structure. In this sense, hybrid choice models provide the ability to disentangle the causation, mediation, and moderation effects typical of structural equation modelling while having a more accurate dependent variable than a rating-based willingness to purchase. To date the only example of hybrid choice models applied to wine consumer research is the work of Palma et al. (2016).

Best-Worst Scaling

A recent evolution in the family of DCE models is represented by best-worst scaling (BWS) (Marley and Louviere 2005), also called “maximum difference scaling.” Similar to the pick-any method, BWS can also be considered an extension of the paired comparison method, offering similar benefits, but a more efficient questioning structure. Respondents are asked to pick the item they consider the most preferred (*Best*) and the item they consider the least preferred (*Worst*) from a set of three or more items for each of the choice sets presented to them – generally not more than 20. Choice sets are created through designs, including full factorial designs, fractional factorial designs, Latin square designs, and balanced incomplete block designs (BIBD).

The relative choice probability of a given pair of *Best* and *Worst* items is assumed to be proportional to the distance between the two chosen attributes on a latent utility scale. The cognitive process, seen from a statistical perspective, is equivalent to identifying every possible pair of attributes available, calculating the difference in utility between the two attribute levels in every pair (this consists of a fixed component plus a random component), and finally choosing the pair that maximizes the difference in utility between them.

The most useful method to calculate the scores was proposed by Mueller-Loose and Lockshin (2013). Alternatively, the same estimation approaches mentioned above in relation to DCEs can also be applied to the analysis of BWS data.

The main limitation of BWS is the time necessary to complete the task, which tends to be higher than other techniques. In addition, in case the number of attributes and levels the researcher wants to test is high, the researcher is forced to acquire experimental design skills to generate designs which could be administered within a reasonable time frame.

There are different types of BWS tasks depending on the objectives of the research. If the scope of the research is simply to identify a ranking between objects (e.g., choice criteria for wine selection), one would use BWS (Type 1) (Flynn 2010). This is the most used type of BWS in wine consumer research. The papers of Cohen (2009) and Goodman (2009) are classic examples of BWS (Type 1). A second type of BWS task can be considered if the researcher needs the respondent to choose the best and worst attribute under different scenarios. Imagine, for example, a case where a researcher wants to understand the most and least important factor for the choice of wine under different consumption occasions. There have not been any BWS (Type 2) in wine consumer research. Lastly, BWS (Type 3) is when one designs a DCE, but respondents are required to select both the best and worst scenarios (e.g., bottle of wine) for every choice set the respondent is presented with (Flynn 2010). The works of Costanigro et al. (2014) and Lockshin et al. (2017) present useful examples of BWS (Type 3).

Experimental Auctions

Experimental auctions are a technique belonging to the family of non-hypothetical choice models. Respondents are given an incentive to buy or obtain a product by bidding for it or by choosing it against some alternatives (i.e., similar to what happens in DCEs and BWS tasks) (Combris et al. 2009). The main advantages are individuals participate in an active market environment, they are exposed to market feedback and they face real economic consequences to the responses given. However, experimental auctions seem to lead to different willingness-to-pay (WTP) estimations, with estimates under auctions conditions significantly higher than those calculated from choice experiments. By providing more product information to consumers, it is possible to reach more consistency between these two techniques.

Some notable applications of experimental auctions in wine consumer research are Combris et al. (2009), Grebitus et al. (2013), and Vecchio (2013).

Neuromarketing Responses to Wine Packaging and Labelling

Neuromarketing techniques (e.g., eye tracking, electromyography, electroencephalography, etc.) have emerged in the last few years. These techniques address the fact that often respondents are not able to express or report how they feel about something, or even more worrying for the researcher, a respondent states/chooses one option, but in reality, subconsciously prefers something else. Fortunato et al. (2014) provide a succinct yet comprehensive review of the advantages and disadvantages of neuromarketing techniques.

Some notable examples of neuromarketing techniques applied to wine consumer research are Gofman et al. (2009), Lopes-Cardoso et al. (2013), Horska et al. (2016), and Laeng et al. (2016).

Revealed Preferences

Revealed preference data can be classified as to whether the individual responsible for the purchase is shown in the dataset. If yes, the researcher is dealing with panel data; if not, the researcher is dealing with scanner data.

The main advantage to using either scanner or panel data is they reflect what consumers have actually done, instead of hypothetical scenarios. These data can be used for both descriptive and inductive approaches. The main disadvantage is they can be very hard to collect, either because retailers do not provide access to these data, although they regularly collect them, or because they are very expensive to purchase. In addition, unless these data are collected before, during, and after an experiment is specifically conducted to influence in-store purchases, it can be hard to measure the causes explaining the phenomena emerging from the datasets, making deductive approaches difficult.

The main advantage of panel data is their ability to link each purchase to a specific individual. This allows the calculation of several brand performance measures (e.g., market share, penetration, purchase frequency, etc.), which form the basis for the analysis of loyalty at specific points in time and over time, and cross-category purchases. In addition, if one also possesses the sociodemographic profile of each individual, one can conduct insightful segmentation analyses. Conversely, the main advantage of scanner data is they provide information about distribution, price, and trade promotions and they allow for very robust time series analyses.

The most common techniques applied in the analysis of consumer preferences toward wine using panel data are Dirichlet modelling and the polarization index. The most common technique adopted with scanner data is regression analysis.

The Dirichlet Model

The Dirichlet model is a stochastic preference model, which allows the understanding of the level of competition between brands (or product attributes, such as grape variety, price point, or origin) in a given market. In order to test whether the market observed by the analyst is Dirichlet-like or not, it is recommended to follow the instructions suggested by Bound (2009) in relation to the use of the Dirichlet software (Kearns 2009). If the data show that one is in a Dirichlet-type market, certain patterns occur in that market, summarized as double jeopardy, growth by penetration, the lack of niche or change-of-pace brands, and the occurrence of the Duplication of Purchase Law (Sharp 2010). This knowledge is useful for a brand manager, because as long as they propose brand strategies whose foundations are based on the abovementioned patterns, they can be sure their brand will grow.

Some notable applications of Dirichlet modelling in wine consumer research are Jarvis and Goodman (2005), Cohen et al. (2012), and Habel and Lockshin (2013).

The Polarization Index

The polarization index, referred to in the literature with the symbol φ *(phi)*, was developed as an independent, standardized measure of repeat purchase behavior, related to but independent of market share. φ is based upon two statistical distributions: the Dirichlet-multinomial distribution (DMD) and the beta-binomial distribution (BBD). These distributions treat individual purchases “as-if” random and offer a highly accurate predictive benchmark of brand loyalty based on market share within a category. The index reflects patterns of consumer loyalty by comparing consumers’ repurchasing behavior toward individual brands to average loyalty levels for the overall category.

Some notable applications of the polarization index in wine consumer research are Jarvis et al. (2007), Krystallis and Chrysochou (2010), and Corsi et al. (2014).

Regression Analysis

Regression analysis is a statistical technique, which allows the estimation of relationships between variables. A wide array of regression analysis approaches have been developed over the years, but only a handful of regression analysis papers using scanner data in wine consumer research have been published (Carew et al. 2004; Stasi et al. 2011; Mueller-Loose and Szolnoki 2012; Torrisi et al. 2006).

A different application of regression is used in *hedonic price analysis* (Rosen 1974). In this case, the price of a good is the dependent variable, against which any other product feature hypothesized to influence the price is regressed (Schamel and Anderson 2003). Some notable applications of hedonic price analysis in wine consumer research are Oczkowski (1994), Combris et al. (1997), and Costanigro et al. (2007).

Practical Aspects of Conducting Consumer Research for Wine

This final section focuses on the practical aspects of conducting consumer wine research. The most important aspect in conducting any research is setting the proper objectives. Next, we look at budgeting or costing the research along with whether it is better to conduct the research in-house or hire an external provider. We discuss some basics of research design and then complete this section with some directions for research reporting. The majority of this section is based on extensive experience in conducting commercial and academic research on wine marketing. Readers interested in a well-written straightforward market research textbook with more detail on issues such as setting objectives, writing survey questions, and presenting results might consider books such as *Applied Marketing Research* (Malhotra et al. 2017).

Setting the Objectives

Setting the proper objectives is the most important aspect for any type of research, academic or applied. Without clear objectives chosen for their relevance and achievability, no research project will provide useful outcomes. It is important not to overreach in setting objectives, but to clarify what the research is to be used for. This will help determine the proper method and the budget to conduct the research.

Research can usually be broken into exploratory or decision-making. Exploratory research is often conducted to understand the context of wine consumption. For example, recent exploratory research in China was conducted to understand who is drinking wine, what are the motivations for choosing wine over other alcoholic beverages, where people tend to buy wine, at what occasions wine is consumed, and who or what might influence these decisions (Cohen and Lockshin 2017). When very little is known about the area in question, exploratory research is usually conducted using interviews. This allows the researcher to ask general questions that can then be explored and followed up. For example, we might interview Chinese wine consumers aged 21–35, who are relatively new to drinking wine, and ask initially about the last occasion they consumed wine. Then we can follow that with questions about the wine: what was it? What country or region? What price was paid? Then, we can move to questions about the consumption occasion: where was the wine bought? Was it consumed there or elsewhere? Who was the wine consumed with? What was the occasion/reason for purchase? These questions can give the basis for writing survey questions to a larger and more representative group, so there is better idea of the population's behavior in buying and consuming wine. This basic understanding is necessary as a prelude to measuring what flavor profiles or packaging or communication concepts are preferred by consumers in a country, region, type of retail outlet, etc.

Designing the Research

Exploratory research in wine lends itself to direct questioning, especially to understand the basic *who*, *what*, *when*, *where*, and *why* (what situations or occasions), since many of these questions concerning wine vary across countries and cultures. This exploratory survey research, when collected from a representative population sample, can provide a good estimate of the competitive landscape for individual brands, regions, or countries, by charting the frequency of purchase/consumption, and if the sample is large enough, brands and origins can be related to different consumption occasions and purchase locations.

Researchers are often interested in what motivates the purchase of a particular bottle of wine. The objective can be to understand why or why not a certain brand, region, country, or wine style is purchased (or not), or it can be focused on how to manipulate the packaging or flavor profile to increase the probability of purchase. These are more decision-based research objectives, and the methods to measure them are different from those used in exploratory research. It is now well-understood that researchers cannot gain much useful information from asking directly why someone bought a specific bottle of wine, because the actual process of selecting a bottle of wine is mostly subconscious and consumers are not able to articulate the underlying reasons (Mueller et al. 2010a). Respondents will provide answers to survey questions about why they chose a specific bottle, but these are often not accurate and are subject to "demand effects" where the respondent tries to answer in a way they feel the research wants.

A better method is to use indirect methods to understand what influences a specific decision as noted in the sections on "Discrete Choice Experiments" and "Best Worst Scaling" above. It is important to specify the consumption situation when conducting a DCE or a BWS experiment, because the same consumer might choose a different wine for different occasions. For example, consumers will choose more expensive wines if the situation is given as a business dinner or a celebration compared to a bottle of wine to have at home with family or friends. Unless the occasion is specified, variance in responses will occur, which will reduce the predictability of the DCE.

DCEs are complex and often expensive to conduct, so it is best to hire someone with expertise to design and run them. The expense is usually in creating the realistic looking bottles to be used in the experiment and in programming the software to provide the choice sets in a randomized design to the respondents. The upside is that complex combinations of attributes can be tested in a realistic manner, including price, label characteristics, regions or countries of origin, and even different consumption occasions.

Sometimes researchers want to test less complex questions about consumer preferences, such which of several label designs is more appealing to consumers or which attribute is more important in choosing a wine (rather than which combination of attributes). The standard method for researching these questions has been to use some sort of Likert scale. As noted in the previous section, BWS can be used to generate ratio level importance weights for attributes or in this case label designs.

Cost of Research and Whether to Do the Research In-House or Hire a Market Research Firm

DCEs and BWS experiments are usually more expensive to design and implement compared to standard Likert scales, but are usually more accurate in predicting consumer preferences for specific attributes (Louviere et al. 2000, 2015). When researchers or companies want to understand the relative importance of changing one or more attributes of a wine, these two choice-based models are the best methods, as noted in the review of techniques above. Ranking works well for comparing overall preferences for small (up to six or seven) products. So the cost to do research goes back to the objectives for the research. The biggest cost for experimental research is in developing the graphics for the bottles. Depending on how many are to be made, this can cost a few thousand US dollars to $20,000 and up for complex designs. If a general rank order of preferred label designs is needed, standard Likert questions can usually separate the top few from the rest, but it is unlikely there will be one design that stands out in this author's experience; ranking can be used to find a preferred design if there are only a few to compare. When a range of label designs are compared, several will be likely rated nearly the same overall, although there may be differences if the sample is broken down into segments, such as age or gender.

Another practical question for conducting wine marketing research is whether to do it in-house or hire a research firm to conduct the research. Whichever direction is chosen, the key to useful research is a clear set of objectives that can be met by the intended research. Larger companies with trained research staff usually opt to do much of their research themselves. Unless tastings are used as part of the research, most wine marketing research is now conducted online. Simple surveys can be designed in-house, and a panel provider engaged to provide the necessary sample. Or the whole process can be outsourced from designing the questionnaire to data collection, analysis, and reporting.

If a wine company wants to conduct research in a foreign country or multiple countries, it is usually easier to hire a market research provider that can conduct all the research across the countries. This way, the translations will be handled professionally, and the data will come back in the same format from each country. It is important to get references from market research companies and to check them before engaging the company. International research can be difficult, so it is important to get an experienced company and an experienced project manager on board. This can be more difficult in regions like Asia, South America, Africa, and parts of Europe. In these places, there are a few multinational market research firms that are often able to manage complex projects, but the cost will be higher than in countries where there is more competition for research management. It is important to do a soft launch for most market research projects, especially large or international ones. Obtaining 50–100 respondents and thoroughly checking their responses to make sure any internal links work, and that any open-ended questions are understood will reduce expensive problems later on.

Smaller wine companies often decide to use their sales facility (cellar door) or customer database as a means to do market research. These methods can provide an indicative direction of consumer opinion but cannot be used to quantify the preferences of the larger wine drinking population. Some wineries will trial new blends with visitors to the winery to see which they like better. This is a good first step in understanding general preferences before deciding on one or two final blends for testing on a more representative audience. Producers should remember that visitors and mailing list customers are a biased sample that knows more about the winery and has more positive thoughts than the general wine drinking public. However, if most wine is sold directly from the winery, then visitors are a good resource to use.

When engaging a panel provider to recruit respondents, expect to pay between US$0.50 and up to US$20 per respondent depending on the difficulty (narrowness) of the recruitment criteria. Very narrow criteria, like people buying luxury-priced products, can cost over US$100 per respondent. General samples of drinking age consumers are rather inexpensive, but recruiting consumers, who drink specific styles of wines (e.g., imported red wines or wines above a certain price point), or specific age groups or geographic locations are more expensive. It is more expensive yet to recruit samples that can be generalized to a population, especially when there are less populated geographic regions or cities to be included and tested to see whether they differ from more populous locations. Our own research shows that the lower availability of wine in less populated regions and cities does affect the size of various subgroups. For example, there are likely to be fewer imported wine drinkers in less populated areas due to the lower availability of these wines, not because wine drinkers don't like them.

More recently there are services that provide respondents for a very low price, such as Amazon's Mechanical Turk (MTurk). Recent research has shown that the quality of responses using these self-selecting panels can be as good as hiring a panel provider, as long as the researcher can clearly specify the respondent profile and conduct some simple data cleaning. The cost per respondent drops dramatically when using these services compared to professional panel providers. On the other hand, panel providers can often reach hard to find consumer subgroups (segments) and can even provide translation services for collecting data in multiple countries. The use of Facebook or other social media is not recommended, because these produce biased samples which cannot be generalized to a population.

One of the specific issues in wine marketing research is the juxtaposition of sensory (tasting) and consumer research, e.g., label and price preferences. Sensory preference measurement is often conducted blind; that is, the respondents do not know anything about the wine they are tasting, except perhaps its color and sometimes the grape variety or origin. They do not see the label or information on the label and do not know the price of the wine. Blind tasting can help establish which blends or sensory profiles are preferred, but it is well known that taste preferences also depend on label information and price. In fact, Plassman et al. (2008) showed that the pleasure centers in the brain were activated during tasting by the subject being told the wine was expensive compared to the subject being told the same wine was inexpensive and the signals were not mediated by sensory organs; the results were provoked merely by the price.

Different label designs and overall packaging can similarly affect consumer preference. Consumer preferences are influenced by knowing the brand, the region, whether or not the wine has won any awards or has high/low point scores by wine writers, and other information available on the package or shelf.

These results show that it is best to use the wine as packaged for the market in order to compare to competitors or to the new packaging for the same brand. Either the actual price or price range should be provided, so consumer expectations fall in line with the actual price of the wine. If only the sensory aspects are being tested, many researchers will not use any price or packaging. However, there is good evidence that price affects the sensory attributes consumers perceive when tasting wine (Plassmann et al. 2008). The recommendation here is to at least provide consumers a price range when doing sensory testing to locate the sensory preferences in a known set of price-based expectations. Current packaging can be compared to potential packaging concepts as long as all the wines are at the same or similar price points and have the same or similar grape varieties and origins. Otherwise, these attributes could influence consumer preferences and bias the research findings.

Conclusion

This chapter has shown that wine possesses some unique characteristics, which affect how research is conducted in order to understand consumer preferences. First, the issue of doing consumer research with an alcoholic beverage was discussed. Then, the complexity of the extrinsic label and packaging attributes and the intrinsic sensory characteristics were used to show how standard Likert-type questions are often inadequate to measure the impact of the different attributes on consumer preference and choice. The bulk of the chapter covered a range of quantitative techniques used successfully to measure consumer wine preferences. Each technique has references of key wine-related literature using those techniques. The final section provided some practical suggestions for conducting research including sampling, cost effectiveness, and research design.

Abstract

Today, beer, wine, cider, spirits, and RTDs (premixed ready-to-drink alcoholic beverages) are a customary part of Australia's drinking culture. Statistics indicated that Australia was a land of beer drinkers. While beer may still dominate the consumption figures, wine has made a significant impact on the Australian beverage market, both as a social drink and particularly when eating at home or outdoors or dining in cafés and restaurants. This chapter traces the story of Australian wine. It explores Australia's early alcoholic beverage consumption; explains how wine became part of Australia's social drinking and dining culture; describes the production, flavors, and use of some wine styles; highlights Australia's unique wine styles; and discusses emerging wine trends. It outlines some strategies the Australian wine industry has utilized to endure market, pest, and climate change pressures to permit its survival and growth on the global wine stage such as promotion of Australian wine regionality and quality, biosecurity, and the use of grape varieties more suited to Australia's climatic conditions. Some topics are discussed within a global perspective.

Introduction

Australians' Relationship with Alcoholic Beverages

Australians live with a somewhat romantic notion of Australian camaraderie interlinked with drinking, that goes as far back as the First Fleet c1788, and many tales exist about celebration and insobriety on the first day of settlement. Australia developed and colonized the bush, where alcohol played a part in terms of being available and a source of solace and leisure for people in a very isolated situation with limited recreational opportunities. Mateship is a common British and Australian colloquial term for an unconditional, strong friendship bond, often between men and sometimes formed under adversity. Ballads and literature produced in the nineteenth and twentieth centuries by convicts and the likes of Australian writers CJ Dennis, Andrew Barton "Banjo" Paterson, and Henry Lawson often made mention of alcohol as being part of the fabric of "mateship" where people worked together during difficult circumstances and celebrated and enjoyed life's milestones or drowned their sorrows with alcohol (Syson 1998).

Australians see themselves as a heavy drinking country (Midford 2005). From the earliest colonial years, it was certainly heavy per capita consumption compared with today, almost double at 13–14 l of pure alcohol, per head. However, volumes consumed in Australia were frequently less than one would have found in Britain during certain periods of the 1800s, so this legend being unique to Australia may be exaggerated (Dingle 1980; Room 2010). Yet, the stories of the bushman working hard for long periods, receiving his pay, and then using the entirety in one go or most of it in a local public house (pub) or inn are pretty accurate (Roche et al. 2009). As Australians have become more health aware, per capita consumption has decreased, and only a small proportion of the population continue a style of drinking where larger volumes of alcohol are consumed over short periods in a week (Roche et al. 2009).There are national and state government programs and laws that are in place to educate people about responsible alcohol consumption and deter drink-driving (Midford 2005).

Total alcohol consumed in 2017–2018 was 9.51 l for each person in Australia aged 15 years and over (Australian Bureau of Statistics Database 2019). It may seem unusual to incorporate the data of under 18 year olds in these statistics (18 years old is the legal alcoholic beverage drinking age in Australia), but the Australian Bureau of Statistics (ABS) states it uses this population as "it is consistent with international standards for measuring trends in apparent alcohol consumption over time." This figure was just above the lowest annual figure since 1961–1962 (9.4 l), and the ABS states that this stalls the recently observed downward trend, which started around 2008–2009. Just above three-quarters of all alcohol consumed was either beer (39%) or wine (38%). Alcohol consumed as wine has declined recently, but it is the decrease in beer consumption that has mainly driven the falling alcohol consumption, with an average decline of 2.4% per year over the last decade (Australian Bureau of Statistics Database 2019).

Figure 1 highlights the Australian per capita consumption of beer, wine, spirit, and alcohol at the beginning of each decade since 1950 until 2010. Alcohol consumption reached a peak in the 1970s and 1980s mainly driven by beer but with a consistent upturn in wine consumption. This increase in wine consumption could link to a number of social factors. At that time, there was a change of women's role in society, the invention of the wine cask (bag-in-box), changes to hotel trading hours, greater accessibility to imported international wine, purported health properties, and the change in cultural scene due to immigration of people from wine-producing countries postwar and a more affluent middle class (Roche et al. 2009)

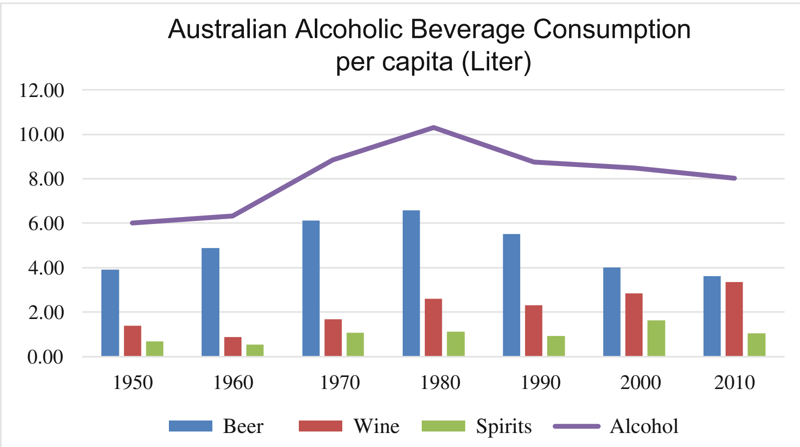

Fig. 1 Consumption of beer, wine, and spirits in Australia per capita (L) over the past seven decades. (Data used for this figure was extracted from Holmes and Anderson (2017))

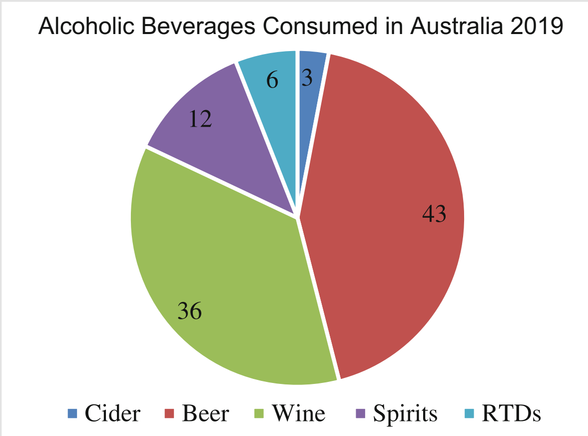
Fig. 2 Alcoholic beverage consumption in Australia today. (Data used for this figure was extracted from the database of Australian Bureau of Statistics (2019))



From a relatively small base, the consumption of wine has now risen to 36% of the beverage market (Fig. 2) with some even suggesting it has become the most popular alcoholic beverage for Australian consumers (Neo 2019). The ABS data within Fig. 2 is estimated consumption for an average Australian 15 years old and over and based on supply information. Apparent per capita consumption data that is included in this publication are calculated by dividing the quantity of beverage or pure alcohol available for consumption, by the estimated resident population of Australia of persons aged 15 years and over in Australia at 31 December each year. Australian's have a diverse, almost overwhelming, range of local wines to choose from with current wines being made by approximately 2257 wine producers. It is a popular alcoholic beverage consumed usually with meals in many settings. Hail and Lockshin (1999) reported that wine is purchased for various reasons and circumstances, including social status, cellaring, immediate consumption, gifting, a barbeque, dinner at home with family or friends, dinner out, celebrations, wakes, weddings, achievements, and milestone events.

The Current State of Art of the Australian Wine Industry

Today, Australia, a new world wine country, is a significant player in the global wine scene. It is the seventh largest wine producer by volume (generating 1.2 billion liters per year) in the world and the largest in the southern hemisphere (but frequently vies with Argentina for this position). Australia is the fifth largest wine exporter (780 million liters), while domestically, 40% of what is produced is consumed (Wine Australia 2019). From 1 July 2017 to 30 June 2018, Australia's total wine exports rose 20% to $AUD2.76 billion. Australia's top 5 export markets by value in 2017–2018 were China, including Hong Kong and Macau (40% of export value); the USA (15%); the UK (14%); Canada (7%); and New Zealand (3%). Germany and the Netherlands were the only European countries that made Australia's top 10

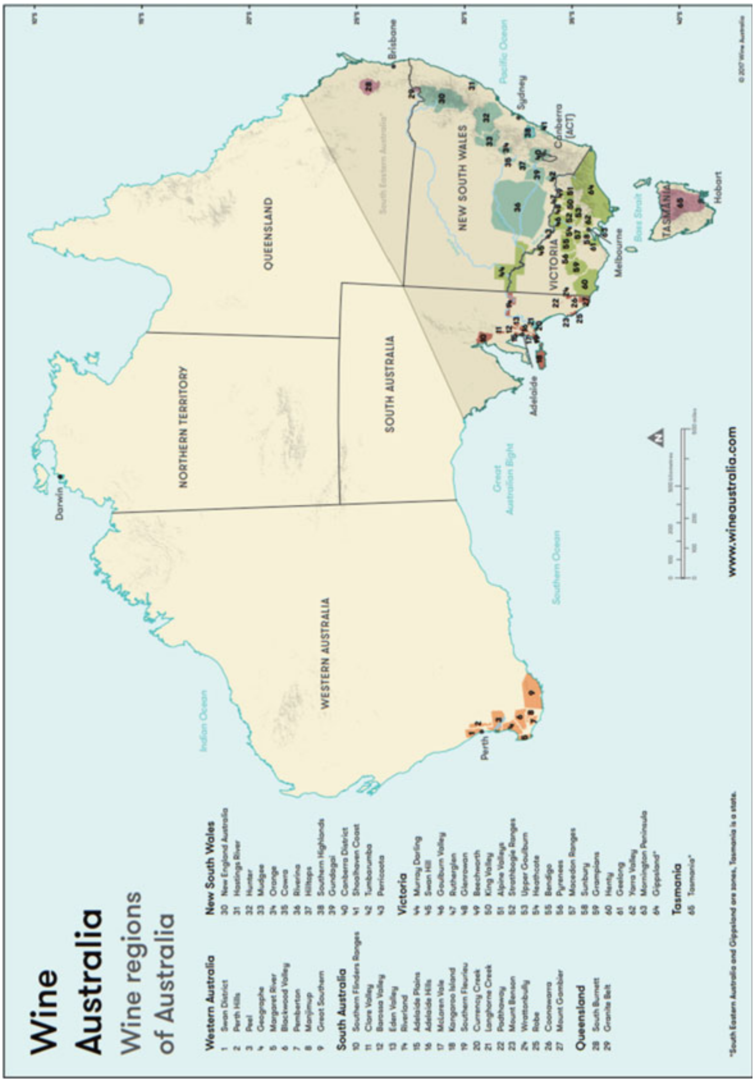


Fig. 3 Map of Australian wine regions which lists Australia's 65 wine geographical indications (GIs) and their location which relates to areas with suitable wine grapegrowing conditions. Note the majority exists in South Eastern Australia, but a cluster of nine GIs are located in southern Western Australia. (Source: Wine Australia)

export markets ranking at numbers 7 and 10, respectively. To meet domestic and international demand, an increase in wine grape plantings/production surged in the late 1990s (Iland et al. 2004) increasing from about 400,000 t in the mid-1970s up to about 1.79 million today (Australian and New Zealand Wine Industry Directory 2019). Now, Australia's 65 wine regions (Fig. 3) produce a diverse range of wine styles – sparkling, dry white, semisweet and sweet white, red and fortified, and from traditional "noble" and new and emerging varieties. These regions have suitable growing conditions for wine grapes, with the remainder of the country being desert or having tropical climes.

Approximately 100 different grape varieties are planted over 135,000 ha of vineyards in Australia, with six red varieties and six white varieties having more than 1,000 ha each (Wine Australia 2019). Shiraz and Chardonnay are the most highly planted grape varieties in several regions, accounting for a combined 46% of Australia's wine production (Wine Australia 2019).

Australia's Grape Varietal Mix Today

Plantings in Australia are dominated by the traditional or noble varieties Shiraz, Cabernet Sauvignon, Merlot, and Pinot Noir (for reds) and Chardonnay, Sauvignon Blanc, Pinot Gris, Semillon, Muscat Gordo Blanco, and Colombard (for whites) (Table 1). Other red varieties include Tempranillo, Grenache, Mataro, Durif, and Sangiovese. The white varieties Verdelho and Viognier further add diversity to the taste and choice of Australian wine. In more recent years, the alternative Italian grape varieties Montepulciano and Nero d'Avola (reds) and Vermentino and Fiano (whites) among others have captured the interest of winemakers and consumers alike.

Nowadays, Australian wine is internationally recognized as being of high quality and good value for money (Bastian et al., unpublished). It is also winning accolades on the international wine scene, for example, just recently an Australian Shiraz wine from the Barossa Valley in South Australia was regarded as the best out of 309 wines entered from 19 countries, in a prestigious and rigorous international wine competition – Syrah du Monde® – that recognizes the world's best Syrah/Shiraz wines.

Distinct Eras of Australian Wine Culture

We refer to the "the beginnings" as the period of pre-British settlement, the "early" years from the arrival of the British to about the 1850–1870s, the "recent" years from about the 1870s to about the 1950s, and the modern era as the years from about the 1960s to present. These four periods encompass the historical alcoholic beverage of our Aboriginal people, the beginnings of grape-based wines, the period in which fortified wine dominated production and then the evolution of the modern Australian industry with the rise in table wine (dry, i.e., no sugar and not fortified with spirit) consumption.

Table 1 Australian wine grape intake for top red and white varieties. (Source Wine Australia 2019)

Variety	2018 (tonnes)
Red grapes	
Shiraz	429,106
Cabernet Sauvignon	248,650
Merlot	105,489
Pinot Noir	53,373
Petit Verdot	22,070
Grenache	13,958
Ruby Cabernet	12,576
White grapes	
Chardonnay	407,940
Sauvignon Blanc	92,610
Pinot Gris	76,232
Semillon	60,437
Muscat Gordo Blanco	58,136
Colombard	56,485
Riesling	25,613

The "Beginnings" (Pre-British Settlement)

There is no doubt European settlers in Australia brought with their arrival an alcoholic culture, but the local indigenous people had one too. We now know, for example, that Aboriginal people tapped the gum trees allowing the sugary sap to collect either in tree hollows or at the base. Natural yeasts present there would ferment this liquid to an alcoholic beverage akin to cider that the local Aboriginal people named Way-a-linah. The European settlers apparently adopted this practice, and when the species was first described in 1844 by British botanist Sir Joseph Dalton Hooker, it was already known as the cider tree or cider gum (Jiranek 2018).

The "Early and Recent Years" (From British Settlement to the Wine Revolution of the 1960s)

Australia's grape wine story is just over 200 years old. It begins with the arrival of the British First Fleet in 1788 at, what is now called, Sydney in the state of New South Wales. During the voyage, grapevine cuttings and seeds had been collected at Rio de Janeiro and the Cape of Good Hope (Gregory 1988). These cuttings and seeds provided the source of Australia's first vineyards at Farm Cove, the site of the first settlement. We know that the first plantings provided table grapes as Maiden (1917) writing for the agricultural gazette of New South Wales provides a quote from a letter written by Elizabeth Macarthur, wife of John Macarthur, a founding figure of the Australian wool and wine industries:

The grape thrives remarkably well. The Governor sent me some bunches this season, as fine as any I ever tasted, and there is little doubt in a few seasons there will be plenty.

Later plantings were established further west along the Parramatta River. We do not know what proportions of table grapes and wine grapes made up the plantings at Farm Cove and along the Parramatta River. We also do not know when or who produced the first Australian wine. Perhaps the people who set up those early vineyard plots made small batches of wine for their own pleasure. Records indicate that privately owned vineyards were planted soon after the establishment of the colony. Julie McIntyre (2012) reports in her book "*First Vintage: Wine in Colonial New South Wales*" that Philip Schaeffer, the colony's first free settler, was producing wine at his farm called "The Vineyard" by 1795. John Macarthur also planted vineyards in that period at his properties "Elizabeth Farm" at Parramatta and at Camden Park to the southwest of Sydney.

We presume that in the early years, the gentry and Government officials would have enjoyed the wine. It is unlikely that the working class were part of the wine scene of those days. They would have preferred their beer, rum, or spirit. The wine would have been produced from Portuguese and South African varieties as the vine cuttings that arrived on the First Fleet were collected at Rio de Janeiro and Cape Town and thus likely to be Portuguese and South African varieties. It was not until the early 1820s that vines from Spanish and French varieties would be producing grapes for wine.

