Nor was there discussion of the possible role of prescription psychotropic medications. This latter omission can be partially justified on the basis that very little is known. In the United States, the Federal Food and Drug Administration has only approved two medications for use in treating ASD, risperidone and aripiprazole, and these are intended to reduce irritability, an important but very limited goal (LeClerc & Easley, 2015), although the off-label use of everything under the sun is common among prescribers—tranquilizers to subdue patients, anti-psychotic agents, antidepressants, hormones like oxytocin, stimulant medications, and so forth.

The American Psychiatric Association provides the following guidance touching on this issue:

“Clinical decision-making without established research evidence to guide practice requires informed clinical judgments drawing on the best available research, adherence to the ethical principles of beneficence and non-maleficence, and sound theoretical reasoning. When usual treatments have failed, psychiatrists may offer non-standard or novel interventions using a shared decision-making approach grounded in the patient’s informed consent and a thorough discussion of risks, benefits, and alternatives to the innovative treatment. Since innovative practice sometimes leads to important scientific advances, it should not be categorically discouraged; however, because it may prove ineffective or even harmful, psychiatrists should proceed with caution in their use of clinical innovation. When considering use of clinical innovation, psychiatrists should consider first consulting colleagues and exploring other resources to ensure that careful thought has been given to possible alternatives as well as to the safest and most effective use of innovative interventions.” (cited from file:///C:/Users/Bthyer/Downloads/APA-Commentary-on-Ethics-in-Practice.pdf)

Clinically innovative practices is a nice way of saying off-label prescribing, using drugs for purposes for which they not been approved. More honest way is to describe it as clinical experimentation on vulnerable human beings. Note the caveat that this is justifiable only when usual treatments have failed. This should be thoroughly documented, with empirical data, before any such off-label prescribing is undertaken. I suggest some more prescriptive guidelines are in order, such as:

- Medication should be tried only after less intrusive methods of treatment have been given a legitimate trial. Examples could include behavior analysis, environmental modification, parent training, etc.
- Whenever medication is intended to produce changes in behavior, affect, or cognition, a credible baseline series of measures of these variables must be taken, prior to introducing the medication. These measures should have acceptable levels of reliability and validity. When the health and safety of the patient with ASD is at risk, this requirement for a baseline may be omitted.
- When medication is provided, ongoing valid assessments of the outcome measures (behavior, affect, cognition) must be obtained on a regular basis, and any changes in the medication regimen should be based on these data. The data must be properly recorded and available in the client’s records.

These recommendations are completely consistent with the fifth step of evidence-based practice “evaluating our effectiveness and efficiency” (Straus, Glasziou, Richardson, & Haynes, 2011, p. 3) as well as in partial compliance with relevant behavior analyst ethical standards:

“(a) Behavior analysts conduct current assessments prior to making recommendations or developing behavior-change programs. The type of assessment used is determined by client’s needs and consent, environmental parameters, and other contextual variables. When behavior analysts are developing a behavior-reduction program, they must first conduct a functional assessment. (b) Behavior analysts have an obligation to collect and graphically display data, using behavior-analytic conventions, in a manner that allows for decisions and recommendations for behavior-change program development” (cited from

Section 3.01 of https://www.bacb.com/wp-content/uploads/170706r_compliance_code_english.pdf)
Other stipulations could readily be made concerning the monitoring of potential side effects, the value of periodic drug holidays, the need for appropriate medication tapers rather than abrupt discontinuance, and the required use of written informed consent from the caregivers for such treatments. See Cohen and Jacobs (1998) for one example of such a form.

Summary

Pseudoscientific therapies for persons with ASD are widely available. They are avidly sought after by despairing parents and caregivers and equally avidly promoted by their advocates. Some advocates are honestly mislead, and others are more akin to therapeutic hucksters and quacks, eager to dishonestly earn money or to acquire a reputation as a marvelous healer. There are many reasons why ineffective therapies can appear to "work," and it requires intense effort over many years to develop a sufficiently strong research base so as to be able to ascertain if a treatment is effective or not. Most interventions tested are not effective, which tends to discourage such long-term research programs. This chapter has provided some guidelines to help recognize a potentially pseudoscientific therapy and described a selected number of these. Far too many remain unrecognized as a bogus treatment. The marketing and sales of pseudoscientific treatments can be a big business, yielding sizeable returns for those who promote them.

There is a growing literature on identifying pseudoscientific treatments, and increasingly practitioners who take a more evidence-based practice approach to care are willing to confront and disclose professionals who dishonestly promote bogus ASD and other therapies under the umbrella of their credentials as a medical doctor, psychologist, social worker, or other types of practitioner. Such efforts should be encouraged, although at times it seems akin to playing "whack-a-mole," in that while temporarily suppressed (e.g., facilitated communication) the practice springs forth anew, perhaps under a different name (e.g., rapid prompting method). The president of the American Speech-Language-Hearing Association deserves credit, for example, for taking on a testimonial editorial that appeared in the *Wall Street Journal* which advocated for a pseudoscientific treatment called the rapid prompting method, which is warmed-over facilitated communication, a long discredited therapy said (erroneously) to permit inarticulate persons with ASD to type fluently (Davis-McFarland, 2018).

Psychologist Jean Mercer has established a Facebook page called *Psychology CE Watch—When Approved Courses Don't Meet Stated Standards* (see https://www.facebook.com/groups/161745967794736/), devoted to disclosing professional continuing education programs which contain pseudoscientific content and coordinating complaints to the American Psychological Association when such CE content does not adhere to the APA's (minimal) required standards of research support. All professionals are welcome to join this page and help identify such programs and to submit complaints through the proper channels. Several previously approved CE programs had had their APA approval removed through this initiative. A couple of divisions of the APA have undertaken a similar initiative, to identify and coordinate complaints about bogus CE courses. This is described on the above website.

Eventually it is hoped, more caregivers of person with ASD who receive pseudoscientific treatments will not just complain but will file lawsuits alleging malpractice at the hands of the professionals delivering the therapy. Winning such lawsuits will be an effective way to discourage providing illegitimate treatments, as will major professional association issuing more position statements condemning the practice of selected pseudoscientific treatments. Science-based treatments are slowly growing in number but are being outpaced by the proliferation of bogus therapies. Professionals in the field of developmental disabilities need to become less tolerant of these cuckoos in our nest, and push them out, before these fledglings come to dominate the marketplace, to the disadvantage of persons with ASD and their families.

Caregiver Treatment Choices

Sarah Carlon, Jennifer Stephenson,
and Mark Carter

Critical Nature of Treatment and Intervention Selection

There are a number of treatment and intervention options available for people with intellectual disabilities. These range from evidence-based treatments (as described in Chap. 28), such as those derived from the principles of applied behavior analysis (ABA), to unsupported treatments (as described in this chapter), such as complementary and alternative medicine (CAM) treatments. On balance, it can be argued that interventions with empirical support represent better options for the majority of individuals with intellectual disabilities compared to interventions without such support.

Families, schools, and governments have finite financial resources, and the economic burden of intellectual disabilities can be significant. For example, the cost of supporting one individual with comorbid intellectual disability and autism spectrum disorder (ASD) over the life span has been estimated to cost US$2.4 million in the United States (US) and US$2.2 million in the United Kingdom (UK) (Buescher, Cidav, Knapp, & Mandell, 2014). In comparison, in both the US and the UK, the estimated cost of supporting an individual with ASD but without intellectual disability over the life span was US$1.4 million (Buescher et al., 2014). In Australia, the total government expenditure on services for people with intellectual disabilities has been estimated at A$3.361 billion each year (Doran et al., 2012).

In addition to financial costs, individuals with intellectual disabilities, family members of these individuals, and professionals who work with them have limited time, resources, and energy to devote to implementing treatments and interventions. Given the finite nature of these resources, it is critical that money, time, and energy are used effectively. While there is no one treatment or intervention that is guaranteed to be effective for all individuals with intellectual disabilities, there are clearly treatments and interventions that are evidence-based and others that are not supported by empirical evidence (Bowen & Snow, 2017; Courtade, Test, & Cook, 2015; West, McCollow, Kidwell, Umbarger, & Cote, 2013). An investment in the use of an evidence-based treatment or intervention is an investment in a treatment or intervention that is more likely to be effective. In contrast, if parents or professionals choose to invest in treatments or interventions that lack empirical support, not only are these treatments/interventions less likely to work, but there is also an opportunity cost. Time, energy, and resources will be devoted to the treatment or intervention that is less likely to be effective, and as a result

J. L. Matson (ed.), *Handbook of Intellectual Disabilities*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-030-20843-1_29

this may lead to the parent or professional forgoing the use of evidence-based treatments and interventions.

Parents of individuals with intellectual disabilities and/or ASD and professionals working with individuals with these diagnoses are typically using a range of treatments and interventions including those that are unsupported by research evidence and/or those that are controversial (Burns & Ysseldyke, 2009; Carter, Stephenson, & Strnadová, 2011; Goin-Kochel, Mackintosh, & Myers, 2009; Haessler et al., 2016; Matson & Neal, 2009; Matson & Williams, 2015). It is therefore important to consider the range of factors related to treatment and intervention decisions made by both parents and professionals in order to understand how these decisions are made and how better decision-making may be supported in the future.

Factors Related to Treatment and Intervention Decisions

In recent years the decision-making, particularly of parents, regarding treatment and intervention use has become a research area of interest. As a result, an increasing number of research studies have been published in this area. It is important to note that most of the published research in this area is related to decision-making regarding treatments and interventions for individuals with ASD, but comorbidity of intellectual disabilities and ASD is common (as addressed in Chap. 49). This research will be presented along with research related to decision-making for treatments and interventions for intellectual disabilities and other specific diagnoses that are characterized by intellectual disabilities, such as Fragile X and Down syndrome.

Decision-Making of Parents

Introduction

Factors that are related to the decisions of parents regarding intervention use have been explored in the research literature. These include both factors that parents have explicitly identified as influencing their decision-making, known as *declared decision-making factors*, and other underlying factors that may influence parent decision-making but that parents may not necessarily be aware of, known as *implicit decision-making factors* (Carlon, Carter, & Stephenson, 2013; Wilson, Hamilton, Whelan, & Pilkington, 2018). *Declared decision-making factors* include factors such as recommendations from others, research evidence, and pragmatic considerations, while *implicit decision-making factors* include parent and child factors such as age, gender, and time since diagnosis (Carlon et al., 2013; Wilson et al., 2018).

Declared Decision-Making Factors

In the research literature, a range of factors have been explicitly identified by parents of individuals with intellectual disabilities, ASD, or both, as influencing their treatment and intervention decision-making. It should be acknowledged that most of this literature relates to the decision-making of parents of children with ASD, which is suggestive for parents of children with intellectual disabilities (e.g., Bowker, D'Angelo, Hicks, & Wells, 2011; Dinora & Bogenschutz, 2018; Tzanakaki et al., 2012). However, where studies have addressed the decision-making of parents of children with intellectual disabilities, these have been included (e.g., Foran & Sweeney, 2010; Prussing, Sobo, Walker, & Kurtin, 2005). In addition, some studies addressed both the decision-making of parents of children with intellectual disabilities and of parents of children with ASD (e.g., Robert, Leblanc, & Boyer, 2015; Wodehouse & McGill, 2009); and some addressed the decision-making of parents of children with ASD including some children with comorbid intellectual disability diagnoses (e.g., Hanson et al., 2007; Shyu, Tsai, & Tsai, 2010). Declared decision-making factors that have been frequently examined in the literature are presented below.

Advice and Recommendations

Parents of children with intellectual disabilities and of children with ASD receive information and advice about treatments and interventions available from many sources. These may include other parents, medical doctors, the Internet, teachers or educators, friends/relatives, autism organizations/associations, popular media, books/authors on autism, therapists (including speech therapists, occupational therapists, behavior analysts, audiologists, and physical therapists), psychologists, disability support groups and newsletters, research literature, childcare providers, and diagnostic services (Carlon et al., 2013; Carlon, Stephenson, & Carter, 2015; Dinora, Bogenschutz, & Lynch, 2017; Prussing et al., 2005).

A common theme in the literature related to the type of information offered to parents by professionals, particularly around the time of their child's diagnosis, is that, while some professionals provide useful advice and guidance, this is not always the case. The information provided can be limited and professionals may not always provide advice that parents consider to be useful in their decision-making (see Carlon, Stephenson, & Carter, 2015; Dinora & Bogenschutz, 2018; Sansosti, Lavik, & Sansosti, 2012; Tzanakaki et al., 2012; Wodehouse & McGill, 2009). Parents can be expected to make complex decisions about treatment and intervention use that can leave them feeling unsupported:

> "… several families indicated that they 'were getting the runaround from professionals and schools… no recommendations… no road map.'" (Sansosti et al., 2012, p. 88)

> "i am using no treatments now, since diagnosis ive been left alone, its like they say shes this, now get on with it." (Mackintosh, Goin-Kochel, & Myers, 2012, p. 57)

> "When a mother of a 4-year-old was asked what advice she would give a pediatrician about how to work with families of children with autism, she said, "Listen. I want them to listen to me. Don't be afraid to offer advice. It is okay. I need it. Don't worry about offending me. Honestly. Be honest with me. Don't give me some run-around because I will know if you are just telling me what I want to hear. Be real."" (Levy et al., 2016, p. 575)

> "My biggest gripe about when you get a diagnosis is that you're a parent — you're not a doctor, you're not a speech therapist, you're not an occupational therapist, but you're given a pack and given the FaHCSIA money[1] and told to make the decision as to how you are going to treat your own child. It all depends on, possibly it all depends on, the first person you see and their opinion that they give you, or you just educate yourself and then try to figure out what your child needs — but it's a bit like a doctor saying, 'You've got cancer. How would you like to treat it?'" (Carlon, Stephenson, & Carter, 2015, p. 122)

Most of the research related to advice and recommendations is limited to the examination of the sources of advice reported to be used by parents, and some qualitative examination of the parent perceived usefulness of such advice. Some researchers, however, have also examined the weight of importance that parents place on recommendations from different sources when making treatment and intervention decisions. Two recent survey studies conducted in the US have provided some insight into the relative level of influence that different sources of information had on parent decision-making regarding ASD interventions and treatments. Dinora et al. (2017) reported that the parents of children with ASD who participated in their study rated developmental pediatricians, their spouse, school staff, speech language pathologists, and primary care physicians as having the most influence (moderate to high influence) on their intervention decisions. Television shows, magazines, social media, and other people were rated as having the least influence (Dinora et al., 2017). Participants in Deyro, Simon, and Guay (2016) were asked to rank six information sources (professional referral, general media, other parents with a child or children with ASD, autism organizations, books, and scientific journals) based on the level of influence on treatment and intervention deci-

---

[1] In Australia, the Federal Government Department of Families, Housing, Community Services and Indigenous Affairs (FaHCSIA) provided eligible families of children under 7 years of age with a confirmed ASD diagnosis up to A$12,000 over 2 years to fund early intervention services provided by a range of approved providers. Parents were provided with information (but not advice) about these services from *Autism Advisors*. The parents were required to choose how to spend these funds.

sions. The source ranked as most influential by the greatest number of participants was professional referrals (48.5%), followed by other parents (20%) and scientific journals (10%). A total of 34.3% of participants indicated that the general media was the least influential source, followed by scientific journals (24.4%), then books, and other parents (5% each).

In Australia, Carlon, Carter, and Stephenson (2015) asked parents of preschoolers with ASD to rate the level of importance they placed on a range of factors (including advice from different sources) when making the decision to use the intervention they nominated as the most important intervention currently being used with their child. On a scale of 1–5 (1 = very unimportant, 5 = very important), advice from therapists received a mean rating of 4.5, advice from teachers or educators 4.1, advice from medical doctors 4.0, advice from other parents 3.9, and advice from friends or relatives 3.2. Consistent with the findings of Deyro et al. (2016), this indicates that parents placed a greater weight on recommendations received from professionals than those received from other sources (Carlon, Carter, & Stephenson, 2015).

Nevertheless, research related to the weight placed by parents on different sources of advice is limited. The findings of Carlon, Carter, and Stephenson (2015), Deyro et al. (2016), and Dinora et al. (2017) indicate that the sources of information that are most frequently addressed in the research literature may not necessarily be the most influential on parent decision-making. For example, other parents are most frequently identified as sources of advice in the literature related to parent decision-making regarding treatments and interventions for ASD (Carlon et al., 2013), yet in Carlon, Carter, and Stephenson (2015), Deyro et al. (2016), and Dinora et al. (2017), parents indicated that other parents had less influence on their decision-making than other sources of advice (such as professionals).

Child Factors

Individual needs. Unsurprisingly, the individual needs or characteristics of the child are frequently reported in the literature as factors considered in decision-making for parents of children with intellectual disabilities and of children with ASD (Carlon et al., 2013; Edwards, Brebner, McCormack, & MacDougall, 2018; Finke, Drager, & Serpentine, 2015; Prussing et al., 2005; Robert et al., 2015). There is also some evidence that parents may place considerable weight on their child's individual needs in their decision-making. In the Carlon, Carter, and Stephenson (2015) survey of Australian parents of preschoolers with ASD, the participants were asked to indicate the level of importance that a range of factors had on both their decisions to use a nominated intervention and to reject a nominated intervention. All participants indicated that the child's individual needs were important in the decision to use the intervention nominated as the most important intervention currently used with their child. It was also the factor with the highest mean importance ratings in both the decisions to use and to reject the nominated interventions.

Age. The age of the child appears to be a factor that is considered by parents in some treatment and intervention decisions, but it has not been as widely examined as an explicitly stated factor in decision-making as other child factors (Carlon et al., 2013; Wilson et al., 2018). However, the implicit relationship between child age and treatment/intervention decisions has been extensively examined and is discussed in section "Declared Decision-Making Factors".

Side effects or adverse effects. Parents of children with intellectual disabilities and of children with ASD have reported side effects or adverse effects of treatments as reasons for discontinuing treatments (Bowker et al., 2011; Prussing et al., 2005). In addition, concerns about the safety and possible side effects of medications have also led to parents rejecting the use of conventional medications and choosing to use CAM treatments as alternatives (Bilgic et al., 2013; Hanson et al., 2007; Wong, 2009). However, it appears that not all parents view CAM treatments as a safe alternative. For example, Prussing et al. (2005) reported that some parents decided not to try CAM treatments with their children with Down syndrome due to concerns regarding efficacy and safety. Nonetheless, although the specific treatments considered by parents as safer or riskier options may vary from parent to parent, the evidence suggests that parents may consider the safety of treatments in terms of actual or possible side effects or adverse effects when deciding whether to commence and/or discontinue the use of these treatments.

Perceived enjoyment. Whether or not the parent believed the child would enjoy the intervention or treatment, including consideration of possible resistance to the intervention or treatment, has been reported to be considered by parents across several studies (e.g., Carlon, Carter, & Stephenson, 2015; Christon, Mackintosh, & Myers, 2010; Shyu et al., 2010). These have been limited to the ASD population, including one study with some participants with comorbid intellectual disability diagnoses.

Perceived child progress. Frequently in the literature addressing decision-making for ASD treatments and interventions, parents have indicated that their perception of their child's progress has influenced their decision to either continue using (Edwards et al., 2018) or to discontinue the use of a treatment/intervention (Bowker et al., 2011; Christon et al., 2010; Edwards et al., 2018). While some parents discontinued treatments and interventions due to a perceived lack of progress, others did so because they believed that the treatment or intervention was no longer required, either because the child's skills had progressed to a level where the treatment/intervention was no longer necessary and/or because the child had completed the treatment/intervention (Bowker et al., 2011; Christon et al., 2010; Finke et al., 2015).

Emotion-Based Factors

The influence of emotion-based factors has mostly been examined in qualitative research regarding parent decision-making for both interventions for ASD and for intellectual disabilities. A sense of hope, both for improvement (Carlon, Carter, & Stephenson, 2015; Finke et al., 2015; Tzanakaki et al., 2012) and for a cure (Carlon, Carter, & Stephenson, 2015; Finke et al., 2015), has been identified by parents as a consideration in treatment and intervention decision-making. Parents have also reported following their own intuition or "gut feelings" when selecting interventions (Carlon, Carter, & Stephenson, 2015; Prussing et al., 2005). Participants in Carlon, Carter, and Stephenson (2015) rated the importance of factors in their decision to use a nominated intervention. They ranked emotion-based factors significantly higher in importance than advice/recommendations. However, these parents placed significantly more weight on service characteristics, research evidence, and child factors than on emotion-based factors. In contrast, when asked about factors influencing decisions to reject a nominated intervention, emotion-based factors were ranked significantly higher than both pragmatic factors, research evidence, and advice/recommendations. For the decision to reject the nominated intervention, emotion-based factors received the highest mean importance ranking of all of the examined categories of factors.

Pragmatic Factors

Unsurprisingly, there are a range of pragmatic considerations that parents of children with intellectual disabilities and of children with ASD take into account when making decisions about treatment and intervention use. One of the first considerations of parents may be whether a specific treatment or intervention is available and accessible to the family. The availability and accessibility of the treatment/intervention have been reported frequently as decision-making factors in the literature (see Carlon et al., 2013; Dinora et al., 2017; Edwards et al., 2018). Some interventions can be restricted to specific diagnostic criteria and/or only offered to individuals with a specific level of functioning, which in turn can limit intervention options (Foran & Sweeney, 2010; Robert et al., 2015).

Related to availability, parents commonly report that there are waiting lists for services, particularly those that are publicly funded (Dinora et al., 2017; Foran & Sweeney, 2010; Robert et al., 2015; Sansosti et al., 2012; Valentine, 2010). In addition to access to intervention services provided as part of public health or education systems, access (or lack thereof) to government funding support and/or to insurance cover has been reported to influence parent treatment and intervention decision-making in several studies (Dinora et al., 2017; Edwards et al., 2018; Grant, Rodger, & Hoffmann, 2016; Mackintosh et al., 2012; Shepherd, Csako, Landon, Goedeke, & Ty, 2018; Valentine, Rajkovic, Dinning, & Thompson, 2010). The cost of treatments and interventions, whether related to access to external funding or not, is a logical consideration for parents. As such, it has been reported across several studies (Carlon et al., 2013; Carlon, Carter, & Stephenson, 2015; Edwards et al., 2018; Robert et al., 2015; Sansosti et al., 2012; Shepherd et al., 2018).

Other pragmatic considerations include the convenience to or impact on the family (Edwards et al., 2018; Rajkovic, Thompson, & Valentine, 2010). Some parents have chosen to discontinue interventions or not implement interventions suggested by professionals because they did not suit their family (Robert et al., 2015). This can be related to a failure to *fit the schedule* of the child and family, and/or to the treatment or intervention being perceived as inconvenient by the family (Rajkovic et al., 2010; Robert et al., 2015; Yingling, Hock, Cohen, & McCaslin, 2017). Time constraints were also reported to be related to intervention decisions across several studies (Carlon et al., 2013).

Research Evidence

Mixed results have been reported regarding the impact of research evidence on parent decision-making regarding treatment and intervention use for both intellectual disabilities and ASD. Although research has been reported to be considered by parents in a number of studies (Carlon, Carter, & Stephenson, 2015, 2017; Deyro et al., 2016; Dinora et al., 2017; Hanson et al., 2007; Prussing et al., 2005; Valentine, 2010), parents continue to use interventions that are not supported by research evidence (Goin-Kochel et al., 2009; Matson & Williams, 2015). In some studies where participants were directly asked about consideration of research evidence, this term was not defined for parents (e.g., Carlon, Carter, & Stephenson, 2015), so even though the parents indicated that research was important in their decision-making, their interpretation of research evidence may not have been the same as the researchers' interpretation of this term. This is possibly because parents may interpret *research evidence* to mean their own efforts to find information about treatments and interventions or anecdotal reports of treatment/intervention effectiveness, as opposed to the findings of empirical studies.

There is limited research addressing parents' ratings of the empirical support for treatments and interventions. Deyro et al. (2016) asked parents of children with ASD in the US to rate the effectiveness of and level of research support for 26 treatments/interventions for ASD. The authors compared these parent ratings to the ratings provided by the National Autism Centre in the National Standards Report as a result of a comprehensive review of the research support for treatments and interventions for ASD (excluding medication; Deyro et al., 2016). The ratings of parents corresponded with the ratings provided by the National Autism Centre for only 9 of the 26 treatments/interventions. In addition, for most of the treatments/interventions rated, parent ratings of research evidence did not correlate with their ratings of the effectiveness of the treatments/interventions (Deyro et al., 2016). Carlon et al. (2017) collected similar data from Australian parents in a pilot study of a parent education package providing information about evidence-based practice, guidelines for selecting interventions, and guided access to two websites that provided information about the scientific efficacy of a range of interventions for ASD. They found that even after the guided access to the websites, parents' ratings of research evidence did not necessarily correspond with the ratings provided on the websites. Ratings of the research support for interventions were positively correlated with the participants' current use of and desire to use interventions, indicating that the participants tended to rate interventions that they were currently using and those that they had a strong desire to use as having strong research support, regardless of the information about research efficacy provided on the websites (Carlon et al., 2017).

Intervention/Treatment and Service Characteristics

Characteristics of the treatment/intervention along with those of service providers delivering specific interventions or treatments have also been reported to be considered by parents of children with intellectual disabilities and with ASD in their decision-making. Intervention characteristics considered have included whether or not the intervention was a diagnosis-specific intervention or more general in nature (Carlon, Carter, & Stephenson, 2015) and whether it would be compatible with other interventions/treatments already being used with the child (Rajkovic et al., 2010; Valentine et al., 2010). In addition, there is some evidence that parents may also consider whether the claims of the proponents of the intervention/treatment are feasible and/or if they fit with the parent's beliefs about the etiology of their child's condition (Bilgic et al., 2013; Prussing et al. 2005).

The characteristics of the staff, including staff experience (Carlon, Carter, & Stephenson, 2015), whether they appeared to be professional (Carlon, Carter, & Stephenson, 2015), and the parent's impressions of their intentions and whether they *fit* with the child and family (Dinora et al., 2017), are also reported to affect parental decision-making. As with the other factors discussed above, there is limited research addressing the weight of importance that parents place on these characteristics in comparison to other factors when making treatment and intervention decisions. Dinora et al. (2017) reported that the fit of the provider with the parent and child was the strongest influence on parent decision-making about ASD treatments and interventions for their US sample. In addition, high importance was placed on staff characteristics by Australian parents of preschoolers with ASD in the survey conducted by Carlon, Carter, and Stephenson (2015).

Implicit Decision-Making Factors

The factors described in the section above were those that were explicitly identified by parents as related to their treatment and intervention decision-making. There are other factors that have been examined by researchers because they have the potential to influence treatment and intervention decisions. These implicit, underlying factors are factors that parents do not explicitly declare and of which they may not be consciously aware. By their nature, implicit factors have tended to be examined in studies using correlational approaches. These data provide an indication of the relative impact of the possible implicit factors relative to others addressed in each study.

It should also be noted that researchers have used available datasets such as health insurance claim data (e.g., Chang, Lin, Tung, Chiang, & Hsu, 2014), service providers' existing records (e.g., Olsson, Elgmark Andersson, Granlund, & Huus, 2017; Paton et al., 2011), and health record databases (e.g., Osunsanmi & Turk, 2016) to examine the relationships between treatments/interventions used by individuals with intellectual disabilities and factors such as gender, age, school class placement (specialized or mainstream), comorbid diagnoses, presence of problem behavior, and living circumstances. The person(s) responsible for deciding whether to use each of the treatments and interventions in these studies is unknown. Decisions may have been made by medical staff, educators, the individual with an intellectual disability, or family members, for example. While these studies provide some insight into the range of factors that may be associated with the use of specific treatments and interventions for intellectual disabilities and/or ASD, they cannot provide unambiguous insight into the decision-making of parents or other caregivers when the decision-maker is unknown. For this reason, the research examined in this section is limited to studies in which data were collected directly from the parent(s), including secondary analysis of such data. Similarly, other research addressing the relationships between implicit factors and healthcare service use and/or expenditure on healthcare for children with intellectual disabilities (e.g., Adams et al., 2016; Lin et al., 2013; Wilkins et al., 2010) has not been considered here because it does not provide insight into the specific treatments/interventions employed by these medical and allied health service providers and related parent decision-making.