One can only imagine the taste of those very early wines. Wines would have been made using rudimentary equipment and fermented by the natural yeast present on the grapes. If the fermentation did not go to completion, then the remaining sugar would have given them a sweet taste. It is likely that the wines would have been drunk early in their life, as it would have been difficult to store the wine without it becoming oxidized. Some spirit may have been added to preserve them.

Food in the early days of British settlement was likely sourced from farms stocked with sheep, pigs, cows, and chickens. Orchards and vegetable gardens would have been established to provide food for the new settlers. The harbor would have provided a source of fresh fish. Lack of refrigeration would have meant that fresh food needed to be eaten or salted (e.g., corned beef) for storage. Stews, often mutton and sometimes kangaroo, bread, and some vegetables would have been regular offerings. Meat and vegetables, following traditional British eating habits, were common and remained so for many years, particularly in working-class families. A colonial-era cookbook (Abbott 1864) featured recipes for lamb, kangaroo, and even wombat stews, roasts, and grills. Bush ingredients – wild spinach and other native herbs – would have been part of the food preparations. Wonga wonga pigeon was a revered local game bird served from about the 1840s with a traditional English bread sauce and was similar to pheasant when roasted (Ancestry 2016). The drink – to wash this all down – would have been beer, rum, or "some sort of spirit" (probably produced illegally). Maybe Australian or local wines were served in some circles, as by the early 1800s a small wine industry had emerged.

In 1816, John Macarthur travelled with his sons to France and collected vine cuttings for shipment back to Australia. In 1831, James Busby travelled to Europe to study grapegrowing and collected and shipped about 650 types of vine cuttings to his vineyards in Australia. Official records indicate that 362 arrived alive and healthy. Plantings were made of these cuttings at the Sydney Botanic Gardens, Kirkton in the Hunter Valley, and the Macarthur family's property at Camden Park. These collections brought French and Spanish grape varieties into the varietal mix of Australian vineyards.

"The James Busby Collection" of colonial vine stock material is a unique and important historic legacy, unmatched by any other new world country (Caillard, 2016, personal communication; Iland et al. 2017). This collection formed the foundation of Australia's fine wine industry. Material from Busby's collection established many vineyards planted in the1800s. Varieties including Riesling, Semillon, Grenache, Mataro, Shiraz, Cabernet Sauvignon, and Pinot Noir can be traced back to the Busby collection or perhaps to William Macarthur's own importations of 1838. Some of these old vineyards still survive today – many in the Barossa Valley, South Australia. Most notable are the Shiraz in the Langmeil "Freedom Block" (the term block in this context refers to a section or portion of a vineyard), Tanunda; the Cabernet Sauvignon in Block 42 in the Penfolds Kalimna block near Nuriootpa; the Mourvedre in "The Old Garden" plot at Rowland Flat; and the Grenache in the Cirillo family's "Old Grenache" block near Nuriootpa. These special, over a century old, vines are most likely the oldest continuously producing vines of each variety in the world. These treasured sites have survived because of the absence of phylloxera, which to date has never been found in South Australia. Grape phylloxera (*Daktulosphaira vitifoliae*) is a tiny aphid-like insect pest (less than 1 mm in length) that destroys grapevines and ornamental vines by feeding on their roots. Once infested, vines will usually die within 6 years. As no eradicative treatment exists, infested vineyards require replanting on phylloxera-resistant or phylloxera-tolerant rootstock. This is expensive, and replanted vines will take approximately 3 years to produce a crop and longer to mature. Due to the leadership and work of wine industry strategy and advocacy bodies, like Vinehealth Australia (https://vinehealth.com.au/) and Australian Grape and Wine Incorporated (https://www.wfa.org.au/), there has been wide uptake by the Australian wine industry of vineyard biosecurity measures. These include limiting visitor access and disinfecting footwear when entering vineyards plus strict quarantine regulations regarding transport of vine material across State and international borders, which has so far prevented infestation by this pest.

The wine industry grew throughout the mid- to late-1800s. Wine was sold through merchants/agents in the cities, and an export market had been established. Domestic sales were to the restaurants and cafés of the day, either direct or through wine merchants. Up to the early 1900s, most wine was sold in bulk – sometimes in cask, other times in 5 or 10 gallon lot containers and sometimes flagons. Some wine was probably sold direct to locals in the vicinity of the winery. Wine exports to Britain began about the 1850s. England was not a wine-producing country, and the ruling classes were keen to develop a wine industry in Australia for a ready supply to the homeland (Woodhouse and Osborn 2012). By 1839, there were 60 varieties of grapes in the colony including Riesling, Cabernet, Shiraz, Tokay, Verdelho, Malbec, Grenache, Carignan, and Mataro (Woodhouse and Osborn 2012). These remained the main varieties for many years. Some of these grape varieties produced Australian fortified wines, wine styles similar to those these grape varieties produced in their countries of origin of Spain and Portugal. Fortified wines, meaning a wine produced through the addition of a spirit (usually Brandy) to a dry or sweet wine, with its higher alcohol and often sweetness levels, were in demand in the British motherland and well suited its cold climate. However, although these wine styles would probably have been less agreeable to consumers in Australia's hot weather, they still dominated early wine style consumption patterns even up until the 1960s and 1970s.

Even though local wine was available, in the early years, the wealthy would have drank mostly imported wine – French and German – as was the custom in the homeland. Although table wines were available, fortified wine production steadily dominated wine trade during the late nineteenth and early twentieth centuries. The shift to fortified wines at around the turn of the century was most likely due to two factors – difficulty with spoilage of dry wines and that fortified wines were easier to produce and sell. By the 1950–1960s, fortified wines were the major part of the wine market.

Port and Sherry (as they were called then) were enjoyed across the socioeconomic spectrum. Men, particularly working-class men, drank beer, but in many homes, there was a bottle of Sherry or Port, often supposedly for cooking and medical purposes or a visit by the church Vicar or Priest. It was not uncommon for ladies – of all social classes – to have a "tipple" of sweet Sherry at the end of the day**.** At social dinner parties and formal functions, it is likely that both beer and wine were served, but after dinner men retired to the parlor to partake of Port and to discuss matters of "importance."

The wines from the 1800s and early 1900s included table wines and fortified wines. A list of wines available from James T. Fallon (grapegrower/vigneron) in 1874 included Riesling (dry and fruity options), Verdelho, Tokay, Shiraz (dry or fruity options), and Clarets (made from Malbec, Hermitage, Mataro, and others). The wine was available in bulk, oak casks – known as quarter-casks (80 l/21 US gallons), hogsheads (242 l/64 US gallons), and puncheons (500 l/132 US gallons) – or in quart or pint bottles. Table 2 displays the 1913 wine list of Thomas Hardy & Sons' Adelaide Wine Cellars. A large proportion of the wine in the 1800s and early to mid-1900s was exported. Frank Osborn of d'Arenberg fame in McLaren Vale began to produce bulk wine in 1928 specifically for the export market (Woodhouse and Osborn 2012). Other companies – Thomas Hardy & Sons and Penfolds – were exporting wine prior to this. Today, exports form a large part (about 60% of total production) of the modern Australian wine industry. It is interesting to see the varieties listed, as in these periods generic terms – for example, Champagne, Hock, Chablis, Burgundy, Claret, Sherry, and Port – were mostly used (see the section "What's in a Name" below).

By the end of the nineteenth century, grapegrowing and winemaking had become a significant part of Australia's agricultural landscape, but beer still dominated the

Table 2 The 1913 wine list of Thomas Hardy & Sons, Adelaide, Wine Cellars (Bishop 1977) which is one example that highlights the availability of dry white and red table wines, relative to sweet and fortified wine styles at the time

White wines	Red wines	Sweet wines
No. 0 Hock	No. 0 Claret	Frontignac
Hock	No. 1 Claret	Madeira
Chablis	Tintara Claret	Muscat
Old Sherry	Old Burgundy	Hardy's Sherry
Oomoo White (a first-class white wine, slightly sweet)	Burgundy	Old White
	Old Port	Old Brandy
	Invalids' Old Port	
	Adelaide Port	
	Old Red (sweet)	

drinking pattern. There was a pub/hotel on the corner of almost every street of every town and city. The corner pub supposedly arose out of the need to house and feed builders constructing dwellings along the street, and pubs either were sold off to pay for remaining building works or were retained to act as focal social gathering places for the locale. Across Australia, in most states, closing time at the public bar was 6 pm in the early twentieth century (Phillips 1980; Room 2010). Six o'clock closing, introduced during World War I, was partly an attempt "to improve public morality" (despite their having being a major drive for this by the temperance societies commencing in the 1870s) and also a war austerity measure. Before this licensing reform by referendum, most Australian hotels and public houses closed around 11 or 11:30 pm (Phillips 1980). A beer on the way home with your mates was a common practice. With 6 o'clock closing, a 1 h, heavy drinking session ensued between "knock-off" time at 5 pm and mandatory closing at 6 pm. Men stood crammed in at bars to consume as many drinks as possible before "time gents" was called. The phrase "6 o'clock swill" is Australian and New Zealand slang for the urgency to buy drinks at the pub before closing time. Bar closing times were extended across Australia in different years. Closing time was changed to 10 pm in Tasmania in 1937, but not until 1955 in NSW and 1966 in Victoria, with the state of South Australia being the last to abolish "the swill" in 1967.

Beer was the drink at dinner and celebrations for men (and some women). Ladies often drank a "shandy," a mix of beer and lemonade (the sweetness of the lemonade most likely masking the bitterness of the beer), in the lounge area, because up until the late 1950s, in Australia women were not permitted in the public bar. Despite the fact that earlier in Australia's colonization, many women were publicans, by 1900 for "respectable women," it had become socially unacceptable to frequent hotels, an outlook that prevailed until the late 1950s (Kirkby 2003), at which time surveys found that only one in four women drank alcohol. Right up until 1970 in Queensland, to serve women alcohol in the public bar was prohibited. Women were able to purchase a drink in the ladies lounge or beer garden, although at a higher cost. However, the public bar was the men's domain. Inequitably, women could be barmaids in the public bar, but they couldn't be customers.

When wine started to be served at restaurants is uncertain. The appearance of restaurants in Melbourne in the 1850s arose probably out of need as the population soared after gold was discovered in 1851. Restaurants where respectable men and women dined together in public appeared relatively late, as occurred in England. Hotels were major providers of food throughout the nineteenth century. Gentlemen also dined at their clubs. The first restaurants of note were European rather than English with the French style dominating international fine dining. Records indicate there was considerable interaction and intermarriage between restauranteurs and wine merchants who supplied the former (Erlich 2008). References also indicate that restaurants were established in the capital cities in the 1870s and 1880s with sixpence meals (Inside Story 2016). The shilling restaurants also provided alcohol, and there was a separate room for the women (Erlich 2008). When hotels were required to close at six o'clock in 1916, the practice of not serving liquor after six spilt over into restaurants, where due to licensing laws most were unable to serve liquor at all, and those limited establishments that could were obliged to have all glasses off the table by mid-evening. The diners of the time became accustomed to having wine served in cups. Wine was being offered at hotels and restaurants in the 1940s and 1950s (and probably earlier). For example, Café Rigoni's advertised 'It's the atmosphere that counts. For something just a little different take her to Café Rigoni's – Soft lights, Sweet Music. Light Wine Served'. Several other restaurants of that period advertised 'wine served with meals' or 'Best select wines and expresso coffee'. Night Clubs offered dinner, wines, dancing and a show (Thompson and Smith 2015). Dining at restaurants had become part of the norm. Before the practice of Bring Your Own "BYO" wine in the mid-1960s, due to the expense of liquor licenses, some restaurants still served wine, just covertly in soft drink bottles and tea cups (The Age 2004). BYO was popular for another 20 years or so, and some restaurants still continue this practice with varying corkage (serving your wine to you) charges.

There is much written about people, vineyards, and wine companies, but there is little information of the taste of the early wines. There are references in the literature of red wines being "full-bodied" and "strong wines." It is likely that some may have had spirit added to them at the completion of fermentation to preserve them. The quality of the wine in those days was variable, but there are several references to excellent wines being produced in this period. For example, in 1827, Gregory Blaxland of Bush Farm sent three pipes (a pipe equals about 500 l) of some colonial wine, lightly fortified with 10% French Brandy (to protect the wine from spoilage) to a London competition. This wine won a Ceres Gold Medal. In the first half of the twentieth century, wine quality would have improved as wine companies introduced modern winemaking equipment, such as stainless steel tanks, presses and refrigeration systems, and more efficient bottling facilities. Wine people talk of the great red wines from across several of Australia's wine regions, for example, Reynella, Coonawarra, and the Hunter Valley of the 1930s to the 1960s.

Food was still influenced largely by traditional British eating habits. Chinese restaurants offered alternative dining venues and cuisine. "Fish and chip" shops were common in many towns and cities. But most dining (eating-out) places were in hotel dining rooms (although there were a few "restaurants"). By the early 1900s, some cafés/restaurants offered a wider variety of alternative style cuisine, for example, French, German, Italian, or Chinese. However, most of the time eating-out and at home was along the traditional British eating habits of "meat and three veg," often potatoes. Meat and three vegetables was the norm (particularly for the working class) right up to the mid- to late 1900s. Below, we present a selection of menus described in the book *Traces: Where Adelaide Ate Out* 1836–1960 by Thompson and Smith (2015) to illustrate this point (Fig. 4).

The advertisements for restaurants in the 1940s and 1950s promoted "Continental and Australian Food" and "Best Continental Foods" and "Finest Italian Specialties and expresso coffee". The Copper Kettle Wine Restaurant was offering oyster cocktail, chicken fricassee, filet steak, Cordon Bleu, and pancake flambé. The choice of cuisine had expanded. Further change was to come with the "Evolution/Revolution" of Australian wine and food that began in the 1960s and continues today.

By the 1940s, the wine industry had progressed from rudimentary winemaking to more modern practices. By the 1950s, Leo Buring was making the sweet lighter wine styles branded under the label "Rhinegold." "Barossa Pearl", a sparkling white wine (made from Muscadelle and Semillon), was created by Colin Gramp in time for the 1956 Melbourne Olympic Games. It was an immediate success. He had introduced pressure tanks from Europe (to trap the carbon dioxide from the fermentation) to produce a fruity, fizzy wine style, modeled on the sparkling wines of Germany. A new segment of wine drinkers were being introduced to wine. However, the large changes came in the 1960s and 1970s. Guenter Prass, one of Australia's well-known and acclaimed winemakers of the mid- to late 1900s, is quoted (after the revolution) as saying, "In the 1950s when you went to dinner you had a sherry as an aperitif, beer with the meal and perhaps a port after the meal. Today you have a glass of wine anytime. .... This is not only a difference, but a revolution" (Allen 2012).

A selection from the menu of a supper at the Southern Cross Hotel in 1839:

Selection of pies — Veal, Giblet, Quail, Pigeon, Pork or Pickled Tongue; **Remove** — Saddles of Mutton, Butt of Beef, 2 Legs of Mutton, 2 Forequarters of Lamb, 6 Roast Geese, 6 Hams; **Dessert** — 6 Plum Pudding, 18 Raspberry, 12 doz Custards, 2 Sponge Cakes.

The menu of the York Hotel in the early 1900s:

Soups — Crème of Chicken, Consomme of a la Creol; **Fish** — boiled Snapper, Oyster Sauce; **Entrees** — Croquettes of Chicken with Peas, Scallops of Veal with Nouilles; **Joints** — Roast Sirloin of Beef, Roast Saddle of Mutton, Roast Black Duck, Salade; Cold Yorkshire Pudding,

Cold — Roast Beef, Lamb, Ox Tongue, York Ham; **Vegetables** — Spinach, Cauliflower, Boiled Potatoes, Baked Potatoes, Mashed Potatoes; **Sweets** — Baked Apple, Dumplings, Cup Custard, Wine Jelly.

Fig. 4 Examples of entries in "Traces: Where Adelaide Ate Out 1836–1960" (Thompson and Smith 2015). These entries present examples of dishes from menus of hotels in Adelaide, South Australia, in the nineteenth and twentieth centuries

The Modern Era (The 1960s Through to Today): The Revolution – The Rise of Table Wine

By the 1960s, fortified wine production was at its peak. However, the influx of migrants and returning soldiers from Europe after World War II saw a rapid change in consumer tastes (Santich 2006). A move away from older Australian drinking practices to a more sophisticated table wine and food restaurant dining culture quickly developed (Kirkby 2003), with a boom in red wine sales during the 1970s and a swing to white wine consumption during the 1980s. Sparkling wines became popular, particularly for celebratory occasions. Varietal wines (wines labelled by grape variety) also became popular and replaced generic terms like Claret and Hock. This simple labelling system made it easier for people to understand wine. Brand names including Penfolds, Jacob's Creek, Rosemount, Wolf Blass, and Lindeman's dominated domestic and international wine trade.

The change in drinking patterns coincided with a change in Australia's eating and dining patterns. During the 1950s and 1960s, men who were interested in wine joined local Bacchus and Beefsteak and Burgundy Clubs. Women also had clubs – the Chicken and Chablis Club. Although, more formal wine tasting clubs are less popular in Australia, today men and women drink both white and red wines, and the clubs are not segregated.

Some Events/Factors that Drove the Rise of Table Wine

The introduction of refrigeration, cultured yeast, stainless steel fermenters and storage vessels, modern presses, and the use of inert gases and a greater understanding of winemaking principles through the wine schools established at Roseworthy Agricultural College (later to become The University of Adelaide) and at Charles Sturt University probably culminated to drive better-made, microbiologically and chemically stable, higher-quality wines. As a result, a table wine culture arose. Most of Australia's winemakers have studied at these two institutions and would have been abreast of this wealth of winemaking innovation and technology but also were more globally mobile and aware of what world wine styles were on offer. With our warm climate and outdoor lifestyle, table wines were clearly more suited than higher alcohol and warming fortified styles and the Australian wine consuming community responded. The invention of the wine cask (bag-in-box) in 1965 by Thomas Angove of the Riverland (Fig. 5) (Byrne 2017) took 2 years to develop and was considered by the press as "an extremely novel idea." It was not designed to replace glass but offered the convenience that people could buy wine in bulk and have just one or two glasses without the need to open a bottle (which in many cases would rapidly oxidize and go brown and smell of bruised fruit even after 24 h). The cask was stored in the refrigerator in the kitchen. It became more common for wine to be served and enjoyed at home with a meal and at gatherings. Special events commanded a higher price offering – often interpreted as serving "a bottle" of wine rather than a cask.

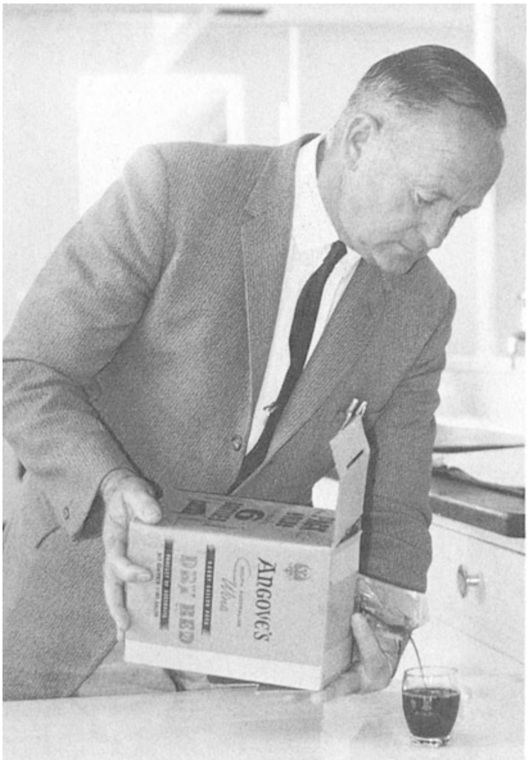

Fig. 5 Bill Marshal demonstrating Angove's bag-in-a-box in 1965. (Photograph provided by Angove Family Winemakers "Angove Family Collection")

Angove Family Winemakers, like many Australian wine companies, have now moved away from the wine cask, preferring to present their range of wines in bottle.

In the 1970s and 1980s, alcohol consumption peaked in part driven by increased wine consumption. The introduction of wine in a flagon and cask had a large role in this increase. Marketing campaigns also drove sales. Many Australians remember the advertisement "Where do you hide your Coolabah." Coolabah was the popular brand of cask red and white wine produced by the then Orlando wine company.

Alongside the increasing interest in the large-volume, medium-priced popular brands of the 1980s Australian wine boom (Anderson and Aryal 2015), a "wine connoisseur" culture developed. These people, often professional men, sought out special wines from both overseas and locally (Johnson and Bastian 2015). Wine knowledgeable people including James Halliday started writing newspaper articles; wine magazines such as Winestate (established 1978) were published, and wine companies ran publicity campaigns (e.g., a popular women's magazine in conjunction with a wine company produced, "Woman's Day and Lindeman present your guide to wine & entertaining," c1983); and interest and knowledge of wine increased. The number of Australian wineries swelled, from just under 500 in 1985 to over 2500 by 2013 (Anderson and Aryal 2015). Doctors, lawyers, scientists, as well as people of other professions established wineries – often as a hobby or as a weekend escape from the city. A boutique winery culture emerged. New vineyard plantings and generational change, in traditional and new wine regions, during the late 1990s and early 2000s saw the wine sector achieve new ambitions (Anderson and Aryal 2015). More recently, interest and activity have increased in cool climate wine styles, sustainability, organic and biodynamic viticulture, preservative-free, terroir, and so-called natural wines. These, along with traditional approaches, have led to a diverse, dynamic, and exciting present-day wine culture. Australian wine is known and appreciated in export markets around the world, especially the UK and the USA, and now more recently China (Wine Australia 2019).

Food and Wine Scene Today

Increased worldwide connectivity through news and entertainment media, the World Wide Web and social media mean patterns in the global food and wine scene are reflected in Australia. The modern Australian café, restaurant, and home meal scene is a melting pot of many cultures. Similar to other nations, immigration leading to Australia's multicultural population has brought Italian, French, Chinese, Vietnamese, Spanish, Lebanese, Thai, Mexican, and many other countries' food culture to the plates and glasses of Australian diners and families. TV shows now feature cooking demonstrations and competitions. People are interested in what they eat and where it comes from (Giles-Smith 2014) and how it is prepared. The phenomenon of world-renowned "celebratory chefs" and "food gurus" has gained a large following by the so-called "foodies." Restaurants, as in Europe and elsewhere around the world, are judged and rated – much like wines are in wine shows. Hats, and other awards, similar to those in European countries, are prized achievements.

Currently in Australia, Chinese cuisine is more than "sweet and sour chicken," "beef and black bean sauce," or "fried rice"; in our large cities, you can enjoy Chinese cuisine in many forms, such as Cantonese, Sichuan, Hong Kong influenced, and Shanghainese. The same could be said of other cuisines, for example, Southern or Northern Italian cuisine. Many of Australia's restaurants are based on locally farmed and grown produce. The food is fresh, creative, diverse, and exciting, and diners today are discovering ingredients that our early settlers used in their food preparation. It is now not uncommon to find indigenous ingredients appearing on restaurants' menus. Offerings can include the likes of wattleseed, lemon myrtle, lilly pilly, and quandong. For example, Orana Restaurant in Adelaide quotes its philosophy as – "to respect the Aboriginal people and Australia's varied food history while celebrating the nutritional properties of indigenous ingredients". Their menu includes dishes such as soup – crocodile with Australian botanicals and kangaroo, smoked potato, feral plum, and wattleseed. Australian cuisine has come a long way from mutton stew and wild spinach eaten by the early settlers. Today, Australian chefs and cooks have a rich and long Aboriginal cultural base – over 60,000 years – to draw inspiration from. Add to this our British heritage and influence of immigrants from many countries, Australia has developed a diverse, interesting, and exciting food scene along with a high-quality and diverse range of wines to partake in with those foods (Santich 2006). With Australia's close proximity to the rest of Asia, its cuisine has been shaped by this Asian influence more so than the USA, Canada, Western Europe, the UK, and other Western nations arising as a result of British colonial settlements. "Modern Australian-Asian fusion" and "Pan-Asian food" are terms often used now to define a number of Australian restaurants' fare.

What's in a Name?

In the old world of France or Italy, top quality wines have been labelled by the region (e.g., appellation, Appellation Controlee AC or Denominazione di Origine Controllata e Garantita, i.e., Denomination of Controlled and Guaranteed Origin, DOCG, respectively) in which they are produced, not by grape variety. These classifications act today as wine quality indicators and have strict controls over various aspects like grape yields and wine production, maturation, tasting, analytical testing, etc. Over the generations, consumers of European wine became familiar with what to expect from a wine from these regions. At the time wine production commenced in Australia in the early 1800s, there were no recognized wine regions, and the wine-consuming population only had experience drinking European wines. For whatever reason, Australia's early winemaking pioneers were not sufficiently confident to label their wines by their variety (e.g., Shiraz) or region.

Up to the 1980s, the wine regions of France and Germany such as Beaujolais or Moselle were commonly used for Australian wines in bottle and in cask. Consumers before this period in Australia's wine history would have grown up with and understood their meaning. However, these names did not relate to the grape varieties that would constitute these wines made from those regions overseas. Claret, an old English word from the 1700s, was also a popular wine description on Australian labels and is a term broadly considered to reflect a light, dry red wine or a Bordeaux wine. In retrospect, the use of these old-world regions for Australian wines was not well considered, as frequently the Australian wine style was nothing like those from those old-world areas.

Clues to the taste of Australian wines throughout most of the first half of the 1900s may (or may not) be gained from their generic names after the "old-world" appellations. Names for white wines included Champagne, Hock, Chablis, White Burgundy, Moselle, and Sauternes. The names broadly reflected a style (e.g., see Table 3). They were frequently made with multiple varieties and did not need to be produced from the variety that contributed to the European style. For example, France's White Burgundy is made solely from Chardonnay, while in Australia the name reflected a style not a grape variety and could be made from a mix of white grapes. Books (Young 1983) and wine show specifications of the mid-1900s indicated, briefly and generally, the following styles in Table 3. In those days, a wine labelled in any of the categories could be produced from any and several varieties.

Red table wines were often labelled Claret or Burgundy (Table 3). Claret was frequently made from both Shiraz and Cabernet Sauvignon and referred to a style of wine that was firm and astringent, often high in tannin and with good cellaring

Table 3 An example of Australian wine styles pre- and mid-1990s (Young 1983)

Wine Name	Wine Style and Taste
White Burgundy	Fuller, rounder, softer white wine
Moselle	A sweet style white wine, usually fragrant
Hock	Fresh, light, dry, fairly acidic with a fragrant bouquet
Burgundy	A full-bodied, fruity red wine with a smoother, round, and softer finish than a Claret
Claret	A full-bodied red wine that is firm and astringent

potential. Wines labelled "Burgundy" hailed mainly from the Hunter Valley in New South Wales, Swan Valley in Western Australia, and northeastern Victoria – all regions quite climatically different to France's Burgundy region. These wines were softer, fruity, and less acidic than Clarets and made from either Shiraz, Pinot Noir, or a blend of both or other reds like Grenache. The Shiraz grape variety is not even grown in France's Burgundy region, which is an area producing Pinot Noir and Gamay grapes. Pinot Noir plantings have diminished in the warmer regions of Australia and are now planted in cooler climates. There have been considerable replantings in Australia to ensure varieties fit the region's climate such as Mediterranean varieties (see below). Australian fortified wines were referred to as Sherry and Port.

The situation changed in the mid-1990s when Australia started labelling their wines by grape variety and its own geographical indications (GIs wine regions; Fig. 3). Wine producers adopted labels displaying grape variety and the region, e.g., Cabernet Sauvignon, Coonawarra, and the like. Then, in 1994, the Winemakers Federation of Australia, a national wine industry advocacy body, signed a wine agreement with the European Union, assenting to cease the use of old-world wine region names on Australian wines entirely. These names are actually akin to the way Australia now uses its own wine region names on its wine labels, for example, the Barossa Valley, Mornington Peninsula, or Hunter Valley. As Australia has become a global wine heavyweight and its winemakers confident, skilled, and knowledgeable of wines from around the world, it too has gradually turned to designate its wine by origin. In so doing, it infers wine quality, grape variety, and wine style to the international market in an effort to assert that Australia generates premium, not just cheap and cheerful, wines of provenance.

Recently, Australia has faced a number of commercial challenges including the enforcement of naming restrictions from the European Union. Examples include the requirement to rename its Rutherglen Tokay (a fortified sweet wine style made from Muscadelle grapes) to Topaque, as the former was considered too close to Hungarian Tokaji (a sweet and complex botrytized wine made from unique, Hungarian varieties such as Furmint and Hárslevelű, plus another four permitted varieties). Wines previously named Champagne are now known as sparkling wine in Australia. Australian winemakers carbonate their sparkling wines with a number of methods including the "methode champenoise." However, labels will not use this term and include "methode traditionnelle" instead if the wine has undergone further fermentation in bottle indicating it is a sparkling wine of high quality. Australian-made Sherry is now labelled with the Wine Australia registered term Apera, yet this name is also under challenge by the Campari group, as it believes it could impact the aperitif Aperol. Prosecco is a documented white grape variety (originating from Italy) on the internationally recognized grape variety list maintained by the International Organisation of Vine and Wine (OIV). Prosecco was being used to label and market sparkling wine styles in Australia with considerable success. Yet this too was challenged as a protected term. The European Commission (EC) asserts that the term "Prosecco" is a geographical indication (GI). The EC attempted to register Prosecco in Australia, which was successfully opposed by the Winemakers' Federation of Australia on the grounds that it is a grape variety. In Australia, we do not prevent the use of the term as a grape variety. This is supported by the TRIPs (Trade-Related Aspects of Intellectual Property) agreement, which is an agreement of the World Trade Organization (WTO) (World Trade Organization Analytical Index (2019)). The agreement specifically provides that a signatory country does not need to prevent the use of a registered GI that is also a grape variety (as a grape variety). Until 2009, the EC recognized Prosecco as a grape variety; however EC Regulation 1166/2009 introduced a decree stating that the vine variety "Prosecco" be renamed as "Glera," another synonym for the prosecco grape instead. Since then, the use of the term Prosecco as a grape variety in the EU has been prohibited.

Increasing Interest in Australian Wine Regionality/Subregionality

A regional wine's style, quality, and prestige are influenced by its place of origin. Protected geographical indications (GIs) have evolved to identify goods originating from a particular area "where a given quality, reputation or other characteristic of the product is essentially attributable to its geographical origin" (World Trade Organization (WTO) Analytical Index 2019). GIs assist in the differentiation between products in the global market (Bowers 2003). Climate and vineyard attributes including geology and soil modify grape chemical composition (Van Leeuwen and Seguin 2006) enabling the discrimination of grapes from different regions (Son et al. 2009; Teixeira et al. 2014). Unlike Europe, Australia does not have the wine laws where local and government regulations constrain viticulture and winemaking practices. The flexibility of winemaking and labelling laws allows winemakers the choice and opportunity to make Australian wines in many different ways. Blending has been a part of Australian winemaking culture for many years, resulting in unique Australian wine styles, such as blends of Shiraz and Cabernet Sauvignon. This follows the rationale of a Bordeaux wine blend where Shiraz replaces Merlot to round out the middle palate of the wine and provide fruit intensity to support Cabernet's tannin structure. Australian wine laws also allow winemakers to make wines from a single variety within a region, from two or more varieties from within a region or from multi-regions. However, in 1993, the Australian wine sector developed a geographical indication (GI) system mimicking the Appellation Controlee of France. The GI system officially describes Australian wine zones, regions, and subregions (see Fig. 3). Although the system is likened to the European appellation system, it is much less restrictive. It aims to protect the use of the regional name, such as Barossa Valley, Coonawarra, Hunter Valley, or Margaret River, under international law and limits its use to describe only wines produced from grapes grown within that GI. The Australian GI system ensures at least 85% of the grapes come from the region and vintage, acknowledged on the label (Johnson et al. 2013). Furthermore, wines from a designated GI should possess unique sensory characteristics and varietal expression deriving from the region, rather than overt viticulture and/or winemaking practices (Johnson et al. 2013).

Knowledge of the specific composition of wines originating from different GIs would allow the characterization and authentication of the wines and valuation of each GI. As such, wine aroma, flavor, and chemical profiles that differentiate wines from distinct regions have received much research interest globally (Cadot et al. 2012; Di Paola-Naranjo et al. 2011; López-Rituerto et al. 2012). European appellations strive to preserve wine typicality by strictly regulating, e.g., the use of permissible grape varieties, harvesting methods, maximum yields, minimum alcohol levels, and production methods (Van Caenegem 2003). Furthermore, traditions and human practices may vary markedly by region or appellation. In vineyard-driven classifications (e.g., Burgundy, Mosel, Barolo), human intervention is strictly regulated, while in other appellations, distinct wine styles are defined by the local winemaking practices (e.g., Amarone della Valpolicella, Champagne, Port). Bordeaux has achieved great economic success by classifying quality of individual wine estates.

Along with their fruit-driven, easy-drinking style and good value for money, the uncomplicated and clear varietal labelling contributed to the enormous success of Australian wine in the 1990s (Easingwood et al. 2011). Australian Shiraz became internationally recognized as a unique wine style with examples coming from the Barossa Valley, McLaren Vale, and Hunter Valley. Aromas and flavors can range from plum, red, blue, and black berries and chocolate to liquorice and spice (Herderich et al. 2007) resulting in medium- to full-bodied wines with varying structure depending on region, climate, and winemaking techniques. As Australia did not have a firmly ingrained concept of terroir, it commonly used brands and price points to create a sense of fine or quality wine in consumers' minds (Johnson and Bruwer 2007).