Implicit Factors

In recent years researchers have examined relationships between a range of possible implicit decision-making factors and parent treatment/intervention decisions for intellectual disabilities (e.g., Sheehan, Kimona, Giles, Cooper, & Hassiotis, 2018; Zablotsky et al., 2015), Fragile X (e.g., Bailey Jr. et al., 2012; Laxman et al., 2018; Martin et al., 2013), and ASD (e.g., Denne, Hastings, & Hughes, 2017; Irvin, McBee, Boyd, Hume, & Odom, 2012; Mire, Hughes, Manis, & Goin-Kochel, 2018; Salomone, Charman, McConachie, & Warreyn, 2015; Zablotsky et al., 2015). The possible implicit factors examined can be broadly classified as either child-related factors, parent-related factors, or family-related factors (Wilson et al., 2018).

Although age was a factor that was explicitly stated as influencing parent decision-making in a number of studies, it has also been widely examined, using correlational approaches, in cases where the parents did not explicitly state that the child's age was a factor that they considered in their decision-making (Denne et al., 2017; Goin-Kochel, Myers, & Mackintosh, 2007; Laxman et al., 2018; Lindly, Thorburn, Heisler, Reyes, & Zuckerman, 2017; Martin et al., 2013; Miller, Schreck, Mulick, & Butter, 2012; Mire, Gealy, Kubiszyn, Burridge, & Goin-Kochel, 2017; Mire, Raff, Brewton, & Goin-Kochel, 2015; Owen-Smith et al. 2015; Salomone et al., 2015, 2016; Sheehan et al., 2018; Shepherd et al., 2018; Thomas, Ellis, McLaurin, Daniels, & Morrissey, 2007; Witwer & Lecavalier, 2005; Wong & Smith, 2006). Other child factors that have been examined include the gender of the child (Laxman et al., 2018; Lindly et al., 2017; Martin et al., 2013; Owen-Smith et al., 2015; Patten, Baranek, Watson, & Schultz, 2013; Salomone et al., 2015, 2016; Sheehan et al., 2018; Shepherd et al., 2018; Witwer & Lecavalier, 2005; Wong & Smith, 2006), the type of diagnosis and/or perceived severity of symptoms associated with diagnosis (Bailey Jr. et al., 2012; Hall & Riccio, 2012; Laxman et al., 2018; Lindly et al., 2017; Mire et al., 2017; Owen-Smith et al., 2015; Patten et al., 2013; Salomone et al., 2016; Sheehan et al., 2018; Thomas et al., 2007; Witwer & Lecavalier, 2005; Zablotsky et al., 2015), time since diagnosis (Miller et al., 2012; Salomone et al., 2016; Zuckerman, Lindly, & Chavez, 2017), comorbid conditions (Bailey Jr. et al., 2012; Laxman et al., 2018; Martin et al., 2013; Sheehan et al., 2018; Zablotsky et al., 2015), age at diagnosis (Lindly et al., 2017; Zuckerman et al., 2017), and presence of challenging behavior (Laxman et al., 2018; Sheehan et al., 2018).

Possible relationships between treatment/intervention decisions and family-related factors have also been examined in the literature. Family income or socioeconomic status has been examined across several studies, and the findings have been mixed (Bailey Jr. et al., 2012; Denne et al., 2017; Irvin et al., 2012; Laxman et al., 2018; Miller et al., 2012; Mire et al., 2017; Owen-Smith et al., 2015; Patten et al., 2013; Thomas et al., 2007); family size was examined in only a small number of studies (Lindly et al., 2017; Shepherd et al., 2018), as was health insurance coverage (Lindly et al., 2017; Thomas et al., 2007; Zablotsky et al., 2015). In comparison, the geographic location of the family was relatively more widely examined (Lindly et al., 2017; Mire et al., 2018; Salomone et al., 2015, 2016; Thomas et al., 2007). Examination of the relationship between ethnic background and treatment/intervention use has mainly occurred in the North American context, where the results have been mixed (Hall & Riccio, 2012; Irvin et al., 2012; Lindly et al., 2017; Owen-Smith et al., 2015; Patten et al., 2013; Reyes et al., 2018; Thomas et al., 2007). Other parent-specific factors examined have included the parents' age (Miller et al., 2012; Shepherd et al., 2018; Wong & Smith, 2006), parent education levels (Denne et al., 2017; Hall & Riccio, 2012; Lindly et al., 2017; Miller et al., 2012; Mire et al., 2017; Owen-Smith et al., 2015; Patten et al., 2013; Salomone et al., 2015, 2016; Shepherd et al., 2018; Thomas et al., 2007; Wong & Smith, 2006), marital status (Hall & Riccio, 2012; Owen-Smith et al., 2015), parents' beliefs or perceptions about their child's disability (including etiology; Dardennes et al., 2011; Lindly et al., 2017; Mire et al., 2017; Reyes et al., 2018), and parent/caregiver stress (Irvin et al., 2012; Thomas et al., 2007).

In general, when relationships between implicit factors and intervention/treatment use have been examined, few significant relationships have been found. Where significant relationships have been found, these findings have not necessarily been replicated in other studies. For example, some beliefs about ASD have correlated with the use of certain treatments and interventions, but the specific beliefs and treatments/interventions these are associated with have varied from study to study (see Dardennes et al., 2011; Lindly et al., 2017; Mire et al., 2017; Reyes et al., 2018). This is possibly a reflection of the idiosyncratic nature of parent decision-making.

Nevertheless, a few consistent findings have emerged. The relationship between the child's gender and treatment/intervention use was examined across a number of studies and was not found to be associated with the use of a particular treatment or intervention in the majority of studies in which it was examined (See Laxman et al., 2018; Lindly et al., 2017; Wilson et al., 2018). Another consistent finding that has emerged across the studies is that when parent education levels and CAM use have been examined, those who are more highly educated have been found to be more likely to use CAM interventions (Hall & Riccio, 2012; Owen-Smith et al., 2015; Patten et al., 2013; Salomone et al., 2015; Wong & Smith, 2006).

Summary

The majority of research related to parent decision-making regarding treatments and interventions has been conducted with parents of preschoolers and school-age children with ASD. Factors influencing parent decision-making include both those explicitly declared by parents as influencing their decisions and other implicit underlying factors that have been examined using correlational research (Carlon et al., 2013; Wilson et al., 2018). The most frequently examined declared decision-making factors include advice or recommendations from others, child factors (such as individual child characteristics), and pragmatic considerations (such as cost, funding, and accessibility). There is limited research related to the weight or level of importance that parents place on the different factors as they make decisions, but the evidence to date indicates that multiple factors are considered by parents as they make decisions and that those factors that are most frequently reported in the research are not necessarily those that have the most influence on parent decision-making.

A vast range of implicit underlying parent, child, and family factors may also be related to parent decision-making. These potential relationships have been examined using correlational research. Few significant relationships have been found in studies examining implicit factors, and where relationships have been found these have not tended to be replicated across studies. There are two consistent findings that have emerged: (1) child gender has not appeared to be related to treatment and intervention decisions; and (2) higher parent education levels have tended to be correlated with the use of CAM treatments. With these two exceptions, overall, the findings in this area have been inconsistent, and this may be reflective of the complex interplay between a range of competing declared decision-making factors and idiosyncratic implicit child, parent, and family factors.

Decision-Making of Teachers

Introduction

Students with intellectual disabilities may be educated in a range of contexts, including inclusive settings where a regular class teacher is responsible for their education through to self-contained settings with a special educator. Teacher decision-making in any setting is complex, and using theories of natural decision-making may be best seen as a process for solving problems, with the solutions constrained by a range of teacher and contextual factors, including values, attitudes, beliefs, resourcing, and system demands (Robinson, 1998; Robinson & Donald, 2015). Conventional theories of decision-making assume that once teachers know about effective interventions, they will make a rational decision to use them and that they will monitor the impact on their students and retain effective practices. The well-documented research-to-practice gap in special education indicates that this does not happen (Gersten, Vaughn, Deshler, & Schiller, 1997). A first step in understanding teacher decision-making in natural contexts is to identify factors that may influence teacher decision-making and the characteristics of teachers that determine which factors are considered. The factors influencing decisions may be conflicting, and an understanding of teacher decision-making requires an understanding of how teachers resolve those conflicts and decide on a course of action (Robinson, 1998).

Evidence-Based Practice

Although the ideal of researchers and the thrust of recent policies such as No Child Left Behind in the US would be that in the main special educators and teachers in segregated and inclusive settings would choose to use evidence-based interventions with research evidence to support them, the research-to-practice gap is widely recognized as a problem within special education (Greenway, McCollow, Hudson, Peck, & Davis, 2013; McLeskey & Billingsley, 2008). Gersten et al. (1997) suggested principles that would support uptake and use of effective practices. Interventions must be feasible and practical for classrooms (the reality principle) and only involve a reasonable amount of change to teacher practices. The changes must be linked to student outcomes. Teachers need the opportunity to practice an intervention with feedback and to link the concepts underpinning research to classroom realities. Simply knowing about an intervention is not sufficient for a teacher to decide to use it.

In the literature addressing the research-to-practice gap, researchers have suggested a range of reasons why teachers do not use evidence-based practices, but there is little investigation of teacher perspectives on the use of research. For example, Cook and Cook (2004), in writing about the education of students with learning disabilities, suggest that within natural decision-making, teachers largely ignore research findings as a factor. They suggest this because teacher preparation does not present research well, there are difficulties in the translation of research to practice, and school cultures may not value research. Similarly, Hornby, Gable, and Evans (2013) summarized the reasons generally why special education teachers are resistant to evidence-based practice as distrust of educational research and interventions described as best practice, a preference for guidance from experienced teachers, a preference for existing practices and lack of appropriate education, and professional development. McLeskey and Billingsley (2008) also noted the two factors of inadequate teacher education about research and the nature of research itself but added other factors related to teaching contexts, such as large caseloads and lack of support that may not always support best practices.

Guckert, Mastropieri, and Scruggs (2016) interviewed highly qualified special educators teaching students with learning difficulties, autism, and severe disabilities and examined their documentation to determine their perceptions and use of evidence-based practices. They found that although all teachers believed they were using evidence-based practices, there was a wide range in awareness of evidence-based practice and research. The aware teachers trusted research and could explicitly state that a practice was evidence-based, used it, discussed it with others, and relied on it. The partially aware group did not provide specific descriptions of evidence-based practices and was hesitant about sharing research evidence with colleagues, sometimes implemented and occasionally relied on evidence-based practice. The unaware group was skeptical about using evidence-based practices and reported it was not common to discuss the source of strategies chosen with colleagues and that they sometimes implemented evidence-based practices but rarely relied on them. Aware teachers reported personalizing research in explicit and effective ways, while the partially aware teachers may not have always implemented strategies effectively and described barriers such as time demands. The unaware teachers were less aware of the sources and components of strategies and were more likely to make unsuitable adaptations.

Decision-Making and Intellectual Disabilities

There appears to be little research directly and specifically examining the decision-making of teachers in regard to students with intellectual disabilities (Greenway et al., 2013), although it appears to be an area of emerging interest, particularly in relation to decision-making for students with severe intellectual disabilities. Greenway et al. (2013) offer one of the few studies specifically investigating teacher decision-making for students with intellectual and developmental disabilities. They interviewed nine teachers about their experiences and perceptions regarding evidence-based practices. Like the participants in Guckert et al. (2016), they had varied understandings of evidence-based practices, but they also discussed their access to resources, interactions with other people and organizations, and the interactions between these. Some teachers valued the autonomy they had as special educators but noted it came with less accountability, less supervision, and less collaboration. They reported that in this context, district policies about evidence-based practices were absent or not seen by others as relevant. Teachers wanted evidence-based resources to be made available, such as curricula and more access to professional learning, consultancy, and research literature, so it appears access to sources of reliable information may limit the use of some practices.

Andzik, Chung, Doneski-Nicol, and Dollarhide (2017) interviewed teachers of students with intellectual or developmental disabilities about the factors affecting decisions to use augmentative and alternative communication (AAC). Teachers described barriers to implementing AAC which were similar to those reported in earlier studies such as the lack of training in AAC, limited preparation time, and variable support from speech language pathologists and others. These practical factors were seen to limit student access to AAC, as did teacher knowledge of assistive technology.

More specifically, Ruppar, Gaffney, and Dymond (2015) investigated teacher decision-making in respect to literacy for secondary students with severe disabilities most of whom had intellectual disabilities. They identified four major factors that contributed to teacher decision-making about literacy. Teacher beliefs concerning the student, learning, and teaching determined the degree of individualization of lessons. Their expectations of the student influenced the goals they set, with those teachers who held lower expectations of their students being more likely to have set restrictive goals. Teachers with high self-efficacy were less likely to seek expert help or professional learning. In addition, Ruppar et al. (2015) identified a range of contextual factors which interacted with the teacher factors including staffing, in-class assistance and teaching materials available, level of support from colleagues, administrators and policies, philosophies about curriculum, personal and professional experiences, and professional development.

This research then, mostly recent, which describes specifically teachers of students with intellectual disabilities, and mostly those teaching students with severe disability, has identified a range of interacting teacher and contextual factors. Within teacher factors include teacher understanding of evidence-based practices, teacher knowledge, teacher attitudes and beliefs about students and teaching, and teacher self-efficacy. Contextual factors include access to resources and reliable information about evidence-based practices, access to support and collaboration with others, administrative and policy issues, and limited time.

Despite this lack of research directly relevant to students with intellectual disabilities, research on the education of students with disability more generally offers further useful information on factors influencing teacher decision-making. Surveys of special educators explore reported practices in relation to teacher characteristics. In addition, investigations addressing the acceptability of interventions to special and general educators and research, often qualitative, which explores special educator reports of their beliefs, attitudes, and practices and the reasons they give for selecting interventions may all contribute.

Practices and Teacher Characteristics

Multiple surveys of special education teachers have revealed that although they may use evidence-based practices, it is common for them to also use unproven and disproven practices. Burns and Ysseldyke (2009) surveyed both special education teachers (about a third of whom taught students with intellectual disabilities) and school psychologists in the US and found that some sound interventions, such as direct instruction, were used frequently. However, there was also high frequency of some ineffective interventions; for example, modality instruction was used as frequently as applied behavior analysis (an intervention with strong empirical support). Although they did not directly examine teacher characteristics in relation to reported use, they suggest that factors such as perceived effectiveness, resource demands, alignment with the teacher's own theories, and intrusiveness may be relevant. They also noted that respondents were members of the Council for Exceptional Children and thus may have been more aware of current research and best practices than nonmembers.

Carter et al. (2011) replicated the Burns and Ysseldyke (2009) survey with Australian special educators, and although they found high levels of use of a number of evidence-based practices, such as direct instruction and applied behavior analysis, they also reported moderate-to-high levels of use of a number of interventions with poor research support, such as modality instruction and perceptual motor programs. There were differences in use depending on the nature of students taught, with social skills training used more with students with severe and profound disabilities. There was no correlation between practices used and qualifications in special education, although the sample was drawn from members of the Australian Association of Special Education, who like the Burns and Ysseldyke (2009) sample may have been more aware of current research. A survey of special education teachers in the Czech Republic (Carter, Strnadová, & Stephenson, 2012) revealed a similar pattern, with high frequency of use reported for the evidence-based practices, applied behavior analysis, and direct instruction but also frequent use of practices without strong empirical support, such as perceptual motor training. Here teachers of students with severe and profound disability generally reported more use of both evidence-based and non-evidence-based strategies, and use of perceptual motor and psycholinguistic training was associated with higher levels of special education training.

Knight, Huber, Kuntz, Carter, and Juarez (2018) surveyed special educators teaching students with intellectual disabilities and/or autism about instructional practices. They found considerable variability in the practices teachers reported that they used but, like previous surveys, found use of both evidence-based strategies such as direct instruction and non-evidence-based interventions such as sensory integration. They also looked at factors that influenced teacher decision-making and found teachers were more likely to use interventions when they had received training or resources related to the intervention in the previous year. Other influences were setting (more use of evidence-based practices in special education classes), caseload, and age of students. The educational level and experience of teachers had little relation to the use of evidence-based practices. The teachers themselves reported that student need, the skills to be taught, and their perceptions of effectiveness of the practice influenced decisions. Decision-making was not generally influenced by research support, expert advocacy, or preservice education, but also recent training and recommendations from other teachers were influential. Similarly, Lawson and Jones (2017) who focused more on minute-to-minute decision-making than intervention selection and who both interviewed and observed teachers found that knowledge of individual students was a factor in all decision-making. Lawson and Jones (2017) also noted consultation with others, training, and mandated programs as influences.

Despite the results from Carter et al. (2011, 2012) and Knight et al. (2018) suggesting that there is little relationship between qualifications in special education and self-reported intervention choices, other research suggests that the nature of teacher qualifications does have an impact on instructional decision-making for students with disability generally. Teachers with special education qualification get better academic results than those without (Feng & Sass, 2012; Hanushek, Kain, & Rivkin, 2002) which suggests use of more effective strategies. Survey research shows special educators who had completed relevant coursework or professional learning were more likely to report the use of effective practices regarding transition (Morningstar & Benitez, 2013). In a survey of special educators working with students with emotional and behavioral difficulties, Stormont, Reinke, and Herman (2011) found special educators were better able to identify evidence-based and non-evidence-based behavioral interventions and were more confident in their intervention choice than regular educators. Bell, Cihak, and Judge (2010) surveyed student teachers in an alternative special education licensure program and found knowledge and use of assistive technology were strongly related to teacher preparation. Participants in this survey also reported perceptions of barriers to the use of assistive technology which included lack of time, knowledge, and funding.

Teacher Attitudes and Beliefs

For students with intellectual disabilities who are educated in inclusive settings, there is also little specific research. There is a view that positive attitudes to inclusion are more likely to lead to teachers making decisions to implement effective practices but that teachers are likely to hold more negative attitudes to the inclusion of students with intellectual disabilities (Avramidis & Norwich, 2002). Carlson, Hemmings, Wurf, and Reupert (2012) noted the importance of positive teacher attitudes to inclusion as an element motivating the use of effective practices. They observed and interviewed six teachers, some of whom taught students with intellectual disabilities, described by their principals as exemplary inclusive teachers. All used evidence-based strategies such as feedback, cooperative learning, and elements of direct instruction. The researchers suggested that other evidence-based strategies such as mastery learning were not used because teachers did not know about them. Use of effective practices was supported by collaboration with families and specialists, good support systems, and appropriate professional learning.

There is little direct evidence linking beliefs and attitudes to intervention decisions, beyond the negative attitudes to inclusion for students with disability. Jordan, Glenn, and McGhie-Richmond (2010) suggested perhaps a quarter of teachers in inclusive settings may believe that a disability is a fixed condition and that students may not benefit from instruction. They make minimal adaptations to instruction and prefer a pullout service model, taking less responsibility for student learning. Similarly, Ruppar, Roberts, and Olson (2018) linked deficit views of disability as fixed and located in the student to different visions of teacher expertise characterized by different teacher behaviors. They interviewed teachers of students with significant disabilities, including intellectual disabilities, their supervisors, and university personnel preparing special educators to explore their visions of expertise. They identified two contrasting visions, strength-based and deficit-based, which were associated with instructional approaches. In the strength-based view, teachers used their knowledge of the student to choose age-appropriate curriculum content and instructional designs, based on student strengths and abilities. In contrast, in a deficit-based vision, the focus was on caregiving and managing behavior rather than instruction. Roberts, Ruppar, and Olson (2018), noting the influence of educational leaders on instructional decision-making, interviewed principals and administrators and found that these leaders "were not able to articulate evidence-based instructional practices" (p. 14). They tended to emphasize caregiving and thus could be considered to hold a deficit view and low expectations of students with severe disabilities and influence teacher practices through these beliefs.

Acceptability

Research on the acceptability of interventions to teachers also provides some relevant information related to teacher decision-making, although this work has been mostly carried out with teachers of students with learning difficulties or behavioral disorders and on behavioral intervention (Boardman, Arguelles, Vaughn, Hughes, & Klingner, 2005; Gajria & Salend, 1996). In relation to these teachers, Boardman et al. (2005, p. 168) stated that "Teachers sought instructional practices that were feasible, were appropriate for their students, were accompanied by all necessary materials and professional development support, and could be individualized for multilevel classrooms." This supported the earlier findings of Gajria and Salend (1996) from a review of research on treatment acceptability for adaptations made for students with disability in mainstream classes. They noted that although choice of adaptations was not solely related to perceived effectiveness, that was a consideration, but for behavioral interventions, the nature of the intervention, the time and resources needed, its theoretical base, and any negative side effects were also considered. For instruction, teachers generally made only superficial changes to lessons rather than adopting new strategies or adjusting curriculum. They preferred interventions that did not need additional resources, did not involve other people, were not time-consuming, and fitted in with their existing practices. Whinnery, Fuchs, and Fuchs (1991) found little difference between special and regular educators of students with mild disabilities in regard to the perceived effectiveness and acceptability of instructional strategies and social behavior interventions addressed in a teacher survey. As in other studies, acceptability was related to perceptions of interventions as effective, but they also noted that teachers may not be aware of some effective interventions.

Policies

Ruppar et al. (2015) noted that policy contexts are one of the factors that might affect teacher beliefs and policies might support or limit the decisions teachers make. The teachers in Greenway et al. (2013) indicated that there were either no relevant district policies for students with intellectual and developmental disabilities or that policies were waived and so policies had little impact on their decision-making. It may be that policies designed for typically developing students are not appropriate for students with disability. Similarly, Boardman et al. (2005) noted that the teachers in their study (teachers of students with learning difficulties or behavior disorders) were often left to make their own decisions, even when districts suggested particular programs. Some studies have explored the impact of district and school policies on teacher behavior. Timberlake (2016) interviewed teachers of students with significant cognitive disabilities and found that they took responsibility for curriculum and instructional decisions, although they did recognize some policy boundaries such as graduation requirements and alternate assessments. Hudson et al. (2016) found special educators expressed varying levels of confidence in curriculum decisions made at higher levels and did not always agree that policy decisions around evidence-based practices for general education were applicable to their students. Lawson and Jones (2017) thought teachers of students with severe intellectual disabilities in Florida, USA, were more subject to policy decisions than those in the UK.

Summary

Overall then, the literature on special educators generally is consonant with research on teachers of students with intellectual disabilities and confirms there are multiple teacher and contextual factors that can interact in various ways to affect teacher decision-making. Table 29.1 presents an overall summary of the factors that have been identified.

Generally, it seems that the principles enunciated by Gersten et al. (1997) 20 years ago to support the use of evidence-based interventions by special educators still hold. Teachers are likely to use interventions that are feasible and practical within the resources available to them (time and materials). They need to be linked to student outcomes so that teachers perceive that the interventions are effective for their students. Where teachers receive education and training in the use of interventions, they are more likely to use them. Finally, teachers who know and understand research and the theories and principles underlying it are more likely to use evidence-based interventions supported by research.

Table 29.1 Factors influencing teacher decision-making

Within teacher factors
Knowledge and understanding, especially of evidence-based practices
Attitudes to the use of research
Teacher qualifications
Teacher training about specific interventions
Teacher theories and philosophies of learning and teaching
Teacher attitudes and beliefs about students with intellectual disabilities (strength-based or deficit-based)
Teacher perceptions of the effectiveness of an intervention
Teacher perceptions of student need
Teacher knowledge of the student
Teacher self-efficacy
Contextual factors
Resources available, particularly time
Feasibility of interventions
Supports available for an intervention
Side effects of an intervention
Fit with existing practices
Policies at school, district, and system level
Interaction and collaboration with others
Available staffing
Skills and knowledge to be taught
Setting
Level of student disability

Decision-Making of Other Professionals

Professionals other than teachers are also responsible for making decisions about the treatments and interventions used with individuals with intellectual disabilities. Notably, there has been much less research in this area than in that of parent or teacher decision-making. In particular, there is very little data related to treatment or intervention decision-making in group homes and vocational programs beyond examination of the treatment decisions of intellectual disability nurses (Williams, Roberts, Irvine, & Hastings, 2010) and some comparisons of medication and service use by individuals with intellectual disabilities living with their parents compared with those living in group homes (e.g., Harrington & Kang, 2016; Osunsanmi & Turk, 2016; Tsiouris, Kim, Brown, Pettinger, & Cohen, 2013). Treatments and interventions for challenging behaviors exhibited by individuals with intellectual disabilities within residential settings have received attention in recent years, with a particular focus on the use of psychotropic and antipsychotic medications (e.g., Bowring, Totsika, Hastings, Toogood, & McMahon, 2017; Doan et al., 2014; O'Dwyer et al., 2017). However, these studies have tended to focus on identifying a range of implicit factors that may be associated with the use of medication without consideration of who was making treatment decisions or the decision-making process undertaken (see Bowring et al., 2017; Doan et al., 2014; Kelly & Su, 2015; O'Dwyer et al., 2017). Thus, this literature provides little insight into how the decisions were made beyond the fact that challenging behavior exhibited by individuals with intellectual disabilities tends to be positively associated with medication use in residential settings (see Bowring et al., 2017; Doan et al., 2014). Other researchers have examined the experiences and practices of residential care staff regarding medication use, including their attitudes toward and understanding of medications (e.g., de Kuijper & van der Putten, 2017; Joos et al., 2014; Lalor & Poulson, 2013). This research has tended to focus on the outcomes of treatment decisions as opposed to how the decisions were initially made and therefore also provides little insight into treatment decision-making.

Although Williams et al. (2010) considered the process of decision-making employed by intellectual disability nurses, it should be noted that other research related to treatment/intervention decisions for adolescents and adults with intellectual disabilities has addressed the outcomes of treatment/intervention decisions as opposed to how those decisions were made (e.g., Harrington & Kang, 2016; Lalor & Poulson, 2013; O'Dwyer et al., 2017; Osunsanmi & Turk, 2016). Most of the research regarding the treatment and intervention decision-making of professionals relates to those working in early intervention, and, similar to the parent decision-making literature, much of this relates to the population of children diagnosed with ASD.

Special education and general teachers may work in early intervention services. The decision-making of teachers working in early intervention is often more collaborative than teachers working in schools. These teachers are often working in teams with other professionals, and best practice guidelines indicate that collaboration with other professionals and, in particular, the family is important (Division for Early Childhood, 2014). Therefore, the decision-making process for those teachers working in early intervention is different to those working in schools. In addition, much of the literature on decision-making of early intervention professionals does not differentiate between the decision-making of teachers and other professionals and paraprofessionals working in early intervention. Hence, it is more appropriate to include research literature related to the decision-making of teachers working in early intervention in the current section than the previous one.

A growing interest has been shown in the decision-making of early intervention professionals in recent years, particularly in relation to ASD interventions. Stahmer, Collings, and Palinkas (2005) conducted focus groups with early intervention providers in the US working with children with ASD regarding the intervention techniques and strategies used. Participants reported using a range of interventions and tended to rate the interventions that they used as being evidence-based, when only about a third of those nominated as evidence-based had research support. Paynter and colleagues have more recently conducted research in Australia examining the knowledge and use of practices by ASD early intervention service providers (Paynter et al., 2017; Paynter & Keen, 2015) and allied health professionals working with individuals with ASD (not necessarily within the early intervention age group; Paynter, Sulek, Luskin-Saxby, Trembath, & Keen, 2018) and the factors related to their decisions to employ different practices. They found that a range of evidence-based, emerging, and unsupported interventions were being used by the early intervention and allied health professionals but that evidence-based practices were being used more than emerging practices and emerging practices more than unsupported practices (Paynter et al., 2017, 2018; Paynter & Keen, 2015). The intervention practices reported to be used most frequently by the early intervention providers in Paynter et al. (2017) were evidence-based practices, and those used least frequently were unsupported interventions. There were, however, some unsupported interventions that were commonly being used more than once per week, including facilitated communication and multisensory environments. The role/profession of the early interventionist did not appear to be related to the use of these unsupported practices, as there were no significant differences between the use of these interventions by teachers, allied health professionals/social workers, and paraprofessionals (childcare workers). Teachers did report using academic interventions more frequently than allied health professionals/social workers and paraprofessionals (Paynter et al., 2017). This indicates that the professional background of the provider may influence some (but not all) of their intervention decisions.

The use by early intervention and allied health professionals of some interventions that do not have empirical support leads to the question of whether research evidence is a factor that these professionals consider in their decision-making. Stahmer et al. (2005) observed that none of the participants involved in their study reported engaging in professional reading. They concluded that:

> "It appears that program marketing, availability of training, provider preference, and external factors such as parent requests influence the use of specific practices more than whether the practice has any evidence of efficacy." (Stahmer et al., 2005, p. 74)

Similarly, Leong, Carter, and Stephenson (2013) surveyed early intervention providers in Malaysia and Singapore and found that even though half of the participants reported that research evidence on the efficacy for sensory integration was the reason that they employed this intervention, few reported using academic journals as sources of information about sensory integration. In contrast, 74.2% of the Australian early intervention professionals surveyed by Paynter et al. (2017) reported that they used research literature (e.g., academic books and academic journals) as sources of information about intervention practices for ASD, and 60.6% used treatment reviews (e.g., "good practice guidelines"). These participants rated both research literature and treatment reviews as trustworthy sources. However, more commonly used sources of information included internal professional development (100% of participants), therapists (e.g., speech therapists; 97%), workshops or other external professional development (89.4%), teachers (81.8%), general web searches (e.g., google; 78.8%), and parents of children with ASD (77.3%). The source of information most commonly used by the sample of allied health professionals working with individuals with ASD but not limited to the early intervention years was workshops or external professional development (100%; Paynter et al., 2018). Ninety-nine percent of participants in Paynter et al. (2018) reported receiving information from research literature, 77.8% from research and professional websites, and 72.7% from treatment reviews. Other frequently used sources included other therapists (99%), internal professional development or training (95.9%), autism associations or organizations and information from general web searches (both 89.9%), teachers and parents of children with ASD (both 89.8%), and professional associations (87.9%).

The allied health professionals surveyed by Paynter et al. (2018) rated research literature as the most trustworthy source of information, followed closely by workshops or other professional development, research and professional websites, treatment reviews, and internal professional development or training which also received a high mean rating of trustworthiness. The source of information with the highest mean trust rating received from early intervention professionals in the Paynter et al. (2017) study was internal professional development. Workshops or other professional development were also considered to be trustworthy, along with a range of other sources including therapists, research literature, and websites (Paynter et al., 2017). This indicates that early intervention and allied health professionals may attribute a similar weight of importance to information received from sources of research evidence to that received from other sources such as other professionals and professional development. Stahmer et al. (2005) also observed that the participants in their US sample tended to rate interventions as evidence-based if they had attended professional development workshops related to the intervention. In addition, 76.2% of the Malaysian early intervention providers surveyed by Leong et al. (2013) stated that they used sensory integration due to benefits described at a conference. Further, occupational therapists were reported to be the most common sources of both information and training regarding sensory integration in Malaysia and Singapore, and over 80% of the participants in the Leong et al. (2013) study reported that advice from occupational therapists was the reason that they used sensory integration. Findings from these studies in the US, Australia, and Asia suggest that workshops, professional development, and advice from other allied health professionals (such as speech therapists and occupational therapists) may have significant influence on early intervention and allied health professional's decision-making.

However, similar to parent decision-making, there are very limited data related to the relative importance placed by early intervention professionals on different factors in decision-making. Paynter et al. (2017) asked the intervention providers to rate the level of importance of 15 possible factors in their decisions to use intervention practices. The child's strengths and needs had the highest mean importance ratings, followed by the family's values, professional judgment, resources available to implement the intervention at their organization, and research evidence. The factors with the lowest mean importance rating were the interventionist's university or other post-school training, their own intuition or "gut feelings," whether they thought the child would enjoy it, and their hope that the intervention would work for the specific child (Paynter et al., 2017). Although 62.1% of participants indicated that research evidence was very important in their decision-making and a further 30.3% considered it somewhat important, there were 8.5% of early intervention providers in this study who considered research evidence to be unimportant in their decision-making (Paynter et al., 2017). Clearly, for at least some professionals, factors other than research evidence influence intervention decisions.

Goldbart, Chadwick, and Buell (2014) considered the rationales provided by speech therapists in the UK for the intervention approaches that they employed with children and adults with profound and multiple disabilities. Although this study cannot provide insight into the weight of importance placed by these professionals on each of the factors in decision-making, it does provide further insight into the range of factors that influence decision-making. The most frequently stated rationales for the use of intervention approaches were the empowerment, development, and behavioral needs of the individual, followed by the opportunity to develop the communication environment and family and carer skills. Unlike the Paynter et al. (2017) sample, these professionals did not frequently consider the views and wishes of the family/carers as a rationale for using any of the specific approaches and also rarely stated that they considered the views of other professionals (Goldbart et al., 2014). Published research evidence was only sometimes provided as a rationale for the use of the intervention approaches examined. The importance of clinical expertise and theories was also mentioned occasionally across the intervention approaches. Some rationales are provided by the participants that were not anticipated by Goldbart et al. (2014) related to practical and organizational issues, such as availability of resources and service structures.

Related to practical and organizational factors that have been considered in the decision-making of professionals, Cheung, Trembath, Arciuli, and Togher (2013) surveyed Australian speech therapists working with individuals with ASD about specific workplace factors that may act as either barriers or enablers to implementing evidence-based practice. The vast majority of participants (97%) indicated that they considered the application of evidence-based practice (EBP) as necessary in the practice of speech-language pathology, and 76% indicated that they had searched for research evidence on a regular basis. Interestingly, these participants viewed themselves in the minority in terms of regular practice for speech therapists, with only 23% agreeing with the statement that “Most speech-language pathologists work according to the principles of EBP when providing services to children with ASD” (Cheung et al., 2013, p. 399), and 41% agreed that there was a divide between research and practice. This is unsurprising considering the evidence that there are some early intervention and allied health professionals who report using interventions that are not evidence-based and that research evidence is not always reported to be an important consideration in professional decision-making (Goldbart et al., 2014; Leong et al., 2013; Paynter et al., 2017, 2018; Stahmer et al. 2005). Workplace culture and support were identified by Cheung et al. (2013) as important features that may either enable or act as barriers to the implementation of evidence-based practice. One participant commented

> “Management staff of my organization are not clinicians and therefore have limited understanding of the need to use EBP. Resources for accessing research are therefore not deemed to be a priority and service delivery decisions are made from an administrative point of view, rather than being evidence-based.” (Cheung et al., 2013, p. 400)

Time constraints within the workplace and the cost of resources such as subscriptions to journals and professional development courses were identified as further barriers to completing professional reading and other professional development that participants believed were necessary for the implementation of evidence-based practice. Finally, less than half of the participants believed that they had an adequate understanding of the process of evidence-based practice involving “(a) defining questions, (b) identifying sources for clinical evidence, (c) finding research evidence, (d) appraising the literature, (e) applying findings to relevant clinical questions for a specific client’s needs, and, finally, (f) evaluating the effectiveness of this process” (Cheung et al., 2013, p. 401). This indicates that even in a sample of professionals who appear motivated to employ evidence-based interventions, there may be several barriers to the implementation of these interventions in practice.

Recommendations

Recommendations for Parents

Evidence reviewed in this chapter suggests that parents tend to consider, or are influenced by, a complex range of factors in decision-making. Consideration of research evidence, however, does not typically feature prominently in decision-making. In addition, providing guidance in interpreting research evidence may not necessarily influence parents once decisions have been made (Carlon et al., 2017). This is hardly surprising given the extensive research on human cognitive biases and the well-documented tendency to accept information that is consistent with an established or initial viewpoint and dismiss disconfirming evidence (e.g., Edwards & Smith, 1996; Taber & Lodge, 2006). This has a number of potential implications for interactions with parents.

It is likely to be of importance that parents are provided with clear quality information *before* they have committed to decisions regarding intervention. This should include “red flags” that are often associated with unproven and/or pseudoscientific interventions such as claims of a cure, interventions that address a wide range of different problems, or diagnoses and exclusive reliance on testimonials (see Stephenson, 2004; Travers, 2016). Such material should also include reliable information on the current evidence base for interventions. Unfortunately, while a number of such sites exist for families of children with ASD, such as the Raising Children Network (Raising Children Network, 2006-2018) and Research Autism (The National Autistic Society, 2018) websites, there do not appear to be equivalent sites specifically for families of children with intellectual disabilities. There is also a need for professionals who provide first line of contact to be in a position to offer evidence-based recommendations. This means that such professionals must have an up-to-date knowledge of the evidence base for interventions as well as the skill to work with families to match and tailor interventions to their specific needs. On the flip side, parents should not be reserved in asking professionals to explain the basis for an intervention recommendation. In fact, as suggested previously, such information should be an integral part of the guidance offered by professionals.

Where parents do decide to invest resources into an intervention, particularly an unproven intervention, it is important to have a strategy to assist in evaluating effectiveness. Kay and Vyse (2005) offer some useful suggestions in this regard. They suggest that parents first identify the changes they expect from the selected intervention and attempt to operationally define the relevant behaviors. For example, parents might be anticipating new words to be spoken by their child or a decrease in self-injurious behavior. This approach reduces the risk that any unrelated maturation or development that is observed in the child will be incorrectly attributed to the intervention. Second, some decision rules can be developed with parents to decide when to continue or discontinue the intervention. A test can then be developed to evaluate the intervention. Simple single-case research designs can be adapted to the purpose with the most basic of these designs involving collection of data on the targeted behaviors before and during intervention. While attempting to rationalize a prior decision represents typical human behavior, particularly when individuals are invested in the decision (Kunda, 1990), the general approach suggested by Kay and Vyse (2005) provides parents with an objective approach for evaluating their decisions as well as offering a possible exit strategy.

Recommendations for Professionals

There is a clear evidence that educational professionals working with individuals with disabilities do not necessarily have an accurate perception of the research base supporting interventions (e.g., Burns & Ysseldyke, 2009; Carter et al., 2011,

2012) and that factors other than the strength of research evidence may weigh strongly on decision-making (Boardman et al., 2005; Carter, Stephenson, & Hopper, 2015). While a variety of contextual factors (e.g., resources, policies, time, student characteristics) should assist in shaping decisions, the degree of research support should undoubtedly be a key consideration. Thus, there is a strong case for improving understanding of the research base for commonly employed interventions among professionals including teachers and early interventionists. This needs to be addressed at the preservice level and updated with in-service training. Caution should be exercised, however, when accessing online sources to identify evidence-based practice. For example, Test, Kemp-Inman, Diegelmann, Hitt, and Bethune (2015) found 43% of websites identified as providing information to teachers about evidence-based practice in special education were not trustworthy.

There are implications for teacher educators as well. It is clear that teacher education programs and in-service professional learning are needed to build an understanding of research, evidence-based practices, and their applications to particular settings (Boardman et al., 2005; Chorzempa, Smith, & Sielo, 2018). Teachers need to look for training in particular evidence-based strategies, but those providing training need to be clear about the impacts on student outcomes and consider the features of interventions that make them acceptable to teachers. The work of Ruppar and colleagues (Ruppar et al., 2018) also demonstrates the need for teachers to carefully consider their attitudes to students with severe disabilities and adopt a position that recognizes the importance of education rather than care.

In addition to making decisions regarding their own practice, some professionals, particularly those in the area of early intervention, may be asked to provide advice to parents, caregivers or other professionals. For example, Leong and colleagues (Leong et al., 2013; Leong, Stephenson, & Carter, 2011) found that advice from occupational therapists was a major factor in the adoption of sensory integration therapy in early intervention centers in Malaysia and Singapore. In addition, there is evidence that parents both value (Carlon, Carter, & Stephenson, 2015; Dinora & Bogenschutz, 2018; Grant et al., 2016) and may desire more guidance from professionals (Carlon, Stephenson, & Carter, 2015; Grant et al., 2016; Levy et al., 2016). Consequently, a strong argument can be forwarded that it is critical that professionals are up to date with regard to the evidence base for interventions (Carlon, Carter, & Stephenson, 2015; Sansosti et al., 2012; Trembath, Hawtree, Arciuli, & Caithness, 2016). In addition, clearly communicating the research base for interventions to parents can be considered an important component of professional practice (Trembath et al., 2016), and this argument logically can be extended to communication with other professionals. Further, Leong et al. (2013) have argued that organized efforts to establish professional relationships between academics and service providers may assist in the dissemination of accurate information to professionals.

Recommendations for Future Research

A number of recommendations for future research arise from this chapter. We currently have substantial research on decision-making of parents of children with ASD but very limited research on other diagnostic groups. Given the distinctiveness of ASD, it is not reasonable to assume that the results of research with this diagnostic category are automatically generalizable to other groups. There is a clear need for further research on other populations. Similarly, the vast majority of the existing research relates to children who are of preschool and school age. Consequently, there is a prescient need for research with regard to decision-making processes with regard to adults who may be accessing vocational services or living in supported residential settings. In particular, there is very limited intervention research with regard to supporting parents and teachers and individuals with intellectual disabilities in more effective decision-making.

Research on teacher decision-making for students with intellectual disabilities is also limited. There has been recent interest in the decision-making of teachers of students with severe disabilities, including severe intellectual disabilities but mostly relating to teachers of segregated classes. There is much less research on teachers of students with mild intellectual disabilities, in both inclusive and segregated settings. Although there has been a lot of interest in promoting the use of evidence-based practices by teachers, there is little work that explores the reasons why teachers decide to use or not use evidence-based practices. Future directions for research would include more work on teacher decision-making, especially for students with less severe intellectual disabilities, and more work on teacher perspectives on the use of evidence-based practices.

Part VIII

Treatment of Problem Behaviors

30

Behavioural Strategies to Address Noncompliance

Brittany Cook, Jessica Duris, Toby L. Martin,
and Lindsay McCombe

Introduction

In the following chapter, we will define noncompliance and discuss its importance, based on the understanding that noncompliance should necessarily be regarded as both a behavioural deficit and a behavioural excess. We'll describe general behavioural approaches to remediating both the deficit and the excess and will review specific empirically supported interventions that address each problem. This chapter is intended for readers who provide care or instruction to persons with intellectual/developmental disabilities (PWIDD) or autism spectrum disorders, either professionally or as family caregivers. A basic understanding of behavioural psychology (including principles such as positive reinforcement, extinction, and stimulus control) will be beneficial.

What Is Noncompliance?

An instance of noncompliance is a failure to behave as instructed within a brief interval following the instruction delivery. Noncompliance therefore presumes an instruction or request, that is, a verbal discriminative stimulus that specifies a desired behaviour or that has at least been correlated with consequences for the behaviour. "Noncompliance" may also refer to a history or pattern of instances of noncompliance. The term "noncompliance" is sometimes used in other ways, such as a failure to adhere to medical procedures or exercise regimes; our usage is confined to the definition provided above.

As a problem behaviour, noncompliance clearly represents a behaviour deficit: in the context of the instruction, a desired behaviour occurs too infrequently or too late. Noncompliance is also a behaviour excess, in that any behaviour other than what was instructed is likely to be unwanted. Often the behaviour that occurs in place of compliance would be undesirable in any context. That is, noncompliance often includes challenging behaviour (CB) that occurs in response to the instruction. Other excesses may be less troublesome, such as simply walking away or sitting quietly. The distinction between the deficit and excess implied by noncompliance guides the organization of the following sections.

General Causes: Deficit

What might cause a deficit in compliance following an instruction? The problem is likely to be one of stimulus control and/or of inadequate repertoire. Instructions will tend to be effective (i.e. to have good stimulus control) when the probability of reinforcement for compliance has historically been greater than the probability of reinforcement for noncompliance. A fundamental strategy to reduce noncompliance is therefore to ensure appropriate reinforcement when compliance occurs and to try to reduce reinforcement for noncompliance. Reinforcement for compliance should be immediate, potent, and reliable. It can be faded and ultimately replaced by natural contingencies once desired behaviour is occurring more reliably.

When providing instructions, it's important to consider that behaviours have intrinsic consequences as well as socially mediated consequences. Some behaviours feel good to do; others are tiring or uncomfortable. Requesting behaviour that is especially effortful may require more extrinsic reinforcement to maintain.

Instructors should also ensure that instructions are distinct (i.e. the instruction sounds different from anything else that the person typically hears) and consistent, especially at first. Once compliance occurs more regularly, the form of the instruction may be varied to promote generality.

Even if attention is paid to stimulus control strategies (i.e. salient instructions and differential reinforcement), PWIDD may not comply with instructions if they lack the skill to perform the instructed behaviour. In such cases it would be important to develop the necessary topographies, for example, through a shaping or chaining procedure.

It may sometimes seem to caregivers that a person engages in noncompliance "on purpose". That is, the caregiver believes that the person can perform the requested behaviour and understands the instruction, but he or she simply chooses not to do it. In many such cases, the caregiver may be correct, but that doesn't mean the strategies recommended here are inapplicable. In behavioural terms, the purpose of a behaviour should be understood as the typical reinforcer that maintains it. In the case of wilful refusal to comply, a plausible reinforcer is the reaction (social attention) of the person who gave the instructions. (The caregiver may in fact recognize this by saying, e.g. "He's just refusing to do it to wind me up".) In such cases it would be best to reduce social attention for noncompliance and improve the reinforcement contingency for compliance.

General Causes: Excess

Like deficits, excesses following instructions are a stimulus control problem. Behaviours other than what was instructed will tend to occur when the probability of reinforcement for them has historically been greater than the probability of reinforcement for compliance.

CBs are those that can seriously impact the well-being and social opportunities of the behaving person and/or the people nearby. These behaviours include self-injury, aggression, property damage, and stereotypy. PWIDD are more likely to engage in these behaviours than the general population; studies show prevalence rates for PWIDD between 5% and 15% (e.g. Holden & Gitlesen, 2006; Rojahn, Matson, Lott, Esbensen, & Smalls, 2001).

CBs can severely degrade quality of life. They may have health impacts on the individual and his or her caregivers, both directly (i.e. through injury) and indirectly (i.e. by making it difficult to access health care). Severe CB is often treated by restrictive procedures including pharmacological interventions which may have negative side-effects. CBs are socially aberrant and may therefore contribute to exclusion from learning environments and other social contexts.

As noted above, CBs by PWIDD are often occasioned by an instruction or request. This relationship is so common that noncompliance is sometimes described as a type of CB or is defined as CB that follows an instruction. However, the relation between instructions and CB is better understood in the context of functional assessment.

Functional Assessment

The general recommendations and specific interventions described in this chapter should be guided by a functional assessment of the actual causes of a given individual's behaviour. Functional assessment is a systematic effort to identify the contingencies (arrangements of antecedents and consequences of behaviour) that maintain a given behaviour. Functional assessment may be performed descriptively by carefully observing and recording the events that precede and follow a problem behaviour. It can also be performed experimentally (it is then often called functional analysis), by manipulating antecedents and consequences in order to temporarily increase the behaviour's frequency. Decades of research on functional assessment procedures have shown that most problem behaviours are maintained by one or more of several common contingencies, including social attention, escape from demand, and direct (nonsocial) stimulation, sometimes called automatic reinforcement.

Escape from demand is especially relevant to noncompliance. In this contingency, a demand is presented that, perhaps through association with the activity requested, is aversive to the individual. Engaging in CB may cause the caregiver to "back off" and remove the request. The CB is thereby strengthened through negative reinforcement. A review of 173 studies (Matson et al., 2011) of functional assessment found that escape from demand was the most commonly determined cause of CB in three of the most frequently reported CB types (self-injury, aggression, property destruction).

Importance

It is important for caregivers to be prepared to deal with noncompliance in part because it is prevalent among PWIDD. Two total population studies in the United Kingdom (Emerson et al., 2001; Lowe et al., 2007) have found that serious CB occurs in approximately 10% of the PWIDD population. Among those who showed CB, noncompliance was described by Emerson et al. (2001) as the most prevalent form, occurring in over 80% of persons with serious CB. Lowe et al. (2007) found that generalized noncompliance occurred in approximately 70% (87% for children; 55% for adults) of PWIDD who display CB. Both studies reported that prevalence of noncompliance was even higher in children than in adults.

CB such as self-injury and aggression can have serious negative effects on the health and well-being of the individual performing them and on the people around him or her. If noncompliance is accompanied by these types of CB, appropriate intervention becomes all the most important. This is particularly true when the noncompliance and CB are functionally related (e.g. in the case of the "escape from demand" function where CB is evoked by an instruction or request and maintained by negative reinforcement).

Improving the behaviour deficit in cases of noncompliance may have multiple benefits. First, simply increasing the desirable behaviour may, independent of any other intervention, reduce the frequency of undesirable behaviour (Ducharme & Ng, 2012; Russo, Cataldo, & Cushing, 1981). Second, the behaviours specified by an instruction may be not merely desired or convenient but critical to the individual's safety or health; street safety and fire response are notable examples (Dixon, Bergstrom, Smith, & Tarbox, 2010; Wright & Wolery, 2011). Finally, promoting compliance may facilitate expanding a person's repertoire in other ways. For example, an individual who follows instructions may more easily come into contact with natural reinforcement contingencies. Complex skills (e.g. behaviour chains that are common in home or work settings) may be easier to build if the component behaviours can be reliably evoked using instructions. There is evidence that generalized compliance can be efficiently taught (Walters, Holborn, & Ediger, 2007), as well as presumably emerging through the teaching of multiple exemplars.

Search Method

We systematically searched relevant databases (CINAHL, Medline, PsycINFO, and Scopus) to gather peer-reviewed evidence for interventions that were aimed at either decreasing noncompliance or increasing compliant behaviours. We used search terms related to intellectual or developmental disabilities or learning disabilities, as this term is commonly used in the United Kingdom, and combined those results with the "AND" operator with "noncomplian∗" "OR" "complian∗".

Initially, 1799 records were identified and upon removal of duplicates, a total of 1149 articles were screened by two of the authors. A preliminary screen of articles to identify original research describing intervention studies and exclusion of compliance studies to medical interventions or policies further reduced our sample to 722 articles. A second strategized review of our sample focused on articles in which noncompliance was treated as a problem behaviour, which left us with a more manageable sample of 140 articles to consider. Ultimately, we primarily focused our attention on studies published in the twenty-first century so as to be mindful of current ethical practices and perceived social acceptability of the interventions presented. Interventions from 23 articles are described in the following sections of this chapter.

Interventions to Remediate Behavioural Deficits

Form of Instruction

The form of an instruction and the way in which it is delivered can influence the likelihood of compliance. Effective instruction delivery has been reported by caregivers as an acceptable addition to compliance training interventions with no perceived disadvantages (Bellipanni, Tingstrom, Olmi, & Roberts, 2013; Benoit, Edwards, Olmi, Wilczynski, & Mandal, 2001; Mandal, Olmi, Edwards, Tingstrom, & Benoit, 2000; Speights Roberts, Tingstrom, Olmi, & Bellipanni, 2008). Guidelines for effective instruction delivery include (a) being in close proximity to the individual; (b) obtaining eye contact prior to making a request and providing praise for doing so; (c) presenting the request as a command instead of a question; (d) waiting 5–10 s for compliance; and (e) delivering praise contingent on compliance (Mandal et al., 2000). As a whole, the strategy has successfully improved compliance in typically developing children as well as PWIDD (Bellipanni et al., 2013; Benoit et al., 2001; Mandal et al., 2000; Speights Roberts et al., 2008). Considerable, but less pronounced increases in compliance have also been observed when contingent praise for compliance was not included (Bellipanni et al., 2013; Speights Roberts et al., 2008). This indicates that while contingent praise is beneficial, the form of the instruction and its delivery alone can sufficiently improve levels of compliance.

The remaining components of effective instruction delivery have not been examined in isolation with PWIDD, but their inclusion is recommended. Firstly, being in close proximity to the individual and obtaining an attending response such as eye contact help to ensure that the individual is aware of the request being made. A single, clear directive is also critical given the nature of this population's disability. Multicomponent requests may be too complex and may thereby increase the likelihood of noncompliance. This includes refraining from providing a rationale for compliance, which may distract the individual and has been reported as ineffective even in typically developing children (Lipschultz & Wilder, 2017). Lastly, the person must be given an appropriate amount of time to process and comply with the instruction. For PWIDD, 5–10 s has consistently been used.

Presenting instructions in an affirmative rather than a negative format can result in greater compliance for PWIDD (Ducharme & Worling, 1994). These authors used high-probability command sequences (HPCS) comparing affirmative "do" and negative "don't" requests with two PWIDD. While compliance with "do" requests readily increased following the intervention, compliance with "don't" requests decreased for one individual and was negligible for the other. When symmetrical requests, that is, requests that require the same responses as the “don’t” requests but are presented in a “do” format, were implemented for the latter individual, levels of compliance substantially increased. For example, the symmetrical request “sit in a chair” was complied with more often than its negative counterpart “don’t lie on the floor”.

Presenting an instruction in a “do” format has also been shown to result in fewer CBs that are incompatible with compliance (Adelinis & Hagopian, 1999). Finally, criterion levels of compliance can be achieved in fewer sessions using “do” as compared to “don’t” requests (Montgomery & Ayllon, 1993).

Based on these findings, caregivers and practitioners should always consider the form and delivery of an instruction during compliance training. Instructions are phrased as “do” requests whenever possible, especially when noncompliance co-occurs with other forms of CB. Formatting instructions as “do” requests, although potentially beneficial on its own, should be used in conjunction with other compliance training methods. It is also important to note that compliance with one request form does not necessarily generalize to the other (Neef, Shafer, Egel, Cataldo, & Parrish, 1983). This suggests that training with “do” requests exclusively is unlikely to increase compliance with “don’t” requests. Alternative strategies are therefore required if caregivers wish to improve compliance with instructions phrased as “don’t” requests specifically.

High-Probability Command Sequences

High-probability command sequence (HPCS) is an intervention commonly used to promote compliance in PWIDD as well as those without intellectual disabilities. This method is also referred to as high-probability instructional sequence, high-probability request sequence, or high-p sequence (Lipschultz & Wilder, 2017). HPCS is frequently used in academic and home environments to promote compliance with related skills and activities (Belfiore, Basile, & Lee, 2008; Humm, Blampied, & Liberty, 2005; Lee, Belfiore, Scheeler, Hua, & Smith, 2004). HPCS has been shown to be an effective intervention method for increasing compliance among PWIDD, including those with autism spectrum disorders (ASD), Down syndrome (DS), and attention deficit hyperactivity disorder (ADHD) (Belfiore et al., 2008; Radley & Dart, 2016).

HPCS is the presentation of a series of instructions or requests for which compliance is highly likely followed by an instruction with a lower probability of compliance (Mace et al., 1988). The result is increased likelihood of compliance for the low-probability request. This method operates on the analogy of behavioural momentum: behaviour reinforced at higher rates will have greater resistance to changes in reinforcement conditions (Nevin, Mandell, & Atak, 1983). In the case of HPCS, the behavioural momentum of compliance with high-probability instructions transfers to the low-probability instruction, making it more probable that the person will comply with the low-probability instruction.