Today however, the Australian wine industry has an increasing interest in wine regionality. The concept of regional typicality of wine is an important one as it not only delineates geographic areas but also permits promotion of Australian wines with recognizable and desirable sensory characters (Lecat and Chapuis 2017; Luykx and Van Ruth 2008; Maitre et al. 2010). This notion is also related with terroir, that is, wine provenance, a holistic definition including the interaction between location (topography, climate, soil), people (tradition, winemaking and viticultural practices), and product (grape varieties, wines) (Vaudour 2002). Terroir has defined many famous regions in Europe, including the prestigious vineyard sites of Burgundy, Mosel, and Barolo or the classified wine estates of Bordeaux. Wine consumers have relied on provenance to predict wine quality and are willing to pay a premium price for them (Benfratello et al. 2009; Casini et al. 2009; Charters and Pettigrew 2007; Johnson and Bruwer 2007). There is also an increasing interest in the production of single vineyard Australian wines – wines that express a "sense of place." Currently, there is industry-wide belief that production of regional and single-site wines will enhance Australia's image as having a segment of high-quality, "terroir"-focused fine wines. From an economic view point, establishing a fine wine image through regional typicality has been a focus of Australian wine businesses as it is seen as a strategy to raise Australian wine's global image around quality and thereby demand higher prices.

Australia has many regional styles; some examples being Clare Valley Riesling, Hunter Valley Semillon, Margaret River Cabernet Sauvignon, Coonawarra Cabernet Sauvignon, Mornington Peninsula and Yarra Valley Pinot Noir, Barossa Valley Shiraz, and Rutherglen Muscat. Several research projects have explored the taste and chemical composition of Shiraz and Chardonnay wines from different regions and within regions. One of the authors of this chapter, Dr. Sue Bastian, and colleagues have led several of these studies. Chardonnay, the white variety most important to Australia at present, encompasses 44% of all white wine production. Yarra Valley, Adelaide Hills, Tasmania, Tumbarumba, and Margaret River are cited as top Chardonnay-producing regions with wine sensory descriptors covering the fruit spectrum, from citrus and green apple to peach, apricot, and tropical fruit (Bruwer and House 2003; Gambetta et al. 2014). Chardonnay is an extremely flexible grape with regard to various winemaking techniques (Gambetta et al. 2014) resulting in diverse wine styles within and across regions (Saliba et al. 2013). Chardonnay grapes are a neutral variety unlike the aromatic floral and perfumed Riesling or tropical and herbaceous, sweaty Sauvignon Blanc grape wines. Australian Chardonnay wines have experienced an evolution of style over the past 40 years. This has been partly driven by the Australian wine show system and reduction in sales. Show judges encouraged a move away from oak forward styles with too much buttery aroma and softened, round mouthfeel due to higher alcohol and yeast lees contact (where the wine is stored in tank or barrel on a deposit or sediment of the now dead yeast that conducted the fermentation) and full malolactic fermentation (MLF, a secondary fermentation performed by lactic acid bacteria that converts grape-derived malic acid to lactic acid to soften the acid taste, provide wine microbial stability, and enhance flavor complexity). Instead, wine shows now reward Chardonnay wines of more elegant, restrained styles with pristine fruit supported (not swamped) by well-integrated oak, maybe partial MLF, and fresher acid or reductive oyster shell notes. This change in style also reflects establishment of more Chardonnay vineyards in cooler climates. The influx of New Zealand Sauvignon Blanc also saw the temporary demise in Australian Chardonnays. Encouragingly, measurement of elements (minerals), amino acids, basic chemical composition, and free and bound volatile aroma compounds, followed by chemometric analysis of the data sets, allowed the discrimination of Chardonnay grapes originating from seven different GIs in South Australia, across two vintages (Gambetta et al. 2017). Classification of Chardonnay grape samples according to region of origin using the fingerprint region of the mid-infrared spectra (1,500–800 cm^{-1}) had an overall success rate of 83% and 81%, for the 2014 and 2016 vintages, respectively (Gambetta et al. 2019). This work provides potential chemical measures to target in future studies of larger numbers of Chardonnay from across Australia's different GIs for characterization and authentication. Authentication of Australian wine provenance is seen by the Australian wine industry as an important piece of the Australian regionality puzzle, particularly as wine consumers globally become increasingly aware of what they consume (Giles-Smith 2014), health, and food safety and are becoming more knowledgeable about wine and wine regions in general and demand authenticity and assurance of wine provenance. Numerous studies are ongoing at the University of Adelaide and other Australian wine science institutions to identify the markers of authentication of Australian wine provenance.

In another study (Johnson et al. 2013), the regional characteristics of 29 Australian Shiraz from ten different GIs utilizing sensory Descriptive Analysis and Multidimensional Scaling were examined. The authors found that for some regions some of the wines from each region were, based on their sensory properties, grouped together. However, it was not definitive to the degree that all the wines of one region identified with a particular region. The greater the diversity of the region in terms of geography and meso-climate, the more difficult was the determination of the common sensory properties. Differences in winemaking practices would also have added to the difficulty in identifying regional origin. The authors suggested future research should use wines made under controlled conditions and/or encompass subregions within regions that are smaller and/or more homogenous in geography as well as a larger sample size. The Barossa Grounds project is one such endeavor, which resulted in the identification of three main grounds (Northern, Central, Southern) with two further supplementary grounds (Eastern Edge and Western Ridge) in the Barossa Valley (Robinson and Sandercock 2014). The Scarce Earth program highlighted 19 wine districts in McLaren Vale (Bekkers 2012), and the Rocks project defined five subregions in Clare Valley (Werner and Roche 2016). Current research involving cross-national Australian viticulture and wine researchers are ongoing to establish the uniqueness of Australian Shiraz, Cabernet Sauvignon (Niimi et al. 2017), and Pinot Noir. These studies are using a combination of research wines and commercial wines as the former, which are typically young, mostly unoaked, and produced with standardized winemaking protocols, do not necessarily reflect the commercial wines and styles available in the market, but they do remove confounding factors introduced by human intervention.

In a recent study, consumers defined Australian fine wines as high quality, good value for money, easy to drink, which consistently show balance, plus diversity, fruity, and regional characteristics (Kustos et al. 2019). The importance of regional typicality has been recognized for some varieties such as Barossa Valley Shiraz, Coonawarra Cabernet Sauvignon, Margaret River Chardonnay, Hunter Valley Semillon, etc.; however research is yet to firmly establish sensory and chemical composition associated to GIs similarly to the old-world appellation system (Conduit et al. 2016; Van Caenegem et al. 2015). Whether from a marketing, consumer, or scientific perspective, the questions remain whether regional typicality is expressed more with less intervention and whether consumers can benefit from the research outcomes. Thus, the connection between Australian GIs, grape varieties, and regional typicality needs to be further explored.

Interest in Organic, Biodynamic, Preservative-Free Wine and a Sustainable Industry

The emerging alternative variety (plantings of grape varieties new to the Australian wine scape) and natural wine scenes have been growing trends in Australia over the past decade, but they represent smaller, niche markets sales-wise. Increased interest in alternative varieties is directed by a desire to ensure the sustainability of the Australian wine industry, particularly in the face of climate change and drought by planting varieties better adapted to hot climates and possibly as a point of differentiation for producers in a crowded wine market. The so-called natural wine movement is led by the momentum and voice of a newer generation of winemakers, who desire to intervene less. Of note for the reader, the term natural wine, if one consults the Australian and New Zealand food standards, is defined as one made from grapes. Although there is no definitive explanation of the term in a practical winemaking context, other than that the wine has to be made from grapes, the term "natural wine" has become more accepted within the Australian wine community as wine being made with less intervention in the winemaking process. Further to this, many wines are made in Australia with low intervention but do not claim to be "natural wine." Some of these natural wines are fermented with natural or wild yeasts (that naturally occur on the grapes) and are often unfiltered and sometimes darker or turbid in appearance. They are frequently unfined before bottling. Fining is a process involving addition of approved processing aids to wines for the purposes of reduction of unwanted compounds, often by precipitation, e.g., wine clarification. On the shelf, natural wines are often hand labelled with handwritten labels and wax-dipped closures. They include some of the so-called "orange" or "amber" wines; white wine made from extended skin contact, which is actually an old-world tradition; and lighter, less alcoholic style reds. This has infiltrated through the whole industry with more established producers making toned-down, less alcoholic wine styles. These new movements combine Australia's strong scientific wine knowledge with past local and international experience and have focused the industry's awareness on the production of wine that aligns with the country it is consumed in. Recently, Australia was renowned for powerful, lavishly, oaked, up-front fruit styles, which were winning many accolades in the important USA, UK, and Asian markets. Now, the dialed down tone of emergent wine styles better suits the Australian climatic drinking conditions, which is warm-to-hot for most of the year. Further to this, a number of producers have installed or converted their traditionally farmed vineyards over to organic or even biodynamic practices to enhance biodiversity in the fauna and flora of vineyards for sustainability and meet consumer demands for wines with lower chemical input. Small segments of vegetarian and vegan consumers have also shaped the Australian industry to take note of the use of certain winemaking aids. For example, research is being conducted and producers switching to vegetable as opposed to animal-derived protein fining agents to remove undesirable levels of tannins causing too much astringency (the roughing and drying textural, mouthfeel sensation) which at high levels lowers wine quality (Kang et al. 2018).

The majority of Australians reside in a concentrated strip around the coast, and drinking and eating are often outdoors, so the less opulent wines are likely to taste better on a hot day at the beach, picnic, or BBQ. Australian's BBQ anywhere, not just at home, and Australia's cuisine is now heavily Mediterranean and Asian influenced with grilled and barbequed meat (including "snags," what Australians call sausages), seafood, salad, garlic, chilli, and ginger. The richer, riper fruit and heavily new oak, oaked styles are less likely to fit this Australian wine and food lifestyle, with the exception during the cooler months. Australian wine consumers are part of the global premiumization trend in mature markets, with value growth exceeding volume growth as consumers turn to higher value products (Wine Australia Market Bulletin 2019), so these less opulent styles are suited to new segments of consumers wanting to reduce alcohol intake. Using different grape varieties that are infinitely more suited to Australia's often hot and harsh or at the other extreme, cool, growing regions, makes good sense for the sustainability of these rural agricultural areas and communities. Many of these varieties have origins in warm Mediterranean conditions and are well adapted to retain the acid and fruit flavor compounds necessary to produce fine wines. Examples include the white grapes Vermentino and Fiano and red Nero d'Avola and Montepulciano. This revival in the Australian wine scene positions drinkers of Australian wine for an extraordinary and interesting period. Recently, studies on the sensory and chemical profiles of wines made from the indigenous grape varieties of Cyprus, demonstrated Australian consumers found these wines acceptable (Copper et al. 2019). Consequently, the exciting opportunity exists to cultivate these grape varieties that may withstand tough Australian current and future conditions.

Australia's Unique Wine Styles

In the following section, the authors introduce you to four wine styles that are generally regarded as being unique to Australia (Iland et al. 2017). It discusses the grape varieties used, how the style developed, what to expect when tasting the wine, and how best to consume it.

Hunter Valley Semillon

The Hunter Valley wine region in New South Wales is approximately a 3.5 h drive North of Sydney. Hunter Valley Semillon is widely considered the iconic wine of the region, but good examples of wine from a variety of grapes including Shiraz, Chardonnay, and Cabernet Sauvignon are also produced there. The Semillon wines are unique, not just for their taste but for the fact that in some cases the wine company, and not the consumer, cellars the wines, sometimes for many years, before their release. Picking of the fruit occurs at relatively low sugar but high acidity levels. This compositional profile promotes the wine's cellaring potential. The fruit is crushed gently to reduce polyphenol extraction that can render the wine astringent and bitter (Jackson 2017) and the juice fermented cool to retain volatile flavor compounds (Jackson 2017) and also to ensure the wine's longevity. The finished wine is clarified, filtered, and bottled and then aged in the bottle for 6 years (or longer) prior to release.

The taste of Hunter Valley Semillon: Overtime the wine slowly develops a golden color, and the aroma develops from subtle grassy, apple, and lemon characters to toasty, vanilla, honey, honeysuckle, straw, and fig characters. As it ages, the wine builds in weight and richness. The best have a refreshing lingering acidity. These wines have great aging potential.

The acidity levels are crisp. It goes well with seafood and fresh chicken dishes. Slightly older, richer styles can handle more rustic flavors.

Riverina Botrytis Semillon

Most of the great sweet wines of the world, for example, those from Sauternes and Barsac of France; Beerenauslese and Trockenbeerenauslese wines of Germany and Austria; and the intricately complex Tokaji wines of Hungary, are made from grapes affected by the fungus *Botrytis cinerea* (Jackson 2017), often called "noble rot." Normally, noble rot and these wines are from cool, humid regions around the world. The climate of the Riverina region in New South Wales is hot and dry; yet wine companies produce world acclaimed examples of *Botrytis*-affected Semillon wines.

While the temperatures in the Riverina region can be high over summer, the climatic conditions later in the season are much milder due to the influence of late autumn rains. Fogs can cover the vineyards for most of the morning, and the humidity inside the vine canopy can reach about 80%, with mean daily temperatures in the order of 14 °C. About midday, the fog clears and bunches dry. The humid, misty mornings followed by drier afternoons are close to ideal conditions for infection and growth of the noble form of *Botrytis cinerea* without the presence of other molds. Even though *Botrytis cinerea* would have infected the vineyards of the Riverina region in various years during the history of the region, it was not until the 1980s that commercial production of botrytis-affected styles of Semillon wines began.

The taste of Riverina Botrytis affected Semillon: The aroma is a mix of fruit and botrytis-induced characters. The aroma characters include spice, floral, perfume, acacia, citrus, lime, pineapple, quince, peach, crab-apple jelly, passion fruit, lychee, orange, tropical fruit, apricot, dried apricot, nutmeg, almond, marzipan, butterscotch, marmalade, honeysuckle, honey, toffee, caramel, treacle, toast, and volatility (ethyl acetate; smell of nail polish remover and acetic acid; aromas of vinegar). These latter two compounds are normal components of wine and, although are referred to as off-aromas in some wine styles, in others, such as the botrytized wines, are considered part of the wine style (Jackson 2017). The taste and texture of these styles are described as sweet, viscous, luscious, soft, creamy, silky, velvety, rich, oily, sumptuous, opulent, and unctuous which may be due in part to higher amounts of glycerol formed from the presence of the microbes including the *Botrytis cinerea* (Iland et al. 2017) but should finish fresh, refreshing, and drying, not cloying or sickly sweet. These are wines that feel round in the mouth. They finish crisp, the sweetness balanced by refreshing acidity.

A beautiful sweet, dessert white wine to rival global counterparts. Pairs extremely well with cheeses including blue vein (Bastian et al. 2009), paté, foie gras and rich milk/dark chocolate. The dessert has to have rich caramel, citrus, or chocolate flavors and the same sweet power level of the wine. It is also good on its own as a dessert.

Sparkling Shiraz

Shiraz is Australia's major red grape variety and is produced in many styles ranging from rosé to fruit forward and generous flavored with full body to more savory, medium-bodied styles. However, it is also used for sparkling wine. These wines are made in a similar manner to white sparkling wines (Iland et al. 2017) – a primary fermentation followed by a second fermentation in the bottle in which it will be sold and served. Each batch of grapes is harvested and processed separately into a dry red wine. After the base wines are made, they are tasted and those with the right characters (normally rich flavor but soft tannins) are selected as base wines. The blend is then assembled. After the composition of the blend is decided, the selected wines are mixed with an amount of sugar solution and yeasts and then transferred to pressure-tested bottles; these are the bottles in which the secondary fermentation takes place and in which the wine is sold.

Most commercial styles remain on yeast lees for 1–3 years. Others may spend a much longer time on yeast lees, 8 or more years. During this time, complexity, the layers of interesting flavor, builds. The level of sugar addition at the dosage stage may range from about 8 to about 40 g/l of residual sugar. Also at this stage, there is an opportunity to add a touch of either younger or older wine to fine-tune the character of the finished wine.

For almost a century, Seppelt has been making Classic Sparkling Shiraz (previously called Sparkling Burgundy) at its cellars in Great Western, in the state of Victoria. Seppelt Show Sparkling Shiraz is a rich and complex wine. The extended time on yeast lees, often greater than 10 years, ensures a harmonious integration of aromas, tannins, and acidity.

The taste of Sparkling Shiraz: As young wines these wines are deep crimson red in color. With age garnet red and brown colors develop. The aroma spectrum can be made up of a mix of fruit and aged characters. Primary fruit characters include spice, pepper, cherry, violet, plum, prunes, plum pudding, mulberry, blackberry, sarsaparilla, licorice, fruit pastille, and jammy. Age brings earthy, sweet, barnyard, leather, mushroom, truffle, meaty, smoky, and chocolate. These wines are rich, full-flavored, and complex, with soft creamy-textured tannins.

Often a wine for celebration. Traditionally consumed chilled at Christmas time in Australia, midsummer and hot. Having a red wine base, it can complement roast meats, including turkey, pork, and beef.

Rutherglen Muscat

Rutherglen is a quaint historic town in the Northeastern part of the state of Victoria. Each year the grapes – Muscat a petits grains rouge – are harvested in batches according to their characteristics and quality and the resultant wines kept separate until their sensory features can be assessed and a decision made regarding which classification increasing in quality – Rutherglen, Classic Rutherglen, Grand Rutherglen, or Rare Rutherglen – they will join. In some years, very little or no wine may be considered good enough to be selected for the rare classification.

The grapes ripen and shrivel (raisin) on the vines, producing natural sugar levels in the range of 17–20°Baumé, sometimes in exceptional years of about 22–24°Baumé. The grapes are picked and crushed and yeasts are added. The mixture is allowed to stand for a few days, and extra sugar is leached from the raisins; the sugar level of the juice may increase to about 25°Baumé. During this time the yeasts slowly ferment the sugar. Just as the sugar level starts to drop, spirit is added to increase the alcohol level to about 18% v/v, and this results in the fermentation ceasing resulting in wines very high in sugar concentration, about 300 g or more of sugar per liter. This contributes to their luscious tastes.

The wine is stored and matured in puncheons (450 l) or larger oak casks for many years (sometimes 50 years or more), gaining complexity. Evaporation plays an important role in the concentration of flavors and other components of these wines. On average, the maturing casks of Muscat lose about 3–5% of their volume each year. The older wines are more complex and are often used in the very special blends.

The taste of Rutherglen Muscat: Expect a luscious, complex, intensely flavored wine. In the higher classifications, you are tasting the influence of many years of ageing in the maker's cellar. The aroma is a mix of marmalade, spice, walnut, fruitcake, toffee, and raisin. The palate is rich, viscous, concentrated, complex, and mellow. The sweetness is balanced with lingering acidity.

This is an after-dinner wine or nightcap. It melds beautifully with chocolate or rich chocolate-based desserts or is a dessert on its own. It can be used to macerate fruits to make special rich, moist fruitcakes or desserts.

Conclusion

While beer still narrowly dominates the consumption statistics as the most consumed alcoholic beverage, wine has made a significant impact on Australian culture, both as a social drink and particularly when eating at home and outdoors or dining in cafés and restaurants. This chapter has provided a brief introduction to the evolution of the wine culture in Australian society. It has traced the drinking and eating norms and evolution and preferences for wine styles of the Australian population across two centuries since the arrival of the British. This has been attributable to social and market forces, climate, Australia's multicultural society driven by various waves of immigration, and the advancement of wine knowledge stemming from cutting-edge grape and wine science research and education. It outlines the growth in confidence and knowledge, plus innovation and resilience of its grape growers and winemakers in a remote, and environmentally challenging, new-world wine nation, to produce value-for-money, good-quality, unique Australian wine styles that are globally renowned and more recently wines of provenance, to become one of the most successful wine-producing countries in the late twentieth and early twenty-first centuries.

29 Wine Trends in China

Larry Lockshin and Justin Cohen

Contents

Abstract

China has become the second biggest economy in the world and growth in wine consumption has been part of the overall economic trend. This chapter provides an overview of wine consumption trends in China starting with an overview of alcohol consumption. The Chinese have always been alcohol consumers; what has changed is the move away from spirits into wine made from grapes. The reasons for this change over the last 50 years are provided as an introduction to the current market for wine in China. Very little consumption data is available from the Chinese government or from reliable data firms; so, much of this chapter is based on the two authors' research in China over the last 6 years. Overall, there has been a move from high-priced prestige wines to lower-priced wines for informal consumption. Even with all the news about online shopping in China, just over 29% is purchased through these channels. The chapter also provides

information on the key countries selling wine to China, Chinese consumers' awareness of different countries of origin, and recommendations for growing wine sales and doing market research in China.

Introduction

In only 50 years, China has grown from a minor market for grape-based wine into the second largest market in the world. However, China has always been an alcohol-consuming country, but preferences have moved considerably in the last 10 years or so. This chapter will detail the current trends in wine consumption in mainland China in the latter part of 2019. In order to be clear and understood by various readers from different countries, we would like to set a few definitions and boundaries before we begin.

First, this chapter focuses almost entirely on grape-based wine. The character and word for wine in Chinese covers products made from rice, other grains, and from grapes. We will use the word wine to refer to an alcoholic beverage made from grapes. When speaking of other alcoholic beverages, such as when giving statistics for types of alcohol consumed, we will use adjectives such as rice wine or grape wine to make sure readers understand what we are referring to. The other clarification we want to make is that we are focusing on mainland China only.

This chapter will discuss the current trends in wine consumption in China. The first part of the chapter looks very briefly at the history of grape and wine production in China in order to dispel the myth that wine drinking is new in China. We then focus on more recent trends in alcohol consumption. This includes wine and provides recent estimates of wine production and wine consumption, to give more context to the current state of affairs. The next section of the chapter looks at the development of Western-style wine and food consumption as China opened its doors to both travel and major wine imports in the 1990s and into the twenty-first century. The following part looks at the role of government policy in the evolution of alcohol consumption from mainly beer and spirits (products over 20% alcohol by volume) and how these changes affected the growth of lower-priced table wines. The growth of wines below luxury level led to changes in the demographics of wine drinkers and to the development of new channels to buy and consume wine.

The main part will focus directly on current trends. Much of the data for this section comes from our own research in China mainly on behalf of the Australian wine industry. Thus, we will provide overall trends without providing much detail due to confidentiality agreements with the research funding organizations. We will also cover the rise of social media and online wine purchasing, noting, however, that our research shows still just over 29% of wine is purchased through online channels. We will describe the retail structure currently in place in China and how both brick and mortar and online selling have accompanied the movement from formal consumption occasions to much more informal consumption. We conclude the chapter with a summary and a few predictions for the future.

Brief History of Wine Production in China

There is evidence of grape and wine production in ancient China as far back as 9,000–7,000 years ago (Zhang and Pan 2002); however, these were native Vitis species and not the *Vitis vinifera* species that are now grown worldwide and the origin of the vast majority of the world's table wines. The first written mention of wine production in China is from the end of the Xia Dynasty about 1600 BC, where wine was made from fermented grain mash, which probably also contained grapes (Li et al. 2018). The first vinifera wine came after the opening of the Silk Road during the Han Dynasty about 135 BC and Marco Polo reported seeing vast vineyards around 1275 (Li et al. 2018). Some of this was made into wine; however, much of these grapes were grown for table use and not for wine (OIV 2017).

The first major commercial winery, Changyu Winery, was established in 1892 with the importation of 120 *Vitis vinifera* grape varieties. French Catholics and Japanese investors set up wineries through the 1920s and 1930s (Li et al. 2018) believing there would be growth and development of westernized wine consumption. But it was Chairman Mao who instructed China to put more effort into the wine industry to reduce the consumption of Baijiu (rice spirits) in 1956 that started the modern move to planting more vineyards and building more wineries (Su 2003). This led to foreign firms, such as Pernod Ricard, establishing grape growing and wine making as commercial operations, in this case Dragon Seal Winery (Li et al. 2018).

Current Wine Production and Alcohol Consumption

China is ranked in the top 10 of wine producing countries in the world (Table 1). This may seem surprising, but Mao's push to replace some of the spirits consumption with wine consumption began to take hold with major wine companies being established in the 1960s (Li et al. 2018). Then French and later Australian companies began to plant grapes and make wine in China, mainly in partnership with local government or private investors in the 1980s. China's production in 1996 was 9.5 million hectolitres, so it has increased about 10% in the 20 years recorded in the table. Domestic production is not increasing quickly due to a number of reasons not relevant to this chapter. There was a peak of about 13.5 million hectolitres in 2012, but production has fallen back to around 11.5 million since then, as it has in most wine producing countries. However, production in China fell to only ten million hectolitres in 2018 (IBIS World 2019). There was a lot of optimism and planting of wine grapes in the 1990s as Chinese wine consumption began to increase and more countries were beginning to consume wine, but there has not been a huge amount of planting recently. There are some premium vineyards being planted in some regions, such as Ningxia and in the northwest, but overall growth in planting has slowed.

The Chinese have always been consumers of alcohol, and as Table 2 shows, the largest categories by volume are spirits and beer. In value, beer and wine are about

Table 1 World Wine Production 1996 and 2016 in millions of hectolitres (Source OIV 2017)

Country	1996	2016

RTD's/High strength Premix	1,724	2,691	6,077	7,073	4,534	3,910
Cider/Perry	1.1	1.2	1.4	1.6	1.9	2.3
Alcohol drinks	**1,725,419**	**1,676,462**	**1,630,274**	**1,728,392**	**1,871,960**	**2,057,085**

equal, while spirits account for more than double the value of either of these (Table 3). Although the annual value of each beverage category varies, beer and wine have mostly been increasing while spirits have just returned to slightly above their 2012 value. Wine also has the highest value per liter of the alcoholic beverages.

Another way to look at the alcohol market in China is to look at penetration – the number or percent of unique consumers buying from each subcategory during a year. Previous research by the Ehrenberg-Bass Institute for Marketing Science has shown that most category buyers buy multiple brands (Sharp 2010), and for alcohol, multiple types of alcoholic drinks (Cohen et al. 2018). The data presented here and throughout this chapter were collected using online professional panel providers in cities across China as noted. Thus, only urban dwelling Chinese Internet users

Table 4 Penetration in percent of alcohol types in China by gender (Cohen et al. 2018; Driesener et al. 2018)

Alcohol type	Overall	Male	Female
Local beer	50	60	40
Local wine	**40**	**44**	**37**
Imported beer	30	36	24
Imported wine	**29**	**30**	**28**
Local spirits	28	41	15
Wine cooler	13	13	14
Imported spirits	12	13	11
Champagne	11	10	13
Alcoholic cider	10	9	10
Sparkling wine	9	9	10
Craft beer	9	9	8
RTDs (mixers)	6	6	6
Repertoire	**2.5**	**2.8**	**2.2**

were sampled, and no rural Chinese were included in the surveys. Table 4 shows beer is consumed at least once per year by 50% of urban Internet-using alcohol drinkers in China, with Chinese wine consumed at least once annually by 40% and imported wine by 29% of these alcohol drinkers. The average repertoire, or the number of different alcoholic subcategories consumed at least once in a year, is 2.5. Consumers do have favorite types of alcohol, but few would drink only one type in a year. Most consumers will drink two-three types.

Males and females differ in their preferences, although local wine and imported wine are consumed by a similar percentage of drinkers. Local spirits, mainly baijiu, is much more preferred by men than women.

Table 5 shows the breakdown of penetration for different alcohol types by age. We can see that younger consumers have a smaller repertoire than older ones and mainly consume beer plus one other beverage at least once per year. The alcoholic drinks repertoire, or number of different types of beverages consumed at least once per year, is calculated simply as the average of different subcategories consumed across all respondents. So, the average alcohol-drinking Chinese respondent under 25 years old drinks at least once annually from about two different subcategories, while those over 35 drink from about 2.7 different subcategories. The consumption of all alcohol types increases as consumers age, with the older consumers having larger repertoires than younger ones. More older consumers drink wine compared to other alcoholic beverages. We will go into more detail about current consumption trends for wine in the second part of this chapter.

These tables highlight that urban Chinese drink many different types of alcohol and, we will see in the later section that wine drinkers drink other types of alcohol as well. This is important to understand because there are very few "wine only drinkers" but mainly alcohol consumers who prefer wine but still drink other alcoholic beverages, as well as other beverage drinkers who drink wine once in a

Table 5 Penetration in percent of alcohol types in China by age (Driesener et al. 2018)

Alcohol type	<25	26–35	36–45	46–55	56+
Local beer	51	46	46	63	56
Local wine	**28**	**38**	**39**	**49**	**67**
Imported beer	21	27	35	37	36
Imported wine	**22**	**22**	**33**	**30**	**44**
Local spirits	22	26	25	43	33
Wine cooler	14	16	14	7	5
Imported spirits	11	11	15	12	14
Champagne	7	13	14	11	6
Alcoholic cider	7	11	13	6	5
Sparkling wine	8	11	11	8	3
Craft beer	7	9	12	6	3
RTDs (mixers)	5	6	10	5	3
Repertoire	**2.0**	**2.4**	**2.7**	**2.8**	**2.7**

while. Previous unpublished research from the University of South Australia showed Australian alcohol drinkers had favorite subcategories (such as wine), but over 80% drank other alcoholic beverages well, so this repertoire behavior is not unique to China.

Development of Western Grape Wine Culture in China

It is useful to have a brief description of the development of grape wine drinking in China in order to understand the current situation in context. As noted above, before the 1980s China mainly drank grain-based alcoholic drinks, mostly high alcoholic content baijiu and lower alcoholic content beer and moutai (distilled sorghum beverage). In 1987, the National Winemaking Conference proposed the Four Changes strategy to the alcoholic beverage industry. This was to change from high-strength alcoholic beverages to ones of lower strength and to move from distilled products to fermented grape wine instead of fermented grain wine (Zeng and Szolnoki 2017). Part of the reason was to reduce total alcohol consumption for health reasons, and part was to allow more grain to be used for food rather than drink.

Along with the political push to grape-based wine, China was also becoming wealthier as incomes grew and private consumption and gift giving were becoming the norm among the educated Chinese (Yang and Paladino 2015). Western wine, especially Bordeaux and Burgundy, were seen as hallmarks of sophistication and became prestigious gifts as well as regular accompaniments to corporate and government banquets. It was mainly the wealthier industrialists and communist party elite, who exhibited this behavior (Zeng and Szolnoki 2017). Contrary to popular myth there is not much evidence for expensive wines being mixed with soft drinks or lemonade to make it more palatable (Hunt 2014). However, in 2012, the then new president, Mr. Xi Jinping, made anticorruption and modest living part of his political platform. This action helped reduce the demand for high-priced luxury wines and increased the consumption of medium-priced wines for everyday consumption along with some special occasion consumption.

As more Chinese entered the middle class and more studied overseas, there was increasing demand for medium-priced imported wines along with imported beer (Zeng and Szolnoki 2017). By 2016, China began signing free trade agreements with wine producing countries: Chile, New Zealand, and Australia, which added to the availability and relatively low price of wines from these countries. At the same time, the advent and quick uptake of e-commerce in China also contributed to wine being more widely known and more widely accessible (Kuo et al. 2015). The current trends in wine consumption stem from this evolution, away from high-priced luxury wine seen as a status symbol and a very high-end gift. This included a focus on the most expensive wines typically among top political officials and wealthy businessmen, mainly consumed at official banquets or in expensive Western restaurants to a more informal alcoholic drink consumed more at home than in restaurants. The rest of this chapter details the current state of consumption: who is consuming, where they are buying and consuming, and motivations for drinking wine compared to other alcoholic beverages. As with most things in China, these developments carry a unique Chinese focus and do not mimic the development of wine drinking in Western countries, although some of the outcomes are similar. For example, in many Western countries, like the USA, UK, and Australia, about 80% of wine is consumed at home or at someone's home and only 20% consumed at bars and restaurants. China has moved from mainly restaurant consumption to a more Western-like pattern, but still has a greater percentage of wine consumed at bars and restaurants compared to Western countries.

Background to Consumer Research in China

The next part of the chapter is an amalgamation of research conducted by a team of researchers at the Ehrenberg-Bass Institute for Marketing Science from 2013 to 2019 funded by Wine Australia and other government wine bodies to understand the China wine market. Some key trade publications, which summarize the research findings, are listed in the references. We have integrated the findings into the rest of this chapter.

More recently, a research program has been initiated in order to create demand for Australian wine in China generously supported by Wine Australia. Until this research, there has been a lack of insight in terms of understanding the wine market in the broader context of alcohol consumption in general. There has not been any rigorous research conducted that identifies why current or potential buyers of wine enter the wine category in China. This is paramount knowledge to generate so that strategies can be developed to grow the number of wine buyers in China.

Current Trends in the China Wine Market

A survey was conducted in July of 2019 of 2871 Chinese people aged 18–65 who earn a minimum of 4,000RMB per month. In addition, they had to have purchased alcohol in the last 6 months. Purposeful sampling was utilized to reach different buying groups: approximately 60% imported wine buyers (the majority of these buyers also purchased Chinese wine), 25% Chinese wine buyers only (don't buy imported wine but do buy other alcohols in general), and 15% alcohol buyers who are non-wine buyers (imported or Chinese). Previous research by the same research group and by private consulting companies, such as Wine Intelligence (Hao and Halstead 2016), focused on imported wine drinkers only and therefore was not able to look at trends for domestic wine consumption or consumption of alcoholic beverages, which could lead to future wine consumption.

Data was collected in 15 Chinese cities representing a range of tier 1 and tier 2 cities. Tier 1 is defined as the largest and wealthiest cities: Beijing, Shanghai, Guangzhou, and Shenzhen, while Tier 2 is the next largest, such as Chengdu, Chongqing, and Wuhan (Wong 2019). The cities were selected for two reasons:

1. To achieve a geographic spread as there are many hypotheses made by industry pundits that China cannot be treated as one country and must be treated as individual city-states due to there being cultural differences across the country,
2. To generate insights that were of current value to wine brands and government wine bodies who are working to build the wine category in China, and these cities were nominated by stakeholders as being where resources are currently being directed.

Figure 1 below contains a map that shows the cities investigated.