To implement a HPCS intervention, a practitioner, behaviour analyst, or parent must identify the setting where the relevant instructions or requests will be administered. After the applicable setting is determined, a list of instructions and/or requests that are important for the individual to comply with can be created. The probability of responding in the absence of reinforcement must then be determined for each instruction or request to develop a hierarchy of high- to low-probability requests. Prior to implementation, a preference assessment should be administered with a variety of items to determine which reinforcers are the most effective for the individual. During implementation of HPCS, a series of high-probability requests are made prior to introduction of a low-probability request to consequently increase compliance with the low-probability request. Reinforcers are presented after each instance of compliance and noncompliance is ignored. The presentation of high- and low-probability requests can be gradually randomized to promote generalization.

A large body of research supports HPCS as an antecedent intervention for promoting compliance in PWIDD and non-IDD populations, beginning with a seminal study by Mace et al. (1988). HPCS has been included in several reviews including most recently Lipschultz and Wilder (2017) and Radley and Dart (2016). Lipschultz and Wilder (2017) made several evidence-based recommendations for application of HPCS. First, HPCS interventions should consist of at least three high-probability instructions or requests before one low-probability instruction or request is presented. Additionally, high-probability instructions should be presented within 5 s of the previous trial, and low-priority requests should always be preceded by a successfully complied high-probability instruction (i.e. a low-probability request should not be given following noncompliance or an error).

An example of successful HPCS is given by Belfiore et al. (2008), who increased compliance with low-probability requests in a 7-year-old male with Down syndrome and moderate intellectual disability in a classroom setting. An ABAB experimental design was used to evaluate the teacher-designed and teacher-delivered intervention. A hierarchy of requests was constructed prior to phase 1, where high-probability requests were complied with 80% or more of the time and low-probability requests were complied with less than 40% of the time. Requests that were complied with 50–70% of the time were not included. Compliance for both low- and high-probability requests were reinforced with praise, and noncompliance was ignored.

The first baseline phase presented low-probability requests without HPCS. In the second phase, three to five high-probability requests preceded one low-probability request. During the return to baseline and subsequent intervention phases, the participant began taking Ritalin. A fading procedure occurred after the fourth phase where one high-probability request was then followed by one low-probability request to promote generalization of the conditions that typically occur in the classroom environment.

The intervention increased compliance with low-probability requests to an average of 78% and removal of the intervention (phase 3) resulted in a return to baseline levels of compliance for low-probability requests (M = 17%). When the intervention was reintroduced, there was a jump to 85% compliance with low-probability requests. When the participant began taking Ritalin and return to baseline occurred, compliance with low-probability requests averaged 25% and improved to 70% in phase 4 when the intervention was reintroduced. Compliance to low-probability requests remained high (M = 77%) when the fading procedure was implemented.

Medium-Probability Command Sequences (MPCS)

For an instruction or request to be considered high probability, it should be complied with or responded to correctly at least 80% of the time. This requirement may create a gap for lower functioning individuals that do not have high probability responding in their repertoire. In such cases, medium-probability requests with compliance 50–70% of the time can be used when high-probability requests do not exist for an individual.

The effectiveness of medium-probability requests was compared to high-probability requests by Romano and Roll (2000) using a simultaneous treatment design with a reversal component for three PWIDD. For each participant, a list of requests was compiled, and each one was requested ten times in order to compute a compliance percentage. Requests complied with less than 40% of the time were considered low-probability, medium-probability were 50–70%, and high-probability requests were 80% or higher.

Each participant started with a baseline phase where the experimenter presented low-probability requests on a fixed interval 1 min schedule. Compliance was praised and noncompliance was ignored. After stability was observed in the baseline phase, the intervention was implemented in which three to four medium- or high-probability requests were presented at 10 s intervals and preceded by one low-probability request.

The researchers found that both high- and medium-probability request sequences increased compliance to low-probability requests that followed for all three participants and there was no difference in effectiveness between the high- and medium-probability request sequences. Romano and Roll's (2000) study demonstrated the principles of behavioural momentum can be extended to medium-probability requests, and thus the authors deemed their experiment a successful replication of Mace et al. (1988).

Errorless Compliance Training

Errorless compliance training (ECT) is a compliance training intervention method developed by Ducharme and Popynick (1993). It is an approach that resembles HPCS but differs in that requests or commands of varied probabilities (not only 80% or greater) are used to fade in lower-probability requests. ECT has been shown to increase compliance in home and education settings. Additionally, it has been shown to be effective in many PWIDD and autism spectrum disorders (Radley & Dart, 2016).

ECT may involve parents, education professionals, behaviour analysts, and/or practitioner support when working with the student. These figures aid in determining a list of requests or commands that the student should comply with and then assist in observing the frequency in which the student complies with each request or command. The frequency of compliance for each request can then be used to build a hierarchy of the requests. Requests that are complied with at a high frequency (i.e. 80% or more of the time) would be level 1 requests. Subsequent levels would have lower frequencies relative to each other; for example, level 2 could have 51–79% compliance, level 3 could have 30–50% compliance, and level 4 could have <30% compliance. Generally, there are four levels used in a program with level 1 having the highest-probability requests and level 4 having the lowest-probability requests (Ducharme & Ng, 2012). By ranking the requests by highest to lowest probability, practitioners can arrange these levels appropriately for each student. The ability to arrange the probabilities in a hierarchy is beneficial as it allows flexibility when determining level cut-offs. This would be beneficial for individuals who may not have high-probability requests as the hierarchy could be constructed relative to the individual's highest probability request.

Initially during ECT, level 1 requests are made, and reinforcement is provided for compliance with the high-probability requests. Once high levels of compliance are established for these requests, lower level requests can slowly be faded in with the level 1 requests (e.g. once all level 1 requests are consistently complied with, level 2 requests can be faded in, etc.). The key is that the lower level requests are integrated with higher level requests at a slow enough rate to increase the compliance of low level requests as a consequence of the high level requests already being complied with. Once all level requests are integrated together, the student should have a high probability of complying with all requests even the requests first deemed low probability.

In an article by Ducharme and Ng (2012), ECT was used to increase compliance with academic-related requests (hence, errorless academic compliance training, or EACT) in three PWIDD in a special education classroom setting. One teacher and two support staff administered the interventions which were tailored to meet each student's needs. Trained administrators conducted all baseline and treatment sessions in the classroom where each administrator was paired with one participant.

A multiple baseline across subject design was used. Baseline rates of compliance and on/off task behaviour were recorded with high interobserver agreement. Prior to implementation, staff completed an EACT introductory workshop, an academic compliance probability checklist, a reinforcer checklist, and a group training during a second workshop. They then developed a hierarchy of requests and demands for each participant and made baseline observations. In this experiment, level 1 requests ranged from 76% to 100% compliance, level 2 ranged from 51% to 75% compliance, level 3 ranged from 26% to 50% compliance, and level 4 ranged from 0% to 25%

compliance, for all but one participant. A third workshop was held to train the administrators for the individual participant treatment procedures. The treatment phase began following this third workshop.

Treatment phase 1 involved reinforcing compliance of level 1 requests, using prompts as needed and ignoring noncompliance. A phase change occurred when a participant complied with at least 80% of requests. Advancement to the next phase involved transition sessions in which a combination of requests from the preceding phase was combined with the new level. Phases 2, 3, and 4 were procedurally the same as phase 1. Follow-up sessions were conducted after phase 4.

Implementation of EACT resulted in an increase in compliance for all four phases of the experiment where the least probable requests showed the greatest increases in compliance. These improvements were maintained at follow-up. Additionally, there were also increases in on-task behaviour and reductions in off-task and disruptive behaviour. This suggests that EACT was effective in improving compliance of all targeted requests and also improved covarying behaviours such as aggression, disruptive, and off-task behaviour.

Radley and Dart (2016) summarized the evidentiary support for ECT and found that it appears to consistently increase compliance of PWIDD. This conclusion is consistent with the fact that ECT is an extension of traditional HPCS, which has an even larger body of evidentiary support. A potential disadvantage of ECT is that it takes time to be implemented, which may be problematic for time-sensitive situations.

Response Effort Manipulation

To date, Fischetti et al. (2012) is the only study to have evaluated the effects of response effort manipulation in relation to compliance training. During their study, three PWIDD were instructed to put a highly preferred toy into a toy bin. Response effort was manipulated by decreasing the distance between the individual and the toy bin from 3 m to 0.3 m. Results indicate that the intervention was only effective for one of three children. Despite using gradual increments, it appears as though the distance between the child and the toy bin was unable to be increased without commensurate decreases in compliance. Complying with the instruction when the bin was 3 m away was only achieved using other compliance training strategies. These results suggest that response effort manipulation can increase compliance for some individuals but its application is limited. In general, tasks should always be in accordance with the skill level of the individual and should be made more manageable when appropriate.

Guided Compliance

Guided compliance is a procedure that involves the presentation of increasingly intrusive prompts contingent on noncompliance (Lipschultz & Wilder, 2017). Typically, it is carried out in accordance with Horner and Keilitz's (1975) least-to-most prompting procedure. The first step of the procedure is the delivery of a verbal prompt (e.g. an instruction). If the individual does not comply within a given time frame, a gestural or modelling prompt is subsequently provided. Continued noncompliance results in a final physical prompt in which the individual is physically guided through the task using the least amount of force necessary. Reinforcement in the form of social praise is usually delivered following compliance with verbal, gestural, and modelling prompts only.

Research evaluating the efficacy of guided compliance in the absence of other types of CB is scarce, but Smith and Lerman (1999) found it could be used successfully. In their study, caregivers of children with developmental disabilities were taught to use the three-step process of guided compliance. Following the initial instruction, caregivers waited 5 s for child compliance before presenting each successive prompt. Levels of compliance for each child improved from 0% to 70% and 23% to 71% respectively. When guided compliance was briefly removed for one individual and both compliance and noncompliance were ignored, compliance immediately decreased below baseline levels.

A multi-element design also allowed researchers to compare guided compliance and HPCS. The former was found to be substantially more effective, and caregivers were equally competent in their implementation of the two procedures.

Results from the Smith and Lerman (1999) study suggest that guided compliance may be particularly useful when noncompliance is due to a skill deficit since each trial inevitably results in the completion of the desired task. Unlike many other forms of compliance training, individuals learn what the appropriate response is as well as how to execute it. Furthermore, guided compliance can be considered a form of escape extinction wherein demands are continually presented regardless of the individual's behaviour. In this way any behaviours that are interfering with the individual's ability to comply with requests are no longer being reinforced by an escape from task demands. Consequently, there is a decrease in the frequency of escape-maintained behaviours and an increase in compliance. Guided compliance with the aim of simultaneously reducing CB and increasing compliance has been widely adopted (Lipschultz & Wilder, 2017).

Guided compliance can be an effective intervention, but it is important that the function of noncompliance is first identified. If the function of noncompliant behaviour is to gain access to social attention, guided compliance may reinforce noncompliance (Kern, Delaney, Hilt, Bailin, & Elliot, 2002). Wilder, Saulnier, Beavers, and Zonneveld (2008) have also reported instances where guided compliance has led to an increase in CB. This may be indicative of the potentially aversive properties of physical guidance and suggests that caregivers must be cautious in its application. Caregivers must also be aware that dependence on gestural, modelling, or physical prompts can develop and that additional procedures such as prompt fading may be required (MacDuff, Krantz, & McClannahan, 2001).

Functional Communication Training

Functional communication training (FCT) is an antecedent intervention method that can promote compliance in PWIDD. FCT is an intervention that teaches PWIDD to make appropriate verbal or nonverbal requests or statements to gain access to a reinforcer (Carr & Durand, 1985). Understanding the function of an individual's behaviour is fundamental for FCT, as it can be applied to both attention- and escape-maintained behaviours like noncompliance. If an individual's noncompliance is maintained by attention, then the therapist should teach the person to verbally or nonverbally ask for attention. For example, the individual should be taught to ask for positive attention instead of not complying with a request in order to receive negative attention. Or if a child does not comply with instructions in order to escape from demands in a school environment, FCT can be used to teach the child to ask for breaks instead of storming out and disrupting the class when they are asked to do their schoolwork.

According to Zangrillo, Fisher, Greer, Owen, and De Souza (2016), FCT should include four procedures. The first is that a qualified professional like a Board-Certified Behaviour Analyst conducts a functional assessment to identify the function of the noncompliance. Second, appropriate alternative responses that the individual is capable of emitting need to be identified. These behaviours will vary depending on the individual's physical, physiological, and cognitive abilities. For example, alternative responses may be written, verbal, ASL, pointing to a picture, etc. (Zangrillo et al., 2016). Third, the individual is reinforced for engaging in the alternative response. Lastly, reinforcement for the target response (i.e. noncompliance) is withheld in order to extinguish the behaviour. When first establishing the alternative response, a small fixed-ratio schedule of reinforcement is used, and as the behaviour develops, the reinforcement schedule is increased (Zangrillo et al., 2016).

FCT was first described by Carr and Durand (1985) and continues to be an effective intervention (Luiselli, 2009). FCT has been and still is very popular with many practitioners as it addresses a primary concern for PWIDD, that is, increasing verbal communication skills (Luiselli, 2009). Once the FCT repertoire is established, it can also be generalized to other requests which increase an individual's adaptive behaviour skills.

Self-Monitoring

Self-monitoring, sometimes referred to as self-recording or self-management, involves regulating one's own behaviours according to specified rules (Martin & Pear, 2015).

Self-monitoring strategies are most effective when they are simple and response effort is manageable relative to reinforcement contingencies (Bialas & Boon, 2010). Noncompliant behaviours in the classroom not only interfere with learning opportunities for the students themselves, but they also disrupt the learning of their peers. Self-monitoring is one method for addressing noncompliance that is especially advantageous in classroom settings as students record their own data, thereby freeing up teacher and educational aide resources (Bialas & Boon, 2010). Self-monitoring also improves student engagement in instructional tasks (Ennis, Lane, & Oakes, 2018). Limited research exists looking at the self-monitoring of compliance for PWIDD, but two studies have shown promise.

Bialas and Boon (2010) used a multiple baseline design across participants to evaluate a self-monitoring procedure during reading, language arts, and mathematics instruction. Participants were three male kindergarten students, aged 5.5–5.7 years, at risk for developmental disabilities in an inclusive classroom setting. The self-monitoring procedure involved a checklist the students used to record their behaviour and colour pictures taped to student desks to serve as visual prompts. Students also graphed their progress after each session. Teachers were instructed to provide no more than two verbal prompts per target behaviour request, and the visual prompts were used as needed. Reinforcers were those typically used in the classroom, such as stickers. Three cubes were placed in front of students at the start of each session. If noncompliant behaviours occurred, a cube was removed, and the opportunity for reinforcement was lost. If all three cubes were removed, regular classroom rules were applied (e.g. a 5 min timeout). During the baseline and maintenance phases, compliance was observed; meanwhile, the students did not use their checklists. The dependent variable was percentage of compliance for two target behaviours: (1) "listening to directions" by sitting quietly and attending to the teacher and (2) "repeating directions" to the teacher verbally.

Results revealed an almost immediate effect of the intervention on the dependent variable. All three participants achieved 100% compliance during the intervention phase, as well as during both of their maintenance assessments. Additionally, a social validity assessment demonstrated that the students liked the self-monitoring procedure and it helped them with their classroom behaviours.

Wadsworth, Hansen, and Wills (2015) evaluated teacher-monitoring and self-monitoring procedures targeting compliance in a special education classroom. Participants were two 9-year-old males and a 7-year-old female, all with an intellectual disability (either moderate or unspecified). Functional behavioural assessments established escape from demands as the function of noncompliance for all three students, and access to preferred items was an additional function for one of the students. A teacher prompting routine was followed during baseline and intervention phases. Four space token boards with pictures or words of the reward to be exchanged after the board was filled with tokens were used. Students earned tokens at a 1:1 ratio for each occurrence of compliance, operationalized as completing or initiating responses to teacher instructions or requests within 5 s. During the teacher-monitoring phase, the teacher added tokens for each instruction complied with. After 80% compliance was achieved for two sessions, teachers prompted students to self-monitor their behaviour and add their own tokens to the board for the self-monitoring phase. During this phase, spaces were added to the token board to thin the reinforcement schedules for token exchanges, and teachers had to agree with at least 75% of the self-administered tokens before students earned breaks or tangible rewards.

The introduction of the teacher-monitoring intervention improved mean student compliance between 29% and 54% as compared to baseline levels. Compliance was generally maintained for all students once the self-monitoring intervention was introduced and remained quite stable even when the reinforcement schedules were thinned. Additionally, social validity data suggested the interventions were effective and produced important results, and that teachers were highly likely to use the procedures in the future.

Self-monitoring is a fundamental adaptive skill that aides in promoting independence, motivation, and student engagement in the classroom (Bialas & Boon, 2010). Studies by Bialas and Boon (2010) and Wadsworth et al. (2015) demonstrated that elementary students with mild or moderate disabilities or who are at risk for intellectual disabilities can successfully self-monitor their compliant behaviours in classroom settings. This was an important practical implication as self-monitoring interventions require minimal teacher resources to implement. Furthermore, Wadsworth et al. (2015) showed self-monitoring to be comparable to the effectiveness of the teacher-monitoring intervention.

Although these studies demonstrated effectiveness of self-monitoring interventions for compliance, the generality of the results is limited. First, long-term maintenance data was not collected in either study, so the persistence of compliant behaviours is unknown. Second, small samples sizes for a narrow age range of participants were studied. The effectiveness with older populations remains unknown. Lastly, only individuals with mild or moderate intellectual disabilities were included in these studies, and it would appear inappropriate to use self-monitoring interventions with lower functioning individuals. However, self-monitoring procedures are relatively simple to implement and offer practical benefits to teachers.

Differential Reinforcement

Differential reinforcement is a schedule or procedure of reinforcement, whereby an individual's compliant behaviour is reinforced at a higher rate than his or her noncompliant behaviour; typically, the latter behaviour is on extinction. Three common procedures for addressing noncompliant behaviour in PWIDD are (1) differential reinforcement of low rates (DRL); (2) differential reinforcement of zero responding (DRO); and (3) differential reinforcement of alternative (DRA) behaviour (Martin & Pear, 2015).

DRL is "a schedule of reinforcement in which a reinforcer is presented *only* if a particular response occurs at a low rate" (Martin & Pear, 2015, p.114). To carry out a DRL procedure, a behaviour analyst in conjunction with an individual and/or their family will set a criterion that describes a low rate of noncompliant behaviour, and once that criterion is set, reinforcement is only provided when noncompliant behaviour does not surpass the criterion. Limited-responding DRL involves specifying an interval of time, for example, 30 min, and setting a limit of how many responses (noncompliant ones) will be acceptable during the time period.

DRO is "a schedule in which a reinforcer is presented *only* if a specified response does *not* occur during a specified period of time" (Martin & Pear, 2015, p. 115). Specific time intervals are set where the undesirable behaviour (e.g. noncompliance) cannot occur. If an instance of noncompliance occurs during that interval, then the specified time interval will restart. Reinforcement is only provided when no instances of noncompliance occur during the specified period of time (i.e. compliance is observed for the entire time interval). As reinforcement increases (i.e. the individual does not perform the undesirable behaviour), the time interval can be increased. This method may be particularly useful for instances where noncompliance coincides with problem behaviours, such as self-injurious behaviour, where instances of self-injury can be easily measured, and where a decrease in self-injury may also produce a decrease in noncompliance.

DRA "is a procedure that involves the extinction of a problem behaviour combined with reinforcing a behaviour that is topographically dissimilar to, but not necessarily incompatible with, the problem behaviour" (Martin & Pear, 2015, p.116). DRA is applicable when a problem behaviour occurs in conjunction with noncompliance, and compliance can be reinforced while the problem behaviour is ignored.

An important consideration when implementing interventions is to ensure that reinforcement in any form is only provided as a consequence to desired behaviours. Conducting a functional assessment to determine the contingencies maintaining noncompliance as well as preference assessments to determine effective reinforcers will provide important information when designing interventions targeting compliance (Lipschultz & Wilder, 2017).

Donohue, Casey, Bicard, and Bicard (2012) examined the effects of differential reinforcement on noncompliance in a 17-year-old male with autism spectrum disorder. The study used differential reinforcement of short latencies in a changing criterion design. Response latency was measured as the number of seconds between the end of the instruction and the response by the participant. Accuracy was measured as the proportion of requests followed by correct responses.

Baseline sessions required the participant to answer instructions before the timer beeped (10 s) in order to receive reinforcement. The intervention phase was similar to baseline with the exception that differential reinforcement of short latencies was used with praise and a preferred reinforcer. The response criterion decreased by 1 s after the participant responded correctly for three consecutive sessions. Incorrect responses received constructive feedback.

Results indicated that the mean response latency decreased each time that the intervention was implemented or the criterion was reduced. The authors concluded that differential reinforcement of short latencies was effective for decreasing response latency because the participant only responded to requests after long periods of time prior to the intervention. The intervention also increased the proportion of correct responses and decreased the proportion of incorrect and no-response requests.

DRL, DRO, and DRA are all well-supported and frequently used methods of consequence interventions for improving compliance in PWIDD. They can also be used in combination with ratio and interval schedules of reinforcement to develop desirable behaviours. Differential reinforcement has been mentioned in several recent reviews including Lipschultz and Wilder (2017), Luiselli (2009), and Scheithauer, Cariveau, Call, Ormand, and Clark (2016).

Interventions to Remediate Behavioural Excesses

Extinction

Extinction procedures can be used to reduce the frequency of behaviours that are incompatible with compliance. While the procedures may vary in their presentation (e.g. social extinction, escape extinction, etc.), the underlying processes remain the same. Reinforcers that have been maintaining noncompliant behaviour are identified and withheld contingent on noncompliance (Martin & Pear, 2015). The result is a decrease in the probability that the individual will engage in the noncompliant behaviour. This creates a situation where compliance is more likely to occur.

Extinction procedures are rarely used in isolation during compliance training (Lipschultz & Wilder, 2017). The majority of its applications are instead supplementary but are often a necessary addition for PWIDD whose noncompliance is accompanied by other CBs (Piazza et al., 1997; Zarcone, Iwata, Hughes, & Vollmer, 1993; Zarcone, Iwata, Mazaleski, & Smith, 1994). One study found that the use of a high-probability instructional sequence was unable to produce an improvement in compliance or self-injurious behaviour when self-injury was being maintained by an escape from task demands (Zarcone et al., 1993). However, when extinction was included such that self-injury no longer provided a break from task demands, levels of compliance and latency to self-injurious behaviour increased. This was demonstrated even when extinction was implemented alone. Piazza et al. (1997) also found that extinction procedures were required but only for one of three individuals. Other studies have found its addition to be redundant (Carter, 2010; Lalli et al., 1999).

Extinction should be considered as a means to reduce problem behaviour so long as those conducting the procedure are appropriately trained and prepared. For example, an immediate but temporary increase in the undesirable behaviour (i.e. an extinction burst) can occur following the implementation of an extinction procedure (Martin & Pear, 2015). If these consequences pose a risk to the person's or another's safety, then extinction should be removed from the treatment package. The correct application of an extinction procedure also requires that a functional analysis be conducted beforehand; otherwise, the contingency that is maintaining the undesirable behaviour may remain intact.

Non-contingent Reinforcement and Non-contingent Escape

Noncompliance is often associated with other forms of CB, such as aggression or self-injury. The function of these behaviours may be to escape from task demands, thereby resulting in noncompliance. If the behaviours are instead being maintained by positive reinforcement (i.e. access to social attention and tangibles or are automatically reinforcing), then engaging in such behaviours may distract the individual and prevent them from adequately complying with requests. One way to promote compliance then may be to use interventions that target CBs that accompany noncompliance.

A relatively simple intervention used for the purpose of reducing CB and increasing compliance in PWIDD is non-contingent reinforcement (NCR). NCR involves the delivery of reinforcement regardless of the behaviour that has just occurred (Martin & Pear, 2015). This is usually done according to a fixed or variable time schedule, where the reinforcer is consistently presented to the individual following a specified amount of time. It is believed that the non-contingent presentation of a functionally relevant reinforcer decreases an individual's motivation to engage in CBs that were being maintained by the same reinforcer. In circumstances where a brief break from task demands or requests is delivered non-contingently, the terminology non-contingent escape (NCE) has been used (Kodak, Miltenberger, & Romaniuk, 2003).

Kodak et al. (2003) demonstrated the effectiveness of NCE for two children with developmental disabilities. Prior assessments had indicated that CB such as aggression was being maintained by escape from task demands. It was found that providing a brief break from instructional task demands every 10 s reduced CB and increased compliance relative to baseline for both individuals. Treatment gains were also maintained when the interval between breaks was increased gradually from 10 s to 2 min. Furthermore, an alternating treatment design allowed researchers to conclude that NCE was equally effective in reducing CB and increasing compliance compared to an alternative intervention (i.e. differential negative reinforcement of other behaviours).

Similar results have also been reported by Ingvarsson, Kahng, and Hausman (2008), who found that providing NCR in the form of preferred edible items decreased CB that was being maintained by access to tangible items and escape from task demands. Considerable increases in compliance were also observed using both dense (i.e. an edible every trial) and lean (i.e. an edible once every fourth trial) schedules of NCR. Again, positive behaviour change was achieved even though a 30 s break from task demands remained contingent on CB. A clear demonstration of the utility of NCR was shown when treatment gains were reversed and subsequently regained during a return to baseline followed by reinstatement of NCR, respectively.

Although there has been limited research documenting the use of NCR methods for increasing compliance specifically, results from the aforementioned studies indicate that NCE and NCR can be an effective form of compliance training in some situations. Its widespread success in treating CB often associated with noncompliance in PWIDD further highlights its potential as a compliance training strategy (Carr, Severtson, & Lepper, 2009). For caregivers with no previous experience, correct implementation of NCR methods can be achieved following a single, 1-hour training session (Noel & Getch, 2016). Unfortunately, NCE and NCR do not teach an individual what the appropriate behaviour is (i.e.

compliance), and so it is best used in combination with other strategies. Accordingly, both Kodak et al. and Ingvarsson et al. incorporated a least-to-most prompting strategy during baseline and treatment sessions. This ensured that the individuals received the assistance necessary to complete the instructional tasks. In order for NCR interventions to be most effective, functionally relevant reinforcers should be utilized, and NCR or NCE should be delivered at a rate equal to the rate of CB during baseline (Lalli, Casey, & Kates, 1997). Once acceptable rates of compliance have been established, gradual reductions in the frequency of NCR or NCE delivery can be made.

Punishment

Punishment interventions may be considered for some individuals whose noncompliance cannot be managed effectively with non-aversive procedures and when noncompliance is accompanied with self-injury or aggression towards others. Punishment should only be used under the guidance and supervision of a Board-Certified Behaviour Analyst or licensed mental health professional and then only as a last resort. When a behaviour analyst uses punishment procedures, special attention must be paid to the ethical code 4.08, which discusses guidelines for using punishment as a behavioural intervention and how it should be a last resort option (Bailey & Burch, 2016, p. 132–135). Failing to abide by the appropriate ethical codes when using punishment can result in suspension or revocation of certification. Additionally, strict policies with regard to the use of punishment procedures should exist at the organization level. Punishment must be used cautiously and with safeguards in place to ensure that appropriate training is provided to individuals implementing interventions to prevent misapplication of the procedure and to ensure the safety of everyone involved.

Timeout. According to Martin and Pear (2015), a timeout is “a period of time immediately following a particular behaviour during which an individual loses the opportunity to earn reinforcers” (p. 122). Timeouts may be exclusionary or non-exclusionary (Martin & Pear, 2015). An exclusionary timeout involves removal of a client from the reinforcing situation and relocation to a different room or area immediately following an instance of the target behaviour, (Martin & Pear, 2015). Non-exclusionary timeouts involve adding a stimulus to the situation following an instance of noncompliance that is associated with less reinforcement (Martin & Pear, 2015), for example, having a child sit on a chair during playtime after an instance of noncompliance or removing a reinforcing toy when noncompliant behaviours are observed. Generally, exclusionary timeouts are more commonly used by professionals and are often used to supplement reinforcement procedures (Lipschultz & Wilder, 2017).

To implement an exclusionary timeout, the target behaviour must be operationally defined, and an appropriate timeout duration and location must be determined. For example, the behaviour may be noncompliant in the form of a child’s tantrum when he is asked to clean up his toys. A parent might escort the child to a chair in the home office where they must remain for 1 min. After the 1 min duration is complete, the child is allowed to resume what they were doing prior to the timeout.

In a study by Handen, Parrish, McClung, Kerwin, and Evans (1992), a timeout intervention was compared to guided compliance as a method of decreasing noncompliance in five children with developmental disabilities, three of whom had a mild intellectual disability. An ABAC experimental design was used, and the order of treatment conditions was counterbalanced across participants. During baseline sessions, compliance was praised, and noncompliance was ignored. During guided compliance sessions, the participant had to respond to requests within 10 s. Praise and uninterrupted play were provided for compliant responses, whereas noncompliance resulted in the adult administering the requests to guide the child to complete the task by placing their hand over the participants hand and guiding the desired response. Once the task was completed, the child was allowed to continue playing.

During timeout sessions compliance was treated the same as in the guided compliance sessions, and noncompliance resulted in a 30 s timeout in a chair facing a corner in the training room. After the 30 s timeout, participants were allowed to return to play. Handen et al. found that mean compliance during baseline was 41% which increased to 85% and 59% during timeout and guided compliance training sessions, respectively. Further examination of the intra-subject data demonstrated that timeouts were more effective at increasing compliance for four of five participants; however, both interventions increased compliance compared to baseline scores.

Determining the function of noncompliance is important when implementing timeouts because if the function is escape from demands, timeouts actually reinforce noncompliance by removing them from the situation and demand. Timeouts are more appropriate when noncompliance is a function of attention since timeouts away from others remove opportunities for reinforcement in the form of attention. Furthermore, if the function of noncompliance is attention, care must be taken to ensure that not too much time is spent putting clients in timeout as the interaction provided by placing the client in timeout may lead to the timeout being reinforcing.

Conclusion

Noncompliance is a prevalent and important problem among PWIDD. It is best understood as both a behavioural deficit and a behavioural excess. Defining it this way (a) clarifies how basic behavioural principles such as reinforcement and stimulus control can be applied to increase compliance and (b) may help caregivers to choose appropriate and effective interventions. Fortunately, a variety of such interventions have been reported in the research literature; many have considerable support.

In general, caregivers should seek to increase compliance by providing simple, clear, affirmative instructions for behaviours that are in the person's repertoire. Positive reinforcement should immediately follow compliance and should be more likely following compliance than noncompliance. Preference assessments can identify effective reinforcers for interventions designed to increase compliance. Various antecedent strategies may be used to increase the likelihood of compliance with a given instruction; one well-tested method is to provide the difficult instruction in the context of several other, easier-to-follow instructions.

When noncompliance includes CB, effective reinforcement-based strategies to increase compliance may be a sufficient strategy—by definition compliance and noncompliance are incompatible and thus covary. Reinforcement-based strategies such as NCE and differential reinforcement may be indicated but should be guided by a functional assessment. Knowing the function of the behaviour helps to ensure noncompliance is not inadvertently being maintained. Other strategies for reducing noncompliance with CB such as extinction and punishment may be effective but should be applied only by qualified professionals.

Stereotypy and Repetitive Behaviors

31

Jessica Akers, Tonya Davis, Stephanie Gerow,
Abby Hodges, and Regan Weston

A category of inappropriate behaviors in which individuals with intellectual disabilities engage that do not fit into the typical classifications of aggressive, disruptive, or self-injurious behavior exists. These behaviors include stereotypy, ritualistic behavior, and perseverative behavior related to unusual interests. Stereotypic behaviors are defined as repetitive, coordinated, seemingly purposeless, rhythmic behaviors that are most often maintained by automatic reinforcement (Chebli, Martin, & Lanovaz, 2016; Rapp & Vollmer, 2005; Singer, Mink, Gilbert, & Jankovic, 2016). Common topographies of stereotypy fall into the following categories: whole body (e.g., body rocking), head (e.g., head nodding), hand/finger (e.g., hand flapping), locomotion (e.g., jumping), object (e.g., object spinning), and sensory (e.g., covering ears; Lam & Aman, 2007). In addition to motor stereotypy, individuals with intellectual disabilities also engage in vocal stereotypy (e.g., repetitive sounds or words; Lanovaz & Sladeczek, 2012).

Stereotypy is not exclusive to individuals with intellectual disabilities; all individuals engage in some form of stereotypy (e.g., tapping feet, nail-biting, humming). When exhibited by individuals with intellectual disabilities, stereotypy is distinguished by the lack of appropriateness and should be considered within the context of developmental and social norms (Cunningham & Shriebman, 2008; Rapp & Vollmer, 2005). Stereotypic movements are present during the first few years of life in as many as two thirds of typically developing infants and in 20–50% of children overall (Tröster, 1994). Stereotypies causing concern, however, are likely to persist beyond infancy and childhood, occur at high rates, appear atypical compared to stereotypy exhibited by same age peers, and interfere with an individual's daily functioning (American Psychiatric Association, 2013; Didden et al., 2012).

Individuals with intellectual and multiple disabilities are at an increased risk of exhibiting such complex stereotypies (Lancioni, Singh, O'Reilly, & Sigafoos, 2009). Much of the research and disseminated information on stereotypy focuses on individuals with autism spectrum disorder (ASD). This is likely due, in part, to the inclusion of repetitive behavior within the diagnostic criteria for ASD. Further, individuals with ASD tend to display more severe and varied topographies of stereotypy (Bodfish, Symons, Parker, & Lewis, 2000; Matson & Dempsey, 2008). Chebli et al. (2016) conducted a systematic review of studies reporting prevalence of stereotypy in individuals with developmental disabilities and found that the median (Mdn)

prevalence of stereotypy was 61% among individuals with developmental disabilities. They also noted that stereotypy is most common in children with specific diagnoses such as ASD (Mdn = 88%), followed by fragile X syndrome (Mdn = 69%), and Down syndrome (Mdn = 63%). Finally, they reported that hand/finger, locomotion, object, sensory, and vocal stereotypies were the most common forms of stereotypy aggregated across studies (Mdn range = 46–49%).

Stereotypy and repetitive behaviors can range from low frequency and nondisruptive to high frequency and highly disruptive. According to the Repetitive Behavior Scale-Revised (RBS-R), a measure developed to evaluate the severity of repetitive behaviors, severity is measured by the following: (a) frequency of the behavior, (b) the extent to which interruption of the behavior leads to emotional responding, and (c) the extent to which the behavior interferes with ongoing activities (Lam & Aman, 2007). Many researchers assessing and treating stereotypy report severity in terms of missed educational and social opportunities experienced by the individual (Miguel, Clark, Tereshko, & Ahearn, 2009; Saylor, Sidener, Reeve, Fetherston, & Progar, 2012; Taylor, Hoch, & Weissman, 2005). These missed learning opportunities are especially detrimental for individuals with intellectual disabilities as they are already at an academic disadvantage. In addition, stereotypy and repetitive behaviors can be extremely stigmatizing, thus increasing the likelihood of the individual being excluded from social interactions.

Research has identified several risk factors associated with stereotypy, including intellectual functioning, communication abilities, diagnosis, and environmental factors. The degree of intellectual disability is correlated with stereotypy, with individuals with severe or profound intellectual disability being much more likely to engage in stereotypy than individuals with mild or moderate intellectual disability (McClintock, Hall, & Oliver, 2003). The degree of intellectual disability can also predict the topography, frequency, and severity of stereotypy. Individuals with lower intellectual functioning are more likely to engage in motor stereotypies such as hand flapping or body rocking, while individuals with higher intellectual functioning are more likely to engage in nonfunctional rituals (Leekam, Prior, & Uljarevic, 2011; Turner, 1999). Similarly, among individuals with ASD, those with a lower IQ engage in more severe topographies of stereotypy at a higher frequency compared to those with a higher IQ (McTiernan, Leader, Healy, & Mannion, 2011).

Communication ability may also be correlated with higher risk for stereotypy. While a great deal of evidence indicates the inverse correlation between communication ability and challenging behavior in general (e.g., Emerson et al., 2001; Emerson & Bromley, 1995; Jones et al., 2008), the same may be true for stereotypy specifically. In fact, Bowring, Totsika, Hastings, Toogood, and Griffith (2017) found that individuals with intellectual disabilities who were nonverbal or lacked clear speech were at a higher risk of engaging in stereotypy.

Finally, several diagnoses are associated with unique stereotypy risk factors. First, stereotypy occurs at higher rates among individuals with ASD than any other developmental disability, with frequency and intensity of stereotypy correlated with severity of the ASD diagnosis (Bodfish et al., 2000; Chebli et al., 2016; Matson, Dempsey, & Fodstad, 2009). Other diagnoses associated with high prevalence of stereotypy include Cornelia de Lange, Cri du Chat, Angelman syndrome, fragile X syndrome, Rett syndrome, and Smith-Magenis syndrome (Cornish & Pigram, 1996; Downs et al., 2014; Dykens & Smith, 1998; Hagerman & Lampe, 1999; Hyman, Oliver, & Hall, 2002; Summers, Allison, Lynch, & Sandler, 1995). Some diagnoses are associated with specific topographies of stereotypy. For example, a defining feature of Rett syndrome is hand stereotypy often manifested as hands joining, wringing, clasping, or mouthing (Downs et al., 2014; Olson & Rett, 1985). Similarly, fragile X syndrome is also associated with hand stereotypy often manifested as hand flapping (Lachiewicz, Spiridigliozzi, Gullion, Ransford, & Rao, 1994; Symons, Clark, Hatton, Skinner, & Bailey, 2003). Last, Cornelia de Lange syndrome is associated with body rocking among other topographies of stereotypy (Oliver, Arron, Sloneem, & Hall, 2008; Sarimski, 1997).

In addition to specific diagnoses, visual impairments among individuals with intellectual disabilities are associated with a higher risk of stereotypy (Bowring et al., 2017). Specifically, increased vision loss is correlated with increase prevalence of stereotypic behaviors (Bak, 1999). Not only are individuals with visual impairment and intellectual disability at a higher risk for displaying stereotypy, but specific topographies are common among this population, including body rocking and eye rolling (Abang, 1985).

Some research has identified certain environmental risk factors of stereotypic behavior. Specifically, individuals in congregate or paid care (e.g., group homes or assisted living centers) are at a higher risk of exhibiting stereotypic behaviors (Bowring et al., 2017). Other studies have produced similar findings of an association of those who live in congregate care with higher rates of challenging behavior, which often manifests in the form of stereotypic behaviors (Holden & Gitlesen, 2006; Jones et al., 2008; Lowe et al., 2007).

When individuals experience a lack of daytime activities, they are more likely to engage in stereotypic behaviors (Bowring et al., 2017). Similarly, Schlaggar and Mink (2003) suggest that individuals are more likely to engage in stereotypic behaviors during times of boredom. As a result, it may be beneficial to increase levels of daytime engagement for individuals who are at risk for exhibiting stereotypic behaviors (Bowring et al., 2017; Lowe et al., 2007). Other environmental arrangements that have been associated with increased stereotypy are instances in which high social or emotional demands are in place (LeMonda, Holtzer, & Goldman, 2012; Schlaggar & Mink, 2003). For example, when an individual experiences times of excitement, he or she may be more likely to exhibit stereotypic behaviors (Schlaggar & Mink, 2003).

Assessment of Stereotypy

To efficiently and effectively reduce stereotypy, a functional assessment is required to determine the variables maintaining stereotypy. Typical pre-intervention assessments of stereotypy include interviews, observations, functional analyses, and competing items assessments.

Interviews and Observations

The purpose of initial interviews is to gather information from key stakeholders such as caregivers, teachers, other professionals, and the individual who engages in stereotypy. Interviews typically consist of questions related to (a) the topography of the behavior; (b) the severity of the behavior; (c) key stakeholders' preferences, resources, and priorities related to possible treatment options; (d) the individual's current strengths and skills, (e) typical situations in which the behavior occurs; and (f) common reactions to the behavior.

This information can be gathered using a combination of open-ended interviews and formal questionnaires. Interviews will cover topics such as typical situations (i.e., antecedents) associated with stereotypy and typical reactions of other people to the stereotypy (i.e., consequences). Questions from an open-ended interview provide the interviewer the opportunity to build rapport through conversation and obtain general information related to the target behavior. Formal questionnaires (e.g., Functional Analysis Screening Tool; Iwata, DeLeon, & Roscoe, 2013) provide the interviewer with a guide for obtaining specific information related to possible functions of the target behavior. The information obtained from the interviews aides in the development of an initial hypothesis regarding the function of stereotypy and the identification of antecedents and consequences to include in subsequent assessments. Unstructured observations can further assist in the identification of the topography of stereotypy, the refinement of an operational definition, and the selection of antecedents and consequences for subsequent assessments.

As previously discussed, the severity of stereotypy can be determined based on the extent to which the behavior negatively impacts the individual's day-to-day functioning or long-term goals. Prior to introducing a formal intervention for stereotypy, the severity of the behavior must be assessed to determine whether the behavior warrants treatment. For example, an individual with intellectual disability may engage in body rocking during unstructured play but not during instructional activities; thus, the behavior does not impede the individual's educational goals. If the individual's social interactions are not negatively impacted, it may be determined that although the individual engages in atypical behavior, the severity does not warrant formal treatment. If after gathering information via interviews and observations the severity is determined to be at a level which warrants intervention, a functional analysis should be conducted.

Functional Analysis

The purpose of a functional analysis is to identify the function of a behavior by systematically evaluating the effect of antecedents and consequences on the occurrences of stereotypy. Typically, the results of the functional analysis suggest a social function or an automatic function. Social functions include sources of reinforcement from the environment (e.g., attention, escape from demands; Cooper, Heron, & Heward, 2007). Automatically maintained behavior is behavior that results in reinforcement independent of changes in the environment.

Traditional functional analyses consist of conditions to assess positive reinforcement (e.g., tangible, attention), negative reinforcement (e.g., escape), and automatic reinforcement (e.g., alone, ignore) as possible functions of the target behavior (Hanley, Iwata, & McCord, 2003; Iwata, Dorsey, Slifer, Bauman, & Richman, 1982/1994). In addition, a control condition, often the play condition, is included in the functional analysis to serve as a comparison condition for the remaining test conditions.

The number of conditions and sessions per condition and the length of sessions have varied widely in the literature. Functional analysis sessions typically last 5–15 min (Hanley et al., 2003). The length of the session should depend on the rate of the behavior, the severity of the behavior, and the social validity of the suggested session length (e.g., presenting pre-academic demands to a 3-year-old for an extended period of time may be inappropriate). Traditional functional analyses often include three to five conditions, with five or more sessions per condition (Hanley et al., 2003; Iwata et al., 1982/1994). However, a number of variations including conducting one test and one control condition (i.e., a pairwise functional analysis; Iwata, Duncan, Zarcone, Lerman, & Shore, 1994) and decreasing the number of sessions (i.e., a brief functional analysis; Northup et al., 1991) have been used in the extant literature.

An additional modification to the functional analysis can be employed in cases in which the interviews and/or observations suggest that the behavior is maintained by automatic reinforcement. The extended alone or ignore assessment consists of consecutive alone or ignore conditions, with no other functional analysis conditions (Querim et al., 2013). This assessment can be a more efficient method to identify the function of the individual's stereotypy, in cases in which the stereotypy is maintained by automatic reinforcement. However, it is important to only use this assessment in circumstances in which previous data suggest automatic reinforcement because this assessment will not lead to the identification of social positive or negative reinforcement as primary or secondary functions of stereotypy.

Interpreting functional analysis outcomes. Functional analysis results are typically displayed in a line graph. To identify the function of stereotypy, the occurrences of stereotypy during each test condition is compared to those during the control condition (e.g., play). The functional analysis results suggest a socially maintained function (e.g., access to attention, escape from demands) if stereotypy occurs more frequently or at a higher rate during one or more test condition as compared to the control condition. The results indicate that the behavior is not sensitive to social contingencies (i.e., automatically maintained behavior) if the individual engages in stereotypy at similar rates across all conditions or if the individual engages in more stereotypy during the alone or ignore condition as compared to the remaining conditions (Hagopian, Rooker, & Zarcone, 2015; Iwata et al., 1982/1994). For the extended alone or ignore assessment, the data suggest an automatic function if the child continues to engage in the behavior throughout the sessions or if the rate of the behavior increases across sessions.

Competing Items Assessment

For individuals who engage in automatically maintained stereotypy, identifying activities or items associated with lower rates of stereotypy can lead to the development of a more effective intervention. Previous research has described the use of a competing items assessment to identify items associated with lower rates of stereotypy (e.g., Groskreutz, Groskreutz, & Higbee, 2011; Nuernberger, Vargo, & Ringdahl, 2013). In a competing-item assessment, the interventionist presents an item or activity during each session and records the duration of stereotypy and item engagement. The items or activities associated with lower rates of stereotypy and higher item engagement can be used during the intervention to reduce stereotypy.

Treatment for Stereotypy

Following the identification of the function of stereotypy, an individualized intervention must be developed. If stereotypy is maintained by social reinforcement, the intervention strategies will follow the same procedures as with other topographies of challenging behavior. If the behavior is not socially maintained, as is the case with most stereotypic behaviors, a different set of procedures will be necessary. In the literature, effective interventions for automatically maintained stereotypy can be divided into three categories: (a) antecedent manipulations, (b) reinforcement-based interventions, and (c) punishment procedures. The most common and well-researched interventions within these categories will be described in detail, including considerations for implementation.

Antecedent Manipulations

Automatically maintained behavior poses a unique challenge for implementing reinforcement-based interventions because the functional reinforcer cannot be manipulated by the interventionist. Due to this difficulty, several interventions targeting the reduction of stereotypy incorporate antecedent manipulations. These manipulations include bringing stereotypy under stimulus control, environmental enrichment, and manipulating motivating operations.

Establishing stimulus control. Stimulus control is demonstrated when a behavior occurs in the presence of one stimulus and does not occur in the presence of another, for example, driving through an intersection when the light is green and not when it is red. Stimuli come to exert control based on a history with specific consequences (Cooper et al., 2007). Interventions which incorporate stimulus control procedures introduce different stimuli (e.g., colored cards) and pair the stimuli with different contingencies. For example, the presence of a green poster emitting a specific behavior will result in reinforcement, whereas in the presence of a red poster, the same behavior will contact extinction. Such arrangements are commonly implemented in conjunction with functional communication training as a means to decrease excessive requesting without observing an increase in challenging behavior due to mands contacting extinction (Saini, Miller, & Fisher, 2016). Discriminated responding is achieved when the individual requests the functional reinforcer in the presence of the stimulus associated with reinforcement and refrains from requesting in the presence of the stimulus associated with extinction.

In regard to establishing stimulus control to reduce stereotypy, the interventionist uses stimuli to signal times in which engaging in stereotypy is appropriate (i.e., will not be interrupted) and inappropriate (i.e., will be interrupted and/or will contact specific consequences). For example, in the presence of the green card, stereotypy will not be blocked, and in the presence of the red card, stereotypy will be blocked.

In contrast to destructive behavior (e.g., aggression, self-injury), it is not imperative for stereotypy to be reduced to zero levels. Some level of stereotypy can be accepted as long as it does not negatively disrupt the individual's day-to-day functioning. Most individuals have certain behaviors which they emit only within the privacy of their own home. Thus, it seems reasonable to provide individuals with intellectual disabilities the same courtesy in the case of stereotypy. In addition, the sensory stimulation accessed by engaging in the stereotypic behavior likely serves as a potent reinforcer for the individual. Rather than denying an individual access to this source of reinforcement, the goal of establishing stimulus control is to reduce the duration of engagement in stereotypy and/or number of settings in which the individual engages in stereotypy. Previous researchers have suggested that this is not only more practical but also more ethical as individuals with intellectual disabilities may have a limited number of available reinforcers (Tiger, Wierzba, Fisher, & Benitez, 2017).

Researchers have evaluated the use of punishment in conjunction with the establishment of stimulus control (e.g., Anderson, Doughty, Doughty, Williams, & Saunders, 2010; Martinez, Betz, Liddon, & Werle, 2016), such that in the presence of the stimulus which signals stereotypy is inappropriate, stereotypy results in a punishment procedure (e.g., hands-down procedure). Punishment rather than extinction may be necessary in these cases because the reinforcing properties of stereotypy cannot be manipulated by the interventionist.

After discriminated responding is achieved (i.e., stereotypy decreases in the presence of the stimulus signaling punishment), the number of implementations of the punishment procedure will decrease, and there is some evidence to suggest that the actual punishment contingency may no longer be necessary in order to maintain suppression of stereotypy. Tiger et al. (2017) demonstrated that after introducing response blocking in the presence of a stimulus for a given amount of time, the presence of the stimulus resulted in suppression of ritualistic behavior even when the punishment contingency was no longer in place. Due to ethical considerations regarding the use of punishment, establishing stimulus control may be an ideal option for including punishment within an intervention without excessive implementation of the punishment procedure.

Bringing stereotypy under stimulus control may also be ideal because it does not require implementation of the intervention 100% of the time. This may be desirable due to the labor-intensive nature of many of the interventions for stereotypy. Once stimulus control is established, interventionists have the option to present the stimulus signaling stereotypy is appropriate in situations in which they are unable to implement the punishment procedure (e.g., caregiver attending to another child) without risking a deterioration of intervention effectiveness. In addition, there is some evidence to suggest that introducing a punishment procedure within a stimulus control arrangement may reduce some of the undesirable side effects of punishment, including the interventionist becoming an aversive stimulus and nonselective response suppression (Doughty, Anderson, Doughty, Williams, & Saunders, 2007).

Prior to introducing stimulus control procedures, the interventionist should consider the type of stimuli to include within the intervention. There is some evidence to suggest including therapist-arranged stimuli (e.g., colored cards, wristbands) may be more effective for the acquisition of discriminated responding as compared to naturally occurring stimuli (Shamlian et al., 2016). However, the selection of stimuli should be thoughtfully considered to ensure the achievement of discriminated responding while avoiding overly stigmatizing stimuli. One reason for decreasing stereotypy is to decrease stigmatization; therefore, the stimuli included should not be unduly stigmatizing.

Environmental enrichment. Environmental enrichment is an antecedent manipulation that has been used to reduce stereotypy by introducing competing sources of noncontingent reinforcement into an individual's environment (Rapp & Vollmer, 2005). The stimuli are considered noncontingent because they remain freely accessible to the individual regardless of his or her engagement in specific responses. Research has shown that increased levels of sensory stimulation can lead to reductions in stereotypic behavior due to heightened levels of stimulation in the immediate environment (Hill, Trusler, Furniss, & Lancioni, 2012; Sidener, Carr, & Firth, 2005). Variations exist regarding the characteristics of stimuli introduced to establish an enriched environment including preferred stimuli (Higbee, Chang, & Endicott, 2005), matched stimuli (e.g., Rapp, Cook, McHugh, & Mann, 2017), and competing stimuli (e.g., Groskreutz et al., 2011). Matched stimuli are those that provide similar sensory stimulation as the stimulation hypothesized to maintain the stereotypy (e.g., music for vocal stereotypy; Ahearn, Clark, MacDonald, & Chung, 2007) and competing stimuli are items associated with lower rates of stereotypy identified using a competing items assessment.

Previous research evaluating the effects of an enriched environment using preferred and nonpreferred stimuli indicates that using a highly preferred stimulus alone does not always result in subsequent reductions of stereotypic behaviors (Higbee et al., 2005; Lanovaz, Sladeczek, & Rapp, 2011). Conversely, researchers have evaluated the effects of matched stimulation on the occurrence of stereotypic behaviors and found that introducing noncontingent access to highly preferred stimuli that produce consequences similar to the hypothesized maintaining consequences of stereotypic behaviors may result in decreases of the targeted behavior (Higbee et al., 2005; Love, Miguel, Fernand, & LaBrie, 2012; Rapp, 2006; Rapp et al., 2017; Saylor et al., 2012). Although identifying highly preferred stimuli that match stimulation produced by stereotypy has been shown to reduce targeted topographies of stereotypy, there are mixed results of the long-term effects of highly preferred matched stimuli on nontargeted topographies of stereotypy (Rapp et al., 2017). Finally, introducing preferred items that serve as competing stimuli for the occurrence of stereotypy has also been shown to be a promising strategy for the reduction of stereotypy in some instances (Groskreutz et al., 2011). Interventions using enriched environments often include multiple intervention components such as enriched environment in combination with response cost (Watkins, Paananen, Rudrud, & Rapp, 2011; Watkins & Rapp, 2014), presession free access to stereotypy (Lang et al., 2009; Lang et al., 2010; Rispoli et al., 2014), or response interruption and redirection (RIRD; Love et al., 2012).

Factors to consider prior to using environmental enrichment strategies include (a) selection of methods for identifying preferred, matched, or competing stimuli, (b) documentation of subsequent reductions in targeted and nontargeted stereotypic behaviors as well as increases in appropriate behaviors, (c) the extent to which prompting is required to promote interaction with stimuli in the environment, and (d) the extent to which additional reinforcement is necessary to increase appropriate behaviors (Rapp & Vollmer, 2005). This type of antecedent manipulation may be ideal as it is relatively simple to implement because there is no need to closely observe behavior due to the noncontingent nature of the intervention. Thus, the extent to which additional resources (e.g., training and man power) are necessary is greatly reduced. Another benefit of environmental enrichment is related to challenging behavior associated with blocking stereotypic behavior. Because response blocking is not a component of environmental enrichment, an increase in other topographies of challenging behavior related to blocked stereotypy is unlikely. Despite the effectiveness of this antecedent manipulation, there is the possibility that the presence of the stimuli (preferred, matched, or competing) may in some cases be more disruptive than the actual stereotypy (Watkins et al., 2011). In addition, there is little evidence regarding the extent to which these stimuli remain effective in reducing stereotypy over time.

Manipulating motivating operations. In situations in which noncontingent access to competing stimuli is impractical (e.g., classroom instruction), it may be beneficial to abolish decrease the individual's motivation to engage in stereotypy. An abolishing operation refers to any event that reduces the value of a specific reinforcer and thereby leads to a decrease in behavior associated with the reinforcer (Laraway, Snycerski, Michael, & Poling, 2003). For example, after eating an entire bag of chips, the value of chips is reduced, and thus, behaviors associated with obtaining chips decrease. In the case of stereotypy, prior to the target activity (e.g., math lesson), the individual is provided with noncontingent access to matched and/or unmatched stimuli (Rapp, 2006), or the individual is able to freely engage in stereotypy (Lang et al., 2010) for a specified duration. Researchers have found this method to be effective for decreasing stereotypy during subsequent research sessions for many individuals. In the cases which it has not been shown to be effective, it has been suggested that perhaps the amount of time allotted for presession exposure was not sufficient to abate subsequent stereotypy. Therefore, researchers have suggested strategies to identify behavioral indicators which suggest that the value of sensory reinforcement has adequately reduced such that stereotypy will decrease (Lang et al., 2010; Rispoli et al., 2014). For example, Rispoli and colleagues used three rejections of the object associated with stereotypy as a criterion for determining the effectiveness of the presession exposure.