As a starting point, it is useful to understand the buyer behavior for wine in the broader context of the alcohol category. Table 6 below shows self-reported market share of alcohol subcategories amongst alcohol category buyers over a 6-month period in 2019. These and the following tables are based on retrospective recall of the last alcohol purchase and/or consumption occasion.

Taking into consideration the sample for this research, there are several noteworthy patterns. Chinese beer is dominant. This accounts for 30% of alcohol buying even with the data skewed towards 85% of the buyers having had to purchase wine, as the research focus was on the wine category. Chinese and imported wine has an equal share of 15% each. This is interesting, as anecdotal reporting from actors in the wine industry as recently as 2016 stated that they believed 4 out of 5 bottles of wine sold in China were Chinese wine. The results from 2019, taking into consideration the sampling, indicate that the share of imported wine is increasing.

There is a prevalent assumption that alcohol consumption differs widely across China. Looking at the share of imported wine buying across the 15 cities shows only a few differences worth reporting. Market share for imported wine is elevated compared to the average of 15% in Chengdu, Fuzhou, Changsha, Wuxi, and Wenzhou; however, the difference is only 3–9% more. It is likely that imported

Fig. 1 Cities investigated in the Chinese Mainland

Table 6 Self-reported market share of alcohol subcategories in China (July, 2019)

Chinese beer	29
Chinese wine	15
Imported wine	15
Imported beer	10
Chinese spirits	8
Champagne	4
Alcoholic cider	4
Craft beer	4
Imported spirits	4
Wine cooler	3
Sparkling wine	2
RTDs	2

wine performs better in Chengdu due to the digital wine platform 1919, a new specialty chain of wine stores, being based in Chengdu. The other cities are much smaller but still have populations over a million and Chinese wine brands are likely to have the same route to market issues that imported wine brands have. In addition, the data collected used online surveys and it is possible that panelists in the smaller cities have a stronger connection with Western culture because the pool of available respondents is smaller than in major cities where being part of survey panels is more common.

Imported beer has a 10% market share and Chinese spirits (i.e., distilled rice wine) only has an 8% share. The small share of rice wine is interesting to note on the back of industry reporting of the leading rice wine brand, Kweichow Moutai, being the most valuable liquor company in the world since 2017 and now being valued at over 200 billion USD in 2019 (Financial Times, 2019). This may be due to the consumers of Kweichow Moutai being older and more traditional and, therefore not represented adequately in the online panels used for data collection (Hancock 2019). There are a number of other small but growing subcategories of alcohol that are currently more prevalent in the Western World. These should not be ignored but for the moment the data indicate that purchase is mainly by young consumers, which suggests a trend in the future where alcohol buyers will have larger repertoires. Larger repertoires for older cohorts were already reported in Table 5.

These data provide context to the wine category in China. They show the Chinese wine and imported wine subcategories together account for roughly the same size of the market as Chinese beer.

Most of the investment in market development is by a few leading wine brands and by major wine exporting countries. It is useful to explore wine purchase by country of origin as the majority of investments in market development at the moment for small- and medium-sized brands come under the umbrella of government actions. Table 7 below reports on the market share of wine by country of origin in China amongst alcohol category buyers over a 6-month period in 2019.

Based on respondent self-reports, just under 25% of all wines purchased in the sample are French. China follows with about 20% market share. Italy, Australia, Spain, the United States, New Zealand, and Chile all have comparable market shares

Table 7 Self-reported market share of wine by country of origin in China (July, 2019)

Country of origin	Market share (%)
France	24
China	20
Italy	9
Australia	8
Portugal[a]	8
Spain	7
USA	6
New Zealand	6
Chile	5
Argentina	3
South Africa	3

[a]Note: Portugal consistently generates overclaimed data across studies executed in China using retrospective recall. This is likely due to the fact that the word for grape and the base of the word for Portugal in Chinese are the same

of 5–9%. Argentina and South Africa are the worst performers in the market with shares of 3% each.

There are mainly small share differences across the 15 cities when looking at buying by country of origin. There is more variability in shares across cities for French and Chinese wines. There is less variation in shares between cities for Italian or Australian wine. With countries like the United States, New Zealand and Chile there are 1 or 2 cities out of the 15 studied where market share is higher than the average. The deviations are mostly in the emerging cities which are gathering interest with the wine industry like Xian, Kunming, Xiamen, Wuxi, and Wenzhou. These differences are driven by distribution and market development activities. Certain countries are more active in particular Chinese submarkets as there is a tendency due to the influence of marketing by government wine bodies for group activities to consolidate human capital and funding for brand development.

France and China both have dominant positions in the wine market in China because they both have dramatically higher mental and physical availability amongst Chinese alcohol buyers. According to Sharp (2010), mental availability makes a brand easy to think of in a buying situation and physical availability makes the brand easy to buy. In the context of China, we explore this from a country of origin perspective. Figure 2 below shows the mental availability of wine by country of origin in China.

We use a construct called category entry points to measure mental market share as provided in Fig. 2. Category entry points are what comes to buyers' minds when they decide to enter a category or what generates the intent to buy from that category. Table 8 below shows a list of relevant category points obtained by conducting a text analysis of vignettes recorded from 300 wine buyers related to their wine consumption and purchase situations (Cohen et al. 2019). Mental market share is calculated based on the proportion of associations to category entry points that alcohol buyers

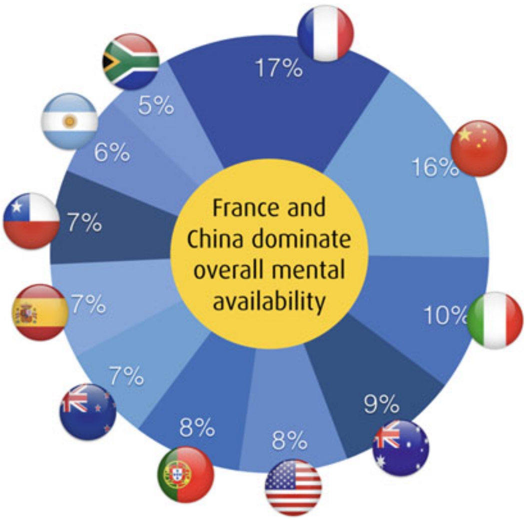

Fig. 2 Mental availability of wine by country of origin in China

Table 8 Category entry points for wine in China

Suitable for a business occasion	When I want to reward myself	Provides beauty benefits	Suitable for Western food
When I want to celebrate	When I want to try something different	Provides health benefits	When drinking/ socializing with foreigners
Suitable for gatherings with friends or family	At meal times	Helps me sleep better	Suitable for women
Suitable for a romantic occasion	Suitable for holidays and festivals	When I want something tasty or delicious	Suitable for men
When I need a gift for someone	When I am at entertainment places	When I want to express/project a high-class image	When I am drinking alone
Suitable for a formal occasion	When I am at friend's place	I want to ensure the wine I choose will not make me discourteous or lose face	When I need to host someone
When I want to improve my mood	When I am at home	When I want to create an atmosphere	When I want something cheap
When I am relaxing	When I am at a restaurant	Suitable for Chinese food	When I want to please others

have for each country of origin out of the total for the wine category. This is a useful way of understanding mental competition. To increase mental availability, brands need to increase their associations to relevant category entry points. The more category entry points related to a specific country, the higher the mental market share.

The above research focused on the occasions that bring Chinese people into the wine category and specifically result in them making a purchase. Purchase is a precursor to consumption. However, it is also useful to discuss the dynamics of consumption occasions. When exploring at home consumption, informal occasions are the majority (55%) followed by inviting guests (32%) and finally by special occasions (14%) (Corsi et al. 2017a). Table 9 below shows the frequency of occasions for at home consumption collected from imported wine buyers (Cohen et al. 2014).

Table 9 shows that roughly half the population of imported wine drinkers investigated in this research were consuming wine at home for a relaxing or informal occasion at least once per week. On the other hand, only 13% of wine consumers host people and only 8% of wine consumers celebrate special occasions at home once a week or more. This is a powerful insight and demonstrates the evolution of wine consumption in China. Wine is not simply a product to consume at special occasions or business functions. There is clearly a trend of regular consumption of wine. This means that marketing must focus on connecting wine brands and country of origin with the more relevant and frequently occurring consumption occasions which will result in increasing penetration and ultimately market share.

The other pillar that affects the purchase metrics reported in the tables above is the physical availability of each country of origin. This relates to the distribution of wine. There is limited industry understanding of the overall availability of wine across sales channels due to the lack of distribution metrics like numeric or weighted distribution that can be purchased from data providers like Nielsen or IRI for other markets. However, retail audits conducted across different cities in China by the authors indicate that brick and mortar retail shelf space is heavily occupied by Chinese and French wine brands. In order to increase physical availability, brands need to make sure their wines are available for purchase in relevant sales channels. Table 10 below reports the market share of sales channels for wine buying over a 6-month period in 2019 based on the self-reported last purchase of 2440 wine buyers across 15 cities.

Table 9 Frequency of consumption by occasion (%) for imported wine drinkers

Consumption Occasion	2–5 times per year (%)	About once every 2 months (%)	1–3 times per month (%)	Once a week or more often (%)
A relaxing drink at home	7	11	28	52
When inviting guest's home for dinner	12	23	48	13
With an informal meal at home	7	13	38	46
Celebrating special occasions at home	35	29	22	8

Table 10: Self-reported market share of wine buying across channels in China (July 2019)

Sales channel	Market share (%)
Wine/alcohol retailer	15

Luxury supermarket	8
Alcohol ecommerce	7
Hypermarket	7
JD.com	6
Tmall	6
General ecommerce	5
Western restaurant	5
Warehouse stores	5
Supermarket	4
Chinese restaurant	4
TaoBao	4
Bar	4
Convenience	3
KTV	2
Traditional small retail	1
Weidian (WeChat)	1

The largest channel for wine purchase in China is specialty alcohol and wine stores, followed by purchasing direct from distributors. These distributor sales are fairly unique to China but have come to play a large role because of the relative security of the origin of the wines and their links with many business people, who buy wine as gifts and for their companies. About 43% of all wine purchased in China is coming out of physical retail: specialty wine and alcohol retailers, luxury supermarkets, hypermarkets, warehouse stores (e.g., Costco), supermarkets, convenience stores, and traditional small retail stores. Ecommerce or online channels account for 29% and on-premise outlets, such as restaurants, bars, and KTV (karaoke bars), add 15%.

What is most surprising is that on-premise consumption of wine is now a smaller percentage of purchasing compared to purchasing for consumption elsewhere – at home, friend's homes, or other private venues. This makes Chinese wine consumption much more similar to where wine is consumed in many Western countries. A major difference between China and most other countries is the relatively large percentage purchased online – almost 30%. We think this is mainly due to the much more developed online ecosystems in China and the crowded nature of the country where driving to shop is difficult and apartments are too small to store much.

Just over one-third of all purchases come from specialty alcohol/wine stores, distributors, and luxury supermarkets. If we add hypermarkets, we have 40%+ of all wine sales. Our interpretation of these figures is that channels which have wine focus as well as a focus on mid- to high-end quality are preferred. Distributors sell the wines these wholesalers represent, which come direct from the producer. Luxury supermarkets and hypermarkets are large chains owned and managed by major retailers, and again focus on high quality and assured sources. Anecdotally, Chinese buyers have spoken about their worry about the authenticity of wines purchased from local stores and restaurants.

Western and Chinese restaurants have a market share of 9%. This is surprising mainly because 10 years ago, the majority of wine seemed to be sold in Western-style restaurants or given as gifts. Convenience stores have a 3% share. Even with a small share there are thousands of convenience stores across major cities in China. This is an underutilized channel by most wine brands. This is also a channel where small format bottles are more common. KTV has a 2% share. This is a really complex channel to navigate for a foreign wine brand. KTV is a karaoke-based entertainment venue that is significant for males to frequent. There is little understanding of how to do business in this channel for foreign producers.

Online and digital channels play a large and seemingly growing role in the sales of wine in China. Aggregating all the digital channels together results in a 29% market share. This is obviously a valuable percentage of total wine sales, but far less than industry pundits claim. This has resulted in an alarming lack of investment in building traditional sales channels. Tmall, part of Alibaba and composed mainly of brand specific sites and leading platform JD.com each have 6% share with specialist alcohol eCommerce sites (where there is huge fragmentation) have 5%. TaoBao only has a 4% market share. This is represented more by individual sellers as opposed to brands. Many imported brands have trouble navigating the complex online environment, since there are so many options: own branded store within one of the big online channels, sold through a distributor's store online, sold through a retailer's store online, or sold by individual shops within a larger website. One sales channel which receives a lot of attention abroad but has a market share of less than 1% is Weidian. Weidian is the shopping component of WeChat where brands can have official sites that have eCommerce built in. WeChat is a very popular platform for communication and payment systems, but it has yet to effectively conquer eCommerce despite what the media would have one believe.

Predictions for the Future

Despite the rapid evolution of China both economically and culturally, it is unlikely that there will be rapid changes in the wine market for the foreseeable future despite China being a global leader in both social media and eCommerce. China is different to the rest of the world due to the great fire wall which results in major digital platforms such as Google, Twitter, and Facebook being blocked. This has given rise to comparable platforms such as Baidu, Weibo, and WeChat. Cohen and Lockshin (2018) discuss some opportunities for small brands with limited budgets to optimize their usage of social media channels such as these to reach consumers. There are also more advanced formats of blogging in China, such as vBloggers (video bloggers) who have enormous audiences. Technology creates opportunities; however, these social media channels still tend to reach current wine drinkers, who subscribe or are linked to wine relevant media. New tactics are required to reach potential and light/infrequent buyers rather than the heavy/frequent buyers already reached. Tables 4 and 5, which report on penetration of alcohol subcategories, justify the importance of thinking more broadly about alcohol overall rather than exclusively about imported wine.

It is not easy for a potential consumer to think about or locate a specific imported wine in a sales channel, whether they are looking for a country of origin or a particular brand. Because of this, the likelihood of being bought is diminished. This is reflected in the claimed purchase data reported in Table 7 and the mental availability data reported in Fig. 2. In order to increase sales, strategies that help build mental and physical availability are required. It costs money to build mental and physical availability. Collaboration between brands, government bodies, and distributors are essential. So, efforts to build mental availability must align with distribution efforts.

Future Research on Wine in China

China is a fascinating market. The more insights researchers uncover, the more it becomes apparent just how much is not actually known. Cohen and Lockshin (2017) provide the most comprehensive review to date on how to conduct research with impact in the China wine market. Good sampling of the population is an impediment to extending knowledge on the China wine market. Researchers must design their surveys to reach users of all alcohol categories, not just wine.

There is a tendency for research on wine in China to focus on the very affluent, highly educated, and worldly (i.e., have lived and studied overseas) and those with a passion for wine, which leads to surveying only those with heavy consumption and high involvement. While researchers can and should understand the behavior and preferences of this cohort of consumers, these types of consumers don't represent where growth in the wine category in China will come from. Acquisition of new customers is paramount. This means that research using current wine consumers in the major markets in China should be expanded to consider a competitive set of consumers of other alcohol subcategories. There are over 150 cities in China with populations over 1 million people. While the research in the 15 cities we report here does not show any major differences, we should not blindly assume that this is or always will be the case. As noted above, sampling is restricted to cities where panel providers can locate consumers, so the rural population has not been part of any market research the authors are aware of. Using online samples in small cities is risky until the size of the sampling pools increases. This will happen and when it does more research should be conducted to see if the patterns of wine buying behavior can be extended across China. In addition, there is a need for research to be conducted in rural areas to understand the role wine plays in alcohol consumption. At the moment, this is not of interest to imported wine brands, but the Chinese wine industry should be able to make inroads selling in rural areas and hence research is necessary to support their domestic industry.

Conclusion

This chapter discussed consumption trends for grape-based wine in China, which was current at the time of writing. It noted that the Chinese have always been alcohol consumers but have begun to grow and import wine over the last 25 years or so. The government encouraged its citizens to switch from high alcohol spirits to wine and at the same time, growing wealth and a consumer focus on the West resulted in such a rapid increase in wine consumption that China is one of the largest imported wine markets in the world. Wine has moved from a specialty drink to one consumed at home and in restaurants and bars, but still trails local beer and spirits as the alcoholic drink of choice for most consumers. Wine is widely available across brick and mortar and online retail outlets; however, knowledge of specific countries of origin and brands is still fairly low, and research has been conducted mainly with existing wine drinkers in major cities, so little is known about the potential for consumption growth in smaller cities and rural areas. It is predicted that major changes have already occurred and the next few years will bring slower growth in the consumption of grape-based wine in mainland China.

Abstract

The Jewish kosher dietary laws and the Muslim halal dietary laws are an integral part of each religion as part of their larger legal frameworks. However, as food and drink are so central to people's daily life, these laws often taken on a greater significance. Therefore, it is useful to understand these laws and how they function to meet the daily needs of their adherents. The kosher (kashrus) dietary laws determine which foods are "fit or proper" for consumption by Jewish consumers who observe these laws. The halal dietary laws determine which foods are "lawful" or permitted for Muslims. For both religions, the food laws are a small part of a comprehensive system of religious laws that cover many aspects of daily life. However, these laws establish a framework, but how an individual Jew or Muslim will live their life is a personal matter often influenced by the standards of the local community and often not necessarily following all of the laws. And the laws themselves will vary as there is no central body currently in a position to harmonize these laws. Although these variations in practice may at times be frustrating for those making products to serve these markets, it is also a great strength internally to be able to respect differences within the group and to learn to celebrate this diversity.

Introduction

The Jewish kosher dietary laws and the Muslim halal dietary laws are an integral part of each religion as part of their larger legal frameworks. However, as food and drink are so central to people's daily life, these laws often taken on a greater significance both for adherents and for the larger society. Therefore, it is useful to understand these laws and see how they function in the broader society and also helpful to understand some of the dietary preferences/cultures that help these systems meet the daily needs of their adherents. (For a more detailed discussion of these laws, please see Regenstein et al. (2003).)

The Religious Significance of These Laws

Before looking into the laws in some detail and how they affect the foods eaten by Jews and Muslims, it is worth considering the religious significance of these dietary laws for Jews and Muslims, in the broader context of these two Abrahamic faiths. The kosher (kashrus) dietary laws determine which foods are "fit or proper" for consumption by Jewish consumers who observe these laws. The halal dietary laws determine which foods are "lawful" or permitted for Muslims. For both religions, the food laws are a small part of a comprehensive system of religious laws that cover many aspects of daily life. Thus, almost no question about how to lead one's life is beyond the scope of these religions legal systems. This is probably the biggest distinction between the Jewish and Muslim religion in comparison to the third Abrahamic faith of Christianity broadly defined. However, these laws establish a framework, but how an individual Jew or Muslim will live their life is a personal matter often influenced by the standards of the local community and often not necessarily following all of the laws. And the laws themselves will vary as there is no central body currently in a position to harmonize these laws, and their probably is no real noncommercial driving force for such harmonization. Although these variations in practice may at times be frustrating for those making products to serve these markets, it is also a great strength internally to be able to respect differences within the group and to learn to celebrate this diversity.

Why do Jews and Muslims follow dietary laws? The explanation by Rabbi I. Grunfeld provides an explanation that really speaks on behalf of both religions although it is clearly of Jewish origin (Grunfeld 1972) but similar thoughts can be found in Muslim documents. (It is also a very traditional document and framed in the male voice.)

> And ye shall be men of a holy calling unto Me, and ye shall not eat any meat that is torn in the field (Exodus XXII:30).
>
> Holiness or self-sanctification is a moral term; it is identical with. . .moral freedom or moral autonomy. Its aim is the complete self-mastery of man.
>
> To the superficial observer it seems that men who do not obey the law are freer than law-abiding men, because they can follow their own inclinations. In reality, however, such men are subject to the most cruel bondage; they are slaves of their own instincts, impulses and desires. The first step towards emancipation from the tyranny of animal inclinations in man is, therefore, a voluntary submission to the moral law. The constraint of law is the beginning of human freedom.
>
> The three strongest natural instincts in man are the impulses of food, sex, and acquisition. Judaism does not aim at the destruction of these impulses, but at their control and indeed their sanctification. It is the law which spiritualizes these instincts and transfigures them into legitimate joys of life.

The Kosher and Halal Markets

Both kosher and halal are important specialty markets in many countries. This section will focus on the USA with a mention of other markets. Briefly, the deliberate consumers of kosher food, i.e., those people who specifically look for the kosher mark, are estimated to be over 12 million Americans (of which 2/3 are not Jewish), and they are purchasing almost 15 billion dollars of kosher products (Lubicom 2012). Other users include consumers who may find kosher products helpful in meeting their own dietary needs such as Muslims; Seventh-Day Adventists; vegetarians; vegans; people with various types of allergies – particularly to dairy, grains, and legumes – and general consumers who for one reason or another prefer kosher products. By undertaking kosher certification, companies incrementally expand their market, i.e., increased incremental sales. In the USA, this means that about 40% of packaged goods in a typical supermarket in the northeastern USA are kosher. Thus, most US consumers will have kosher products in their home, even though they do not realize that they do. In Europe more and more products are taking on kosher markings although the numbers are much smaller than in the USA. Traditionally, Europe has used a different system. The local rabbi inspects the plant and then tells the community which products are acceptable. Unlike the system using markings, there is no fee for service with this arrangement. But that also means there is no legal commitment from the plant to let the rabbi know when they are making changes.

On a global scale, the halal market is a significant component of trade in foods. The number of Muslims is estimated to be between 1.3 and 1.8 billion people (i.e., 20 to 25% of the world's population!), and inter-country trade in halal products continues to grow. In many countries halal certifications acceptable to the national government have become necessary for products to be allowed to be imported. Thus, the religious needs have become part of the secular environment of everyone within these countries. In the USA, this market is now emerging and slowly increasing the number of domestic products. In Europe, because of immigration, the halal market is expanding rapidly, but hard numbers are difficult to obtain. But simply the number of Muslims in many of these countries assures that there is a viable market for halal products.

The products covered by these markings may be traditional foods that have no relationship to kosher or halal, but, on the other hand, some companies and some products are directly associated with the culture and food preferences of each of these communities. One of the challenges for adherents in Western countries is the tension between traditional religious and cultural food habits and the desire of the younger generation to go more mainstream. Thus, products in both categories, i.e., traditional and "secular," are needed that are also religiously acceptable.

The Kosher Dietary Laws with References to the Halal Dietary Laws

The Jewish dietary laws predominantly deal with three issues, all focused on the animal kingdom with a fourth set of laws dealing with the holiday of Passover that are added to the regular laws but focus more on the plant kingdom.

There are also many additional laws dealing with special issues such as grape juice, wine, and alcohol derived from grape products; Jewish supervision of milk; Jewish cooking, cheese making, and baking; equipment kosherization; purchasing new equipment from non-Jews; and old and new flour.

The Muslim dietary laws cover much of the same territory as the first two kosher issues but not the last two, and they bring in issues such as alcohol and live animal feed. On the other hand, their dietary laws remain constant throughout the year.

Allowed Animals

Ruminants with split hoofs that chew their cud (ruminants), the traditional domestic birds (e.g., chicken, turkey, duck, and geese), and fish with fins and removable scales (i.e., visible and they do not tear the skin; cycloid and ctenoid scales are permitted, while ganoid and placoid scales are not permitted; all fish with scales have fins) are generally permitted. The most controversial fish is the swordfish (Govoni et al. 2004).

Pigs (which have often become the symbol of both kosher and halal observance) and camels (a ruminant without a complete split hoof) are not permitted although the latter is halal. The rabbit among commercial food animals is also permitted in halal as are other generally "vegetarian" animals. The list of allowed animals is definitely greater for halal than kosher.

Among commercially available birds, the ostrich family is prohibited for kosher but is accepted as halal. Determining which birds are kosher and halal is a bit more complicated because the original scriptures (i.e., Hebrew Scriptures and Quran) are not as specific.

Animals that spend their entire life in the water are permitted according to the Quran. However, subsequent writings by Muslim scholars in the various sects and schools of Islam have led to a great deal of divergence with respect to the acceptability of marine life. A few fish are controversial in the kosher community because of the question as to whether their scales meet the Jewish requirements. The biological definition of scales is broader than the Jewish definition!

Most insects are not kosher. A few types of grasshoppers/locust are kosher and halal. Modern IPM (integrated pest management) programs that increase the level of insect infestation in fruits and vegetables can cause problems for the kosher consumer, who must inspect produce suspected of having insects and then remove any insects found. The red pigments carmine and cochineal are not permitted by most rabbinical supervisors, although a few do permit it because it comes from the inedible shell. The Muslim community also debates this topic although many of the Muslim schools of thought again prohibit most insects other than locust. However, bee's honey and shellac (lac resin), an insect exudate are permitted by most kosher and halal authorities. As the food industry moves to more and more use of insects, each of the communities will need to address some key issues. For both, the question of what may be eaten will need to be addressed. It is unlikely that the Orthodox Jewish community will accept any insect products since for most Jews the tradition of eating insects has been lost. However, their use in animal feed will probably not be a problem. For Muslims, on the other hand, the use of insects that might be considered filth (i.e., najis) may present difficulties.

Obviously any ingredients coming from a prohibited animal or an animal not properly slaughtered religiously (see below) also present problems. As a practical matter, many ingredients that can come from both animal and plant sources are cheaper coming from an animal, so proper supervision of food companies is needed.

Prohibition of Blood

Ruminants and fowl must be slaughtered according to Jewish law by a specially trained religious slaughterman (shochet) using a special knife designed for the purpose (chalef). Before starting to slaughter animals, the shochet does say a prayer.

The knife must be razor sharp and totally free of nicks. It must have a very straight blade that is at least twice the diameter of the neck of the animal to be slaughtered. This knife is checked after each slaughter. The cut is done horizontally across the neck in a specifically designated region. Both carotid arteries and both jugular veins along with the windpipe and esophagus are cut. When done right on calm animals, this leads to strong bleeding which leads to rapid unconsciousness of the animal in a calm fashion. A key animal welfare aspect of this process is the absence of nicks, which if present would activate the pain receptors in the skin region of the cut.

The Muslim community uses a similar slaughter along with a blessing over each animal or bird. They highlight sharpening the knife properly but not sharpening the knife in front of the animal, not allowing another animal see the slaughter, and having the animal facing Mecca. However, the emphasis on avoiding nicks is not part of their training. The design of the knife is also not specified although work by Dr. Temple Grandin at Colorado State University (personal communication) has suggested that the long straight blade has definite advantages, and both she and her disciples are recommended such a knife for halal slaughter of animals. Recently an instrument to measure the sharpness of knives and to show that the knife is nick free has been developed by the Anago Company in New Zealand (anago.co.nz). The hope is that these improvements will be adopted by the Muslim community.

Both communities are concerned with animal welfare. Again a traditional Muslim text summarizes this nicely: "Allah has decreed that whatever is to be done should be perfect and sublime. Hence, when you kill, kill well; and when you slaughter, slaughter well: sharpen your blade and handle with kindness, that which you slaughter."

Some Muslim scholars permit pre-slaughter stunning of an animal, and some rabbis permit post-slaughter stunning. Both of these are controversial, and many more traditional Muslim and Jewish consumers reject these processes.

Slaughtered animals for kosher are subsequently inspected for visible internal organ defects by rabbinically trained inspectors, with a special emphasis on the lungs. Both discolorations and connective tissue adhesions between lung lobes and/or with the lung cavity (sirchas) must be examined carefully to determine if the meat is acceptable. This involves both an internal inspection with the lungs in place and further work after the lungs are removed from the rest of the carcass. The failure rate can be significant and impacts the cost of kosher meat as if rejected, the entire carcass is moved to the secular supply, often with a price discount. In modern times, starting in the USA, the rabbis ruled that only a few sirchas are permitted for the strictest meat. This is referred to as "glatt" meat and the term "glatt" can really only refer to mammals. The Jews living in the Muslim world during the dark ages (Sephardim) were stricter and required that there be no lung adhesions. This meat is referred to as "Beit Yosef" meat.

Meat and poultry must be further prepared by properly removing certain veins, arteries, prohibited fats, blood, and the sciatic nerve. The removal of the sciatic nerve is difficult in some animals, e.g., cattle and sheep, while much easier in deer, so as a practical matter in most countries, the hindquarters (which contain the sciatic nerve) are moved to the secular trade. Again in the Sephardic tradition, the hindquarter was used, and as Israel is a Sephardic country, such meat is available there although most practicing Jews of European origin (Ashkenazic) will not use such meat.

To further remove the prohibited blood, red meat and poultry must then be soaked, salted, and rinsed within 72 h of slaughter. Livers and hearts will be handled separately. The heart must be opened and any coagulated blood removed. The liver must be broiled in a dedicated broiler until it is at least half cooked. If more than 72 h are needed, then according to some rabbis, meat may be specially washed (begissing, a real wash and not just a light spray), and this wash procedure may be repeated for up to two more times, each time within 72 h of the previous washing. This is done to make sure the blood and meat surfaces remain moist. However, this process of begissing has been rejected by most consumers who require glatt or Beit Yosef meat.

The soaking is done for half an hour in cool water (not cold); thereafter, the salting is done for 1 h with all surfaces, including cut surfaces and the inside the cavity of a chicken or turkey. After the hour of salting, the meat is then rinsed three times. The salted meat must be able to drain throughout, and all the blood being removed must flow away freely. The special crystal size used for this process is called kosher salt (crystals large enough to not dissolve in an hour, but small enough to adhere and totally cover surfaces). Most salt is actually kosher, so in this case, the word kosher refers to the crystal size, which has become very popular with many secular chefs, especially those on TV and various social media!

Some concern has been raised about the salt level in kosher meat. Note that only the surfaces are salted, generally using primal cuts (i.e., 20–40 pound pieces of meat), and that the penetration of the salt is less than a half centimeter in red meat (NY Department of Agriculture and Markets, personal communication). Many pieces of meat, as consumed, have therefore not been directly subjected to the salt treatment. If salt content in a diet is a very important consideration, then one should cut off all surfaces and not use any of the drippings that come out during cooking as much of the salt that goes into the meat at the surface is cooked out with the drippings.

Any ingredients or materials that might be derived from animal sources are generally are available in a kosher and/or halal form derived from plant oils. A possible exception might be normative mainstream gelatin, which is now being produced from kosher beef hides or fish. Also some kosher rennet, the cheese-coagulating enzyme, is obtained from the dried fourth stomach of a kosher-slaughtered milk-fed calf although most commercial cheese today is made using microbial enzymes that come either from genetically modified bacteria or other microbes whose coagulating enzyme(s) can be successfully used. Microorganisms must be produced in kosher or halal systems (i.e., all ingredients and the equipment are kosher or halal).

Because of the need for the lung inspection, it is rare to have dairy cows even brought to kosher slaughter as they generally cannot pass the lung inspection. So all processed kosher meat products unlike most secular processed meat products, which use dairy cow meat, need to be made from the same meat that would be served at the table.

The Muslim community is concerned with the slaughter of the animal; thereafter, the product is turned over to the secular authorities for the necessary health inspections although it should be noted that both religions require an anti-mortem inspection, i.e., before the slaughter of the animal to determine that it is healthy and not show signs of visible injuries.

Prohibition of Mixing of Milk and Meat

Thou shalt not seeth the kid in its mother's milk. (Exodus XXIII:19, Exodus XXXIV:26, Deuteronomy XIV:21).

This passage appears three times in the Torah (the first five books of the Hebrew Scripture) and is therefore considered a very serious admonition for kosher practice. As a result, the law cannot be violated even for nonfood uses of such mixtures such as pet food. Neither can one derive benefit from such a mixture. The meat side of the equation has been rabbinically extended to include poultry (but not fish) as both meat and poultry need to be inspected, deveined, salted, and soaked. The dairy side includes all milk derivatives.

Keeping meat and milk separate in accordance with kosher law requires that the processing and handling of all materials and products fall into one of three categories:

1. A meat product
2. A dairy product
3. A neutral product called "pareve"

The pareve category includes all nonmeat or nondairy products and includes all plant products along with eggs, fish, honey, and lac resin (shellac). To assure the complete separation of milk and meat, all equipment, utensils, pipes, steam, etc. must be kept in the properly designated category.

Pareve ingredient or product must be produce on equipment that has undergone equipment kosherization (see section on "Equipment Kosherization"). This separation of products into these three categories including during production makes kosher products of interest to people with other lifestyle choices, e.g., vegetarian (dairy and pareve) or vegan (pareve – although clearly the few animal products need to be checked).

Other Kosher Issues

Grape Products

To be kosher, all grape juice-based products can only be handled by observant Jews from grape-pressing to final processing. If the juice is heated (mevushal) to at least 140 °F (or 60 °C, some rabbis require a higher temperature), then it can be handled by any worker, as an ordinary kosher ingredient. Thus, preparing a quality wine is more difficult after heating. In recent years, such wines have been produced successfully, and the author has seen news articles indicating that this or that wine had even won a wine tasting award when competing with non-heated (non-mevushal) wines. Technically, a non-mevushal wine may only be handled by a Sabbath observant Jew when being served to other such observant Jews. (Note: the term "Sabbath observant Jew" is used to denote someone who is Orthodox and tries to observe most traditional Jewish laws.)

The traditional kosher wine is made with Concord grapes and added sugar. It is a totally different product from the normal wines and is more closely related to a very sweet dessert wine. It can be enjoyed in its own right. For religious purposes, the wine can be either this sweet Concord grape wine or any other wine that has been properly supervised during its preparation.

Jewish Cheese (Gevinas Yisroel)

Most normative mainstream kosher supervision organizations require that a Sabbath-observing Jew add the coagulating agent, i.e., the agent such as chymosin that causes curd formation. Any ripened cheese that does not meet this requirement is unacceptable. This rule does not apply to fresh cheeses.