There are several benefits to manipulating motivating operations as a strategy to decrease stereotypy. The first two align with benefits of environmental enrichment. First, the intervention is relatively simple to implement and thus would not require extensive staff training (Rispoli et al., 2014). Second, the exclusion of response blocking within the procedures will reduce engagement in challenging behavior related to stereotypy being blocked. Third, it has been suggested that decreasing the value of sensory stimulation may lead to a subsequent increase in the value of other more socially appropriate reinforcers such as social interactions. Finally, because the items are not present during the "intervention period," the distractions related to noncontingent access to the items are eliminated.

Despite the benefits of this antecedent manipulation, it is important to consider the possibility of extensive time being required to achieve presession sensory habituation. In the Rispoli study, one participant required 26 min of presession access before displaying the behavioral indicators associated with habituation. It is also unclear how long the effects of manipulating the motivating operations will remain effective due to relatively short session lengths (e.g., 10 min) reported within the research.

Reinforcement-Based Interventions

The extant literature provides ample evidence that reinforcement-based interventions can be used to increase socially appropriate behavior and decrease stereotypy (e.g., Gehrman, Wilder, Forton, & Albert, 2017; Greenberg, Lau, & Lau, 2016; Lancioni et al., 2008). Previous reviews of the literature indicate that research supports the use of reinforcement-based interventions to reduce inappropriate behavior in individuals with intellectual disability (Brosnan & Healy, 2011; Chowdhury & Benson, 2011). Furthermore, professional organizations and leaders in the field recommend the use of reinforcement-based interventions for the reduction of inappropriate behavior (BACB, 2014; Horner et al., 2005).

When developing reinforcement-based interventions for stereotypy maintained by access to automatic reinforcement, highly preferred items or activities can be introduced as reinforcers. Alternatively, the reinforcer can be an item or activity that is associated with low rates of stereotypy, based on the findings from a competing items assessment. The use of competing items in the previous section referred to noncontingent access to these stimuli, whereas within reinforcement-based interventions, these items are provided contingent on the individual engaging in specific responses or refraining from engaging in stereotypy. Each of the interventions described below includes the use of reinforcement to decrease stereotypy but differ based on the behaviors in which the individual must engage to access reinforcement.

Differential reinforcement of alternative behaviors (DRA). DRA involves providing reinforcement contingent on the occurrence of an alternative, appropriate behavior (Cooper et al., 2007; Tiger, Hanley, & Bruzek, 2008). Although

DRA is one of the most common function-based interventions for socially maintained challenging behavior, researchers have also evaluated the efficacy of DRA to reduce automatically maintained stereotypy (e.g., Bennett, Reichow, & Wolery, 2011; Lancioni et al., 2008). Prior to implementing DRA, an alternative behavior must be identified, the source of reinforcement must be selected, and the schedule of reinforcement for the alternative behavior (e.g., fixed ratio 1, fixed ratio 5, variable ratio 5) must be established. It is also important to include teaching strategies for the alterative behavior (e.g., modeling), especially in cases in which the alternative behavior is not part of the individual's current skill repertoire. To implement the intervention, reinforcement should be provided contingent on the occurrence of the alternative behavior.

Differential reinforcement of incompatible behaviors (DRI). DRI is a variation of DRA, in which reinforcement is provided contingent on a behavior that is incompatible with the topography of stereotypy (Cooper et al., 2007). To implement DRI, a behavior that cannot occur simultaneously with the stereotypy (i.e., the incompatible behavior) must be identified, the source of reinforcement must be selected, and the schedule of reinforcement for the incompatible behavior must be established. During the intervention, the interventionist provides reinforcement contingent on the individual engaging in the incompatible behavior. The same considerations related to teaching strategies discussed in the DRA section are also applicable for DRI.

One of the relative strengths of DRI interventions is that they involve teaching the individual a response that cannot occur at the same time as the stereotypy. Thus, as the frequency of the incompatible behavior increases, the frequency of stereotypy decreases. For example, Colón, Ahearn, Clark, and Masalsky (2012) demonstrated the efficacy of teaching appropriate verbal behavior to decrease vocal stereotypy for three children with ASD. This intervention, along with RIRD, resulted in decreases in vocal stereotypy. As was the case in this study, DRI is recommended when the interventionist is able to identify a feasible and appropriate incompatible behavior based on the topography of the stereotypy.

Differential reinforcement of other behaviors (DRO). Several studies have evaluated the use of DRO to reduce stereotypy (e.g., Gehrman et al., 2017; Nuernberger et al., 2013). DRO involves providing reinforcement contingent on the absence of stereotypy (Cooper et al., 2007). Prior to implementation, the length of the interval (i.e., length of time the individual is required refrain from engaging in stereotypy) and the source of reinforcement are selected. Often, the interval length is based on the baseline rate of stereotypy (e.g., Gehrman et al., 2017; Nuernberger et al., 2013). Reinforcers may be identified with a preference assessment or competing items assessment. The intervention consists of providing reinforcement if the individual does not engage in stereotypy for the predetermined length of time.

DRO may be especially well-suited to treat stereotypy as it does not require the identification of appropriate incompatible or alternative behaviors. It may be difficult to identify appropriate incompatible behaviors that the individual can engage in for extended periods of time. As an example, placing hands in lap would function as an incompatible response for an individual who engages in repetitive hand flapping; however, keeping hands in lap may impede academic engagement. In this case, it may be more practical to reinforce the absence of hand flapping than to reinforce keeping hands in lap. Similarly, it can be difficult to identify and teach an alternative behavior to replace automatically maintained stereotypy. In the majority of DRA interventions, the appropriate alternative behavior persists because the behavior results in access to the same reinforcer that the inappropriate behavior produced. However, in the case of automatically maintained stereotypy, it may be difficult to identify an appropriate alternative behavior that results in the same form of reinforcement produced by the stereotypy. If a highly preferred item or activity is designated as the reinforcer (i.e., not function-based), the alternative behavior may not occur at high rates because it is not functionally related to the stereotypy. For these reasons, it may be more feasible to reinforce the absence of stereotypy than to reinforce particular behaviors that will replace stereotypy.

When deciding whether to implement environmental enrichment, in which reinforcers are freely available, or a DRO procedure, the interventionist must consider the benefits and disadvantages of each. The benefit of introducing reinforcers noncontingently, as is the case with environmental enrichment, is the response effort for the interventionist is extremely low; however, because the reinforcer is freely available, there is a chance that stereotypy could be adventitiously reinforced. Within a DRO procedure, adventitious reinforcement would be eliminated because the reinforcer is only delivered in the absence of stereotypy. While this is ideal, implementing DRO also requires additional resources as constant observation is required to determine whether the individual engaged in stereotypy during the interval.

Punishment Procedures

By definition, punishment is the immediate presentation or removal of a stimulus after the occurrence of a behavior that reduces the future frequency of that behavior (Azrin & Holtz, 1966). Punishment procedures remain a controversial topic among behavior analysts, with controversy existing regarding both ethics and efficacy of punishment procedures (DiGennaro Reed & Lovett, 2008). From an ethical perspective, behavior analysts must adhere to the responsibilities associated with all human service providers: to do no harm, provide clients with the least intrusive procedures, and provide effective treatment (Cooper et al., 2007). Unfortunately, adhering to these responsibilities does not always provide a clear decision-making model regarding the use of punishment. In some cases, procedures involving punishment may be less intrusive and/or more effective than procedures without punishment; therefore, in some cases use of punishment may be ethical (DiGennaro Reed & Lovett, 2008; Foxx, 2005). The Association for Behavior Analysis established a task force on the right to effective treatment. In this seminal work, Van Houten et al. (1988) point out that specific behavior change procedures are not inherently *good* or *bad*, but instead treatment selection should be based on a myriad of information including risks the behavior poses, controlling variables, treatment effectiveness, and treatment risks. In the case of stereotypy, in which the controlling variables are often unknown or cannot be controlled by the interventionist, punishment procedures may be necessary for effective treatment. Review of the literature indicates in the cases in which punishment has been implemented to treat stereotypy, the punishment procedures are considered relatively less intrusive in that they are combined with reinforcement-based procedures and do not involve delivery of physical pain. With interventionists called to select effective and ethical treatment, it stands to reason that continued empirical investigations of the effectiveness punishment procedures are warranted (DiGennaro Reed & Lovett, 2008; Lerman & Vorndran, 2002).

A variety of punishment procedures to reduce stereotypy have been evaluated across the literature. The most common punishment procedures include RIRD, response blocking, hands-down, verbal interruption and reprimand, and response cost.

Response interruption and redirection. RIRD involves interrupting the targeted stereotypy and redirecting the individual to emit several socially acceptable responses. RIRD was introduced by Ahearn et al. (2007) as a procedural variation to response blocking because it is physically impossible to block vocal stereotypy. In this initial evaluation of RIRD, contingent on stereotypy, the interventionist prompted attendance and delivered prompts for appropriate vocalizations until the participant emitted three consecutive correct responses in the absence of vocal stereotypy.

RIRD is the most frequently evaluated punishment procedure to treat stereotypic behavior, with the vast majority of published studies reporting successful reductions of stereotypy. While several studies have indicated the success of RIRD to reduce motor stereotypy (e.g., Ahrens, Lerman, Kodak, Worsdell, & Keegan, 2011), the majority of literature has evaluated the effectiveness of RIRD on vocal stereotypy. This may be a result of relatively few punishment procedures (e.g., response blocking) being compatible to treat vocal stereotypy.

Several procedural variations have been evaluated across the literature. One such variation is the number of redirection demands delivered. The most common approach involves the interventionist prompting the participant until he or she emits three consecutive correct responses; however, at least one study found RIRD to be effective with the completion of only one redirection demand (Saini, Gregory, Uran, & Fantetti, 2015). This variation was not only effective but also resulted in shorter implementation time. Another procedural variation involves the topography of redirection demands. In most studies, the redirection tasks match the topography of the targeted stereotypy. For example, if aiming to reduce motor stereotypy, the interventionist interrupts motor stereotypy and redirects the individual to complete socially acceptable motor tasks such as motor imitation. Similarly, if aiming to reduce vocal stereotypy, the interventionist interrupts vocal stereotypy and redirects the individual to complete socially acceptable vocal responses such as answering questions. However, initial evidence indicates that the similarity between stereotypy and redirection topographies is not necessary for effective treatment. In fact, several studies have found RIRD involving redirection to appropriate motor tasks has successfully reduced vocal stereotypy, and redirection to appropriate vocalizations has successfully reduced motor stereotypy (e.g., Ahrens et al., 2011; Cassella, Sidener, Sidener, & Progar, 2011; Shawler & Miguel, 2015). These variations are particularly assuring because RIRD should not be limited to treat stereotypy only among individuals capable of emitting a variety of socially acceptable responses that match the topography of the targeted stereotypy. In other words, RIRD may be successful in reducing vocal stereotypy among individuals who can emit no appropriate vocal responses and only a few appropriate motor responses.

One of the many strengths of RIRD is the fact that it is successful in reducing both vocal and motor stereotypy. Additionally, although the primary purpose of RIRD is to reduce stereotypy, several studies have also found an increase in pro-social behaviors, such as appropriate vocalizations (e.g., Shawler & Miguel, 2015). This could be attributed to the fact that in the literature, RIRD often involves reinforcement procedures such as praise for appropriate vocalization and compliance with redirection demands.

Response blocking. Response blocking involves the interventionist physically preventing or redirecting a targeted response. For example, response blocking for hand mouthing could involve physically blocking a hand moving toward the mouth or physically removing a hand from the mouth. Response blocking has been shown to be an effective procedure to reduce motor stereotypy across several studies; however, the exact behavioral mechanisms which contribute to this success, punishment, sensory extinction, or prompting of alternative behaviors, have yet to be determined (Langone, Luiselli, & Hamill, 2013).

While effective, several factors should be considered when choosing to implement response blocking. First, response blocking may increase other forms of challenging behavior. Second, response blocking can be time intensive in that the interventionist must be in close proximity to the client at all times to block targeted stereotypy. Langone et al. (2013) addressed these two drawbacks by implementing punishment within a stimulus control arrangement. Specifically, the interventionist wore a tennis wristband during initial response blocking sessions. Later the tennis wristband alone, without implementation of response blocking, maintained low levels of motor stereotypy. More research is needed to determine the success of such procedures. The last consideration of response blocking involves evaluating the targeted stereotypy immediately following response blocking sessions. Rapp (2006) found response blocking to be effective at reducing stereotypy during intervention sessions; however, in the 5 min after response blocking sessions, the targeted stereotypy increased to levels above those observed immediately before intervention sessions.

Although response blocking is associated with some drawbacks, initial evidence supports the success of response blocking to reduce motor stereotypy. Needless to say, response blocking is physically incompatible with vocal stereotypy, as vocal responses cannot be physically blocked or redirected. With careful considerations, response blocking may be an effective treatment to use individually or as a component of a treatment package.

Hands-down. A hands-down procedure is somewhat of an extension of a response blocking procedure. While response blocking is typically terminated at the prevention or redirection of a targeted stereotypic response, the hands-down procedure involves extending this prevention or redirection by placing the individual's hand down, typically at his or her side or on a table, for a specific amount of time. Hands are manually kept in a specific location for a short period of time, typically spanning 1–10 s. Interventionists only use enough force to prevent occurrence of targeted stereotypy rather than attempt to completely immobilize an individual's hands.

The hands-down procedure is associated with the same drawbacks and considerations associated with the response blocking procedure. Prior to implementing this procedure, less intrusive procedures should have been introduced and shown to be ineffective as this is the most intrusive punisher reported in this chapter. If it is determined that this procedure is necessary, interventionists should also consider beginning the intervention with a shorter duration of hands-down (e.g., 1 s) and progress to longer hands-down durations if necessary to reach desirable treatment effects (e.g., Doughty et al., 2007).

Verbal interruption and reprimand. In some cases, stereotypy may be effectively treated with a mild verbal interruption and reprimand. This procedure involves interrupting the occurrence of stereotypy by delivering a reprimand. Reprimands typically involve a short statement indicating the targeted behavior should be terminated (e.g., "time for hands-down" or "no movie talk"). What differentiates verbal interruption and reprimand from response blocking is that the targeted stereotypy is not physically blocked from occurring; instead, the interventionist is simply providing redirection instructions. As a result, a strength of this procedure is that it can be used to reduce both vocal and motor stereotypy.

Although ease of implementation and the mild and unobtrusive nature of verbal interruption and reprimand make this procedure appealing, relatively few studies have evaluated the effectiveness of verbal interruption and reprimand in isolation. This procedure is most often introduced as one component of a treatment package (e.g., Rapp et al., 2017), and the results of studies in which it has been implemented in isolation have been mixed for effectiveness. Rapp, Patel, Ghezzi, O'Flaherty, and Titterington (2009) found verbal reprimands to be effective for reducing vocal stereotypy for two of three participants, but a response cost procedure was required to reduce vocal stereotypy for the third participant.

Response cost. Response cost is a negative punishment procedure in which a specific amount of reinforcement is lost contingent on the targeted behavior (Cooper et al., 2007). Because the procedure is predicated on the removal of reinforcement, the individual must initially have access to reinforcement which can be removed.

Several studies have evaluated the effectiveness of response cost to reduce both vocal and motor stereotypy. In the majority of these studies, response cost has been evaluated as part of a multicomponent treatment package. For example, Shillingsburg, Lomas, and Bradley (2012) evaluated the effectiveness of response cost first with noncontingent reinforcement and then with DRO. In the first phase of the study, the participant had noncontingent access to a preferred computer, but the computer was turned off for 20 s contingent on vocal stereotypy. In the second phase of the study, the participant earned tokens within a DRO contingency. Earning a specified number of tokens resulted in access to the preferred computer, but tokens were lost if he engaged in vocal stereotypy. Both treatment packages successfully reduced stereotypy.

With several studies indicating its potential effectiveness, response cost should be considered as an intervention to reduce levels of both vocal and motor stereotypy. However, rather than implemented as a treatment in isolation, response cost should be used as a component of a treatment package. Not only have most studies evaluated response cost as part of a treatment package, but also response cost would be impossible to implement if the individual did not have access to preferred stimuli which could be removed contingent on targeted stereotypy. Such preferred stimuli may be provided as part of a noncontingent reinforcement procedure, token economy, or other reinforcement-based procedure.

Conclusion

Within this chapter several research-based interventions for automatically maintained stereotypy have been described. These interventions include antecedent manipulations, reinforcement-based interventions, and punishment procedures. One of the more promising interventions appears to be establishing stimulus control with the inclusion of a punishment procedure. The benefits and initial positive findings in the literature make it a prime target for additional research. Overall, many of the studies discussed within the chapter included multicomponent treatment packages which should be a primary consideration for interventionists planning to address stereotypy. While there is sufficient evidence suggesting the interventions presented in the chapter are effective in reducing stereotypy for short durations, it is unclear to what extent these interventions remain effective over time. Future research should evaluate the effectiveness of interventions across longer periods of time (e.g., days, weeks, months) and provide recommendations for recapturing previously observed reductions in stereotypy following a collapse in treatment effectiveness (e.g., how and when to identify novel competing or matched stimuli).

Self-Injurious Behavior

32

Mindy Scheithauer, Colin Muething,
Kristina R. Gerencser, and Nathan A. Call

Introduction

Given that the term self-injurious behavior (SIB) may seem self-explanatory, some may be surprised at how the literature struggles to reach a consensus definition (Rojahn, Schroeder, & Hoch, 2007). Some discussions on the topic even point out that certain behaviors that cause tissue damage to the person who emits them are common in most cultures, such as picking a scab, or even socially acceptable, such as piercing one's ears. Even a cursory review of the topic brings one in contact with a host of definitions and potential synonyms, such as non-suicidal self-injury and self-harm behaviors (Jacobson & Gould, 2007). Such inconsistency in terminology is an indicator of how different disciplines focus on specific forms of the behavior or specific subgroups of individuals who engage in this type of behavior (Rojahn et al., 2007). For example, behaviors such as cutting exhibited by individuals without intellectual and/or developmental disabilities (IDD) have been related to diagnoses of anxiety and depression (Jacobson & Gould, 2007) and have therefore been studied in the psychiatry and psychology fields by individuals with training in these disorders. That literature often makes mention of the intentionality of these self-harm behaviors, with converging evidence suggesting that it may serve to aid in the regulation of negative affect or arousal (Klonsky, 2007).

SIB exhibited by individuals with IDD is less likely to be covert and more likely to have repetitive qualities than self-harm behaviors occurring in populations without IDD (Whitlock, Eckenrode, & Silverman, 2006). Although it is possible that individuals with IDD may engage in self-harm of the type more commonly seen in individuals without IDD, the literature on these different types of SIB generally do not overlap. This makes it difficult to ascertain whether, or to what degree, this may occur. The specific forms of SIB, or the *topographies*, most often emitted by individuals with IDD also tend to differ from those without IDD and include head or body hitting, banging the head or other extremities on hard surfaces, self-biting, skin picking, eye-gouging, etc. This type of SIB is generally studied by psychologists with training in IDD, behavior analysts, and special educators (Rojahn et al., 2007). It is also important to distinguish between SIB exhibited by individuals with IDD from other behaviors prevalent in this population

that pose significant risk of harm, such as pica or elopement. In contrast to these behaviors, the SIB directly produces tissue damage, whereas these other dangerous behaviors may produce damage only as an indirect consequence.

Prevalence and Risk Factors

Estimating the prevalence of SIB is complicated, as much of the research on the topic employs differing definitions, instruments, and sampling strategies (Rojahn et al., 2007). For example, a point prevalence study found that 14% of individuals with IDD engaged in SIB (Griffin, Williams, Stark, Altmeyer, & Mason, 1986). However, all of the individuals evaluated resided in facilities in the same state, making it challenging to ascertain how well such a finding can be extended to the broader population of individuals with IDD. In contrast, a study of all of the individuals with IDD in Sweden found that 31% engaged in SIB (Lundqvist, 2013). Yet a similar study in England found that only 4% engaged in SIB (Emerson et al., 2001a). Thus, it is most appropriate to assume that the prevalence of SIB ranges between 4% and 30%, depending on the particular study.

Aside from overall incidence, establishing prevalence of SIB among certain subgroups can be helpful in identifying risk factors and developmental trajectories. For example, researchers have examined gender disparities in the prevalence of certain challenging behaviors, finding that certain topographies are more commonly observed in males, such as aggression (McClintock, Hall, & Oliver, 2003). However, such a gender difference does not seem to appear for SIB (Baghdadli, Pascal, Grisi, & Aussilloux, 2003), with similar rates found in males and females.

One of the variables most strongly correlated with SIB is the level of intellectual disability (Borthwick, Meyers, & Eyman, 1981; Griffin et al., 1986). In a meta-analysis of 22 prior studies, the authors found a highly significant association between the degree of intellectual disability and SIB, with SIB more likely to occur in individuals with a severe or profound degree of intellectual disability compared to those with a mild or moderate degree of intellectual disability (McClintock et al., 2003). The same study demonstrated that SIB was more likely to occur in individuals with deficits in receptive and expressive language than those without such language deficits.

The prevalence of SIB also varies based on the etiology of the individual's IDD, with higher prevalence among individuals with IDD associated with specific genetic disorders. For example, Arron, Oliver, Berg, Moss, and Burbidge (2011) identified prevalence rates of SIB of 45% for Angelman syndrome, 77% for Cri du Chat syndrome, 70% in Cornelia de Lange syndrome, 51% in Fragile X syndrome, 64% in Lowe syndrome, 52% in Prader-Willi syndrome, and 93% in Smith-Magenis syndrome. Self-injury is also highly prevalent in Lesch-Nyhan syndrome, with over 90% of individuals engaging in SIB (Anderson & Ernst, 1994). Yet, for other syndromic forms of IDD (e.g., Down syndrome), SIB is less common except in those with profound intellectual disabilities (Cooper et al., 2009). Additionally, certain syndromes are associated with increased prevalence of specific topographies of SIB. For example, of individuals with Prader-Willi who engage in SIB, 75% exhibit skin picking (Neidert, 2007). Individuals with Smith-Magenis and Cri du Chat syndromes are far more likely to engage in pulling on themselves (e.g., pulling out hair or nails) compared to individuals with idiopathic IDD (Arron et al., 2011; Finucane, Haines Dirrigl, & Simon, 2001; Smith, Dykens, & Greenberg, 1998). Similarly, individuals with Lesch-Nyhan who are self-injurious are likely to engage in self-biting (93%; Anderson & Ernst).

Of the developmental disabilities associated with intellectual disabilities, perhaps the most research on factors associated with increased risk of SIB has occurred with autism spectrum disorder (ASD). Therefore, we turn to this literature to identify other potential risk factors. Estimates of the prevalence of SIB in individuals with ASD range from 35% to 60% (Baghdadli et al., 2003; Rattaz, Michelon, & Baghdadli, 2015; Richards, Oliver, Moss, & Nelson, 2012; Richman et al., 2013;

Shattuck et al., 2007). Individuals with co-occurring ASD and intellectual disability are more likely to engage in SIB than those with ASD or intellectual disability alone (Lundqvist, 2013; McClintock et al., 2003; Rojahn, Wilkins, Matson, & Boisjoli, 2010). However, in at least one study, developmental regression was not found to be associated with increased probability of SIB (Lance, York, Lee, & Zimmerman, 2014). Severity of ASD symptomatology (Baghdadli et al., 2003, 2008), early speech deficits (Baghdadli et al., 2008), stereotypy (Richman et al., 2013), atypical sensory processing (Duerden et al., 2012), impulsivity (Duerden et al., 2012; Richman et al., 2013), and limited daily living skills (Baghdadli et al., 2003, 2008) have also all been found as related to SIB.

Development of Self-Injurious Behavior

It is important to note that SIB can occur as part of typical development, with up to 15% of typically developing children engaging in SIB (Romanczyk, Kistner, & Plienis, 1982). The age of onset of SIB for typically developing peers is similar to those found in retrospective studies of individuals with IDD who engaged in SIB, with most children beginning to engage in SIB prior to the age of 5 (Schneider, Bijam-Schulte, Janssen, & Stolk, 1996) and an average age of onset of 17 months (Kurtz et al., 2003). Kurtz, Chin, Huete, & Cataldo (2012) followed 32 children under the age of 5 who were at risk for IDD and engaged in SIB and found that more than half had an onset of SIB before 1 year of age.

Although the age of onset of SIB may be similar between typically developing children and those with IDD, the prevalence rates among individuals with IDD described above are much higher than the estimated 15% of typically developing children. To better understand the higher prevalence of SIB among children with IDD, it is important to understand the course of emerging SIB. To study this, Richman and Lindauer (2005) conducted a longitudinal study, tracking SIB over the course of about a year using direct observation of 12 children (age 12–32 months). They found that for some children who began engaging in SIB, the topography was similar to a past stereotypic behavior that did not cause damage or physical harm. For example, some of the participants who engaged in head hitting previously engaged in arm-waving in the head and shoulder region. In another study, Oliver, Petty, Ruddick, and Bacarese-Hamilton (2012) found that, in a sample of 943 children with severe intellectual disability, those who engaged in high-frequency repetitive behaviors were more likely to engage in SIB than those who did not engage in high-frequency repetitive behavior. However, increased odds for other topographies of challenging behavior were also associated with repetitive behaviors, making the specific relationship between repetitive behaviors and SIB unclear. Alternatively, it is possible that repetitive behaviors are related to challenging behaviors more broadly or that some alternative variable is causing both repetitive behaviors and challenging behaviors to occur. There is a need for additional research to evaluate the relationship between repetitive behaviors and the development of SIB specifically.

A major difference in SIB between typically developing individuals and those with IDD is the persistence of the behavior. In typical development, SIB usually resolves by age 5 (Romanczyk et al., 1982). For individuals with IDD, the course of SIB is more heterogeneous, as there are examples in the literature of SIB remitting, as well as several examples of SIB occurring well into adulthood (e.g., Cooper et al., 2009). Cooper and colleagues sought to identify the course of SIB in adults with IDD by following a cohort of participants for a 2-year period. Some individuals exhibited occasional SIB followed by a remission period (39% of individuals with SIB). However, SIB persisted for the majority of individuals (62%). Other research has also supported the tendency toward persistence of SIB among individuals with IDD, with estimates of 71% of individuals engaging in SIB continuing to do so over 7 years (Emerson et al., 2001b) and 84% persistence over 20 years in another study (Taylor, Oliver, & Murphy, 2011).

Impact of Self-Injurious Behavior

SIB can have a profound negative impact on the individuals who emit the behavior, with the most obvious negative consequence being physical injury. In less severe cases, most topographies of SIB have the potential to cause bruising, redness, and lacerations. In severe cases, many topographies, such as head hitting, head banging, self-biting, or eye-gouging, have the potential to cause permanent physical injury (Anderson & Ernst, 1994) and may cause wounds that increase the risk of infection or loss of sensory function (e.g., Barrera, Violo, & Graver, 2007).

In addition to the detrimental effect of causing physical harm, SIB also has the potential to produce significant negative collateral outcomes. For one, SIB increases the risk of restrictive placements, including hospitalization (Mandell, 2008) and residential care (Allen, Lowe, Moore, & Brophy, 2007; Lakin, Hill, Hauber, Bruininks, & Heal, 1983). Such out-of-home placements may further impede quality of life by limiting access to educational, employment, or leisure opportunities (Crossland, Burns, Leach, & Quinn, 2005). Individuals with IDD who engage in SIB are also more prone to experience manual or mechanical restraints (Jones, Allen, Moore, Phillips, & Lowe, 2007).

The presence of SIB can also be a substantial stressor for caregivers. Parents of children with IDD who exhibit challenging behavior in general are often significantly more stressed than caregivers of children without behavioral concerns (Davis & Gavidia-Payne, 2009). The presence of challenging behavior, including SIB, can negatively affect caregiver's quality of life through outcomes such as decreased marital satisfaction (Hall, Bouldin, Andresen, & Ali, 2012) and challenges with employment (Hartley, Barker, Baker, Seltzer, & Greenberg, 2012). For instance, it is not uncommon for the parents of children with severe SIB to receive calls from their child's school to retrieve their child when school personnel find it challenging to keep the student safe. In addition, when at home, children with severe SIB often require increased supervision to prevent injuries. This resulting time and need for vigilance can result in increased callouts from work and decreased time for self-care on the part of the caregiver.

Causes of Self-Injurious Behavior

In a seminal paper, Carr (1977) explored several theoretical explanations of the possible origins of SIB. These included an operant behavior hypothesis, which conceptualized SIB as a learned operant behavior (maintained by positive or negative social reinforcement); a self-stimulatory hypothesis in which SIB is thought to produce sensory stimulation that maintains the behavior; an organic hypothesis in which SIB is the result of abnormal physiological processes; and a psychodynamic hypothesis, in which SIB is meant to reduce guilt or assist with the ego. Carr reviewed the literature supporting each of these theories. He found several examples in the literature to support the operant and self-stimulatory hypotheses, based on changes in SIB that occurred following environmental manipulations. He also found support for the organic theory from studies demonstrating an association between certain topographies of SIB and specific genetic syndromes, changes in SIB related to medication changes, and increased rates of SIB among individuals experiencing potentially painful physiological conditions (e.g., ear infections). Carr dismissed the psychodynamic theory of SIB as unsubstantiated, likely as a result of the constructs being difficult to operationally define in individuals with IDD.

In summary, Carr (1977) identified a few potential hypotheses for causes of SIB that have since been studied in more depth over the past 40 years. The organic hypothesis has been further studied through potential neurobiological models of SIB, including the underlying changes in neurotransmitters related to the occurrence of SIB. Additional evidence has also emerged related to how SIB may be associated with pain and sensory experiences. In today's literature, these theories are often referred to as sensory models of SIB. Carr's operant and self-stimulatory models have also continued to receive attention, specifically in the domain of applied behavior analysis and behavioral models of SIB. These various models are described in more detail in this section.

Neurobiological Models of Self-Injurious Behavior

Several studies have attempted to identify underlying neurological causes and correlates of SIB exhibited by individuals with IDD. At the present time, there is no overarching consensus on a single neurobiological model of SIB, but numerous hypotheses have been proposed in the literature. It is important to note that several neurobiological models have acquired significant support from preclinical work with animals but remain unstudied in humans. A review of this literature is beyond the scope of this chapter (for an overview of this work, see Devine [2012]). Instead, we present a few of the most prominent neurobiological models and support for them within human research.

Endorphin dysregulation and opioid release are related neurobiological mechanisms that may be associated with SIB. Specifically, endorphins serve as inhibitory neuropeptides that affect pain perception. Some theories suggest that individuals who engage in SIB do so to access the release of endogenous opiates that occur as a result of the behavior (Richardson & Zaleski, 1983; Sandman & Kemp, 2011). In this model, SIB may be considered an addictive behavior for which the subsequent release of opiates acts as reinforcement for the behavior. Support for this theory comes from research identifying higher levels of endorphins among individuals who engage in SIB compared to control groups (Sandman & Kemp, 2011).

There is also varying support for the role of dopamine in SIB. Dopamine has a heavy concentration in the caudate nucleus. This is relevant to SIB because evidence exists for a relationship between diminished caudate nuclei volumes and diagnoses of Lesch-Nyhan syndrome, which is characterized by high prevalence of SIB (Wong et al., 1996). MRI studies also indicate decreased caudate nuclei volumes associated with SIB with individuals with ASD and Fragile X syndrome (Wolff, Hazlett, Lightbody, Reiss, & Piven, 2013). Given the high concentration of dopamine in the caudate nuclei and the diminished size of this area in individuals who engage in high rates of SIB, researchers have suggested differences in dopamine levels as potentially contributing to SIB in the neurobiological model of SIB.

A relationship between SIB and the neurotransmitters glutamate and gamma-aminobutyric acid (GABA) has also been proposed, as elevated rates of glutamate in the plasma levels of individuals with ASD and related disorders have been consistently noted (e.g., Rojas, 2014; Shinohe et al., 2006). The roles of serotonin (5-HT) in SIB have also been discussed, as there are consistent findings of elevated blood levels of 5-HT in ASD (e.g., Adamsen et al., 2014; Muller, Anacker, & Veenstra-VanderWeele, 2016). Given the high prevalence of SIB in ASD, some researchers have proposed a potential connection worthy of additional study.

Additional support for several of these theories comes from research on the effects of drugs that impact these various biological processes and the impact that they have on SIB. A brief summary of some of the more commonly studied drugs, and how they may impact and subsequently lend support to some of the above theories, can be found in the treatment section below.

Sensory Models of Self-Injurious Behavior

Although less systematic research has been conducted on these models, a common proposed hypothesis for the occurrence of SIB relates to sensory abnormalities. Specifically, the concept of pain has received significant attention in the literature. In typically developing individuals, pain is mediated by nociceptors, which are peripheral sensory neurons that have a high threshold for activation. The sensitivity of nociceptors can be altered based on repeated exposure to physical trauma or most relevant to this subject, SIB. Specifically, unlike the opioid model proposed above, this framework suggests that individuals who engage in SIB may have nociceptors that are more sensitive to pain and therefore actually have a diminished pain threshold (Symons, Harper, McGrath, Breau, & Bodfish, 2009; Symons, Shinde, Clary, Harper, & Bodfish, 2010). This decreased threshold may then create abnormal sensory experiences that are related to the causes of SIB.

A related sensory theory is that SIB occurs as a means of promoting immune response in reaction to illness or other physiological issues. For instance, SIB frequently causes inflammation, which subsequently can result in the body releasing an immune response or an instinctive response to guard that area from future damage (Peebles & Price, 2012; Symons, 2011). This theory may partially explain studies identifying increased rates of SIB during times when the individual is likely experiencing physiological discomfort from an underlying medical condition (Bosch, Van Dyke, Smith, & Poulton, 1997). For example, SIB has been shown to be related to allergy symptoms (Kennedy & Meyer, 1996), menses (Taylor, Rush, Hetrick, & Sandman, 1993), and ear infections (Carr & Smith, 1995).

Behavioral Models of Self-Injurious Behavior

In addition to biological factors that may increase the risk of SIB, environmental factors can lead to the emergence and maintenance of SIB. The behavioral model views all behaviors, including those that are problematic like SIB, as a function of the consequences that maintain it and the antecedents or environmental events that evoke it (Hanley, Iwata, & McCord, 2003; Iwata, Dorsey, Slifer, Bauman, & Richman, 1982/1994). This model views SIB as learned (i.e., operant) behavior. For example, a young child may engage in a tantrum when asked to brush his or her teeth. During the course of the tantrum, the child may drop to the ground and end up hitting his head on the floor. Given that most caregivers' first concern is their child's safety, it is likely that the child's caregivers respond to the head hitting by shifting their focus from brushing teeth to ensuring the child is safe and preventing further injury. Some may even soothe the child or offer preferred items in an attempt to calm him (Thompson & Iwata, 2007). Although this strategy is logical in terms of ensuring the safety of the child, some children with IDD may subsequently learn that in the past this behavior of head banging has resulted in the removal of an aversive demand of teeth brushing or the presentation of attention from a caregiver, which are both likely preferred outcomes (Beavers, Iwata, & Lerman, 2013).

As discussed above, SIB is more likely to occur among individuals with language and communication deficits. The behavioral model views SIB as communicative. In the above example, the child's head banging might be a means of communicating a desire to avoid brushing his teeth (Tiger, Hanley, & Bruzek, 2008). Assuming that SIB has historically resulted in the removal of demands, the child is more likely to engage in SIB in future events when an aversive demand is presented. In this situation, we would say that SIB is maintained by access to escape or that the function of the behavior is escape from demands (Hanley et al., 2003). Similarly, in a situation where a preferred toy is removed, the child engages in SIB, and the toy is subsequently returned; the SIB might be viewed as a request for the toy to be returned. Said another way, if SIB has historically resulted in access to preferred items, in future situations when a toy is removed, the child may be likely to engage in SIB. In this situation, we would say that SIB is maintained by access to tangible items or that the behavior serves a tangible function.

Assessment of Self-Injurious Behavior

Functional behavioral assessments are a category of procedures that are conducted to identify the function of challenging behavior or what is maintaining those behaviors. Functional behavioral assessments are standard practice when treating self-injurious behavior (Emerson, 1992). In fact, they are required by law in public school systems for children with special needs (including ASD) who engage in challenging behaviors such as self-injury (Drasgow & Yell, 2001; Gresham, Watson, & Skinner, 2001). A description of functional behavioral assessments can be found in Chap. 25 of this book. However, there are special considerations when assessing SIB. Specifically, we will discuss the experimental FA, which is the most intensive and experimentally rigorous method of identifying the function of challenging behavior (Vollmer, Marcus, Ringdahl, & Roane, 1995), as it relates specifically to the assessment of SIB.

Overview of Functional Analyses for Self-Injurious Behavior

An approach to analyzing the behavior-environment interaction and identifying the function of challenging behavior is known as a functional analysis (FA). This approach, described by Iwata et al. (1982/1994), has become a standard assessment used to identify the function of challenging behaviors such as SIB. In this assessment, the environmental antecedents and associated consequences are manipulated in isolation in a series of test conditions (e.g., attention, tangible, demand). For example, in an attention test condition, the therapist's attention is diverted at the start of the session, and the therapist provides a brief reprimand following SIB. This condition is analogous to one in which caregivers have to attend to something other than their child but return their attention to their child in the event of SIB in an attempt to calm him/her. In an escape test condition, the therapist provides demands and gives the child a short break following SIB. This condition is analogous to the brushing of teeth example mentioned earlier. The caregiver requests their child to brush his teeth, but then following SIB, the task is terminated and the child is allowed to escape the demand. Test conditions are designated to evaluate if SIB is maintained by positive reinforcement (access to attention or preferred items), negative reinforcement (escape from demands), or automatic reinforcement (meaning the behavior persists in the absence of external social reinforcement).

Professionals directly observe and record instances of SIB and compare rates of the behavior in the test to a control condition where the child has free access to attention and toys and no demands are made. Elevated rates of SIB in one or more test condition(s) compared to the control condition provide evidence that the variable tested in that condition maintains SIB. Beavers et al. (2013) reviewed published FAs across a 30-year period, and SIB was assessed in 55% of the reviewed FAs. SIB was found to be maintained by attention for 21%, maintained by access to preferred tangible items for 11%, and maintained by escape from demands or other aversive stimuli for 27% of participants. In addition, 9% of the studies concluded SIB was multiply maintained (i.e., more than one function).

Special Considerations for Severe Self-Injurious Behavior

In FAs, there are often special considerations when evaluating SIB compared to other topographies. As a result, we focus this discussion on these modifications as they specifically relate to SIB. Depending on the level of intensity, SIB can pose a significant risk to an individual's safety. For example, for an individual who engages in severe eye-gouging, a single instance of SIB could lead to permanent loss of vision. Similarly, in cases of extreme head banging, one head hit to a hard surface could result in a concussion. To assess the variables that maintain SIB using a traditional FA, the behavior must be allowed to occur multiple times. It is important to note that in a recent review of 99 participants who completed FAs for severe challenging behavior in an inpatient setting, injuries during assessment were very low, and overall the assessment was deemed safe so long as appropriate precautions were taken (Kahng et al., 2015). As a result, clinicians should *not* assume that severe SIB precludes the use of FAs. Instead, modifications and safety measures should be considered and incorporated into the procedures.

One approach to mitigating risk of harm during the FA is to develop clear termination criteria. For example, a clinician may decide to stop any session in which 20 instances of SIB occur. Alternatively, the clinician may elect to run short sessions (e.g., 3–5 min sessions as opposed to 10 min which is a common practice). These criteria should be set in conjunction with a medical professional who can assist in identifying the number of instances of behavior that can occur in a short period of time without the risk of injury.

If a single incident of SIB poses a risk of permanent damage, additional precautions should be considered. For example, protective equipment (Dorsey, Iwata, Reid, & Davis, 1982; Moore, Fisher, & Pennington, 2004) may be used during the assessment. A helmet may be worn for an individual who engages in head banging or arm splints or padded gloves for an individual who hits themselves or engages in self-scratching. When the setting allows, therapists may also consider padding walls or hard surfaces to prevent the impact of topographies of SIB that include forceful contact with these kinds of surfaces.

Although the potential of increased safety may make the use of protective equipment appealing, it is important to consider that these devices may interfere with identifying some functions (e.g., Borrero, Vollmer, Wright, Lerman, & Kelley, 2002). For example, it is important that SIB still persists at some level that makes assessment feasible. If the protective equipment was to eliminate SIB completely, then a function of SIB will not be able to be concluded using this assessment. The use of protective equipment may also eliminate SIB that occurs to access automatic reinforcement in the absence of the protective equipment. For example, if a child engages in hand-to-head hitting because the behavior itself automatically produces reinforcement, it is possible that this reinforcement would be eliminated by the addition of a helmet. As a result, you may get low rates of problem behavior in an alone or ignore condition of the FA when the helmet is on. This creates the risk of ruling out an automatic function when in fact the behavior is maintained by automatic reinforcement without the helmet (i.e., a false negative for an automatic function). As such, the potential impact of the protective equipment on problem behavior should always be considered when interpreting results of the FA.

An additional modification is to focus the FA on less dangerous behaviors that are in the same response class as more intense SIB (Borrero & Borrero, 2008). Often, when individuals engage in severe SIB, there are behaviors that commonly precede the SIB that serve the same function. Fritz, Iwata, Hammond, and Bloom (2013) describe a systematic method for identifying these precursor behaviors while observing a minimal number of targeted dangerous behaviors. First, clinicians can interview client's caregivers and conduct unstructured observation to identify hypotheses about behaviors that are likely to precede SIB and serve the same function. Next, these hypothesized precursor behaviors and the more severe behaviors are measured during brief exposure to antecedents that are likely to evoke problem behavior (e.g., removal of preferred items, placing nonpreferred demands). Probability analyses can then be used to compare the occurrence of potential precursor behaviors and target behaviors. In the probability analyses, the clinician identifies the chance of various events occurring given the occurrence of other events. For example, if the primary target is severe SIB and the hypothesized precursor is screaming, the clinician would identify the probability of severe SIB occurring when screaming has occurred. The inverse would also be calculated, determining the probability of screaming during times when severe SIB has occurred. The absence of these behaviors (e.g., the probability of severe SIB occurring in the absence of screaming) is also calculated. Comparing these calculations allows the clinician to identify the likelihood that screaming does in fact commonly precede and serve the same function as SIB.

After identifying precursor behaviors, the function of these less dangerous behaviors can then be identified in subsequent FAs. Assuming the precursor behaviors generally precede SIB, reinforcing these behaviors in the FA should limit the amount of more severe SIB that occurs in assessment. Thus, safety can be maintained, and the function of the targeted topographies of SIB can still be identified, so long as the precursors serve the same function.

Another method of increasing safety for severe SIB in FAs is to only allow a single instance to occur in each session. Typically, multiple instances of the targeted behavior are allowed to occur, and it is recorded in terms of its rate, duration, or the percentage of intervals in which it occurred. However if the target behavior poses a significant risk, as in the case of high-intensity SIB, the latency to a single instance of the severe behavior may serve as an alternative measure that does not require repetition of the behavior. In conducting a latency-based FA, the clinician presents various potential events that may evoke SIB (establishing operations) and measure how long it takes from the onset of this event until the time that SIB occurs (Thomason-Sassi, Iwata, Neidert, & Roscoe, 2011). After SIB occurs, the hypothesized functional reinforcer is delivered, and the session is terminated, meaning that only one instance of the severe behavior is expected to occur in each session.

The use of shorter sessions and protective equipment, assessment of precursor behavior(s), and evaluating latency to SIB are possible modifications to consider when conducting FAs for individuals who engage in SIB. However, in addition to considering these modifications to the standard FA (Iwata et al., 1982/1994), practicing professionals need to ensure proper oversight throughout the assessment process to safeguard the individual from potential injuries. If redness, bruising, or other sign of injury is observed during assessment, it is best to air on the side of caution and terminate the assessment to ensure safety until a new assessment plan can be created. Whenever possible, a medical professional should be consulted regarding the potential impact and injury from SIB. In addition, for severe cases of SIB where the risk of injury is high, it is best to consult with a behavior analyst who specializes in the assessment and treatment of severe challenging behavior or refer to a treatment facility that has the proper facilities and expertise.

Assessment of Automatically Maintained Self-Injurious Behavior. SIB is more likely to be maintained by automatic reinforcement than other topographies of problem behavior commonly exhibited by individuals with IDD. In a review of published FAs, Beavers et al. (2013) found that 25% of cases of SIB were maintained by automatic reinforcement, whereas aggressive and destructive behaviors were maintained by automatic reinforcement for only 2% and 11% of cases, respectively. As such, a further discussion of problem behavior maintained by automatic reinforcement is warranted.

As described above, problem behavior maintained by automatic reinforcement is identified through continued occurrence of the behavior in the absence of social consequences. By ruling out the influence of social consequences, it is assumed that the behavior produces the reinforcement directly. Unfortunately, it is often difficult to identify the specific form of automatic reinforcement that SIB is producing. For instance, SIB might be maintained by positive automatic reinforcement (the behavior is producing a preferred internal experience), negative automatic reinforcement (the behavior is reducing an aversive internal experience), or some combination of the two. Vollmer (1994) suggests an example where an individual who engages in self-scratching to the point of injury may do so because the behavior produces temporary alleviation of an uncomfortable "itchy" sensation or automatic negative reinforcement. For other individuals, SIB may result in the release of endorphins or other physiological effects that are desired and serve as positive reinforcement for the behavior. Note that both of these examples and several of the examples described below directly relate to and may be better explained by the sensory and neurobiological models of SIB. However, they are being discussed here in the context of research on assessment techniques for SIB that has been primarily focused on in the behavioral literature.

There have been several examples in the literature in which researchers have identified the specific type of automatic reinforcement produced by challenging behavior. For example, Piazza, Adelinis, Hanley, Goh, and Delia (2000) conducted competing item assessments with individuals with automatically maintained challenging behavior. This assessment included items that produced stimulation that either matched or did not match the type of automatic reinforcement hypothesized to be produced by the participants' topography of challenging behavior. For example, one participant engaged in problematic hand mouthing that was automatically maintained. The researchers hypothesized that the automatic reinforcement was the result of either stimulation to the hand or oral stimulation. Therefore, his matched stimuli included items that produced similar stimulation (e.g., hand massager for hand stimulation or a mouth guard for oral stimulation). They found that access to matched items was more likely to result in low rates of challenging behavior when compared to items that were not matched to the hypothesized automatic reinforcement produced by the behavior. This finding was replicated across three different participants with automatically maintained challenging behavior, supporting the authors' hypotheses about the specific mechanism of automatic reinforcement maintaining behavior for those specific clients.

Another method of testing for the specific type of automatic reinforcement produced by SIB involves the use of protective equipment or other procedures that block a specific sensory consequence of the behavior (McKerchar, Kahng, Casioppo, & Wilson, 2001). For example, head banging may be maintained by several sensory inputs including the visual stimulation produced by movement of the head, the sound the head makes when it hits a surface, or the impact on the head. One can test the hypothesis that impacts to the head are producing automatic reinforcement by having the individual wear a helmet. Under this condition, any potential visual or auditory stimulation remains, but impacts to the head are attenuated. If SIB decreases when the helmet is worn, one can infer the behavior was maintained by the impact and not auditory or visual input.

Further complicating the issue of automatically maintained SIB is the potential for it to be multiply maintained by both automatic and social reinforcement (McKerchar et al., 2001; Scheithauer, Lomas Mevers, Call, & Shrewsbury, 2017; Smith, Iwata, Vollmer, & Zarcone, 1993). Assessing for multiply maintained SIB is challenging but is often important in guiding treatment. For example, consider a child who engages in SIB that is maintained by both automatic reinforcement and escape from demands. First-line treatments for the automatically maintained SIB are likely to include access to other preferred items that may compete with the automatic reinforcement or delivery of alternative reinforcers for the absence of SIB. Neither of these treatments is likely to resolve escape-maintained SIB. Thus, it is important for clinicians to determine whether automatically maintained SIB is also maintained by social consequences.

There are a handful of examples of this type of assessment in the literature (Contrucci Kuhn & Triggs, 2009; McKerchar et al., 2001; Scheithauer et al., 2017; Smith et al., 1993). The basic concept behind these assessments is that they control for the automatic reinforcement that is produced by the challenging behavior by using protective equipment (e.g., Scheithauer et al.) or providing preferred items that are known to compete with the automatic reinforcement (e.g., Smith et al.). Social test conditions are then repeated with these procedures in place. If problem behavior persists in test conditions designed to evaluate the role of social reinforcement after SIB maintained by automatic reinforcement has been reduced, then the behavior is likely also maintained by the associated social reinforcers.

Another issue further complicating the assessment and treatment of automatically maintained SIB is the possibility of self-restraint (Fisher & Iwata, 1996). According to a study of individuals with IDD admitted to a treatment facility for severe SIB, 21% of participants also engaged in self-restraint during assessment (Hagopian, Rooker, & Zarcone, 2015). Self-restraint occurs when an individual restricts his or her own movement through topographies such as sitting on the hands, wrapping hands in clothing, wrapping limbs around another person, or actively seeking out protective equipment such as arm restraints. When individuals present with severe SIB and self-restraint, it is important that the relationship between the two behaviors is thoroughly assessed, as self-restraint can often create difficulties in interpreting assessment and treatment results that are targeting SIB. There are several potential relationships between these behaviors (Fisher & Iwata, 1996). First, self-restraint may serve the same function as SIB, whether by producing automatic (Derby, Fisher, & Piazza, 1996) or social reinforcement (Rapp & Miltenberger, 2000). Second, SIB may be maintained by access to self-restraint (Rooker & Roscoe, 2005). For example, a teacher may prevent a child from engaging in self-restraint that interferes with classwork. However, if the child begins to engage in SIB, the teacher may allow self-restraint because it is the less dangerous of the two behaviors. Finally, self-restraint may be maintained by negative reinforcement in the form of discontinuation of SIB (Scheithauer et al., 2015; Smith, Iwata, Vollmer, & Pace, 1992). In this scenario, it is assumed that SIB actually produces aversive consequences. Self-restraint then occurs as it has historically resulted in avoiding or stopping SIB and the related aversive consequences. This can be an especially complicated explanation because if avoiding SIB is preferred, then one would expect the individual to simply refrain from engaging in SIB. However, in this scenario, it is possible that the SIB is not under the control of operant contingencies. Instead, the behavior may be the result of some physiological process that is not under the immediate control of the individual (e.g., tic disorders). It is also possible that the SIB produces some form of immediate positive reinforcement (e.g., sensory stimulation) followed by a later aversive consequence (e.g., pain). Thus, the self-restraint may serve as a self-control response to prevent the individual from engaging in an impulsive behavior that will result in immediate reinforcement but long-term aversive consequences.

In summary, SIB maintained by automatic reinforcement is difficult to assess and treat for numerous reasons. Most of the research in this field has relied on single-subject methods conducted in highly specialized settings, likely due to the intensity of assessment and intervention that is often necessary and the complexity of individual cases. Additional work is needed to identify best-practice methodologies that can be more widely disseminated across clinicians and be used in less specialized clinics.

Treatment Models for Self-Injurious Behavior

Pharmacological Treatments

Few drug studies have specifically targeted SIB in individuals with IDD (Gormez, Rana, & Varghese, 2014; Minshawi, Hurwitz, Morriss, & McDougle, 2015), and those that do directly assess SIB have generally relied on small-N designs. However, there is a larger body of research that targets behaviors related to SIB in this population, such as repetitive behaviors, irritability, and disruptive behavior. A summary of this literature is beyond the scope of this chapter: see Doyle and McDougle (2012) and Fung et al. (2016) for reviews of these topics. Instead, we focus on the most commonly studied drugs that target SIB specifically.

Antipsychotic drugs, which act as dopamine antagonists, are one of the oldest classes of drugs used to target maladaptive behaviors in individuals with IDD. Haloperidol, a typical antipsychotic, was one of the earliest drugs used to target SIB and related behaviors (e.g., Burk & Menolascino, 1968). Whereas reductions in maladaptive behaviors, including SIB, were noted, these drugs are not widely used as a first-line treatment today due to serious side effects, including dyskinesias (McDougle, Stigler, Erickson, & Posey, 2006; McPheeters et al., 2011). Instead, atypical antipsychotics are commonly used for individuals who engage in SIB. Two atypical antipsychotics (risperidone and aripiprazole) are approved drugs for use with ASD, based on randomized clinical trials demonstrating improvement in problem behavior broadly (Marcus et al., 2009; McCracken et al., 2002; Owen et al., 2009; Shea et al., 2004). Risperidone has also been shown to improve caregiver ratings of SIB specifically (Aman et al., 2002). A few studies have also directly targeted

SIB, with direct observation as the primary outcome measure with mixed results (Cox & Virues-Ortega, 2016).

The opiate blocker naltrexone is another drug studied in the treatment of SIB and is somewhat unique in that the primary target of those studies has been SIB specifically, as opposed to problem behavior more broadly. Sandman (1988) conducted a study analyzing the effects of naltrexone (an opiate blocker), on SIB with four individuals with IDD. Self-injury improved for three of the four, lending support for the neurobiological model describing the role of increased endorphin release in SIB. Additional support emerges from findings that individuals with higher levels of endorphins following SIB are more likely to respond to opiate blockers as treatment (Sandman, Hetrick, Taylor, & Chicz-DeMet, 1997; Scifo et al., 1996). Other theories suggest the mechanism of action for these drugs is lowering an individual's pain threshold, resulting in increased pain from the SIB and subsequent reductions. The positive effects of naltrexone have been replicated (e.g., Bernstein, Hughes, Mitchell, & Thompson, 1987; Bodfish et al., 1997; Gibson, Hetrick, Taylor, Sandman, & Touchette, 1995; Kars, Broekema, Glaudemans-van Gelderen, Verhoeven, & Van Ree, 1990); however, other studies have failed to replicate the positive results, finding that naltrexone does not result in significant improvements over placebos (Willemsen-Swinkels, Buitelaar, Nijhof, & van Engeland, 1995; Zingarelli et al., 1992). In a recent review of clinical trials evaluating opiate blockers, six out of ten published clinical trials identified statistically significant improvements in SIB (Roy, Roy, Deb, Unwin, & Roy, 2015). Unfortunately, there are currently no indications as to the characteristics that might predict a positive response. As a result, additional research is needed.

Medications targeting 5-HT have also been studied as a treatment for SIB. Open-label trials have suggested clomipramine, a tricyclic antidepressant (TCA), may be effective at reducing SIB (e.g., Garber, McGonigle, Slomka, & Monteverde, 1992). Selective serotonin reuptake inhibitors (SSRIs) are also now commonly prescribed. Fluoxetine is the most common SSRI studied as a treatment for SIB, with open-label trials indicating effectiveness in decreasing SIB in individuals with IDD (Bass & Beltis, 1991; Markowitz, 1992; Ricketts et al., 1993). Fluoxetine has also been shown to improve skin picking in a small randomized clinical trial (Simeon et al., 1997). Paroxetine, sertraline, and fluvoxamine have also been studied using retrospective reviews and open-labeled studies targeting SIB. Reviews of this literature have been mixed, with some suggesting the drugs may be effective (Janowsky, Shetty, Barnhill, Elamir, & Davis, 2005) and others suggesting there is insufficient evidence (Sohanpal et al., 2007). In summary, although medications targeting 5-HT have been studied, additional large-N clinical trials are needed to definitively determine efficacy.