Kosher whey can be created more easily than kosher cheese. If all the ingredients and equipment used during cheese making are kosher, then the whey will be kosher as long as the curds and whey have not been heated together above 120 °F (49 °C) before the whey is drained off. This is true even if a rabbi has not added the coagulant. So the cheese is not kosher, while the whey is. This has led in the USA to the situation where human grade whey is kosher. If it is not kosher, it generally is used as animal feed at a price discount. Generally, whey is dried by spray-drying. This is a difficult piece of equipment to kosherize (see below), so the equipment is kept kosher all the time. (For more information, please see Regenstein and Regenstein (2002a, b).)

Cholev Yisroel

Some kosher-observant Jews are concerned about possible adulteration of milk with the milk of nonkosher animals, such as mare's milk or camel's milk, and therefore require that the milk be watched from the time of milking (i.e., on the farm). "Cholev yisroel" milk is required by some of the stricter kosher supervision agencies for all dairy ingredients. Rabbis who accept non-"cholev yisroel" milk in the USA do so for two reasons. First, they believe that the laws in the USA and many other developed countries are strong enough to assure that adulteration does not occur. Second, the nonkosher milks are worth more money than kosher milks, so there is no incentive to add the nonkosher milk.

Passover

The Passover holiday occurs in spring and requires observant Jews to avoid eating the usual products made from the five Biblically prohibited grains: wheat, rye, oats, barley, and spelt (Hebrew, chometz). One can only eat the special unleavened holiday bread from wheat (Hebrew, matzos). Some matzos are made to a stricter standard with rabbinical inspection beginning in the field. For others supervision does not start until flour milling. Matzo made from oats and spelt are now available for consumers with wheat allergies.

In the middle ages, the rabbis of Europe noted that people also made flour products derived from corn, rice, legumes, mustard seed, buckwheat, and some other plants (Hebrew, kitnyos), so they prohibited these for Passover as they might be mistaken for chometz. In addition to the actual "flours" of these materials, many contemporary rabbis also prohibit derivatives such as corn syrup, corn starch, and corn starch derivatives such as citric acid. A small number of rabbis permit the oil from kitnyos materials, or liquid kitnyos products and their derivatives such as corn syrup. The major source of sweeteners and starches used for production of "sweet" Passover items are either real sugar or potato or cassava (tapioca) starches. These starches have different properties, which affects the end product. The matzos can be ground into either a course meal (matzos meal) or a very fine meal (matzos flour). However, these like bread crumbs are already baked, and so baked goods and other products using them will have a different outcome. (Note: Matzos for year-round use does not need to meet the special rules for Passover matzos, so regular wheat flour can be used and the time to process it and bake it is not an issue.)

Kosher: Other Processing Issues

Equipment Kosherization

There are three ways to make equipment kosher or to change its status back to pareve. Rabbis generally frown on regularly going from meat to dairy or vice versa. Most conversions are from dairy to pareve or from treife (nonkosher) to one of the categories of kosher. There is a range of processing procedures to be considered, depending on the equipment's prior production history.

After a plant, or a processing line, has been used to produce kosher pareve products, it can be switched to either kosher dairy or kosher meat without a special equipment kosherization step. It can also subsequently be used for halal production (from pareve or dairy lines, not always from meat lines) and then, finally, for nonkosher products. In many cases, a mashgiach (the rabbinically approved kosher supervisor) is needed on-site for equipment kosherization, so it normally is beneficial to minimize the number of changeovers from one status to another. Muslims also have a procedure for changing equipment that generally involves a supervised washing. In a few cases, when pork was used, they might require that contact surfaces be sandpapered.

The simplest equipment kosherization occurs with equipment that has only been used for cold products. This requires a good liquid caustic/soap cleaning – i.e., the type of cleaning done normally in most food plants. Some plants do not normally do a wet cleanup between runs (e.g., a dry powder packing plant or a chocolate line), and these would need to seek specific rabbinical guidance for the changeover if permitted. Materials such as ceramics, rubber, earthenware, and porcelain cannot be koshered.

Most food processing equipment is operated at cooking temperatures, generally above 120 °F (49 °C), the temperature that is usually rabbinically defined as "cooking." However, the exact temperature for "cooking" depends on the individual rabbi and may also be product specific (range 110 to 140 °F (~43 to 60 °C)) with 120 °F (49 °C) being agreed upon in the USA for dairy products. Such equipment must be thoroughly cleaned with liquid caustic/soap. The equipment must then be left idle for 24 h, after which it is "flooded" with boiling water in the presence of a kosher supervisor. The details depend on the equipment being kosherized. In some cases, particularly foodservice establishments, a "pogem" (bittering agent, oftentimes ammonia) is used in the boiling water in lieu of the 24 h wait. The absolutely clean equipment (e.g., silverware) is put into the pogem containing boiling water followed by a second boiling with clean water.

In the case of ovens or other equipment that uses "fire," or dry heat, kosherization involves heating the metal until it glows. Again, the supervising rabbi is generally present while this process is taking place. Sometimes the same oven can be used sequentially for pareve and dairy baking. The details are beyond the scope of this chapter and require a sophisticated rabbinical analysis. If kosherization of an oven is needed, this often requires the use of a blow torch to heat surfaces to "red hot."

Kosher and Allergies

Many consumers use the kosher markings as a guideline to determine whether food products might meet their special needs including allergies. There are, however, limitations that the particularly sensitive allergic consumer needs to keep in mind. The kosherization procedure may not yield 100% removal of previous materials run on the equipment.

In a few instances, where pareve products contain small amounts of fish (such as anchovies in Worcestershire sauce), this ingredient may (but not always) be marked as part of the kosher supervision symbol as fish cannot be used directly with meat. Many certifications do not specifically mark this if the fish in the initial material is less than 1/60 by volume (a special amount used). Although a number of these issues have already been discussed, it may be helpful to also bring a few of them together here, only for a first screening of products.

Blessings

There are many blessings for food along with many other blessings. So to say the right blessing, one needs to know something about the food you are eating. Some blessings are specific, e.g., tree fruit versus ground fruit. Some can cover the whole meal, e.g., the blessing over bread, which follows the blessing for washing the hands, and are said without interruption between them. Sometimes a single product requires more than one blessing, e.g., one of the "Chex" products is corn on one side and wheat on the other side. Those have different blessings and so you start with the wheat facing up and say its blessing. Then one turns the product over and says the blessing for corn.

Additional Information About the Halal Dietary Laws

Although a number of these issues have already been discussed, it may be helpful to also bring a few of them together here. It is also clear that the amount of detail for halal is less than kosher. This is consistent with the idea that the distinction of halal and haram is for human *ease*, goodness, guidance, and mercy.

Halal Dietary Laws

The halal dietary laws define food products as halal (permitted) and haram (prohibited) and put a few items to go into the category of makrooh (questionable to detestable), which is often the most controversial area. The law deals with the following five issues; all but the last are in the animal kingdom.

Prohibited and Permitted Animals

As previously mentioned, pork is prohibited, as are the carnivorous animals and birds of prey. However, most Muslims consider horsemeat to be makrooh. Birds are specifically those that do not use their claws to hold down food.

The animals fed unclean or filthy feed (e.g., formulated with biosolids (sewage) or protein from tankage) and must be quarantined and placed on clean feed for a period varying from 3 to 40 days before slaughter to cleanse their systems. This is an area where Muslim needs are not being met in some cases although many Muslims would like to have more meat and poultry available from animals that have met this requirement.

Food from the sea, namely, fish and seafood, are the most controversial among the various denominations of Muslims. Certain groups, particularly Shiia, only accept the kosher fish, i.e., with fins and scales although many also accept shrimp, while others consider as halal everything that lives in the water all the time. But others may consider some of these makrooh and avoid them. Animals that live both in water and on land (amphibians) are not consumed by the majority of observant Muslims.

The status of insects is uncertain except that locust is specifically mentioned as halal. However, from legal discussions, it seems that both helpful insects, like bees, ants, and spiders, and harmful or dirty creatures like lice, flies, and mosquitoes are all haram.

Eggs and milk from permitted animals are also permitted for Muslim consumption. Unlike kosher, there is no restriction on mixing meat and milk.

Prohibition of Blood

According to the Quranic verses, blood that pours forth is prohibited for consumption. There is general agreement among Muslim scholars that anything made from blood is unacceptable.

Proper Slaughtering of Permitted Animals

In addition to those discussed earlier, there is the rule that only after the blood is allowed to drain completely from the animal and the animal has become lifeless can the dismemberment begin.

Prohibition of Alcohol and Intoxicants

Consumption of alcoholic drinks and other intoxicants is prohibited. One of the scholarly passages on alcohol is particular interesting in terms of food science. It actually talks about the entire production cycle: “Allah’s curse falls on ten groups of people who deal with alcohol. The one who distills it, the one for whom it has been distilled, the one who drinks it, the one who transports it, the one to whom it has been brought, the one who serves it, the one who sells it, the one who utilizes the money from it, the one who buys it, and the one who buys it for someone else.”

Although there is no allowance for added alcohol in any beverage like soft drinks, small amounts of alcohol contributed naturally from food ingredients may be considered an impurity and hence ignored. Synthetic or grain alcohol may be used in food processing for extraction, precipitation, dissolving, and other reasons, as long as the amount of alcohol remaining in the final product is very small, generally below 0.1%. Each importing country may have its own guidelines for both natural and other alcohol. Generally beverage alcohol is most frowned upon. Some will suggest that in food products that are cooked, the alcohol is vaporized. This has been shown not to be the case through research done by the USDA (Larsen 1995). Among the foods that are often not thought about as containing alcohol are breads. They can have up to 0.2 to 0.3% or so alcohol.

In addition both communities also have rules about blessings for food. However, the Muslim religion also tries to guide its adherents, and their particular guidelines for eating and for table manners are particularly interesting.

For eating:

1. Never criticize any food.
2. Du’a (say a supplication) before each meal.

3. Du'a after each meal.
4. Eating less.

> Nothing is worse than a person who fills his stomach. It should be enough for the son of Adam to have a few bites to satisfy his hunger. If he wishes more, it should be: One-third for his food, one-third for his liquids, and one-third for his breath. (Tirmidhi and Ibn Majah)

5. Eating slowly.
6. Moderation.

> Eat of the good things. We have provided for your sustenance, but commit no excess therein.... (Al-Qur'an 20:81)

7. Sharing.
8. Eating together.

> Eat together and not separately, for the blessing is associated with the company. (Ibn Majah)

And for table manners:

1. Sit down while eating and/or drinking.
2. Eat together and share food.
3. Serve others first, especially guests.
4. The host is the first to start eating and the last to finish.
5. Take smaller portions of food on the plate.
6. Eat from one's own side of the plate and not from the middle.
7. Finish the plate of food without leftovers.
8. Eat with the right hand.
9. Wait for everyone to finish before finally leaving the table.

Both Kosher and Halal

Biotechnology

Rabbis and Islamic scholars currently accept products made by simple genetic engineering; e.g., chymosin (rennin) was accepted by the rabbis about half a year before it was accepted by the US Food and Drug Administration. The basis for this decision involves the idea that the gene isolated from a nonkosher source was not "visible." Subsequently, it is copied many times in vitro and then eventually injected into a host where it is then reproduced many times. Thus, the original source of the "gene" is essentially totally lost by the time the food product appears. The production conditions in the fermenters must still be kosher or halal, i.e., the ingredients and the fermenter, and any subsequent processing must use kosher or halal equipment and ingredients. A product produced in a dairy medium would be kosher dairy. Mainstream rabbis may approve porcine lipase made through biotechnology when it becomes available, if all the other conditions are kosher. Islamic scholars are still considering the issue of products with a porcine gene; although a final ruling has not been established, the leaning seems to be toward rejecting such materials.

If the gene for a porcine product were synthesized (i.e., it did not come directly from the pig), Islamic scholars still need to determine if they will accept it. Again, the leaning seems to be negative. Because the religious leaders of both communities have not yet determined the status of more complex genetic manipulations; such a discussion is premature. (For more details, please see Chaudry and Regenstein (1994).)

Kosher and Halal Foods

A key consideration is that which is called Jewish food and what is called kosher food need to be distinguished. Kosher food is food that meets the technical requirements of the Jewish religious laws as interpreted by the consumer and/or the person's religious advisor. The same is true for halal for Muslims. But what is religiously acceptable does not mean it is what most people of these two faiths actually eat and especially what they might have eaten in the recent past.

Many Muslims live in countries where they are a majority, there are 57 countries that are part of the OIC (the Organization of the Islamic Conference) that wish to be identified as Muslim majority or have a sufficiently large Muslim population that their government wants to recognize this unique aspect of their country. In these cases, the food of the population tends to reflect the dominant food style. So, for example, Pakistani, Malaysian, Moroccan, Egyptian, and such countries have their own cuisines, and the halal interaction is real but has a limited impact on the cuisine for those who are or are not practicing Muslims. The biggest difference is probably in whether alcohol is or is not incorporated into the meal. Therefore, it seems that discussing in detail these foods would be redundant with material already available.

On the other hand, Jews, as a wandering people, have incorporated the foods of many countries and have adopted them to their religious requirements, their culture of holidays with different meanings, and the fact that overall they were poor. Only in modern times has this food of poverty become celebrated. Again, in Christian countries, with their heavy emphasis on pork and often the mixing of milk and meat, the food of Jews both daily and on holidays was different from others. In the Muslim countries, the distinction was much less. The absence of dairy and pork in most of these countries meant the Jews and Muslim diets could be similar although as seen earlier, the meat would have to be different, most Muslim neighbors would eat in the Jewish home and, other than meat, the religious Jew might even eat in a Muslim home.

So, this section will focus on the diet and eating habits of the Jew in Europe. The rules for baking and the absence of dairy breads meant that bakeries had to be supervised. This was often a part of the job of the local rabbi. This would certainly require at least a daily visit if the bakery was owned by a Gentile and had no Sabbath-observing Jewish employees. And if Jewish owned, it might be required to take challah. This is a small portion of large amounts of dough that must be removed, a prayer said, and the material burned – again the details are beyond this chapter. And the rules for working with ovens going back and forth between dairy for cakes and other items versus pareve for bread and pareve cakes would require all involved to have a basic understanding of that component of the law.

Breakfast and lunch would generally be dairy or pareve with no meat eating until evening, if there was enough money to buy some meat. This is also due to the customs that developed in switching from meat to dairy or vice versa. The custom in going from meat to dairy is to wait a fixed period of time which was most often 6 h but in a few cultures was 3 or 4 h (e.g., Germany) or even 1 h (e.g., Holland). On the other hand, going from dairy to meat was much shorter, with some accepting a good rinsing of the mouth, while others waited 1 h. (Note: Some dairy products like some dry cheeses were considered meat like and then required the same wait to switch as meat.) Thus, timing of meals became important. If one had a pareve meal, regardless of whether one used meat dishes or dairy dishes, the quick mouth rinse is all that is required to switch.

For example, like many other cultures, the meals were heavy on starch, and a meat meal would also often be a stretch of the little meat available, i.e., a dough-filled food like kreplach, which is the Jewish version of a wonton or a ravioli, is popular. A relatively unusual grain popular with European Jews has been buckwheat, which is known as kasha. It would often be served with traditional pasta. In America buckwheat is grown in the region around Penn Yan in upstate New York along Seneca Lake in the Finger Lakes region, which calls itself the buckwheat capital of the USA. The kasha is also a filling for another traditional "double starch" food, the knish, a larger dough-filled food. The most common filling is potato although other fillings were common, while in modern times, the fillings have become more varied. So, other traditional fillings might be kasha, cabbage, and liver. Other fillings now include sweet potato, spinach, and cheese with fruit. Obviously, the kosher versions need to carefully separate the meat, dairy, and pareve items.

The use of liver has been the focus for the use of edible offal. Because the liver is one of the few front quarter offal meats, its use in Jewish cooking has almost become symbolic. It does have to have some forbidden fat removed, and because of the high level of blood, it needs to broiled, at least to halfway done. Chopped liver, much coarser chopped than a classical pate, becomes an important appetizer in modern times.

The heart of the weekly cycle of the Jewish week is the Sabbath. As all Jewish days start at sundown, dinner on Friday night is accompanied by special prayers including the wine and special bread, i.e., challah, an egg-based "rich" bread. (The term challah does have two meanings, a type of bread and the removal religiously of a piece of dough.) So the focus of Jewish culinary has been on this weekly festival, but that means that there are a whole bunch of special rules that have to be followed as work is prohibited on the Sabbath. What does “work” mean? It is all of the activities associated with the building of the Temple in Jerusalem.

So cooking on the Sabbath, a day of joy and celebration, becomes a little tricky, given that to celebrate you want hot meals for the official meals. The traditional solution is the “Blech,” a metal covering of the stoves, so the fire can be left on for the entire Sabbath. The oven may also be left on the whole night and day. Changing settings on the Sabbath is very complicated. In modern times, especially with electric stoves, special Shabbos stoves have been developed to deal with the complex requirements. Other household appliances also have to be adjusted, e.g., the light in the refrigerator needs to be turned off. No electricity can be turned on or off, so the use of timers has become fairly common. A key is that all food must be at least half cooked when the Sabbath begins or in practice when the homemaker accepts the beginning of Shabbos within the allowed window. There is some discretion in Jewish law as to when a person can begin following the Sabbath rules. Because it is such a special holiday, some people might want to start earlier than the last possible time – it is a sign of respect for the holiday to start early.

The Friday night dinner is fairly easy. And brisket and chicken are probably the most traditional meats for Friday night in the USA. But, the two meals on Saturday are more of a challenge. The traditional solution is cholent, a bean, potato, and cheap meat dish, e.g., flanken (rib bones) that is fatty and needs long cooking. So, Jews developed some of the early slow cooker foods, put in the oven on Friday afternoon, and held until needed. Another such slow cooking dish is tsimmes, usually based on carrots, often with sweet potatoes and even dried plums (prunes) and other sweets (e.g., pineapple) to celebrate the sweetness of the day. This can be made with meat, a tradition that is also found in the foods of many Muslim countries, e.g., Malaysia and Morocco.

Another traditional appetizer for Shabbos dinner is gefilte fish. A lot of traditions surround this interesting fish dish. It traditionally was made from carp, a very tasty fish with two challenges. The first is that if it comes out of a muddy river, so it may have a muddy flavor. This flavor is water soluble and the live fish can be purged. So when and how does one do that? In the bathtub of course. The homemaker would buy the fish on Wednesday and bring it home and put it in the bathtub. Thankfully, carp are pretty hardy and survive the trip home. Obviously, the young people in the household would enjoy this temporary pet as most Jews did not generally have pets (which are subject to some of the kosher laws). So Jewish children’s literature is filled with stories involving this fish in the home, both realistic and sometimes more fanciful outcomes. On Friday morning the fish would be killed, often by the senior female in the household. This worked out fine in traditional homes where one took a hot bath once a week and in a Jewish home that meant on Friday in preparation for the Shabbos. Originally, the carp was just cooked, but it has a lot of “flying Y bones” which are a nuisance for many, especially children. So a chopped form was developed and put in the belly cavity of a second carp for cooking (baking). But after a while it became its own dish. Grandma would then prepare the traditional gefilte fish by adding the other ingredients that would include fat (often a bird fat, i.e., schmaltz, the Jewish meat spread in place of butter); egg; matzo meal, the ground matzos associated with Passover; and, of course, salt and pepper. And, of course, that meant grandma tasted the mixture to be sure it was "right." But carp have worms. Therefore, grandma would be the only one with intestinal worms! (If the worm cannot be seen, it cannot be a kosher issue. There are also other more complex interpretations that suggest that fish worms are not an issue but that is beyond the scope of this chapter.) The fish in some form would then be boiled for an hour or more and that both killed the worms and softened the bones. This was then served with horseradish to give more flavor, but often with beets added to give a nice contrast and to cut down the sharpness of the horseradish.

The many Jewish holidays throughout the year also developed special foods. If the holiday came on the Sabbath, the Sabbath rules dominated. Depending on the holiday, the degree of rules varied somewhere between everyday rules and almost Sabbath rules. And the challenge sometimes is that the holiday comes on Sunday and one cannot prepare meals for another day on the Sabbath or it came on Friday and one had to prepare the Sabbath meals but not violate the holiday rules.

So working through the Jewish calendar, the special holidays and their foods will be discussed briefly.

Rosh Hashanah. The Jewish New Year is a serious religious holiday. It is also a time of hope for a sweet new year. One would like to dip a new fruit in honey and say the special prayer for getting to this time. So apples or another fruit that one had not eaten in a while, preferably from the fall harvest would be used. Taglich are baked goods with lots of honey. Honey cake is another favorite. Plums were also often available around this time in Europe, so various forms of plum cakes are also associated with Rosh Hashanah.

Yom Kippur. This is the major fast day in the Jewish calendar. It is a day of atonement and completes the 10 days of the New Year holiday. During the 10 days, a Jew is supposed to seek atonement from others that he/she might have harmed during the year. Only then can one seek atonement from G-d. Obviously, the meal going into the fast is relatively bland. The hard part is breaking the fast, where eating too much or too fast is a challenge to avoid. Herring in wine sauce and herring in cream sauce are two pickled fish favorites. Note that the cream sauce is based on sour cream, a tie to Central Europe where sour cream was a way to preserve milk and was not as complicated religiously as cheese. Sour cream is also used to sweeten the strongly acidic (sour salt, citric acid) taste of borscht (beet soup that could be made pareve or with meat) or Schav (sorrel grass with sour salt – a specialty dish that even most Jews would have to admit that they never tried it!).

Succoth. This is the festival of the booths/huts commemorating the wanderings in the desert after the exodus from Egypt. Meals are supposed to be eaten in the Succah and many observant Jews will even sleep in these huts. Even beyond the observant Jewish community, this holiday is very popular as more and more people build their own Succah at home rather than use the communal Sukkah that is usually at the synagogue. Young people in particular seem to enjoy the "camping out at home" experience. The Succah are often decorated with foods including strings of cranberries, apples, various squashes, and other fall fruits and vegetables.

Hanukkah. This is the holiday closest to Christmas, so despite being a minor holiday in the Jewish calendar, it has become a part of the winter celebrations in the USA. It commemorates the military victory over the Romans and the restitution of the Temple in Jerusalem. The miracle was that the oil needed for the holy light at the top of the ark holding the five books of the law (Torah) was enough for 1 day, but it lasted for the 8 days needed to make new oil. So the goal is to eat oil. European Jewry general uses latkes, potato pancakes, as the major holiday food, while Sephardic Jews from the Muslim countries often use long jelly-filled fried doughnuts called sugganiot. And the highly debated point is whether latkes should be covered with sour cream or applesauce. Some solve the problem by doing both. Note: A brief summary of many Jewish holidays center around celebrating persecutions of Jews, where the Jews were victorious and then choose to celebrate the holiday, with food often being central.

Tu B'Shevat. This is a very minor holiday, but it is very food related. It is a celebration of the trees and plants. It has a formal meal with a set order, i.e., a Seder, that requires fruits not eaten for a while. For many the tradition is at least a month for it to be new food. This Seder is also accompanied with wine, starting with white and adding a little red followed by red with a little white followed by red wine. Thus four glasses are drunk along with at least four new fruits, with the blessing of the wine and the fruit and having reached this season. A more traditional meal may be served after the Seder, but at other times, the meal is essentially fruit and wine.

Purim. This is in some ways the Jewish Halloween. It is celebrated by wearing costumes, including adults. The villain is a government official named Hamen. He apparently wore a triangular hat or at least that is the rumor. A sweet-filled triangle cookie, called a Hamentaschen, literally a Hamen's pocket, is eaten. The traditional fillings were prune butter and mohn, a poppy seed paste. In modern times many of the sweet flavored jams are used along with chocolate. There is also a tradition of sending food baskets to friends with at least two different items.

Passover has generally been the most celebrated Jewish holiday, possibly because it is centered around a large family gathering the first two nights called the Seder (when used alone it means the Passover meal and not the Tu B'Shevat meal), which retells the story of the exodus from Egypt without ever using the name of Moses in the Hebrew text. The Seder plate has a number of symbolic foods that are also used for various ceremonies during the prayers before the meal. The parsley or greens are dipped in salt water to commemorate slavery in Egypt. A piece of unleavened matzos (afikomen) is put away as the official desert. The matzos are eaten with both bitter herbs and charoses, the mortar used to build the pyramids. In the Ashkenazic world, charoses is made with apples, nuts, and wine. In the Sephardic world, dates are often the base for the charoses. Again four cups of wine are drunk. Some newer traditions such as including a cup of water for the role of Miriam (the sister of Moses and a key player in the story of the exodus) have been added in some homes. The special meal requires that all the plant materials be acceptable, i.e., no chometz or kitnyos and no insects.

A Word About Matzos. The wheat may be watched from the harvest in the field (Schmura) or only from grinding. The water, the only other ingredient in the matzos of the poor, which is the only matzos that can be used for the ceremonies, must be lukewarm and held overnight. The matzos must be baked within 18 min. Modern factories use continuous vibrations to prevent any rising so can use a continuous process. Handmade matzos are made in 18-min cycles with a full cleanup before continuing. Richer matzos using fruit juices or eggs are only permitted by Ashkenazim for children, the elderly, and the sick. Sephardim are more liberal about this and also allow most kitnyos.

Shavuot. The final holiday of the yearly cycle is the festival of the giving of the law. It is tied directly to Passover by the counting each day of the Omer, originally the grain offering on the three pilgrimage festivals. It is traditional that meals on this day be dairy. So various puddings, e.g., kugels, are made. Noodle, matzos, and potatoes along with eggs can all be used for the kugels. These often will have cheese (e.g., cottage, pot or farmers cheese, i.e., fresh cheeses added). (A kugel for a meat meal will generally have fruit added, the most common being apples.)

A Word About the Issue of Whether a Holiday Is 1 or 2 Days. Many of these holidays are 1 day in Israel, but when Jews worried about getting the “timing” right, the rabbis instituted 2 days in the diaspora.

The Muslim calendar has a few key holidays. And obviously different Muslim countries have country focused holidays; some may also be tied to the country’s Muslim religious history.

Ramadan is certainly the most widely known holiday. It is a whole lunar month. And it is a month of fasting. This means that fasting and other restrictions are observed during daylight hours. A predawn breakfast (Arabic, Suhur) and a celebratory meal in the evening (Iftar) are eaten. The normal pattern is to break the fast at sundown with dates, other fruit, and rose water. Then the evening prayers are said before the big meal. Often this meal is eaten communally, and the night prayers said thereafter.

It should also be noted that fasting in Islam is fairly common and many Muslims fast once or twice a week regularly. It should also be pointed out that Muslims pray five times a day with the major communal prayer being on Friday early afternoon. Jews, on the other hand, pray three times a day. Those who are observant often do actually pray this regularly.

Note that the Muslim calendar is a lunar calendar, so each year the calendar moves up about 10 days. Ramadan can occur at any season. On the other hand, the Jewish calendar is also a lunar calendar, but it has a leap month (seven times every 19 years) so that holidays retain their relationship to the seasons as many are tied to the harvest cycle in Israel.

At the end of Ramadan, the first few days of the new month are the first of the two Eid festivals (Eid al-Fitr). The second Eid (Eid al-Adah) is about 3 months later and commemorates the almost sacrifice of his son Ishmael by Ibrahim as told in the Quran. (Some may recognize this as a different version of the Abraham and Isaac story.) On both occasions there is usually a desire for every family to formally sacrifice an animal, generally a sheep or goat, for the holiday. This presents a logistical and animal welfare challenge. It should also be noted that Muslim practice is to consider that one-third of the animal is for the family. The second third is for relatives and friends, and the final third is for the poor.

The second Eid occurs when many Muslims are meeting one of the five pillars of Islam, which is the Haj, the pilgrimage trip to Mecca, and Medina in the Kingdom of Saudi Arabia. That means that the many millions of people on Haj all need to have an animal sacrificed in a short period of time. In this case most of the animals will be going to the poor. Based on discussions with some Muslim leaders in the UK, the author believes that Saudi Arabia should be complimented for working hard to improve animal welfare and work out systems to get this meat to people in other countries where it is needed. The transport of the many live sheep needed from other countries is an area where more work is needed to meet the highest modern animal welfare standards.

Thus, both communities have worked out the integration of their religion with their daily life, where food and drink and socializing all need to work together for a meaningful life of each Muslim or Jew with a full range of actual religiosity.

Conclusion

The kosher and halal food laws serve as the framework for the eating habits of Jews and Muslims, respectively. These rules limit food choices, but still allow for a very varied diet. In many cases, the foods of both religions represent the foods of many countries and often, particularly for Jewish food, the adaptation of economical foods to their dietary requirements. To be successful, a global food supply will need to take into consideration the food needs of the various religions around the world.

Abstract

Public health nutrition is concerned with the promotion and maintenance of good health through nutrition and the prevention of nutrition-related illness in humans. Nutrition communication plays an important role in the dissemination of credible and practical dietary advice and promoting healthful dietary behaviors. The purpose of this chapter is to provide insight in the changes in public health nutrition communication, by addressing the history, key themes, concepts, and approaches of nutrition communication in the Netherlands. The chapter concludes with a broader view of the challenges of public health nutrition communication and presents potential future directions for this field.

Introduction

Malnutrition is one of the greatest health issues of our time, affecting at least one in three people in the world (WHO 2017). To date, many countries face a double burden of malnutrition, with high rates of undernutrition co-existing alongside overweight, obesity, and diet-related noncommunicable diseases (Willett et al. 2019). Good nutrition is fundamental to prevent malnutrition in all its forms. Changes in the global food system, increased food-related marketing and changing lifestyles, however, have led to a global dietary intake pattern in which people often consume too little nutrient-dense foods and too much high-energy dense foods (James 2008; Popkin 2001). Over the past decades, the food system and food environment have changed in such a way that it is simple to get access to a surplus of inexpensive, highly palatable, energy-dense foods that are heavily marketed (Steeves et al. 2014). This type of environment stimulates people to consume more energy than required, and therefore it is concluded that the global rise in overweight and diet-related noncommunicable diseases is a natural response to the current food environment (Swinburn et al. 2011). Current trends in food production and food consumption also impose an undue burden on sustainability. Food production, for instance, is an important driver of ecosystem degradation (Millennium Ecosystem Assessment 2005), with food responsible for 20–30% of the environmental impacts (Tukker et al. 2011). This implies that providing a global population with healthy diets from sustainable food systems is an immediate challenge that requires large reductions in food losses and waste and major improvements in food production practices (Willett et al. 2019). Furthermore, it asks for consumers' willingness and ability to change their (current) behavior (Van Loo et al. 2017). Altogether, it is not surprising that health and sustainability goals have found their way into public health nutrition communication.

Healthy eating habits make an essential contribution to a healthy lifestyle. The context for public health nutrition communication in the Netherlands, however, is comparable to other Western countries: many people do not eat according to current dietary guidelines. Compared to other Europeans, Dutch adults consume more alcoholic and nonalcoholic beverages, dairy products, and snacks and desserts. In contrast, consumption of vegetables and fruit are among the lowest in Europe (Geurts et al. 2017). Additionally, the prevalence of overweight and obesity is on the rise in the Netherlands. To date, one out of two Dutch adults has overweight (National Institute for Public Health and the Environment 2018). This has important implications for health, contributing to the increased prevalence of diabetes, cardiovascular diseases, and selected cancers (Wyatt et al. 2006). As a result, different national and local authorities, schools, civil society organizations, and private parties have set up preventive and interventive initiatives to reduce the prevalence of overweight and obesity in the Netherlands. Although the solution to this public health problem often requires actions and policies that reside outside the individual consumer, it is nevertheless important to increase the personal significance of these issues for individuals, increase nutritional knowledge, change norms and beliefs about healthy eating, and motivate people to improve current dietary behaviors. The Netherlands Nutrition Centre is the organization primarily responsible for behavior-focused public health nutrition communication in the Netherlands. The Centre provides consumers and professionals with scientific and independent information about healthy, safe, and sustainable food choices and encourages consumers to develop and maintain healthy and more sustainable eating habits. The Centre is funded by the Ministry of Public Health, Welfare and Sport and the Ministry of Agriculture, Nature and Food Quality.

The focus of this chapter is to illustrate the challenges of public health nutrition communication, thereby taking the Dutch context as a case study. In this chapter, the key themes, concepts, approaches, and challenges of public health nutrition communication are described. Firstly, the history of public health nutrition communication in the Netherlands and the current mission and vision of the Netherlands Nutrition Centre are outlined. Then, the primary nutrition education tool that is used in the Netherlands is introduced, after which the main concepts that are included in the health-promoting activities of the Netherlands Nutrition Centre are described. On the basis of these concepts, several approaches that have been developed throughout the years are reported, together with their reach and (potential) impact on the general population. Finally, this chapter describes the general challenges of public health nutrition communication and presents potential future directions for this field.

The History of Public Health Nutrition Communication in the Netherlands

It is 1941. The Netherlands are at war, and professor Cees den Hartog is asked to become the director of the precursor of the Netherlands Nutrition Centre (hereafter referred to as “the Centre”): a nutrition education center fully funded by the government that aims to provide housewives with information about how to survive in times of food scarcity. Basic sustenance products such as milk and sugar are no longer available, and people have to resort to new and unusual products such as pea flour, sugar beet, and flower bulbs. The first activity of the Centre, therefore, is to organize food courses and cooking demonstrations to provide housewives with the practical skills to prepare these foods without food waste. This is urgently needed, because the total daily energy intake of inhabitants in cities such as Amsterdam dropped to less than 580 calories per day (Stein et al. 1975). In addition, the Centre also launches its first edition of the "Guidelines for Contemporary Nutrition." This booklet not only contains an explanation about the functioning of the human body, down to the cell level, but also provides information on the main function of the different macronutrients (i.e., carbohydrates, fat, and proteins) and micronutrients (i.e., vitamins and minerals). Finally, the booklet contains reference tables showing how many grams are needed of a particular nutrient in order to "close the gap between theory and practice." Throughout the years, this booklet is distributed among 100,000 housewives – a huge print run during that time (Bast 2014).

After World War II had ended in 1945, the context for public health nutrition changed rapidly. The country had gone through a period of reconstruction, and the food landscape transformed quickly under the influence of growing prosperity. Fat, salt, and sugar consumption were on the rise, and people started to adopt an eating pattern that was completely different compared to that of the beginning days of the Centre. The proportion of fat in people's daily dietary intake, for instance, increased from 30% to 40% between 1945 and 1960 (Bast 2014). Consequently, nutritional deficiencies were replaced with dental problems and overweight, and professor den Hartog concluded that something different was needed to convey nutritional guidelines in such a way that they were actually understood and used. After being exposed to the "basic seven food groups" developed by the US Department of Agriculture, he decided that a similar method was needed in the Netherlands, and in 1953 the first version of the "Wheel of Five," the primary nutrition education tool in the Netherlands, was launched. During these years, the Centre primarily educated the general population through leaflets, public lectures, movie nights, and radio spots, and the tone of the message was often didactic. One of the brochures of this time, for example, said: "we especially encourage those women living alone to no longer neglect one's nutrition as too many of you are still doing" (Bast 2014). In addition, fear-arousing communications consisting of a fear appeal that stressed the severity and personal risks of unhealthy eating were used. Between 1960 and 1970, the Centre started, for instance, to focus on the health risks of excessive sugar consumption, thereby showing images of rotten teeth with the message "exposure to sugar is harmful for your teeth" (Bast 2014).

In the early 1990s, the Centre changed its tone of voice. The idea of "good" and "wrong" foods was abandoned, and particular food products were no longer banned from current diets. Instead, the Centre started to communicate clearly that everyone was free to make their own choice and included the importance of consumers' total eating pattern, instead of focusing on specific choices, in its nutrition education communication. In 2000, the Centre and three other organizations merged into what is now still known as the Netherlands Nutrition Centre. Although the precursors of the Centre always called on the general population to change their behavior, this behavioral aspect – in addition to providing information and education – became more and more important in the next years. In line with this, the Centre's communication style changed from "sending the message" to a more stimulating and motivating way of communication. This shift is inspired by rapid advances in the research on the nonphysiological factors that might influence when, what, and how much people eat (Nestle et al. 1998; Story et al. 2002) and the rise of psychological health behavior models that focus on understanding and changing behavior, such as the transtheoretical model (Prochaska et al. 2002) and dual-process models of human behavior (e.g., Strack and Deutsch 2004). On the basis of these models, consumers are now inspired and motivated to eat healthily, safely, and sustainably, thereby taking into account the impact and role of the social and physical environment on their behavior.

Mission and Vision of the Netherlands Nutrition Centre

As of the "relaunch" in 2000, the Centre acknowledges that promoting health behavior can take place at different levels, including the micro level (the personal level), the meso level (the organizational and community level), and the macro level (the policy level) (cf. de Vries et al. 2018). The main aim of the Centre, therefore, is to encourage changes on all levels in order to support consumers to develop and maintain healthy and sustainable dietary intake patterns. At the micro level, the goal of the Centre is that people in the Netherlands are motivated to eat in accordance with the Wheel of Five and that they have the knowledge and skills to make healthy and sustainable food choices. In this context, health education is used as one of the strategies to inform and educate people about healthy and sustainable eating. At the meso level, the Centre strives toward a food environment that is arranged in such a way that healthy and sustainable food choices are available and accessible to everyone, thereby focusing on both the family context and schools, work sites, and other food environments. Further, the Centre supports health professionals (e.g., dietitians, physicians, teachers) with tools and advice regarding healthy and sustainable dietary intake patterns. Also at this organizational level, the retail sector, catering industry, food industry, and trade associations are advised on how to implement measures to reformulate foods and how to change the direct food environment to make it easier for consumers to adopt healthy dietary intake patterns. Finally, at the macro level, the Centre informs policy makers on strategies and approaches that governments can use to encourage consumers to change their dietary behaviors, including the implementation of front-of-pack labeling and bans on food-related marketing to children (cf. Mozaffarian et al. 2018)

The Wheel of Five: A Point of Reference for Healthy Eating in the Netherlands

As said, healthy dietary habits are important for maintaining good health and preventing diet-related chronic diseases. Strategies to promote a healthy diet include the development of food-based dietary guidelines. These guidelines provide practical advice to consumers on foods, food groups, and dietary patterns to provide the required nutrients, prevent chronic diseases, and promote overall health while considering culture-specific food preferences (EFSA 2010).

Based on an optimization model, scientific evidence, information on dietary patterns, and expert knowledge, the Netherlands Nutrition Centre and the National Institute for Public Health have derived specific food-based dietary guidelines for different target groups, visualized in the Wheel of Five (see Brink et al. 2019 for a detailed description of this development process). This model visualizes a recommended dietary pattern that offers the best possible combination of health benefits and nutrient provision, based on Dutch foods habits (Brink et al. 2017; see Fig. 1 for a visual illustration of the Wheel of Five).

This tool is the foundation for all nutrition education in the Netherlands. By now, the model has been updated six times after its first launch in 1953, and its most recent update is from 2016.

The Centre advises consumers to mainly eat foods from the Wheel of Five, to eat the right amounts from each segment (each day), to vary the consumption within the different food groups, and to limit the consumption of foods that are not part of the Wheel of Five (no more than 15% of the total energy involved). Foods that are not in of the Wheel of Five are divided in two categories: daily and weekly choices. The

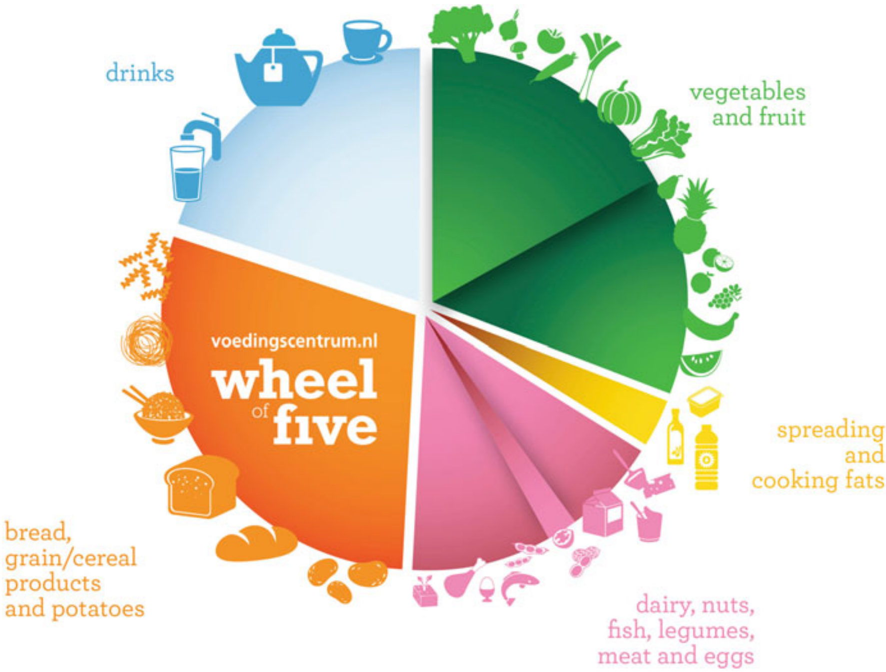

Fig. 1 The Wheel of Five: the practical information tool used by the Netherlands Nutrition Centre to give examples of healthy dietary patterns

advice is to consume no more than three to five foods or drinks from the daily food choices (e.g., light soda, small biscuit, a piece of chocolate) and no more than three foods or drinks per week from the weekly food choices (e.g., regular soda, sugary desserts, cakes, or large biscuits) (Brink et al. 2017). By alternating between food groups in the segment containing fish, pulses, meat, eggs, nuts, and dairy products, consumers can comply with the recommendation that they eat "more plant-based foods and fewer animal products."

A specific example of a recent change in Dutch dietary guidelines is that the fish recommendation has been reduced from two to one servings per week, with the explicit recommendation to consume only sustainably caught or cultivated types of fish. In the Netherlands, two out of three people consume less than one serving of fish per week (National Institute for Public Health and the Environment 2019). For health purposes, one serving per week versus no serving makes a big difference, but adding a second serving does not lead to significant additional health gains. Increasing to two servings, however, would place a heavy burden on sustainability. Thus, this updated recommendation gives sufficient health benefit and also contributes to sustainability.

The Main Concepts Involved in Public Health Nutrition Communication in the Netherlands

To address the public health issues related to poor dietary intake and to provide people with knowledge and skills to make healthy and sustainable food choices, the Centre employs different strategies and approaches. Firstly, elements of the intervention mapping protocol are used to gain insight into the main issues involved around eating and drinking and to outline the steps that can be taken to tackle the issues raised. Further, this approach makes it possible to identify the personal and environmental factors that determine individuals' dietary intake patterns (Kok et al. 2016) and translate theory into actual program materials and activities, following specific intervention matrices (Bartholomew et al. 1998). Following this protocol, the main concepts are explored to understand the target group's existing knowledge, awareness and risk perception, habits and impulsive behaviors, attitudes and beliefs, capabilities, self-efficacy, and intentions. Finally, it is explored whether and how social influences (i.e., social norms, social networks, and social support) may stimulate or impede behavior. Knowing the target audience and understanding their barriers to change also helps to develop messages and strategies that are personally relevant and that will resonate in ways that may lead to behavior change (Fitzgibbon et al. 2007; Viswanath and Bond 2007).

The past decade has seen a rapid increase in the use of storytelling to enhance health communication and promote behavior change (Robin 2006). In addition to more traditional approaches of information provision, the Centre also employs an information approach that is built on narrative storytelling. Within this context, the Centre uses the "touch-tell-sell" method. In the touch layer, the goal is to increase awareness by "touching" emotion. It is assumed that content that provides an emotional connection becomes more personally relevant. A mood-inducing film that touches upon the barriers people encounter when trying to eat healthier and the feelings that go along with this is an example of a "touching story." In the tell layer, it is about informing and inspiring people. Providing people with concrete advice which food choices they could make to improve their current dietary behavior is an example of this. In the sell layer, it is about motivating and seducing people to undertake real action, e.g., switching from sugar-sweetened beverage to water or from cake to banana. The use of engaging and transporting stories in health communication may be effective for various reasons: they may reduce resistance against behavioral change, facilitate processing of new and/or difficult information, produce cognitive and emotional effects that create stronger attitudes and intentions, and provide social connections and role models for behavior change (Green 2006; Kreuter et al. 2007).

Although public health nutrition education and communication have the potential to change individuals' behavior, it is also known that they can only have their impact if their message reaches the target population. Therefore, the Netherlands Nutrition Centre uses different communication channels to reach its target group. In the next section, the different communication channels that are used are described.

Communication Channels

Website

The Centre seeks to explain the relevance of scientific knowledge and translate it into easily understandable, balanced, and practical guidelines and advice. The website provides all the information and advice that is collected throughout the years and helps people the find the right information about healthy, safe, and sustainable eating. The website is updated daily and attracts more than 20 million visits a year, which is considerable for a country with 17 million inhabitants. The information that is available at the website focuses largely on the concepts of knowledge, awareness and risk perception, and capabilities and use strategies such as providing information, risk personalization, self-monitoring of behavior, guided practice, and action perspective.

Brochures, Books, and Leaflets

Since the early days of the Centre, books and brochures are important promotional documents that are used to inform people about healthy, safe, and sustainable eating. On average, more than 1.3 million brochures are distributed per year. These brochures contain specific information for specific target groups, such as (expectant) parents or people with overweight or diabetes. Although all brochures, books and leaflets can be ordered by consumers directly, the majority of brochures and leaflets are distributed through healthcare organizations or by health professionals, such as dieticians. The concepts that are most often targeted in these brochures and leaflets are existing knowledge and awareness, by providing readers with (new) information and action perspective. Finally, consumers are assisted through several books to eat more healthy and sustainable and develop and maintain a healthy weight.

Mass Media Campaigns

Mass media campaigns have long been used in the journey to improve public health. Although mass media campaigns are often not sufficient to initiate direct behavior change, they have shown to be effective in influencing potential mediators of change such as knowledge, attitude, risk perception, or social norms (Reid 1996). Further, they have the potential to promote public health by agenda setting and can be used as a powerful tool in broader health promotion strategies (de Vries et al. 2018). Throughout the years, the Centre has launched different media campaigns with the aim of agenda setting and creating awareness of a need to act (i.e., change). In 2002, for example, the Centre launched the "Maak je Niet Dik!" campaign: an initiative to promote prevention action on weight gain. This specific campaign had the goal to put weight-gain prevention on the public agenda and to induce more positive attitudes and intentions toward prevention of weight gain among consumers. An independent evaluation of this campaign showed that this campaign reached a large proportion of the population (i.e., 65% of the respondents was able to recall at least one campaign message) and led to more positive attitudes toward the prevention of weight gain, but was not strong enough to induce substantial changes in other predictors of behavior change, such as awareness of personal body-weight status or overweight-related risk perceptions (Wammes et al. 2005). This finding may be explained by the finding that respondents did not perceive a personal susceptibility to gain weight and therefore may not have experienced a personal need to change. One of the specific learnings after this campaign, therefore, was to improve the Centre's planning and testing of campaign content and format with the target audience.

Most recently, the Centre initiated the nationwide campaign "De Eetwissel," a campaign aimed at inspiring people to make small improvements in their current diet by switching from an energy-dense food product to a nutrient-dense product (i.e., from white bread to whole grain bread) and subsequently to eat more in accordance with the Wheel of Five. The campaign was launched in the first week of January, a period during which consumers are naturally inclined to form New Year's resolutions. These resolutions involve the development of self-initiated plans at the first day of a new year, which fitted well with the campaign aims. Behavioral determinants that were targeted in this campaign were knowledge, attitude, self-efficacy, and action planning. This campaign secured significant funding to enable frequent and widespread exposure to campaign messages on national television. The first two flights of the campaign reached 6.2 million people, including 4.2 million individuals with a lower education. Online and on social media, the campaign received a stunning number of 12.7 million views, once again indicating that the campaign had sufficient reach across the population. More importantly, however, campaign evaluations showed that a large part of the population had seen or heard and remembered the campaign message and reported an increased intention to make a daily "food switch" in line with the Wheel of Five. There is no information available on the impact of this specific campaign on actual consumption behavior. As yet, campaign effectiveness with regard to behavior change is unclear. Although isolation of the independent effects of mass media campaigns is difficult (Wakefield et al. 2010), the Centre has plans to carry out a yearly evaluation of the specific behavioral determinants (e.g., awareness, knowledge, and attitude) that are involved in consumption behavior (see also "Future Directions").

Social Media

In addition to more traditional communication channels, such as radio and television, social media channels are used as a mechanism for mass information dissemination and engaging audiences in conversations and interaction. Through social media, the Centre can target and reach a broader variety of audiences, in particular those who may prefer to receive nutrition information through these channels. Social media monitoring tools further allow the Centre to learn more about what diverse audiences are saying about health and nutrition and help to identify information gaps and adjust messaging accordingly. Likewise, by answering health-related questions and responding to comments, social media are a powerful tool for customer service. Finally, social media influencers help the Centre to drive online conversations on healthy and sustainable eating and increase social media engagement. In addition, these influencers help to promote messages and increase the Centre's reach of public health nutrition communication.

The Centre uses different social media channels to engage with consumers and professionals. Firstly, Facebook is used to inform and interact with professionals and consumers about (new) activities (102k followers). Secondly, Twitter is used to inform the general population about new activities and to interact with professionals and media (25 k followers). This is done by the corporate account but also by the individual accounts of the Centre's experts on health, food safety, sustainability, and behavior change (together more than 6k followers). Thirdly, Instagram is used to share food recipes and short videos with consumers (37k followers), whereas LinkedIn is used to update and interact with professionals (13k followers). Finally, the Centre has started a YouTube channel to produce and distribute video content (8k followers). This is important considering that a large percentage of the internet traffic will be for video in the near future. By now, the videos on this channel have more than seven million views.

mHealth: Mobile Applications

The quick growth of smartphones has led to a proliferation of smartphone software applications ("apps"). From a public health perspective, these apps can potentially enhance the delivery of health behavior change interventions to individuals (Hebden et al. 2012) and increase nutrition knowledge and support individuals in making healthy, safe, and sustainable food choices. The Centre has therefore developed and launched different applications that may support behavior change. These apps are often built on the concepts of self-monitoring of behavior, goal setting, and planning coping responses. The "Eetmeter" app (translated as "measure what you eat"), for instance, is a self-monitoring tool with which consumers can monitor their daily eating patterns. See Fig. 2 for a visual illustration of this application.

There are three monitoring elements: actual food intake, exercise behavior, and weight status (i.e., body mass index). Users receive feedback and advice on the nutrient and energy content of their tracked foods and the extent to which they eat in accordance with the Wheel of Five. Further, users receive personalized advice about how they could improve their eating pattern. By now, this app has been downloaded more than 1.5 million times and has more than 800 k regular users.

The "Eetmeter" app has recently been linked to an application with which consumers can compare products (i.e., branded items) on nutrients such as salt, sugar or saturated fat, or allergens, by scanning the barcode of the different products. This application is titled the "Kies Ik Gezond?" app (translated as "Do I choose Healthy Choice?" app). See Fig. 3 for a visual illustration of this application.

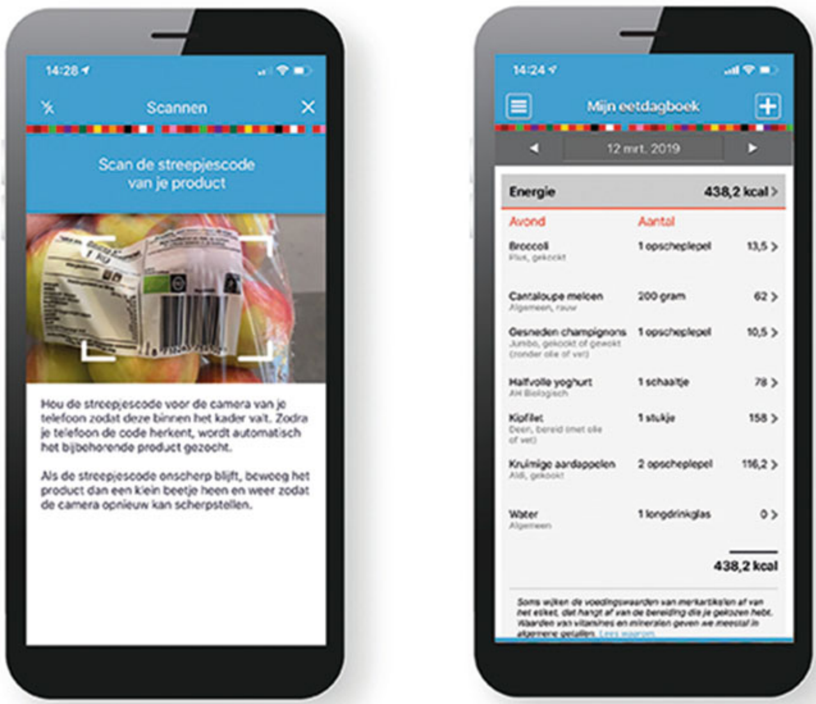

Fig. 2 A screenshot of the "Eetmeter" app.

Fig. 3 A screenshot of the "Kies Ik Gezond?" app.

With this app consumers can also search a food database that covers 90% of the product portfolio available in Dutch supermarkets and receive information on whether or not the product is included in the Wheel of Five. One year after its release, the app has now more than 200,000 downloads, with increased downloads every month.

Schools

One important setting to educate children, adolescents, and young adults about healthy and sustainable eating is the school context. The Centre is, therefore, involved in different initiatives that aim to positively influence children's nutrition knowledge and health behavior at school. First of all, the Centre contributes to the "Healthy Daycare" program: a practical method that supports childcare organizations to make a structural and integral contribution to good health and a healthy lifestyle in young children. Along the same line, the Centre plays an important role within "The Healthy School" approach: a national program that supports schools for primary, secondary, and vocational education in the education and monitoring of healthy behaviors in children. The materials and advice of the Centre help schools to develop effective policy with regard to health promotion and to create a school environment, both physical and social, that facilitates healthy eating behavior in children. Finally, the Centre has developed the "Healthy School Canteen" program: a school-based prevention program designed to create a healthy food environment and promote healthy food choices in secondary schools and schools for vocational training. This intervention entails a multicomponent strategy involving all parties: students, teachers, parents, school boards, canteen employees, municipal health services, and caterers (cf. Mensink et al. 2012). While completing the four steps of this program, schools are guided toward a healthy school canteen, a canteen in which between 60% and 80% of the visible assortment is in accordance with the Wheel of Five (Veldhuis et al. 2017). Between 2016 and 2018, the number of schools with a healthy school canteen according to the guidelines of the Netherlands Nutrition Centre increased from 78 to more than 500 schools. There is a rapid growth in the number of schools that have improved their assortment. To date, one out of four secondary schools in the Netherlands has an assortment that is in accordance with the guidelines, and the large majority of other schools are working on the implementation of these guidelines. Ultimately, the Dutch government would like to see all school canteens in the Netherlands become healthy school canteens. To help reach this goal, the Centre continuously informs schools about the healthy school canteen program and stimulates and motivates schools to improve their assortment.

In addition to these universal school-based prevention programs, the Centre acknowledges that nutrition education is a viable strategy to teach young people about nutrition and to provide them with skills to make healthy food choices (Contento et al. 1992). An example of such a program is "Weet wat je eet" (translated as "Know what you eat"): a free online learning package focused on healthy and sustainable eating aimed at students 12–15 years. The package consists of nine online lessons and one practical lesson about food temptations. Important elements are knowledge about eating in accordance with the Wheel of Five and one's energy balance. Information is transferred through interactive games and quizzes. During the lessons, specific health aspects of food are discussed, and students are encouraged to self-monitor their own eating habits. In addition, students learn to read and interpret food labels and make food preparations. Effect evaluations have shown that this program increases the nutritional knowledge of students, in particular of those with a lower educational level. To date, no information is available on whether this increased nutrition knowledge has translated into more positive eating habits. Here, the same issues apply as with the evaluation of mass media campaigns: it is rendered difficult for the Centre to independently assess the behavioral effects of a nutrition education program without tracking or monitor students' actual food consumption throughout the day. Within this context, the Centre is therefore focused on strengthening the collaboration with research scholars in the domain of health promotion to develop and evaluate nutrition education programs. Specific examples of programs that are already developed in such collaborative effort are "Smaaklessen" (translated as "Taste Lessons") aimed at children 6–12 years in elementary school and "Krachtvoer" (translated as "Power Food") aimed at adolescents 12–14 years attending preparatory secondary vocational education. These programs have been shown to increase children's knowledge and several other psychosocial determinants of healthy eating behavior (Battjes-Fries 2016) and had short- and longer-term favorable effects on adolescents' fruit consumption and snack choices (Bessems et al. 2012).

Challenges in Public Health Nutrition Communication

Reaching and Engaging Individuals Who Benefit Most from Nutrition Advice

By connecting both directly (via the website, social media, and apps) and indirectly (e.g., via healthcare professionals) with consumers, the Centre reaches many people throughout the population. An important challenge, however, is to have impact on those who might benefit most from nutrition advice, as there is evidence that preventive activities can have varying impact on different socioeconomic groups within a population. In particular, it has been shown initiatives that are primarily based on information provision are largely ineffective among those with a low socioeconomic position (Beauchamp et al. 2014). These differences are often explained by structural barriers such as neighborhood-related factors or limited financial resources but also because of the differences that exist among social classes in accessing, processing, and taking advantage of information and their capacity to act on it (Viswanath 2006). Communication inequalities in public health nutrition communication could therefore widen existing differences among social classes. Indeed, there is ample research that have linked low health literacy with lifestyle behaviors and health outcomes (DeWalt et al. 2004; Carbone and Zoellner 2012). Consequently, socioeconomic disparity in nutrition is well documented (Darmon and Drewnowski 2008), with nutrition literacy being an important factor accounting for differences in dietary habits.

The Netherlands Nutrition Centre has taken several steps to gain more and better insight into the specific strategies that can be applied to reach individuals with low health literacy skills and/or low socioeconomic position. First, readability assessments and screening tools are used to evaluate how current and future education materials match the literacy skills of the individuals targeted (cf. Carbone and Zoellner 2012). This is done in order to ensure that the Centre's information is available and understandable to all of those who need it, regardless of their social class, cultural, and individual backgrounds. Second, the Centre is involved in different national and local initiatives that pay attention to health-related socioeconomic inequalities. Here, evidence for and practice-based knowledge of tackling health differences are shared and disseminated within the own organization via an internal working group. Third, the Centre invests in research that aims to gain insight into the specific needs of those with a lower socioeconomic position with regard to nutrition information. On the basis of this information, the Centre tailors its education material to the specific needs of intervention recipients.

Despite these efforts, however, it should be acknowledged that improving health literacy and dietary behavior involves more than effective transmission of health and nutrition information. Thus, although nutrition knowledge is an important condition for adopting healthier eating patterns, it is usually an insufficient trigger for behavior change (Worsley 2002). If the ultimate goal is to eliminate health and nutrition disparities, we also need to focus on overcoming structural barriers to health. In this context, evidence-informed government nutrition policies are therefore recommended as an important step toward the reduction of dietary and health inequities (Mozaffarian et al. 2018).

Achieving Sufficient Exposure for Public Health Nutrition Communication in Today's Food Environment

An important factor in determining the success of public health nutrition communication is exposure. If the intended audience does not frequently hear or see the communication message, then there is limited probability that the message will lead to any changes in the behavior of interest. Within this context, it must be acknowledged that there is huge difference in resources between public and private sectors that they can provide to develop and deliver strategies to have an impact on nutrition behavior. The food industry spends billions of euros on creative and pervasive advertisements to encourage the purchase and consumption of their foods. The marketing of energy-dense foods and beverages, in particular, is widely recognized as contributing to an obesogenic environment for children and adults. Within this context, the public sector has to compete with highly constrained budgets with specific health-related messages, such as the potential health benefits of healthy eating. Promoting such positive outcomes is rendered difficult as it has fierce competition to gain consumers' attention, processing capacity, and willpower. Moreover, these positive outcomes are weighed heavily against other motives such as taste, price, and convenience (Verbeke 2008).

Trustworthiness of Public Health Nutrition Communication

Similarly, the number of dietary behavior-related messages that reach consumers in today's media and communication environment is overwhelming. One of the most influential factors that can impact message reception is the extent to which the target audience perceives the source and message as trustworthy. There are several examples of how the trustworthiness of public health nutrition communication could be affected. Firstly, there are several examples within the literature about how financial interests may have influenced scientific findings. For example, there are concerns about biases introduced by industry funding with regard to calorie control, physical activity, and sugar-sweetened beverage consumption (Nestle 2016). As a result, an increase in the public's confusion about nutrition and appropriate dietary choices may arise (Hornik and Kelly 2007). Secondly, growing numbers of individuals, both health professionals and lay people, have created food and nutrition blogs, websites, and videos and are using (social) media to promote books or others products, attract new clients, and build networks. These individuals may all have different interests in providing nutrition information and may introduce confusion about the concept of "healthy eating." If these food-related debates receive widespread media attention, then it is highly likely that it leaves the general public with the impression that public health nutrition communication is full of inconsistencies and that nutrition messages are contradictory, are confusing, or lack clear personal benefit. This misinterpretation fuels confusion, which may prevent consumers from adopting better eating habits (Miller et al. 2006). The challenge of nutrition centers, therefore, is to strategically position itself in this playing field and keep up with the latest food trends and hypes and appeal to the needs, expectations, and interests of the general population, without losing its trustworthiness and scientific credibility. Before designing a health message or media campaign, the Netherlands Nutrition Centre therefore always invests in becoming knowledgeable about the target audience. For this aim, the Centre conducts literature searches, surveys or interviews, focus groups, or pretests to gain insight in the target group's determinants of nutrition behavior. This helps to tailor the communication style toward the consumers' needs and expectations.

Integration of Health and Sustainability in Public Health Nutrition Communication

Sustainable dietary guidelines are more and more seen an essential part of a coherent twenty-first-century food policy. They provide an essential first policy step, a clear steer on how people should and could be eating at population level (Mason and Lang 2017). Although there is still debate about the sustainability issues to be included (beside greenhouse gas emissions and land use, Van Dooren 2018) and the implementation of new calculation methods to combine nutrition, environmental impact, affordability, and preferences (Van Dooren 2018), the main issues to be addressed are clear. Willet et al. (2019) demonstrated that a change in diet – more plant-based, with lower environmental impacts, and with halve the food waste – is necessary to feed in 2050 ten billion people with a healthy diet within the planetary boundaries. As a result, various European countries (e.g., Finland, Sweden; the Netherlands; Belgium, the UK, Estonia) and also Canada have started to integrate sustainability principles into their dietary guidelines. This approach was backed up by scientific background reports of different regional or national health authorities (e.g., Norden 2014; Health Council of the Netherlands 2011). In other countries, sustainability principles were considered but ultimately not included (Australia, the USA) (Gonzalez Fischer and Garnett 2016). The key dietary sustainability messages that emerge from evidence and dietary guidelines are, for instance, consuming a primarily plant-based diet, reducing meat consumption, and consuming seasonal field-grown fruit and vegetables (cf. Seed and Rocha 2018). At the level of the consumer, the required change in dietary intake pattern asks them to adapt their current eating behavior, both at a conscious and at a habitual and automatic level. Hence, nutrition-related messages will have to be developed in ways that guide consumers toward a healthier and more sustainable eating pattern, preferably in the context of a step-by-step approach to change decisions at the level of meals and snacks. Although it may not yet be clear what health and sustainability information has to be provided to effectively stimulate the required changes, it is crucial not to overload consumers with written information related to the food-environment issue. Instead, these strategies should combine multiple-food-related values that consumers can easily identify with and pay attention to the whole diverse range of consumers and their dietary choices (cf. de Boer et al. 2014). Altogether, there is thus a direct challenge for public health nutrition communication to increase consumer knowledge of the interplay between health and sustainability and stimulate the needed changes in intake patterns.

Future Directions

Extending National Food Consumption Surveys with the Assessment of Behavioral Determinants

In many countries, national food consumption surveys are conducted. Food consumption data give insight into the consumption of foods, the intake of macro- and micronutrients, and the development of food and nutrition trends (Ocké et al. 2005). This insight is important for formulating and evaluating food policy. In addition, these data can be used for public information purposes and scientific research. We propose to extend these consumption surveys with questions that give more insight into consumers attitudes related to nutrition, health and sustainability, as well as other behavioral determinants of food choice and intake behavior. This makes it possible to annually assess concepts such as nutrition knowledge and literacy, awareness and risk perception, attitudes, beliefs, risk perception, self-efficacy, perceived barriers, and social norms related to food consumption. The assessment and monitoring of these behavioral determinants could provide nutrition centers with further insight into the short- and long-term effectiveness of its communication efforts and help to elucidate which concepts related to nutrition, health, and sustainability should be targeted in future initiatives. Altogether, this will help to develop messages that are supported by behavioral and health communication theory and that will further encourage consumers to initiate and maintain healthy and more sustainable dietary choices.

Joining Forces Across Countries

In many countries, there are independent organizations that are responsible on the country level for nutrition and health education. In some of these countries, the development of guidelines and nutrition education happens ad hoc, for instance, by a committee of experts. To enhance learnings on nutrition education between countries, the *European Public Health Nutrition Alliance* (EPHNA) was set up in 2014. The EPHNA is a network of European Nutrition Centres, independent organizations that are responsible for nutrition and health communication on a national or regional level. To date, the network has 15 members, and it is continuously growing. The network has the support of the World Health Organization. Member countries have very similar tasks and responsibilities and share their insights and materials on themes such as nutritional guidelines and criteria for school meals. All of the organizations have many projects that inspire others and give them opportunity to learn and work together on many different levels. The EHPNA wants to expand its network and become the leading partnership on nutrition communication between European countries. Funding of cross-country structures is likely to increase efficiency in public health nutrition communication, as it will lead to all Europeans being provided with the most adequate information on nutrition. Structures like EPHNA are recommended especially for continents where not all countries have guidelines yet and where the nutrition transition is happening quickly, such as Africa and Asia.

Political Commitment for a Systems Approach to Prevent Malnutrition in All Its Forms

Malnutrition is the leading contributor to the global burden of disease (WHO 2017). Recognition of the need to address the common drivers of undernutrition, obesity, and climate change has therefore become a key focus of the Lancet Commission on Obesity. As a result, ending "malnutrition in all its forms" has become a high-profile global ambition (Swinburn et al. 2019). If we aim to prevent and reduce the current increase in malnutrition (FAO et al. 2019), then the focus must be on the food supply and improving the quality of diets while reducing total energy intake (cf. Popkin et al. 2012). This asks for evidence-based evaluated programs and policies that go beyond the individual level but also take social contexts such as public policy, industry practices, and the immediate food environment into account. Although some countries are making steady progress in tackling the issues related to malnutrition, the large majority of countries fall short in governance, policy, and program responses (WHO 2013). One potential reason for the difference in countries in terms of success is the extent to which important stakeholders within those countries are willing to act and to keep on acting to attenuate the drivers and manifestations of malnutrition. Without such a commitment, policies, programs, and resources needed to improve nutrition and generate environmental benefits are unlikely to be adopted, effectively implemented, or sustained. A systems approach, as a promising example, is a method for informing action including policy development, program design, implementation, and governance (Swinburn et al. 2019). Within this context, behavior change communication has been proposed as a necessary complement to direct changes to the food systems and environment, as it enables individuals to respond to these changes (Hawkes et al. 2013). Governments (top-down) and municipalities (bottom-up) both can play an important role in public health nutrition communication, by further implementing national food-based dietary guidelines, and implement effective preventive and interventive efforts to reduce overweight and obesity. In line with the NOURISHING framework, then, it is important to provide individuals with evidence-based nutrition information and stimulate nutrition literacy through nutrition education (Hawkes et al. 2013). Specifically, public health nutrition communication plays a crucial role in increasing public awareness about the beneficial health effects of good nutrition.

Conclusion

Since the launch of the Netherlands Nutrition Centre, eight decades ago, public health nutrition communication has seen huge progress. In the last century, nutrition science focused first at foods, then nutrients, and now back to foods and food patterns. Also, focus on health is extended with sustainability. Public health nutrition communication had to keep up with these rapid changes in nutrition science and take people through these changes. From an approach largely focused on the passive transfer of information at the individual level, the Centre moved to stimulating and motivating behavioral change communication as a complement to changes to food environments and food systems. Step-by-step food-related behavior change processes are unraveled, and trigger points for action are identified.

A key challenge in nutrition communication is to reach and engage the individuals who benefit most from better nutrition. There are huge health and lifestyle differences between socioeconomic groups, and public health communication inequalities could widen these existing differences among social classes in the adoption and maintenance of a healthful diet. Public health nutrition communication must pay close attention to such inequalities and reflect the particular needs of specific groups of individuals, resulting in communication campaigns in nutrition that are beneficial to all groups in society. This asks for a continuous evaluation of the tone of voice of communication. A further challenge is to integrate health and sustainability in public health nutrition communication. The big opportunity for nutrition communication in the next decades is to capitalize on the growing consumer interest in food and health and turn this into behavioral change. To increase the impact of nutrition communication on people's diet, a good exposure to credible and practical dietary advice is required. In today's food and media environment, with high availability and heavily advertising of unhealthy foods and opposing diet-related messages, this requirement is not always fulfilled. Finally, joining forces across countries in public health nutrition communication is relevant to speed up progress and increase impact.

32 Sensory Responses in Nutrition and Energy Balance: Role of Texture, Taste, and Smell in Eating Behavior

Kees de Graaf

Contents

Abstract

Billions of people, almost 40% of the world's population, are either overweight or underweight, which is a direct consequence of the food environment. In more and more countries in the world, people are overweight in a large part due to the obesogenic food environment. The obesogenic food environment leads to an overconsumption of energy; it is obvious that sensory characteristics of food have a tremendous impact on food choice and intake. The chapter deals with the effects of texture, taste, and smell on intake. The effect of texture on energy intake is dramatic. Liquid and soft foods are consumed at much higher rates compared to more harder foods. The energy intake rate of energy dense liquids (like sugar

sweetened beverages) and soft solids (like cake, sausage roll, minced meatball) is in the range of 150–450 kcal/min, quickly leading to overconsumption of energy. Liquid and soft solid calories are not well sensed by the sense of taste, due to their short oro-sensory exposure time per kcal ingested. Various recent studies show that across the food supplies in Australia, Malaysia, the Netherlands, and the USA, sweetness, umami, saltiness, and fat sensation intensities relate to concentrations of carbohydrates, protein salt, and fat in food. So, taste serves as nutrient sensing system, and this sensing system contributes to satiation. The role of smell is different. Retronasal smell sensations coming through flavors within foods do not have an impact on satiation; odors in the environment may lead to sensory specific appetites. In summary, sensory signals from foods have a large impact on energy intake, and designing foods in an optimal way leads to a higher satiating efficiency per kcal, while maintaining palatability. In this way we can make the healthy choice the happy choice.

Introduction

One of the biggest nutritional problems in the world is obesity. For a number of years, the prevalence of obesity has surpassed the issue of undernutrition. Globally, more than 820 million people remain undernourished, whereas more than 2 billion people are overweight or obese (Willett et al. 2019). The global prevalence of diabetes, which is strongly associated with obesity, doubled in the past 30 years. Prevalence of overweight and obesity varies greatly between countries with highest prevalence in the South Pacific and the USA and lowest prevalence in South Asia and sub-Saharan Africa (Abarca-Gómez et al. 2017).

Before the 1960s it was thought that obesity was a metabolic or neurobiological disorder and that the cure or prevention of obesity was a matter of medical treatment of adjusting circulating levels of appetite and satiety hormones or repairing the hypothalamus. Since the paper of Schachter in 1968 (Schachter 1968), it has becoming increasingly obvious that the food supply in the world around us plays an important role in overeating. First it was thought that only obese people were sensitive to external signals from the food environment (Schachter 1968); later it became apparent that most humans, both normal weight and overweight people, eat differently in different eating environments (e.g., Rodin 1981; Swinburn et al. 1999).

The increasing prevalence of obesity and overweight is caused by changes in the food environment resulting in modifications of eating behavior. In general for optimal health, people eat too little fruits, vegetables, legumes, nuts, whole grains, and fish, whereas they consume too much animal source products, added sugar, saturated fats, refined grains, and so-called highly processed foods (Willett et al. 2019). In the last few years, there is also an increasing attention to the consumption of so-called “ultraprocessed” foods and its association with the prevalence of obesity (Schnabel et al. 2019). The definition and usefulness of this concept are strongly debated (Gibney et al. 2017). However, in the context of this narrative, there is a strong societal pressure to decrease salt, sugar, and fat levels in foods. This makes the issue of obesity and the regulation of appetite also a sensory science issue.

Fig. 1 Two meals of 1675 kcal: the left-hand side meal is with high-energy-dense foods and the right-hand side is with low-energy dense foods. (Courtesy of The Laboratory for the Study of Human Ingestive Behavior at The Pennsylvania State University, Director: Barbara J. Rolls, PhD)

The satiety literature shows that there are dramatic differences in the satiating capacity of foods. For some foods, it is very easy to overeat, whereas from others it is much more difficult. While for some diets people may have real difficulties to ingest enough calories for energy balance, for most diets in the current food environment, it is very easy to overeat. One of the most important properties of food that is related to overeating is the energy density of foods. Figure 1 gives one picture with two meals by Barbara Rolls, Penn State University, USA. Each meal contains 1675 kcal, on the left with high-energy-dense foods and on the right with low-energy-dense foods. Almost everyone will intuitively understand that the satiating capacity of the left meal is considerably smaller than the satiating capacity of the meal on the right-hand side.

In an unprecedented series of carefully designed studies, Barbara Rolls and colleagues showed how crucial energy density is in moderating daily energy intake (e.g., Rolls 2009, for a review, and the chapter by Rolls, this Handbook on portion size). Energy density is probably the most important food characteristic that affects energy intake and energy balance, and for an overview of this work, the reader is referred to papers of the Rolls ingestive behavior lab (Rolls 2016). This chapter does not deal with energy density, but with texture, taste, and smell. However, it may be good to realize that when energy density is cut by a factor of 2, the weight and sensory exposure per kcal ingested is doubled (e.g., Bell et al. 2003).

Figure 2 shows a version of the satiety cascade of Blundell et al. (2010). In this cascade, one makes a distinction between satiation, i.e., the processes that bring a meal to an end, and satiety, the absence of hunger in between meals. From this figure it is clear that sensory and cognitive factors mainly play a role around the time of eating. Sensory factors like taste and smell are operational during eating and less so in between eating occasions. From that perspective it may be expected that sensory factors have larger role on satiation than on satiety.

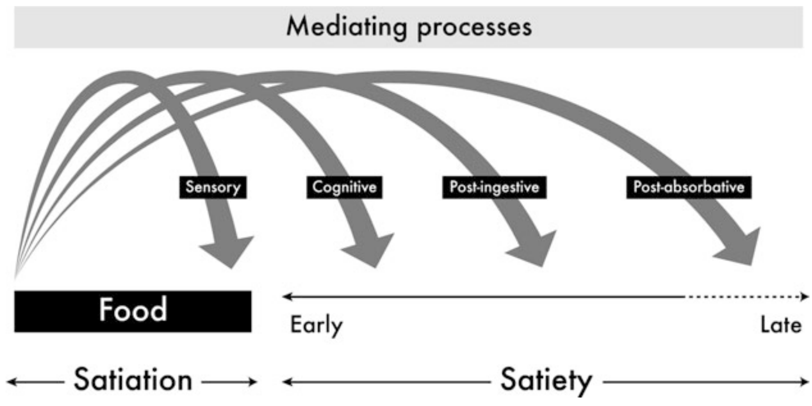

Fig. 2 Satiety cascade John Blundell, referring to different phases, influences on satiation and satiety. Satiation refers to processes that bring a meal to an end; satiety refers to the absence of hunger in between meals. Sensory, cognitive, postingestive, and postabsorptive factors refer to different physiological and psychological processes involved in eating. From this cascade, it is clear that sensory processes are mainly operational around the time of eating

This chapter deals with the role of texture, taste, and smell in food intake. First, the role of texture is discussed. There is a large body of literature that shows that texture has a dramatic impact on satiation (=meal termination), but also on satiety and subsequent energy intake compensation. The section on taste deals with the role of taste in dietary patterns across the globe, but also with its role in satiation and the regulation of food intake. Finally, the role of smell is discussed, both as a property of food and also as a characteristic of the ambient environment. The discussion is focused on what we know and do not know in this area and possible future direction of research both from a more societal perspective and from a fundamental science point of view.

Role of Texture in Food and Energy Intake

Texture and (Expected) Satiation

Texture has a strong effect on satiation, ad libitum food intake, i.e., people get a meal with plenty of food, and they can eat as much or as little as they want. By measuring ad libitum food intake, one measures satiation or meal termination (see Blundell et al. 2010). The softer a texture becomes, the more people eat. People consume more from liquids than from semisolids or solids. This was became clear for the first time from a study of Zijlstra et al. (2008), where people consumed on average about 800 g (30% more) of a liquid chocolate milk, compared to about 550 g from a semisolid chocolate custard with the same energy density, macronutrient composition, and palatability. Four years later, Hogenkamp et al. (2012) obtained a similar result with liquid and semisolid yogurts, where the intake of the liquid was about

30% higher compared to the semisolid (Hogenkamp et al. 2012). In a later study of Lasschuijt et al. (2017), it was observed that the ad libitum intake of a soft model food was about 30% higher than the intake of harder foods matched for energy density and palatability. McCrickerd et al. (2017) also showed that people consumed about 10% less from a thick porridge compared to a thin porridge with equal palatability ratings at each of two levels of energy density.

It should be acknowledged though that one needs certain differences in texture to produce differences in satiation. In the study of Zijlstra et al. (2010) with soft and harder version of three solid savory foods (luncheon meat, meat replacer, and candy), there were no differences in ad libitum intake. Apparently the differences were too small to result in changes in intake.

Hogenkamp et al. (2011) varied the texture and flavor of various dairy products, and they observed that variation in texture produced much stronger effects in expected satiation than variations in flavors. Changes in texture from liquid to more solid versions of the same product produced large differences, whereas changing the flavor from a typical fruity flavor (lemon; low-energy density) to a more creamy flavor (merengue; high-energy density) did not have an effect (Hogenkamp et al. 2011). McCrickerd et al. (2012, 2014) also showed that slightly viscous thicker drinks enhanced the expected satiety compared to slightly thinner drinks.

Texture and Satiety, Subsequent Energy Intake Compensation

Mattes was one of the first scholars to show that liquid foods have a weaker satiating capacity than solid food (Mattes 1996, and see also ▶ Chap. 33, “The Role of Eating Frequency and Snacking on Energy Intake and BMI” by Mattes, this Handbook). Later, this was confirmed again and again. A comprehensive systematic review of preload-test meal studies by Almiron-Roig et al. (2013) showed that liquid preloads lead to less energy intake compensation than semisolid or solid preloads, showing that liquids have a weak satiety effect. One of the most impressive studies in this respect is the study from Cassady et al. (2012), where subjects consumed solid and liquid preloads after which they were served an ad libitum test meal. Additionally, they were told that the preload would either be liquid or solid in the stomach. Both the real solid versus real liquid and the belief, expectation that the food would be solid in the stomach led to higher satiety rating and lower intake in a subsequent test meal (Cassady et al. 2012).

The notion that liquids and solids have different satiating effects, not only after one time but also after repeated exposure, was also elegantly shown by DiMeglio and Mattes (2000). Four weeks of consuming a liquid form of carbohydrates (soda) did not lead to energy intake compensation and led to a higher body weight, whereas 4 weeks of consumption of the same carbohydrate, but then in solid form (gel), did lead to energy intake compensation and a stable body weight (DiMeglio and Mattes 2000).

The relevance of the weak effects of liquids on satiation and satiety for nutrition and obesity is paramount. There is a large body of literature that shows that the consumption of sugar sweetened beverages leads to obesity, both from long-term experimental clinical trials (e.g., Rogers et al. 2016) and from observational prospective cohort studies (e.g., Malik et al. 2010). The Dutch Health Council is one of the first public health institutes to recommend minimizing the intake of sugar sweetened beverages, not only soft drinks but including fruit juices (Kromhout et al. 2016).

The Role of Eating Rate and Oral Processing Characteristics in Satiation and Satiety

The effects of texture on satiation and satiety are abundantly clear. One of the principle questions is the biological mechanism behind the weak satiety effects of liquid calories. The evidence suggests that eating rate has a big role in this effect. In the study of Zijlstra et al. (2008), liquid chocolate milk led to a 30% higher ad libitum consumption compared to a semisolid chocolate custard. The chocolate milk was consumed much faster than the chocolate custard. When the eating rates were made equal, this difference between the ad libitum intake of the liquid and the semisolid disappeared. In a subsequent study Hogenkamp et al. (2010) manipulated the mode of consumption, consuming liquid yogurt either with a straw (faster) or with spoon (slower). It was observed that eating liquid yogurt with a spoon led to lower eating rates and ad libitum intake than consuming the liquid yogurt with a straw, not only once but ten times in a row at breakfast (Hogenkamp et al. 2010).

The results of other studies reinforce the idea that eating rate is an essential variable in the satiating capacity of a food. Viskaal-van Dongen (2011) showed across a sample of more than 40 foods that eating rate predicted ad libitum food intake (Viskaal-van Dongen et al. 2011). A systematic review by Robinson et al. (2014) confirmed the idea that eating rate, manipulated in various ways, is positively related to energy intake.

Recently, van den Boer et al. (2017) published a paper with the eating rates of more than 250 regularly consumed Dutch foods. She observed that the energy intake rate could vary between 0 kcal for water, diet drinks, and more than 400 kcal/min for sugar sweetened beverages like apple juice and full-fat chocolate milk. Examples of solid foods with a high-energy intake rate were products like meatballs, sausage rolls, cake, and soft cookies which were consumed at rates of more than 200 kcal/min. This would imply that eating 10–15 min from such product is enough to cover the regular energy needs for a day. Table 1 gives the top ten foods and drinks in kcal/min in the Netherlands. The energy intake rate may be considered as a measure for the obesogenic capacity of a food.

Another piece of evidence in the direction that eating rate is important in the satiating capacity of foods and drinks is the notion that soup is a satiating liquid. Soup, a liquid which is normally eaten with a spoon, has a much lower eating rate than liquids that are usually drunk (Viskaal-van Dongen et al. 2011; van den Boer et al. 2017). In a study of Mattes (2005), apple soup was equally satiating to apples and much more than apple juice. The finding suggests that cognitive factor and oral processing characteristic play a role in this effect. Extensive studies by Forde et al. (2013, 2017, see also ► Chap. 35, “The Impact of Eating Rate on Energy Intake,

Table 1 The top ten beverages and solid foods in the Netherlands in terms of energy intake rate (=kcal/min). (Source: van den Boer 2017)

	kcal/min
Liquids	
1. Full-fat chocolate milk	471
2. Breakfast fruit drink	330
3. Apple juice	297

Body Composition, and Health" by Forde's, this Handbook) for European and Asian foods suggested that oral processing characteristics like time of food in the mouth and number of chews per gram/kcal were positively correlated with measures of expected satiety/satiation. A recently comprehensive published systematic meta-analysis of Krop et al. (2018), on oral processing and appetite and food intake, confirmed that the number of chews and longer time of food in the mouth leads to earlier satiation. The oro-sensory exposure time of food in the mouth is directly and linearly related to the duration of the exposure to taste. The role of taste exposure in satiation is discussed in the next section of taste.

Role of Taste in Food, Energy Intake, and Weight Status

Taste Space of the Food Supply

In the last 5 years, three groups worked independently on the taste profile of whole diets, one in Australia (Lease et al. 2016), one in France (Martin et al. 2014), and one in the Netherlands/Malaysia (Teo et al. 2018). They did this by profiling hundreds of commonly consumed foods that were more or less representative for the consumption patterns in these countries. Figure 3 shows the results on the taste space in three dimensions from the study of Martin et al. (2014) in France. The studies in the Netherlands and Australia yielded similar taste configurations.

From Fig. 3, it is clear that the main taste distinction across the food supply is the sweet-savory/salty dimension. The fat sensation (not fat taste, see below) dimension is orthogonal on the sweet-savory/salty dimension, indicating that both sweet and savory/salty can be easily combined with fat sensation. Bitter-sour tastes are more articulated in the third dimension.

As the legend of Fig. 3 shows, the grouping of foods into taste clusters in the French database yielded (1) savory/salty/fatty, (2) sweet, (3) sweet/sour/bitter, (4) bitter, (5) salty/umami/sour/bitter (condiments, sauces), and (6) salty foods/drinks. In comparison, Teo et al. (2018) in the Netherlands also got six taste clusters, (1) neutral, (2) sweet/sour, (3) sweet/fat, (4) savory/salty/fatty, (5) bitter, and (6) fatty. The difference between the two clusters may come through the way of data collection. Martin et al. (2014) used foods as consumed in the home of consumers (bread with spread, rice with sauce); Teo et al. (2018a) mainly profiled single frequently consumed foods (e.g., bread without spread; rice without sauce) that encompassed >80% of the regular energy intake in the Netherlands. The Dutch taste database included a category of frequently used butters/margarines, which make up the fatty cluster.

Taste as a Nutrient-Sensing System

In textbooks, the taste systems referred to as a nutrient-sensing system. Sweet signals the presence of energy/carbohydrates in foods, salt intensity represents sodium concentrations, umami may be related to the protein content of food, and sour and bitter relate to the PH and the concentration of potentially toxic substances. Since a number of years, it is also clear that free fatty acids have a taste signalling function (Keast and Costanzo 2015; Running et al. 2015), not to be confused with the fatty, smoothing mouthfeel properties of triglycerides.

The three groups that constructed the taste databases also investigated the relationships between the taste intensity and nutrient concentrations within more or less representative food supplies in various countries, i.e., Australia (Lease et al. 2016), the Netherlands and Malaysia (Teo et al. 2018a), France (Martin and Issanchou 2019), and the USA (van Langeveld et al. 2017). Table 2 summarizes some of the correlation coefficients as found in these studies. This Table shows that sweetness intensity does *not* signal the energy content of foods, but it does correlate with the carbohydrate content across the food supply. As hypothesized, umami intensity relates to the protein content, salt intensity relates to the sodium concentration, and fattiness/fatty mouthfeel (not fat taste) is associated with the fat content of food. As one might expect, this is not a one-to-one relationship but a fuzzy association that depends on the structure of foods, the presence of taste, and other confounding factors. However, these data do confirm that taste intensity is related to the nutrient content in representative food supplies across the world.

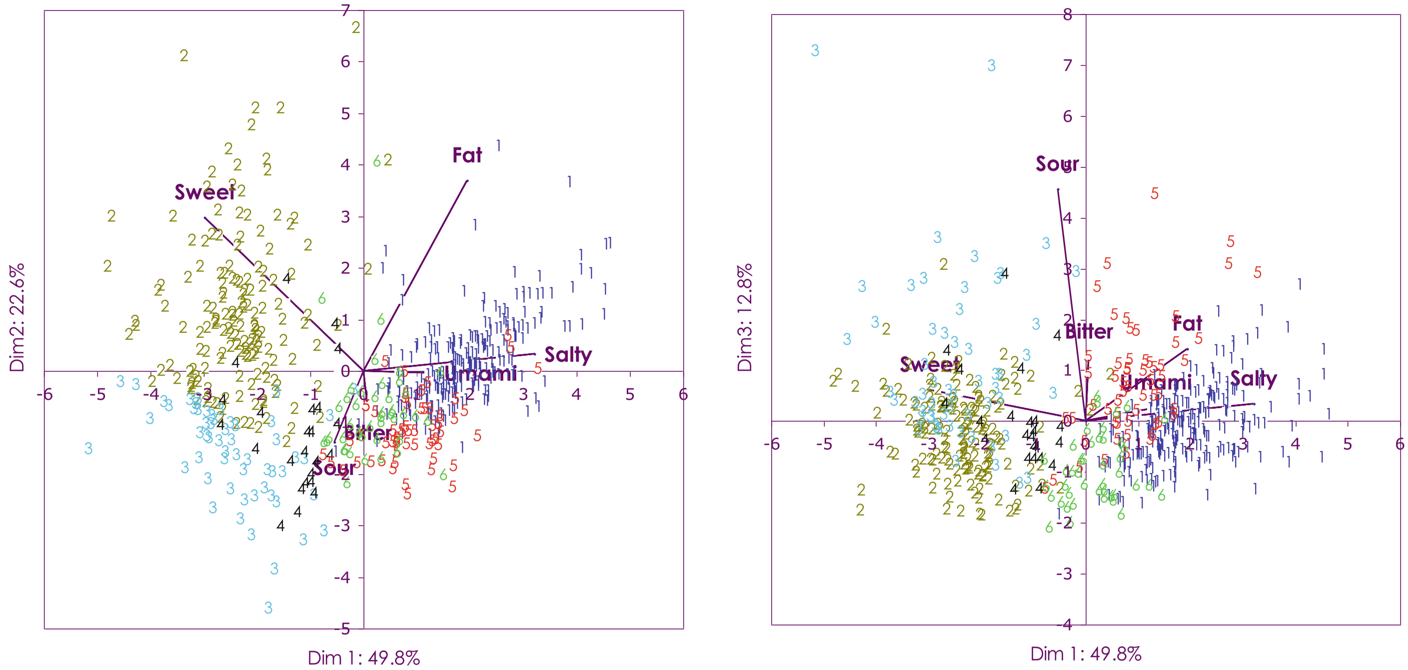

Fig. 3 Biplot representations from covariance PCA of 590 food means (planes 1–2 and 1–3). Twelve trained panelists rated at least 75 food items per month for a period of 8 months. The numbers in the figures refer to six different taste clusters: 1, more salty/umami/fatty and less sour/bitter/sweet foods, compared to the average; 2, sweeter than the average and less intense for other tastes; 3, sweeter than average foods, which, unlike the food in Class 2, were also more bitter and sour than average; 4, mainly bitter; 5, more intense saltiness, umami, sourness, and bitterness than average; and 6, salty foods. (Source: Martin et al. 2014)

Table 2 Correlation of taste intensity with nutrient concentrations in various representative food – databases across the world. (Source: Lease et al. 2016; Van Langeveld et al. 2017; Teo et al. 2018b; Martin and Issanchou 2019)

	N foods	Sweet – energy	Sweet – CHO	Umami – PRO	Salt – sodium	Fat sensation – fat
Australia	377	−08	41	27	64	65

Malay	423	04	33	51	52	42
France	≈350	−11	57	62	77	72

Taste Patterns, Preferences and Energy Intake, and Weight Status

Following up on the previous paragraphs, one might expect that a substantial part of our energy intake comes from foods with a dominant sweet, salty, savory taste, and/or a fatty mouthfeel. This is indeed what van Langeveld et al. (2018) and Teo et al. (2018) showed in an analysis of taste consumption patterns in the Netherlands and Malaysia. They observed that more than 50% of the energy intake comes from sweet, savory, and fatty tasting foods, both in the Netherlands and in Malaysia.

One of the popular narratives in the public health debate is that consuming (too much) sugar/sweetness makes you fat. One should lower the sweetness/sugar levels in foods, as this will lead to a lower sweetness preference, a lower sugar intake, a lower energy intake, and in the end a lower body weight. The idea of the adjustment of taste preferences to exposure levels comes from the early work with salt by Bertino, Beauchamp, and colleagues in 1980s, who showed that the long-term exposure to a low-salt diet leads to lower optimal levels of salt in foods (Bertino et al. 1982, 1986). However, it is questionable whether or not this also applies to sweetness. In a recently published study from Wise et al. (2015), one experimental group was exposed to a low sweetness/sugar diet for a period of 4 months. The results showed that optimal preferred sweetness levels did not change (Wise et al. 2015). A similar conclusion was reached by a systematic review/meta-analysis of Appleton et al. (2018) on the effect of repeated exposure to sweetness on generalized preferences for sweetness. This field needs further attention.

Another narrative is the sweet tooth hypothesis for obesity. Sweetness signals energy; obese people consume more energy, which is caused by a higher consumption of sweet foods, driven by a higher preference for sweet foods compared to normal weight people. The results in Table 2 show that sweetness does *not* signal energy. Saltiness and fattiness have much higher correlations with the energy content than sweetness (Lease et al. 2016; Teo et al. 2018b; Martin and Issanchou 2019).

The idea that obese people have higher preferences for sweet foods or higher sweetness levels in food is also a myth. Already from the early 1980s onward, there have been studies showing that preferences for sweetness are similar for obese and normal weight people (e.g., Frijters and Rasmussen-Conrad 1982; Alexy et al. 2011; Hill et al. 2009; Bobowski and Mennella 2017; Deglaire et al. 2015). A recent study of van Langeveld et al. (2018) demonstrated that overweight and obese people also do not consume more sweet tasting foods than normal weight people.

With respect to taste preferences, taste intake patterns, and obesity, there is more evidence for a heightened liking and intake for savory, salt, fatty foods than for sweet. The narrative review of Cox et al. (2016) suggests that there is some evidence for a heightened fat preference in overweight and obese people compared to normal weight people. This finding is in line with the work of Deglaire et al. (2015) which showed that French obese/overweight people have higher preferences for salty/savory/fatty foods. This is also congruent with the findings from Van Langeveld et al. (2018), who observed that Dutch overweight/obese people have a tendency to consume more salty/savory fatty food compared to normal weight people.

The Role of Oro-sensory Exposure Time to Taste in Satiation

From the studies cited under the section of texture, the eating rate and oral processing characteristics like time of food in the mouth, chews/per gram, or kcal of food have a strong effect on satiation and food intake. Holding food in the mouth for longer time or chewing more leads to lower intakes (e.g., Zijlstra et al. 2009). One pertinent question in this discussion is what type of signalling is responsible for this earlier satiation.

Two studies (Weijzen et al. 2009; Bolhuis et al. 2011) looked at satiation as an effect of oro-sensory stimulation with taste while keeping eating rate constant. Weijzen et al. (2009) did a study with sweet lemonades, and Bolhuis et al. (2011) did a study with salty tasting tomato juice. Figure 4 summarizes the results of these

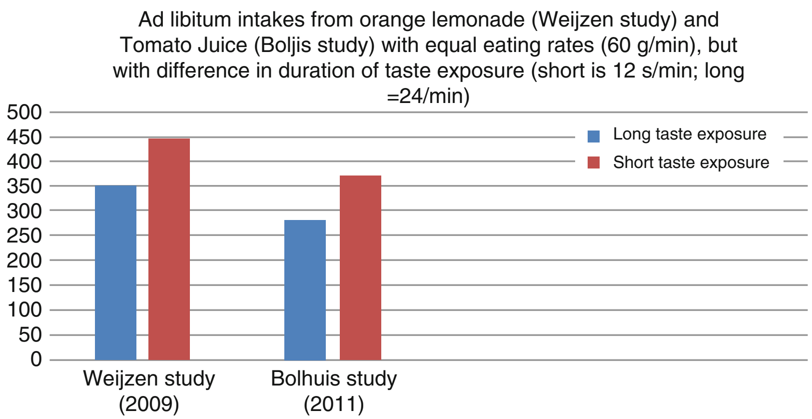

Fig. 4 Average ad libitum food intakes (=satiation) from orange lemonade in the study of Weijzen et al. (2009) and tomato juice in the study of Bolhuis et al. (2011). In both studies the eating rate was constant, and the only factor that was manipulated was the oro-sensory exposure to taste. This was done by varying the sip size through peristaltic pumps. Small size leads to higher exposure times and a lower intake

studies. In both studies ingestion rate was constant, implying that it was only the exposure to taste that was different. In both studies ad libitum intakes (satiation) decreased around 30%, while the exposure duration to taste increased with a factor of 2. The results of these two studies indicate that taste exposure may be strongly involved in meal termination.

Role of Smell in Food and Energy Intake

Smell may effect food pleasantness and consequently choice and intake through two routes, orthonasal stimulation and retronasal stimulation. Orthonasal stimulation reflects smelling foods from the ambient environment, whereas retronasal stimulation reflects aroma perception during eating and swallowing the foods (Buettner et al. 2001). Small et al. (2005) showed that signals from ortho- and retronasal odors are processed by the brain in a different way, i.e., the perceptual processing is different. Retronasally odors are perceived on the tongue and in every language denoted as "tastes," e.g., chocolate taste and strawberry taste (Murphy et al. 1977). In this perspective odors are both perceived from within the body and from outside the body in the environment.

As is discussed above, increasing or prolonging taste stimulation leads to earlier satiation. In a number of studies, a similar idea was tested for retronasal smell stimulation. Is it possible to lower ad libitum food intake through a higher/longer exposure to odor substances? This idea was worked out by Ruijschop in a series of technically advanced studies. However, none of the studies about increasing retronasal aroma stimulation led to a decrease in ad libitum food intake (Ruijschop et al. 2008, 2009; Ramaekers et al. 2014a). In the study of McCrickerd et al. (2014), the addition of a creamy flavor did not also affect satiety. This notion concurs with the notion of Hogenkamp et al. (2012) that flavor as part of the food and perceived retronasally does not affect satiation.

On the other hand, orthonasal odor stimulation coming from the ambient environment may lead to an increase in appetite. Several studies showed that ambient odors lead to an increased appetite which is specific to the food that the odor is cuing (Fedoroff et al. 2003; Ramaekers et al. 2014b; Zoon et al. 2016). For example, smelling banana increases the appetite for banana, but also for other sweet foods. Smelling tomato soup increases the appetite for tomato soup, but also for other savory food. This effect is called sensory-specific appetite, and it is a mirror of the well-known sensory-specific satiety effect (Rolls et al. 1981).

Ramaekers et al. (2014b) showed that the effect of odor on appetite does not only occur immediately after exposure but continues for at least 20 min under the condition that the food is not eaten. This effect is produced by active and passive smelling (Ramaekers et al. 2014c) and occurs rapidly when switching from one odor to the next (Ramaekers et al. 2016).

Although the effect of ambient odor stimulation on specific appetite is clear, the effects on actual food choice are more ambiguous. Zoon et al. (2014) did not find an effect of clearly detectable odors on food choice. Three French studies from the laboratory in Dijon demonstrated that ambient exposure to ambient fruity odors below threshold level increased the choice for fruit in a subsequent lunch (Gaillet et al. 2013; Gaillet-Torrent et al. 2014; Chambaron et al. 2015). However, a later study by Mors et al. (2018) failed to find an effect of subthreshold bread and cucumber odor on subsequent choice at lunch.

Although in general there is a positive relationship between appetite rating and actual subsequent food intake (de Graaf 1993), this is not always the case (Mattes 1990). With respect to the effects of ambient odors on the amount that people eat, there are mixed results. Zoon et al. (2014) found no effects on the amount eaten, Fedoroff et al. (1997) found only an effect in restrained eaters, and, surprisingly, Coelho et al. (2009) observed a decrease in food intake, also only in restrained eaters. However, in a recent study by Proserpio et al. (2019) with obese women, it was found that intake of a vegetable soup at lunch was substantially increased (466 g vs. 369 g) after exposure to a bread odor compared to a no-odor condition.

Summarizing the role of smell on food intake, it is clear that smell plays a role. Odors in foods, perceived retronasally, have a dramatic effect on palatability and therefore will also effect intake. Retronasal odors have a small role in satiation. The role of ambient odors is clearly different; they may attract attention to a food, eliciting sensory-specific appetite. However, it is not entirely clear under what circumstances ambient odors affect food choice and intake. Do the odors need to be consciously be perceived or not? does it only work when people are hungry? does it only work for some people (e.g., obese) and not for others (normal weight, restrained eaters)? All these questions need answers, before we can apply this knowledge to improve healthy food choices.

Discussion

Sensory science forms the bridge between food and health, as sensory signals from food determine to a large extent what is eaten and how much is eaten. The texture and taste of food play a major role in satiety and food intake. Harder textures that lead to lower eating rates may contribute to a less obesogenic food environment. The measure kcal/min may be a good measure for the obesogenic capacity of a food. Taste stimulation, for a large part determined by texture and eating rate, has an essential role in signalling satiation. This point of view is in line with the idea that the taste system senses nutrient concentrations in foods. The sense of smell mainly plays a role as a priming agent in the environment; its role in food choice and intake is an important research area in the future.

The role of food texture in nutritional issues is important, as it is clear that sugar sweetened beverages have an important contribution to the high prevalence of overweight and obesity across the world. The basic and most plausible biological explanation for this fact is that calories from liquids are not well sensed by the sense of taste, and therefore we do not compensate for the ingested liquid calories.

This observation gives rise to two other questions. The energy from sugar sweetened beverages is not well sensed with little subsequent energy intake compensation. How is that with the energy coming from solid sugars? Are they sent accurately and compensated for later onward? Does a high intake of solid sugars lead to overconsumption of energy? Results from meta-analyses (Te Morenga et al. 2013) are clearer on sugars in liquid form than in solid form. The role of solid sugars in energy intake and long-term energy balance is one of the most pressing nutritional issues of today. In this respect we need carefully controlled randomized trials.

Another question is whether the lack of sensing from sugar sweetened beverages also applies to other liquid calories. Soup is a satiating liquid, probable due to its lower eating rate and higher oro-sensory exposure time compared to liquids that are drunk. The question is whether liquid from not-sweet beverages are also not sensed. One issue in this respect is that in the normal food supply, most liquid calories taste sweet, and there are relatively few sources from non-sweet calories in a liquid form.

The non-sensing of liquid calories compared to solid calories is also a fundamental question from a neuroendocrinological perspective. The nucleus tractus solitarius is the first relay station of the taste system on its way to the thalamus and other parts of the brain. The NTS is also the part where satiation is determined and which receives input from vagal afferent from the GI tract. It would be interesting to look at the neurobiological consequences of liquid and solid food intake.

The central role of eating rate in the satiating capacity of food and satiation is obvious and reproducible from short-term intake studies. One of the challenges is to investigate whether a slowing down of the overall energy intake rate of the whole diet leads to reductions of energy intake and long-term energy balance. This challenge also requires long-term well-controlled nutrition intervention studies.

With respect to sweetness, there are still a number of pressing questions on the table. Is it possible to change to generalized preference for sweetness, or is the inborn liking for sweetness stable and not subject to change? Various studies have shown that sweetness preferences decline from early childhood to adulthood (Bobowski and Mennella 2016; de Graaf and Zandstra 1999; Zandstra and de Graaf 1998). However, sweetness preferences in adults seem less likely to change (Wise et al. 2015; Liem and de Graaf 2004). The review of Appleton et al. (2018) discusses the need for long-term intervention studies in this context.

Overall, it is clear that sensory responses play a big role in nutrition behavior. There are still numerous questions to be answered, and answering these questions may help to create a healthy food environment that tastes good.

Conclusion

Obesity is one of the most pressing nutritional problems in the world today, due the obesogenic food environment which induces the overconsumption of energy. Sensory characteristics of food play a paramount role in energy intake. Soft and fluid textures with a high energy density easily lead to overconsumption. Food design may be used to develop products with a high satiating capacity per kcal. This may help to limit intake while maintaining palatability.

The Role of Eating Frequency and Snacking on Energy Intake and BMI

33

Stephanie R. Hunter and Richard D. Mattes

Contents

Abstract

Eating frequency and the prevalence of snacking in particular have increased in Western nations over the past 35 years. There is strong epidemiological evidence that there is a positive association between eating frequency and energy intake. However, whether this translates to an increase in BMI is less clear. With adjustment for underreporting, a major confounder in eating frequency outcomes, the sometimes reported negative association between eating frequency and BMI, is often reversed. Snacks are most problematic when they are unplanned and evoke weak compensation, contributing to increased energy intake. Mechanisms that contribute to this include a weak satiation/satiety effect, distracted eating, low

thermogenic (heat production) response, and disrupted biological cycles. Although snacks are commonly energy dense, this attribute alone does not make them more problematic, as fruits and vegetables as snacks can also increase total energy intake. Thus, problems with snacks do not necessarily stem from the food themselves but rather how they are incorporated into a diet. Snacking as part of an energy balanced diet can help manage short time intervals allotted to eating, contribute positively to the nutrient quality of the diet, and may moderate blood sugar and metabolic disease risk factors.

Introduction

Total energy intake is a product of portion size and eating frequency. Theoretically, there is an inverse relationship between these variables that permit stability of energy intake, and if that balance matches energy need, body weight would remain stable. However, the high prevalence of overweight and obesity indicates the expected reciprocity does not hold for approximately two-thirds of the US adult and one-third of the global adult populations, and the prevalence is rising rapidly for children and adolescents (Malik et al. 2013b; Ng et al. 2014). There is considerable evidence that portion sizes have increased in Western populations, and this has been linked to positive energy balance and weight gain (Mattes 2014). Less attention has been focused on eating frequency, but its contribution to overweight and obesity may be as great, if not greater than the changes of portion size. Nationally representative data from the National Health and Nutrition Examination Surveys (NHANES) in 2009–2010 reveal that while energy from meals increased by 63 and 112 kcal/day in males and females, respectively, energy from snacks increased more: by 132 and 142 kcal/day in males and females, respectively, in the past 40 years (Kant and Graubard 2015). While most research on snacking is in the United States and Europe, snacking is prevalent globally. For example, in the United States, 97% of adults, 83% of adolescents, and 98% of children snack; in the United Kingdom, 84% of women and 75% of men snack (O'Connor et al. 2015); in China, about 73% of adults and 46.3–58.8% of children and adolescents snack (Wang et al. 2012); in Mexico, 73.2–79.4% of children and adolescents snack, while 66.5–74.5% of adults snack (Duffey et al. 2014); and in Brazil, 78.7% of adolescents and 72.2–74.8% of adults snack (Duffey et al. 2013). Thus, snacking is an important area to target for reduction of energy intake to control overweight and obesity.

Eating frequency and snacking are not synonymous as people skip meals, but snacking generally leads to increased eating frequency (Mattes 2018). American adults report about 4.96 eating episodes per day (Kant 2018). European countries report eating frequencies between 4.9 and 7 occasions per day (Huseinovic et al. 2016). Adults in China report less than 1 snack per day (Wang et al. 2012). Adults in Mexico report 1.9–2.1 snacks per day (Duffey et al. 2014). Adults in Brazil report 1.4 snacks per day (Duffey et al. 2013). Adults in Finland consume an average of 3.6 snacks per day, but range from 1 to 12 (Ovaskainen et al. 2010). Over the past 35 years, energy intake from snacks increased from 300 to 526 kcal per day in US adolescents. Adult men and women in the United States consume about 421 and

586 kcal per day from snacks (Mattes 2014), while adults in Mexico consume 207–336 kcal per day from snacks (Duffey et al. 2014), and adults who are light (one to two snacks/day) and heavy (three or more snacks/day) snackers in Brazil consume 342–894 kcal per day from snacks (Duffey et al. 2013). About 9% of the US population consumes more than 50% of their daily energy from snacks (Kant and Graubard 2015), while in Finland, 25% of adults consume a greater proportion of their total daily energy intake from snacks than meals (Ovaskainen et al. 2010), and in the Mediterranean countries and Canada, snacks contribute more energy than breakfast (Huseinovic et al. 2016; Larson and Story 2013). Overall, in Western nations, snacking contributes about 15–30% of daily energy intake (Mattes 2018); daily energy intake from snacks is also high in Mexico (16.7%) (Duffey et al. 2014), Nordic countries (29%) (Huseinovic et al. 2016), Central European countries (31%) (Huseinovic et al. 2016), the Middle East (20%) (Ng et al. 2011), and Brazil (19.6%) (Duffey et al. 2013), but in China, snacking contributes only 4% of energy intake in adults (Wang et al. 2012). However, there has been a dramatic increase in snacking since 2004 in China that, along with other developing countries, is expected to undergo future growth (Nielsen 2014).

Two major problems in the literature that limit confidence in measuring eating frequency outcomes are underreporting and defining snacking behaviors. Often consumers, especially those with overweight or obesity, underreport energy intake on questionnaires (Mattes 2018). This may be especially true for snacks compared to meals. For example, in one tightly controlled trial in women with overweight or obesity who were provided ad libitum access to meals and snacks in a metabolic facility for 24 h, energy derived from snacks was disproportionately underreported compared to energy from meals and was correlated with underreporting of total energy intake (Poppitt et al. 1998b). Participants omitted about 400 kcal of energy intake from snacks.

Different definitions of meals and snacks can also lead to mis- or underreporting (Leech et al. 2018). Common definitions of snacks include consideration of: time of day, amount of energy consumed, eating alone, short eating periods, standing while eating, nutrition quality, and type of food (Hess et al. 2016). The most common terminology is that "snacks" are "ingestive events (food or beverage) that occur between meals" (Hess et al. 2016). However, the lack of a definition of meals hampers application of this definition. Because different definitions can lead to varying results, the role of eating frequency in both energy intake and BMI and mechanisms for the associations will be reviewed. Because the overwhelming majority of the population chooses to snack, it is assumed this behavior is not easily eliminated so must be addressed by other means. Thus, this review will focus on snack choices, determinants of increased snacking, and the negative and positive facets of snacking.

Eating Frequency and Energy Intake: Review of Literature

Epidemiological data reveal that increased eating frequency results in increased energy intake (Zhu and Hollis 2016; Wang et al. 2016; Kerver et al. 2006; Kim and Kim 2010; Bachman et al. 2011; Edelstein et al. 1992). NHANES data reveal that both adolescents and adults who snack four or more times per day consumed 1.5 times more energy than those who did not snack (Sebastian et al. 2011; Sebastian et al. 2010). Forty-year trends in NHANES data reveal energy from snacking increased by 3% and 5% in males and females, respectively (Kant and Graubard 2015). This increase was not fully offset by a reduction in meal energy intake. Additionally, men and women who consumed two or more snacks in addition to three meals consumed significantly more energy than those who consumed one or no snacks (Hampl et al. 2003). Light (one to two snacks/day) and heavy (three or more snacks/day) snackers in Brazil consume significantly more energy per day (381 and 786 kcal/day) than those who do not snack (Duffey et al. 2013). Overall, epidemiological and observational data from the United States and Brazil provide strong evidence of a direct relationship between eating frequency and energy intake.

Some clinical trials report increased energy intake from increased eating frequency. This holds across the life cycle and in individuals who are lean or have obesity (Toschke et al. 2012; Berteus Forslund et al. 2005). Still, this evidence base is not uniform. Other studies observed no increase in energy intake with increased eating frequency (Taylor and Garrow 2001; Johnstone et al. 2000). However, many trials are of less than 1 day in duration, and the validity of extrapolating findings to the longer-term, nutritionally meaningful (months to years) intake is uncertain. Additionally, clinical trials often entail controls that reduce their ecological validity and recruit limited sample sizes which undermine conclusions relating eating frequency to energy intake (Johnstone et al. 2000; Allirot et al. 2013).

Additional evidence supporting a role for eating frequency in increasing energy intake is its purposeful use in clinical cases to increase body weight. Clinical nutrition guidelines recommend small frequent meals (6–10 meals) for patients with early satiety, anorexia, and gastrointestinal symptoms (Dashti and Mogensen 2017). Malnourished patients who consumed three meals and two snacks increased their energy intake by 600 kcal/day (Kruizenga et al. 2005), and snacking in nutritionally at-risk older adults increases energy intake (Zizza et al. 2007). In these populations, weight gain is warranted and improves health.

Eating Frequency and BMI

The contribution of eating frequency to BMI is unclear. In a study of Seventh Day Adventists (a relatively healthy population that refrains from smoking, infrequently consumes alcohol, and largely follows a vegetarian diet in the United States and Canada), those who ate more than three times per day had a significantly higher BMI compared to those who ate three times per day (Kahleova et al. 2017). Those who ate only one or two times per day had a lower BMI compared to those who ate three times per day. Further, men in the Health Professionals Follow-Up Study, a sample of 20,064 health professional males aged 40–75 in the United States from 1992 through 2002, had a higher risk of weight gain with increased eating frequency (van der Heijden et al. 2007). In a similar study, Swedish men and women with obesity had higher eating frequency and energy intake than normal weight men and women

(Berteus Forslund et al. 2005). Surprisingly, many studies report increased eating frequency and energy intake, but no change (Sebastian et al. 2011) or decreased BMI in adults (Zhu and Hollis 2016) and adolescents (House et al. 2015). Interestingly, breakfast skipping, which may lower eating frequency, is associated with obesity and higher BMI. The question is how this apparent inconsistency (i.e., higher energy intake without higher body weight) can be reconciled.

Epidemiological evidence is notoriously biased by underreporting. When underreporting is considered, negative associations between eating frequency and BMI are often reversed. This has been observed for males and females in NHANES data as well as The Continuing Survey of Food Intakes by Individuals in America (CSFII) data (another nationally representative sample of the United States population (McCrory and Campbell 2011)). In the National Diet and Nutrition Survey in British adults, where eating frequency was negatively associated with BMI, men and women who were overweight underreported energy intake by 27% and 31%, respectively. When participants with implausible energy intakes were excluded from the analysis, there was a positive association between eating frequency and BMI (Murakami and Livingstone 2014). Another explanation is that individuals with overweight or obesity may actually reduce eating frequency to decrease their energy intake to control their weight (Wing and Hill 2001). This results in an erroneous conclusion that reduced eating frequency is associated with high BMI, while the association is actually due to reverse causality.

Clinical trials assessing the role of eating frequency on body weight also have limitations (Hutchison and Heilbronn 2016). Most notably, they are often short term (8 weeks or less) so lack the power required to ascertain a sustainable effect of eating frequency on BMI (Hutchison and Heilbronn 2016). Longer-term trials (greater than 12 weeks) have reported no change in BMI or energy intake (Huseinovic et al. 2013).

Taken together, there is evidence that high eating frequency and snacking is prevalent around the world and that increased eating frequency results in greater energy intake in Western nations, but the evidence this leads to increased BMI is less clear. The expected association is often only noted after correction for underreporting.

Mechanisms for Positive Associations Between Eating Frequency and Energy Intake

Planned Eating

While children (Birch et al. 1991) and adults (McKiernan et al. 2008) are capable of compensating for energy from snacks, it is often not practiced. Compensation largely depends upon whether the snack is planned. Weight loss studies have shown that when the number of eating occasions is planned and there is a fixed energy intake, increased eating frequency will not lead to weight gain (Bachman and Raynor 2012; Cameron et al. 2010). In France, the mid-afternoon eating occasion called the goûter is eaten by most children and adolescents as well as some adults (Chapelot et al. 2004). When compared directly, goûter consumers requested dinner later and consumed less energy than non-goûter consumers, whether the non-goûter group consumed a mid-afternoon snack or not (Chapelot et al. 2004). Another study in lean and obese adults found that those who regularly consumed snacks prior to the research study compensated better for the supplemented snacks of low or high energy or no snack than did participants who were not habitual snack consumers (Whybrow et al. 2007). Thus, when an extra eating occasion is planned or is part of a routine, strong energy compensation may occur. In contrast, compensation commonly does not occur in pre-load (Rolls et al. 1991) or short-term (Chapelot 2011) studies. A theoretical model proposed by McCrory and Campbell suggests that when energy intake is not monitored, there is an increased risk of appetite dysregulation and weight gain especially when eating frequency exceeds six times per day (McCrory and Campbell 2011).

Weak Satiation/Satiety

Snacking may be uncompensated due to lowered feelings of satiety after such an eating occasion. A larger eating occasion results in a lower reported nadir in hunger and desire to eat, and a higher peak in fullness, which determines the time until an appetite sensation of sufficient magnitude is experienced to motivate a new eating occasion. Snacks lead to smaller changes in appetite than meals if they are defined as having lower energy content (Bellisle et al. 2003). Students in France who self-defined meals and snacks reported higher energy intake at meals and rated feelings of hunger and thirst as more intense before meals but less intense after meals compared to snacks (Bellisle et al. 2003). However, when energy intake is the same, subjects consumed less energy at a load 20 min later when they perceived the eating occasion as meal foods compared to snack foods (Capaldi et al. 2006). However, energy intake was not different 3 h later. When daily energy intake is controlled, increased eating frequency does not have as large an effect on appetite. Normal weight participants who consumed one meal reported lower hunger, desire to eat, and overall composite appetite ratings, calculated as the mean of hunger, desire to eat, and inverse of fullness ratings, over a 4-h period compared to when the participants consumed the same meal as two eating occasions in a 4-h period, although there was no difference during the final hour of testing (Perrigue et al. 2016). Another study in men who were overweight or had obesity reported lower levels of fullness over the day with six versus three isocaloric eating occasions (Leidy et al. 2010). However, the literature is not conclusive, and other studies have reported higher eating frequency to suppress hunger and energy intake (Speechly et al. 1999). Resolution of this issue may require factoring in the definition of snacks.

Gut Peptides, Glucose, and Insulin

Gut peptide release and gastric emptying are sometimes used as "objective" biological indices of appetitive sensations, although the degree to which they determine or are even associated with appetite, energy intake, or BMI is debated. Obese adults consuming three or six meals a day in a hypocaloric feeding study for 8 weeks did not report differences in hunger, fullness, or have different ghrelin or PYY concentrations between groups (Cameron et al. 2010; Leidy and Campbell 2011). However, equi-energetic feeding regimens composed of 2 or 12 eating occasions per day revealed greater fluctuations in glucose, insulin, and ghrelin during the 2 compared to the 12 eating occasion patterns in a day (Solomon et al. 2008). The 12 eating occasions per day, identified as a nibbling eating pattern, resulted in stable plasma insulin and ghrelin concentrations. However, this could be problematic. If a drop in insulin or a rise in ghrelin is a signal that drives ingestive behavior, then eating frequently essentially eliminates the signal, possibly desensitizing those with high eating frequencies to endocrine signaling systems that drive ingestive behavior. Subjects who consumed isoenergetic meals hourly for 6 h compared to subjects who consumed two isoenergetic meals 3 h apart had a delayed onset of gastric emptying, but there were no differences in overall gastric emptying rate nor differences in subjective measures of appetite (Jackson et al. 2007). However, the results of these studies must be interpreted with caution as meal patterns were fixed, and it is not clear how findings from such controlled studies hold under more naturalistic eating conditions.

Distracted Eating

Distracted eating occurs when the consumer is eating, often where portion size is not fixed, while engaged in some other activity (e.g., eating from a large bag of food while watching television). As a result, they may lose track of what and/or how much they have ingested so cannot use this knowledge to adjust subsequent intake. Distracted eating can lead to increased energy intake later in the day (Hess et al. 2016). Undergraduate women who consumed a fixed lunch while watching television ate significantly more cookies as an afternoon snack compared to undergrad women who consumed the same lunch without distraction (Higgs and Woodward 2009). Subjects who consumed a standardized lunch while playing a computer game reported feeling less full immediately after lunch, had a less accurate recall of lunch foods, and consumed more biscuits at a taste test 30 min after lunch compared to subjects who were not distracted while eating the same lunch at the same rate (Oldham-Cooper et al. 2011). However, most of these results are from adults 20–47 years old with healthy BMIs (Robinson et al. 2013). Thus, assessment of more heterogeneous populations is needed to validate these findings. More representative data are available through the American Time Use Survey. Americans spent an average of 64 min a day eating and drinking as a primary activity, lower than 30 years ago, and 16 min a day eating as a secondary activity (Zick et al. 2011). Another 57 min a day for males and 69 min a day for females were spent drinking anything other than water as a secondary activity, and this is positively associated with BMI.

Thermogenesis

A number of trials reveal increased eating frequency decreases diet-induced thermogenesis, defined as the increase in energy expenditure above basal fasting levels divided by the energy content of the food ingested (Westerterp 2004). The idea is that a decrease in diet-induced thermogenesis would result in more efficient use of energy in the body resulting in positive energy balance and weight gain. Normal weight men who consumed breakfast as four isocaloric eating occasions 60 min apart had lower diet-induced thermogenesis compared to when breakfast was consumed as one isocaloric eating occasion (Allirot et al. 2013). This has also been reported elsewhere (Nacht et al. 1986; Tai et al. 1991). However, this is not observed in all studies (Smeets and Westerterp-Plantenga 2008; Belko et al. 1987; Molnar 1992; LeBlanc et al. 1993). Overweight women tested in a metabolic chamber who consumed two, four, or six meals per day at designated times had no difference in total energy expenditure nor energy balance (Taylor and Garrow 2001). Notably, unplanned eating events may exert a weak thermogenic response. In one trial, lean healthy women consumed similar diets but as six eating occasions per day (regular meal pattern), or varying between three and nine meals per day so that the total number of meals per week were the same over 14 days (irregular meal pattern) (Farshchi et al. 2004). The participants then followed their normal diet for a 14-day washout period. For the last 14 days, the participants consumed the opposite treatment of the first 14 days. Participants consumed more energy when consuming the nine meals per day versus six or three. The thermic effect of food was lower after consuming the irregular meal pattern versus the regular eating pattern. Thus, in addition to excess energy consumed, unplanned eating occasions may also be problematic because of decreased thermogenesis. Whether diet-induced thermogenesis actually has biological relevance is debated (see Bellisle et al. 1997), but to the extent that it is meaningful in the context of eating frequency, it appears to contribute to positive energy balance.

Is the Nature of Snack Foods or Snacking Behavior More Problematic?

Snacking may be defined by the nature of the foods ingested. Often snack foods are considered disproportionately energy dense (Hess et al. 2016). Some argue such foods pose a risk because they deliver a high energy load yet have low satiety properties. However, an assessment of the relative contributions of portion size, eating frequency, and energy density to energy intake revealed the later accounted for the least amount of variance in this outcome (Duffey and Popkin 2011). Additionally, the concept of energy density fails to coincide with a wide array of expected associations (Running and Mattes 2012). For example, trends in the energy density of the food supply have not tracked changes in population weight or BMI. Additionally, evidence based on foods at the extremes of the energy density continuum do not support the concept.

Fruits and vegetables have high water content and, as a consequence, are low in energy density. Thus, increased intake is promoted as an approach to manage energy intake and body weight. However, increased consumption of fruits and vegetables may not be the solution for better energy management. They do not promote nor sustain satiety as is often assumed (Carmody et al. 2011; Drewnowski 1998; Poppitt et al. 1998a). In epidemiological studies, BMI is not different across various levels of fruit and vegetable intake. The European Prospective Investigation into Cancer and Nutrition (EPIC) study, which collects dietary data across ten European Countries to study the relationship between nutrition and cancer, found BMI and energy intake were not significantly different in adults across quartiles of fruit, vegetable, and legume intake (Nöthlings et al. 2008). Adult women in the Nurses' Health Study did not differ in BMI across quintiles of fruit, vegetable, and fruit and vegetable intake (He et al. 2004). Randomized controlled trials show similar results. In the Women's Healthy Eating and Living Trial (WHEL), subjects following the "5-a-day" recommendations consumed more fruits and vegetables every day, but did not have different energy intakes per day nor body weight compared to the control group (Pierce et al. 2007). In another study, adults with overweight or obesity consumed 20% of their estimated energy requirements as fruit and vegetables for 8 weeks with no other dietary guidance (Houchins et al. 2012). Subjects with obesity gained more weight than patients with overweight, but both gained weight during the intervention, and this was due to incomplete compensation. Lean participants in the study fully compensated for fruit and vegetable intake and did not gain weight during the intervention. Thus, if energy from fruit and vegetable consumption is not compensated, excess energy from intake of these snacks can still lead to increases in body weight. Therefore, recommendations to increase fruit and vegetable consumption, especially as snacks, should emphasize the importance of energy balance (Mattes and Tan 2013).

Caloric beverages represent an even more extreme example of how low energy dense foods can be problematic for weight gain (whether consumed with a meal or as a snack). Their consumption as snacks has increased in China and the United States in the past 18–30 years (Piernas and Popkin 2010; Wang et al. 2012; Duffey et al. 2013) and is prevalent in Brazil (Duffey et al. 2013), Mexico (Duffey et al. 2014), and children in Scotland (Macdiarmid et al. 2009) and the Philippines (Adair and Popkin 2005). In China, beverages consumed as snacks contributed about 25% of energy intake (Wang et al. 2012), while in the United States, 50% and 40% of the energy consumed from snacks comes from beverages in males and females (Mattes and Tan 2013). Sugar-sweetened beverages are positively associated with weight gain and obesity in children and adults (Bray et al. 2004; Malik et al. 2006; Malik et al. 2013a), possibly because they are not as satiating as solid foods (Mattes and Tan 2013). This is due to a plethora of factors, including quicker orosensory processing time, increased gastric emptying rate, and intestinal transit time (see Mattes and Tan 2013). Thus, ingesting low energy dense beverages as snacks may lead to increased energy intake due to their weak effect on appetite regulation and energy compensation. However, the risk they pose is not limited to their use as snacks. Both lean adults and those with obesity who consumed matched beverage and solid foods with a standardized lunch had weaker dietary compensation and higher energy intake the remainder of the day after the beverage compared to the matched solid food (Mourao et al. 2007). Adults who are lean or have overweight or obesity who consumed 20% of their estimated energy requirement as juices for 8 weeks had incomplete dietary compensation and weight gain (Houchins et al. 2012).

In contrast to beverages, nuts are rich in fat and low in water so have very high energy density. The prediction then would be that they should be associated with positive energy balance and weight gain. However, epidemiological, clinical, and mechanistic studies with nuts indicate they are not problematic for weight gain (see Tan et al. 2014). This has been attributed to their high satiety value, inefficient absorption, and possible enhancement of resting energy expenditure.

Aside from energy density, it has been proposed that snacks varying in macronutrient content will have varying effects on satiety, compensation, and energy balance. However, this was directly tested in a four-arm crossover study where lean men consumed a standard lunch, and then a high fat, high protein, or high carbohydrate snack 240 min later (Marmonier et al. 2000). During the study, participants were deprived of time of day cues, and freely requested dinner, which was an ab libitum buffet. Dinner requests were significantly later after the high protein snack compared to the high fat or high carbohydrate snack, but energy intake was not different at dinner between treatments, and there was no energy compensation for any snack. It may be that foods varying in sensory appeal or cultural meaning will exert differential effects on appetite and such foods may vary in macronutrient profiles, but the latter does not appear to be the driving force in the response to their ingestion.

Taken together, this evidence indicates risks posed by snacking are not necessarily related to the nature of the foods themselves, but rather to how they are incorporated into the diet. If planned and energy compensated, any food can be included in an energy-balanced diet. However, at the same time, snacking that is not planned and does not lead to precise energy compensation can pose a risk for weight gain regardless of the nature of the food.

Why Are We Snacking More?

Palatability is the strongest predictor of food intake (Mattes 2008) and is often rated highly as a motivation to snack (Hess et al. 2016). Nutritional quality is also a consideration and its importance has been growing, but frequently, snacks are not held to the same nutrition standards as meals (Kant 2018). Additional enablers for snacking include hunger (Cleobury and Tapper 2014; Caruso et al. 2014), temptation (Cleobury and Tapper 2014), convenience (Caruso et al. 2014), emotional eating (i.e., boredom or stress) (Cleobury and Tapper 2014), enjoyment/reward (Verhoeven et al. 2015; Kant 2018), affordability (Nestle and Jacobson 2000; Drewnowski and Darmon 2005), and availability (Nestle and Jacobson 2000). The latter is likely a critical issue. Snacks are widely available, including in grocery stores, restaurants, vending machines, pharmacies, gas stations, hardware stores, auto repair centers, etc.

(Farley et al. 2010). Changes in the culture of eating have also been important. The acceptability of eating almost anywhere at any time has allowed for increased eating frequency (Bellisle 2014). Indeed, the incidence of snacking is greater outside the home than inside and is particularly high when individuals are at the worksite. It also occurs in transit (Liu et al. 2015). Therefore, the numerous motivations and availability of snacks may lead susceptible individuals to consume energy when it is not planned for and consume excess energy (Baskin et al. 2016).

Concerns with Snacking

Snacking commonly leads to increased energy intake resulting in positive energy balance and increased BMI. Consequently, snacking is primarily viewed as a negative health behavior by clinicians and policy makers who provide recommendations to manage body weight. Depending on the type of snacks consumed, they may increase the contribution of food constituents associated with undesired health outcomes or displace desired nutrients (Larson et al. 2016). However, snacks are especially problematic when they are unplanned, uncompensated, and contribute to an irregular eating pattern.

Nonhomeostatic factors that motivate snacking can lead to energy intake at times that are different than homeostatic signals and can therefore disrupt 24-h biological cycles (circadian rhythms). This can lead to negative cardio-metabolic outcomes. In the 1946 British Birth Cohort, irregular meal and snack patterns were associated with an increased waist circumference, BMI, and prevalence of metabolic syndrome (Pot et al. 2016). Hunger reportedly has an endogenous circadian rhythm, independent of wake time or time since energy was last consumed (Scheer et al. 2013). When energy is consumed during a time when the circadian clock promotes sleep, such as in shift work, energy expenditure, hunger, and leptin and PYY concentrations are reduced (McHill et al. 2014). One particular concern is eating later in the evening before sleeping. Observational studies have reported a positive association between evening food intake and BMI, while consuming a larger proportion of total energy intake during midday was associated with a lower risk of being overweight or obese (Wang et al. 2013). However, multiple cultures (e.g., Spain) typically consume a large meal later in the evening, yet have lower rates of overweight and obesity than cultures that complete the largest eating events earlier in the day (e.g., United States) (Ng et al. 2014). In some studies, late eating has been associated with increased energy intake, but this association may be mediated by increased eating frequency, which leads to eating closer to sleep onset and increased daily energy intake (Reid et al. 2014).

Benefits of Snacking

Though snacking has been vilified in the media and by health professionals, increased eating frequency can be a part of a healthy lifestyle (Hartmann et al. 2013). In fact, because a high proportion of the US and global populations snack

(Kant and Graubard 2015; Dunford and Popkin 2017), it should be a priority to determine how to make this habit more healthful. Dietary recommendations regarding snacking are limited. Prior to 2010, there were no recommendations regarding snacking behavior in the dietary guidelines (Kant and Graubard 2015). The Dietary Guidelines for Americans recommend decreasing snack foods, but also recommend a dietary pattern of three meals and two snacks per day, and the distinction between the two is not clear.

Snacks can help manage short time intervals allotted to eating. One of the most commonly reported barriers to healthy eating among adults is lack of time (Pelletier and Laska 2012; de Mestral et al. 2016). Americans are spending less time cooking, and only slightly more than half of Americans spend any time on food preparation (Smith et al. 2013). Commutes to work take away time from food preparation (Christian 2012). The lunch hour for over half of Americans lasts less than 30 min, and 29% of employees report working during their lunch breaks (Half 2018). Lack of time is also a barrier to regular family meals. Due to busy schedules, families may not feel they have time to prepare or sit down around the table for a meal and resort to snacks as a quick meal alternative (Jones 2018). Therefore, the convenience of some snacks can help manage these short times allocated to eating.

Snacks can, and often do, contribute positively to the nutrient quality of the diet. Eating frequency and diet quality are positively associated based on NHANES 2009–2012 data (Zhu and Hollis 2016). Eating frequency was positively associated with total fruit, whole fruit, whole grains, dairy products, and seafood and plant protein in men and women. NHANES 1999–2004 data in adults revealed that snacking was associated with higher HEI-2005 scores, although modestly (Zizza and Xu 2012). However, this must be placed in context. In the Healthy Aging in Neighborhoods of Diversity across the Life span (HANDLS) study in White and African American adults in various neighborhoods throughout Baltimore City, 84% of the population reported consuming snacks, which contributed about 20% of their daily energy intake, had total HEI-2010 scores that were 2% and 4% higher for both African American and White males, respectively, and 1% and 7% higher for African American and White females, respectively, indicative of increased diet quality. However, African American and White men classified as snackers reportedly consumed 483 and 583 kcal/day more than their non-snacking counterparts, and African American and White women classified as snackers reportedly consumed 365 and 468 kcal/day more than their non-snacking counterparts. Thus, the benefit in nutrient quality came with a disproportionately higher energy content, so the overall value must be interpreted with caution. This point is further highlighted by data on Australian adults indicating that meal frequency and eating occasions, but not snack frequency, were positively associated with diet quality, whereas higher snack frequency was associated with lower compliance to dietary guidelines (Leech et al. 2016).

Higher eating frequency is clearly beneficial in select populations. Increased eating frequency helps patients at risk for malnutrition increase their energy and nutrient intake. This is also true for children and the elderly, who cannot consume enough energy through three eating events per day due to early satiation. Frequent eating may also help meet energy needs of those who are more physically active (Drapeau et al. 2017). However, interestingly, this may stem from a higher proportion of eating events deemed to be meals rather than snacks (Chapelot 2011).

Though much of the concern with increased eating frequency stems from its contribution to energy intake, some have proposed there are benefits of increased eating frequency on other health outcomes. Perhaps the most studied outcome is blood sugar. Consumption of an isocaloric diet as six versus three eating events per day tended to moderate blood sugar (Leidy and Campbell 2011). Men in the Health Professionals Follow-Up study who ate three times per day had a lower risk of type 2 diabetes than those who ate one to two times per day. However, there was no association between those who consumed snacks in addition to three meals compared to those who didn't snack on type 2 diabetes risk after adjustment for BMI (Mekary et al. 2012). Further, there was no association between eating frequency and risk of type 2 diabetes in the Nurses Health Study (St-Onge et al. 2017). Healthy men and women who consumed their usual diet as three or nine meals per day with the same energy intake had reduced fasting plasma total cholesterol and LDL and HDL cholesterol when nine meals were consumed compared to three (Arnold et al. 1993). However body weight, fasting triglycerides, LDL:HDL, and insulin and glucose AUC were not different between groups (Arnold et al. 1993). Increased eating frequency was associated with decreased cardiovascular mortality in NHANES data, even after controlling for HEI score and energy intake (Chen et al. 2016). Cross-sectional data reveal increased eating frequency is associated with lower total and LDL cholesterol (St-Onge et al. 2017). Men who consumed a diet of 17 snacks per day for 2 weeks had reduced fasting total cholesterol, LDL-Cholesterol, insulin levels, C-peptide excretion, and cortisol levels compared to when they consumed a metabolically identical diet as three meals a day for 2 weeks (Jenkins et al. 1989). However, in many studies, there is an inverse association or no association between eating frequency and health outcomes (see St-Onge et al. 2017). Overall, it is not clear if eating frequency improves risk factors for metabolic disease. The American Heart Association concludes that "altering meal frequency under isocaloric conditions may not be useful for improving traditional cardio metabolic risk factors" (St-Onge et al. 2017).

Conclusions

There is strong evidence that eating frequency is positively associated with energy intake in Western nations. An association between eating frequency and BMI is less clear, but with correction for underreporting, a positive association is apparent. Multiple mechanisms have been proposed to account for these associations. Lower satiety, thermogenic, and endocrine effects, circadian misalignment, as well as eating while distracted may contribute. Snacks are likely especially problematic for energy balance when unplanned as they often elicit incomplete energy compensation. However, snacking can contribute to a healthful diet and, because the majority of the population snacks, should be used to advantage. Snacking can fit in a fast pace of life allotting only short time intervals to eating. It can also improve diet quality and promote beneficial effects on cardio-metabolic health. Overall, it may be argued that the benefits or complications associated with high eating frequency will be determined more by how the portion sizes and the balance of the nutrient profile of the diet are adjusted rather than the nature of the foods comprising each eating event.