N-Acetylcysteine (NAC), an over-the-counter dietary supplement, has also been shown to be effective with SIB when given at higher doses than is suggested as a supplement. NAC acts through enhancing antioxidant activity and reducing release of glutamate. NAC has shown promising results in open-label case studies (Marler, Sanders, & Veenstra-VanderWeele, 2014; Percinel & Yazici, 2014) and a small clinical trial targeting skin picking (Grant et al., 2016).

Another class of medications that has received attention in research is antiepileptic or anticonvulsant drugs, operating through stimulating GABA receptors. One of these medications, divalproex sodium (i.e., Depakote), was evaluated in an open-label trial with adults with ID and SIB with promising results (Ruedrich, Swales, Fossaceca, Toliver, & Rutkowski, 1999). However, a randomized clinical trial with a youth population studying valproate found no significant effect on indirect measures that are often related to SIB (such as irritability; Hellings et al., 2005). Therefore, additional research is needed to determine whether this class of medications should be indicated for SIB. There are also several other drugs not discussed here that are commonly prescribed for off-label use with this population, including anxiolytics, stimulants, and mood stabilizers (Tsiouris, Kim, Brown, Pettinger, & Cohen, 2013). Similar to anticonvulsant drugs, these need additional research before becoming clinically indicated for the treatment of SIB.

Sensory Treatments

There is some variability in the literature related to defining sensory approaches to the treatment of SIB (Ottenbacher, 1991). Here we discuss some of the documented cases of effective interventions in the literature that describe their approach in terms that relate to sensory input (Bright, Bittick, & Fleeman, 1981; Dura, Mulick, & Hammer, 1988; Favell, McGimsey, & Schell, 1982; Wells & Smith, 1983). Sensory integration is a commonly used approach among occupational therapists. Sensory integration is based on the concept that there is a breakdown in how sensory input is organized and analyzed, leading to self-stimulatory behavior such as SIB (Ayres, 1972). Sensory integration therapy for the treatment of SIB hypothesizes that including stimuli that satisfy the sensory dysfunction (i.e., the breakdown in organization and analysis of sensory input) will organize sensory processes and therefore decrease SIB. For example, Bright and colleagues included 1 h sessions once per day in which the individual was exposed to noncontingent vestibular, tactile, and auditory stimulation. This type of stimulation was included after observation that SIB occurred less frequently when tactile and vestibular stimulations were provided. The frequency of SIB decreased across the 5 months of data collection.

Other researchers have found mixed results for the use of sensory integration in the treatment of SIB (Arendt, MacLean, & Baumeister, 1988; Kinnealey, 2005; Mason & Iwata, 1990). Kinnealey found that SIB improved for the 1 h immediately following sensory integration, but the improvement did not maintain outside of this hour. Similarly, Mason and Iwata found that sensory integration therapy with attention (i.e., the therapist provided high-quality attention to the client during therapy) successfully reduced the frequency of SIB during therapy sessions. However, when the attention component was removed, the sensory integration sessions alone did not affect the frequency of SIB. These disparate findings may be related to the various factors commonly included in therapy. Specifically, during sensory integration sessions, there are typically no demands present, and attention is provided at least intermittently. These factors alone may contribute to decreases in SIB observed during the therapy sessions (Mason & Iwata) but may not create generalized improvement outside of treatment sessions. As such, discrepancies in the literature on the success of sensory integration therapy may stem from when observations are conducted (e.g., during appointments compared to a period of time after completion of the appointment) and the types of components included in the therapy.

Behavioral Treatments

The literature is rife with examples of behavioral treatments for SIB (Kahng, Iwata, & Lewin, 2002). Extinction, or the disruption of the relationship between SIB and the functional reinforcer, is a common treatment component. In cases of SIB, extinction consists of first identifying the functional reinforcer through behavioral assessments (see above and Chap. 25). After identification, the simplest way to disrupt the relationship between the functional reinforcer and SIB is to no longer provide the reinforcer when SIB occurs. For example, if SIB is maintained by escape from demands, then extinction could consist of following through with demands despite the occurrence of SIB. In the example discussed above with brushing teeth, this could involve hand-over-hand prompting to ensure the child completes teeth brushing. Conversely, if SIB is found to be maintained by access to attention, then extinction could involve ignoring all instances of SIB.

Extinction alone can effectively reduce SIB (Goh & Iwata, 1994), but greater and more rapid reductions occur when used in conjunction with a reinforcement component (Mazaleski, Iwata, Vollmer, Zarcone, & Smith, 1993; McCord, Thomson, & Iwata, 2001). Thus, it is common to incorporate reinforcement-based procedures when treating SIB. Kahng et al. (2002) found that more than 40% of 700 cases reporting treatments of SIB in the literature included a reinforcement component. There are several different methods by which reinforcement can be included in the treatment. First, differential reinforcement of alternative behavior (DRA) is commonly used and is implemented by identifying an alternative and appropriate behavior that results in access to the functional reinforcer (Vollmer & Iwata, 1992). For SIB maintained by access to escape, DRA could include providing a break contingent on compliance with demands (Roberts, Mace, & Daggett, 1995). Similarly, for SIB maintained by access to attention or tangible items, DRA treatments have been successful that target a functionally equivalent communication response, such as a request for the relevant reinforcer (Fisher, Kuhn, & Thompson, 1998; Hanley, Iwata, & Thompson, 2001). For problem behavior maintained by access to attention, this treatment could involve teaching the child to ask for attention and providing reinforcement when he or she does so.

Another form of reinforcement, differential reinforcement of other behavior (DRO), consists of providing reinforcement following a period of time without SIB. When SIB is maintained by positive or negative social reinforcement, the functional reinforcer is generally delivered when the required time interval without SIB has occurred. For example, if SIB is maintained by access to attention, a therapist may provide high-quality attention when the child has gone a specific amount of time without engaging in SIB (Mazaleski et al., 1993; Mazaleski, Iwata, Rodgers, Vollmer, & Iwata, 1992; Vollmer, Iwata, Zarcone, Smith, & Mazaleski, 1993). Other times, an arbitrary reinforcer (e.g., a preferred item that is not the functional reinforcer) may be provided, especially if the behavior is automatically maintained, because the functional reinforcer is difficult to deliver under such circumstances (Cowdery, Iwata, & Pace, 1990).

Noncontingent access to preferred items or functional reinforcers is another common strategy incorporated into treatments for SIB. This treatment technique can operate through decreasing an individual's motivation to access a functional reinforcer. In addition, when the functional reinforcer is being delivered noncontingently, it is no longer being provided contingent on SIB, which disrupts this relationship through extinction. For example, if SIB is maintained by access to escape, providing noncontingent breaks on a specific time schedule might decrease the individual's motivation to engage in SIB to get that same break while also implementing extinction as the break is no longer being provided contingent on SIB (Vollmer, Marcus, & Ringhdahl et al., 1995).

For automatically maintained SIB, providing noncontingent access to preferred items or attention may consist of creating an enriched environment that competes with the automatic reinforcement produced by SIB, subsequently decreasing motivation to engage in SIB (Shore, Iwata, DeLeon, Kahng, & Smith, 1997). To identify items that may sufficiently compete with automatic reinforcement and decrease SIB, a structured assessment can be conducted prior to starting treatment. This assessment, called a competing items assessment, consists of exposing the individual to various conditions in which a variety of potentially preferred items are freely available. Clinicians can then record item interaction and SIB to identify items likely to compete with SIB (Piazza et al., 1999; Piazza et al., 2000).

The strategies of differential reinforcement and noncontingent access to preferred items described above are often first-line treatments as they are minimally intrusive to the individual undergoing treatment. However, in some situations, reinforcement strategies alone are not sufficient to reduce SIB. For example, in the case of automatically maintained SIB, it may not always be possible to identify reinforcers that sufficiently compete with the functional reinforcer. In this situation, there are other strategies that can be considered.

Response interruption and redirection is one of these strategies that has resulted in decreases in SIB (Turner, Realon, Irvin, & Robinson, 1996). In this treatment, a clinician interrupts SIB and redirects the individual to emit an appropriate response, such as completion of demands or engaging in appropriate play. The effectiveness of this intervention may be the result of punishing the SIB by redirecting to a less-preferred task or interrupting a pattern of behavior that has historically resulted in automatic reinforcement (creating sensory extinction for additional instances of the behavior).

Response blocking of SIB is also a common component included in the treatment. Response blocking involves physically preventing the behavior from occurring. For example, for SIB that involves hitting, the therapist would place a physical barrier (e.g., therapist's hand or a soft surface) between the client's hand and the targeted area of the body to prevent the hitting from occurring. While effective, similar to response interruption redirection, there is debate on whether the mechanism responsible for reductions in SIB from response blocking is attributed to sensory extinction (Reid, Parsons, Phillips, & Green, 1993; Smith, Russo, & Le, 1999) or punishment (assuming that the blocking procedure is aversive; Lerman & Iwata, 1996).

Sensory extinction can also be implemented through the use of protective equipment used to eliminate or decrease the reinforcement or stimulation produced by engaging in SIB (Rincover & Devany, 1982; Roscoe, Iwata, & Goh, 1998). These techniques are only likely to be successful if the automatic reinforcement is sufficiently reduced by application of the protective equipment. Some protective equipment used in the literature may also operate through increasing the effort that it takes to engage in the behavior. For example, mechanical arm restraints that make it more effortful for the client to bend his or her arm may make it more difficult to engage in hand-to-head SIB (Deshais, Fisher, Hausman, & Kahng, 2015). As a result the response effort may be too high for the amount of automatic reinforcement produced by the behavior, subsequently reducing the frequency of the behavior (Irvin, Thompson, Turner, & Williams, 1998). It is important to note that when using protective equipment or mechanical restraint, it is important to consult with individuals with expertise in the use of these procedures for behavioral treatments and with medical professionals to ensure safety and proper care. For example, in using arm restraints, it is important to follow strict protocols for application, removal, and frequency of breaks to avoid muscle atrophy. In addition, the ultimate goal of treatment is generally to reduce and fade out the use of protective equipment so as to not use them as a long-term solution. Misuse of these technologies can result in physical damage if proper case is not taken.

Finally, when the methods described have been exhausted and are unsuccessful, and SIB is severe enough to cause significant harm, then it may be appropriate to consider the use of punishment procedures. These are events that are delivered following SIB that are nonpreferred and therefore likely to decrease future instances of SIB. Systematic assessments can be conducted prior to treatment to identify potential punishers (Fisher et al., 1994), with common procedures being blocking the individual's line of site, restraint, and time-out (Kahng et al., 2002). It should be noted that punishment procedures should only be implemented with highly trained clinicians in situations where other treatments have proven ineffective and the behavior is serious enough to warrant the invasiveness of the procedure. In addition, it is crucial that the effectiveness of the procedure is systematically analyzed to ensure that any punishment procedures used are effective and necessary.

Generalization and caregiver training are crucial components of all behavioral treatments for SIB. Although the topic of generalization is outside the scope of this chapter (see Stokes & Baer, 1977), clinicians should take care to ensure that treatments for SIB generalize to naturally occurring situations, environments, and caregivers. Caregiver training is an equally important component of treatments for SIB. Clinicians should consider robust training practices, including behavioral skills training followed by frequent checks for integrity. Research has shown that decreased fidelity negatively impacts treatment effectiveness (Fryling, Wallace, & Yassine, 2012).

Nonevidence-Based Treatments

Families of children with IDD such as ASD are increasingly seeking out complimentary, alternative treatments that have not been supported in the literature (Brondino et al., 2015). Some of these interventions are touted as treatments for challenging behavior including SIB. For example, individuals have made claims that the use of cannabis is effective in the treatment of SIB. However, these claims have been limited to anecdotes and small case studies (Kruger & Christophersen, 2006). Other studies have focused on the use of music (Lundqvist, Andersson, & Viding, 2009) or yoga (Rosenblatt et al., 2011) to reduce SIB. However, the scarcity of data limits the validity of findings pertaining to the use of these interventions.

Clinicians should focus on the use of strategies that meet evidence-based standards and should discuss with caregivers the possible limitations or harmful effects of nonevidence-based treatments. Broadly, evidence-based strategies involve interventions that have been systematically evaluated using randomized group trials or well-controlled single-subject designs that suggest the procedures are effective. Specific criteria have been proposed to identify an intervention as well established and probably efficacious within the field of psychology (Tolin, McKay, Forman, Klonsky, & Thombs, 2015). Due to the low prevalence of extremely severe cases of SIB and the intensity of assessment and treatments necessary for these cases, it is possible that some commonly used treatments described above may fall short of these proposed criteria. Nonetheless, the criteria serve as a guide for clinicians for identifying the type of studies that should be used to support the use of specific interventions.

Multidisciplinary Approach

In studying and treating SIB, it is important to consider a multidisciplinary approach whenever possible. In the development of SIB, it is likely that a variety of environmental, sensory, genetic, and physiological factors contribute to the emergence of SIB. For example, a child may engage in SIB that is escape maintained when presented with schoolwork (explained by the behavioral model). However, the child may engage in higher rates of SIB when presented with schoolwork during times that the child is also not feeling well, which is best explained by the sensory or neurobiological models. There are several examples in the literature of these situations where environmental and physiological factors act in conjunction to impact rates of SIB (e.g., Kennedy & Meyer, 1996). In this situation, one theory alone is not sufficient to adequately explain the child's SIB, and a combination of theories is necessary. Similarly, in treatment, it is common that children with IDD who engage in SIB will be undergoing multiple modalities of treatment. In these scenarios, it is important to assess the impact of each component of the child's treatment and to collaborate across providers. As such, techniques that consider multiple potential variables that may impact SIB will allow for the most comprehensive assessment and treatments. Especially in the case of severe self-injury, it is recommended that professionals work across disciplines to evaluate medical, sensory, and behavioral causes and potential treatment components (Minshawi et al., 2015).

Pica

33

Matthew O'Brien

Pica is an eating disorder that is characterized by the consumption of nonfood substances. It is believed to affect individuals with intellectual and developmental disabilities (ID/DD) at a disproportionally higher rate than typically developing individuals (Ali, 2001). Pica is often referred to as a self-injurious behavior (SIB) based upon the potential for numerous harmful outcomes, including poisoning, infection, intestinal blockages and perforations, and even death (Sturmey & Williams, 2016). Given such outcomes, it should not be a surprise that much research has been dedicated to understanding the etiology of pica and searching for effective treatments. In fact, several books have been written exclusively on the subject of pica (Sturmey & Williams, 2016; Young, Sherman, Lucks, & Pelto, 2011). Yet, there continues to be a debate about the cause(s) and the most effective treatments for this disorder. Additionally, there is still much to be learned about its effects on different populations, prevalence rates, and connections to other disorders. This chapter presents an overview of pica in the ID/DD population, including what is known about diagnosis, prevalence, theories of etiology, and prevention and treatment research.

Diagnosis

Pica comes from the Latin word for magpie (T.E.C, 1969), a bird that is notorious for eating nearly anything, including nonfood items. Like the magpie, individuals diagnosed with pica consume nonfood items. This behavior is the essential feature of pica diagnosis. The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5; American Psychiatric Association, 2013), which characterizes pica as an eating disorder alongside anorexia and bulimia, defines pica by four criteria:

1. Persistent eating of nonnutritive, nonfood substances for a period of at least 1 month.
2. The eating of nonnutritive, nonfood substances is inappropriate to the developmental level of the individual.
3. The eating behavior is not part of a culturally supported or socially normative practice.
4. If occurring with another mental disorder (e.g., autism or intellectual disability), or during a medical condition (e.g., pregnancy), it is severe enough to warrant independent clinical attention.

Based on these criteria, individuals exempt from a diagnosis of pica include those from cultures where consumption of nonfood items is accepted and may be perceived to offer health benefits

(e.g., consumption of clay by pregnant women in Kenya; Geissler et al., 1999) and very young children (i.e., below the age of 2 years) for whom exploration of objects by mouth is deemed a typical behavior. It could still be argued that for both of these exempt groups, the absence of a diagnosis does not preclude intervention to prevent harmful outcomes, including toxicity to a developing fetus (Gundacker et al., 2017). Moreover, mouthing of hands and objects without consumption, which is distinguishable from pica, may pose health risks warranting treatment as well.

The DSM criteria do not offer further classification of pica behavior based upon important dimensions, such as severity, frequency, and form or type of item consumed. Although there are no validated tools available to evaluate pica severity, the *Severity Index for Pica* was created by Don Williams to delineate pica from mild to life-threatening forms (Sturmey & Williams, 2016). This scale categorizes five levels of severity (mild, moderate, severe, dangerous, and life-threatening), discriminating based upon the size and potential danger associated with the items consumed, the frequency of pica, and the negative outcomes experienced by the individual (e.g., surgery to remove an item).

Case reports of pica have documented the consumption of many different nonfood items, resulting in dozens of forms of pica, each with a unique name. Items targeted for consumption range from those more commonly documented, such as dirt, sand, clay (geophagia), and ice (pagophagia), to those rarely described in the literature, including glass (hyalophagia) and drinking urine (urophagia). McAdam, Breidbord, Levine, and Williams (2012) classified the various forms of pica found in case reports and research literature into six categories: biological secretions (e.g., blood, vomit, feces), biological solids (e.g., skin, fingernails, hair), chemicals (e.g., copper, lead paint chips), food items (e.g., raw potatoes, eggs), organic materials (e.g., dust, laundry starch, book pages), and materials causing physical damage (e.g., sharp items, stones, cigarette butts). Whether these classifications provide insight into the etiology of pica or are helpful in treatment selection has not been studied.

Epidemiology

It is difficult to provide an accurate estimate of the prevalence of pica in the general population in cultures where pica is not an acceptable behavior (APA, 2013). Nevertheless, rates of pica within the general population are believed to be much lower than those for individuals with developmental disabilities (Matson, Belva, Hattier, & Matson, 2011), with the possible exceptions of pregnant women (Fawcett, Fawcett, & Mazmanian, 2016) and very young children (Barltop, 1966). Among individuals with a developmental disability, prevalence estimates vary broadly, which is likely due to the combination of differences in how researchers have defined pica, the data collection methods used, and differences across the sampled groups (e.g., community setting versus institution). At the low end of the range, Hove (2004) found that 2.9% of adults with ID living in the general community displayed pica according to a survey completed by healthcare workers on their clientele. On the high end, Danford and Huber (1982) reported pica in 25.8% of children and adults with ID living in an institution. Studies of ID/DD individuals living in institutional settings have generally found higher rates of pica than studies of ID/DD individuals living within the general community (Matson et al., 2011). This may be attributable to the increased severity of disability and challenging behavior often found in institutionalized individuals. In fact, several studies have noted that the risk for pica in individuals with ID increases as the classification of intellectual disability moves from mild to moderate to severe/profound (Ashworth, Martin, & Hirdes, 2008; Smith, Branford, Collacott, Cooper, & McGrother, 1996; Tewari, Krishnan, Valsalan, & Roy, 1995).

Within the ID/DD population, a few subgroups are likely at an increased risk of pica. Individuals with Prader-Willi syndrome, a rare genetic condition, often exhibit insatiable appetites (hyperphagia) and obsessive foraging for food, even including food that has been discarded (Dykens, Leckman, & Cassidy, 1996). Additionally, individuals with Prader-Willi syndrome may consume nonfood items, such as paint chips or paper (Dimitropoulos et al., 2000) and contaminated food (Dykens, 2000). Despite strong evidence that pica is a dangerous behavior more likely to occur in individuals with Prader-Willi syndrome, to date no known studies have sought to estimate the prevalence of pica in this group, and Prader-Willi syndrome is conspicuously absent in most writings about pica in ID/DD populations.

Numerous case studies, predominately from the field of applied behavior analysis (ABA), report on assessment and/or treatment approaches for pica with individuals diagnosed with an autism spectrum disorder (Falcomata, Roane, & Pabico, 2007; Hagopian et al., 2011; Ing, Roane, & Veenstra, 2011; Mitteer, Romani, Greer, & Fisher, 2015; Piazza et al., 1998; Rapp, Dozier, & Carr, 2001; Slocum, Mehrkam, Peters, & Vollmer, 2017). However, only a couple of studies have examined the prevalence of pica in individuals with autism. The highest estimate of pica in autism came from a study by Kinnell (1985) who reviewed case records of 70 individuals of all ages with autism. Sixty percent had pica at some stage in life, leading Kinnell to suggest that all individuals with autism should be screened for pica. Clark, Vandermeer, Simonetti, and Buka (2010) identified a slightly lower prevalence rate (48%) of pica in a sample of 48 children with autism using a community sample. Finally, among adults in an institution with both autism and ID, Lovullo and Matson (2009) found 36% displayed pica. Most of the individuals included in these studies had also been diagnosed with ID, which raises the possibility that the connection between autism and pica is more likely a function of cognition deficits than the diagnosis of autism.

Cri du chat syndrome is a genetic condition often resulting in moderate to severe intellectual disability. In addition to a number of self-injurious behaviors, pica is regularly observed in this population. Based upon reports by 66 families of children and adults with Cri du Chat, 27% of the participants displayed pica (Ross, Collins & Cornish, 2002). However, like autism, it is unclear whether pica is particular to this syndrome or individuals with more significant cognitive impairments.

Etiology of Pica

Many theories have been posited on the cause of pica. Given the many forms of pica, it seems highly unlikely that a singular account could explain all pica cases. In fact, Sturmey and Williams (2016) devote an entire chapter in their book on pica in the ID/DD population strictly to etiology, with descriptions of ten different accounts for the existence of pica. As these authors note, each theory may make more sense "…in relationship to different populations and all with very limited quantities of evidence to support or test them…" (pg. 37). As such, for individuals with ID/DD, a behavioral explanation may be most appropriate, given the deeper history of assessment and effective treatments coming from that line of work.

Despite some overlap among the theories, theoretical accounts with supporting research may generally be categorized into one of three broad perspectives: biomedical, psychiatric, or behavioral. Each of these areas is described below with both supporting evidence and challenges to the suppositions. Note that the descriptions below are related to pica that is deemed aberrant within the culture that one lives, which excludes some culturally supported examples of pica (e.g., geophagia in African communities). Additionally, a number of theories that have been proposed are not described below as they have insufficient or no evidence in the research literature to support their account.

Biomedical Perspective

Biomedical accounts are based upon the premise that pica is the result of nutritional deficiencies, neurological impairment, and/or faulty neurochemical transmission. Nutritional deficiencies in individuals with pica have been the focus of much research and serves as one of the earliest hypotheses on the cause of pica (Young et al., 2011). Theories based upon nutritional deficits suggest that individuals who exhibit a nutritional shortfall are more likely to seek out nonfood items to resolve the insufficiency (Cavdar, Arcasoy, Cin, Babacan, & Gozdasoglu, 1983) or the insufficiency leads to a neurological disturbance, which produces pica behavior (Chisholm & Martin, 1981). The prime foci of nutritional deficit arguments have been inadequate zinc and iron (Miao, Young, & Golden, 2015), with the latter receiving the majority of interest and the most research evidence. Indeed, numerous studies have shown a link between iron-deficiency anemia and pica (Young, 2010). It should be noted that many studies linking iron deficiency and pica have focused largely on pregnant women and young children, which are populations most likely to suffer from iron deficiencies (McLean, Cogswell, Egli, Wojdyla, & de Benoist, 2009). The most convincing study is a meta-analysis conducted by Miao et al. (2015), in which the data for 43 previous studies with a diverse range in population demographics was examined to determine whether a link between iron and zinc deficiencies and pica exists. The authors found a strong correlation between pica and low iron level, as well as pica and low zinc levels. Unfortunately, this link does not provide a clear indicator of the direction of the relationship (i.e., Do deficiencies cause pica or does pica lead to deficiencies?). A challenge to the iron and zinc deficiency hypothesis is that iron and zinc supplementation rarely has been shown to reduce pica behavior (Gutelius, Millican, Layman, Cohen, & Dublin, 1962; Nchito, Geissler, Mubila, Friis, & Olsen, 2004), outside of a few case reports (e.g., Arbiter & Black, 1991; see study by Lofts, Schroeder, & Maier, 1990 for exception).

A neurological impairment hypothesis suggests that pica is the result of brain damage, dementia, or faulty neurochemical transmission. Evidence for pica as a result of brain injury is scant and largely confined to nonhuman animal studies (Aggleton & Passingham, 1981) and case reports (Lilly, Cummings, Benson, & Frankel, 1983). However, dementia patients may provide some clues as to the cause of pica. At least three studies have found higher rates of pica, particularly coprophagia (consumption of fecal matter), in individuals with dementia (Ghaziuddin & McDonald, 1985; Morris, Hope, & Fairburn, 1989; Josephs, Whitwell, Parisi, & Lapid, 2016). These studies have offered a number of possible explanations for the connection between pica and dementia, but the most common suggestion is that pica results from atrophy of the medial temporal lobe, a structure mostly associated with semantic memory.

Singh, Ellis, Crews, and Singh (1994) posited that pica may be caused by faulty dopaminergic neurotransmission. This hypothesis is supported by a study they conducted involving three adolescents with ID and a history of pica. All three participants were exposed to three conditions: a no-medication baseline, a thioridazine condition (a medication with anti-dopaminergic effects), and a methylphenidate condition (a known dopamine agonist). If pica is the result of deficient dopamine transmission, then differences in the rate of pica should be demonstrated across these conditions. Indeed, Singh et al. found that the thioridazine condition was associated with the highest rates of pica, and the methylphenidate condition resulted in the lowest rates of pica, supporting their hypothesis. Interestingly, no further studies have been conducted to test this hypothesis.

Psychiatric Perspective

Theories from a psychiatric perspective have argued that pica is a manifestation of another mental illness or a form of obsessive-compulsive disorder (OCD). Pica has been tied to several psychiatric diagnoses, including schizophrenia (Sinha & Mallick, 2010) and depression (Jawed, Krishnan, Prasher, & Corbett, 1993), but any theories explaining the relationship between these diagnoses and pica have not been fully elucidated.

Pica has been conceptualized as a form of OCD by some who see pica behavior as a compulsive act (Gundogar, Demir, & Eren, 2003; Luiselli, 1996; Stein, Bouwer, & van Heerden, 1996; Zeitlin & Polivy, 1995). In this model of pica, individuals have obsessive thoughts, often brought about by life stressors, about nonfood items. The obsessive thoughts are then relieved by the act of eating the items they have obsessed about. Support for this account comes from a few studies demonstrating remission or reduction of pica behavior when a common pharmacologic treatment (e.g., selective serotonin reuptake inhibitors) or behavior treatment (e.g., exposure and response prevention) for OCD has been employed (Gundogar et al., 2003; Stein et al., 1996; Zeitlin & Polivy, 1995).

Behavioral/Learning Perspective

Within a behavioral framework, pica is explained as a result of some rewarding outcome (i.e., reinforcement) resulting from pica behavior or due to an individual's failed discrimination of appropriate consumables. Thus, pica behavior may be learned or the result of poor stimulus control. Identifying the rewarding outcome for pica behavior has been the focus of numerous studies. Pica has rarely been found to be maintained by socially mediated reinforcers, but at least one study (Piazza, Hanley, & Fisher, 1996) identified social attention as the function- or reward-maintaining pica. More commonly, pica is thought to be reinforced by the sensory stimulation associated with consuming the nonfood items (e.g., the texture, taste) or, in the case of tobaccophagia (eating cigarette butts), the physiological effects derived from the tobacco. In support of a sensory stimulation hypothesis, studies by Piazza et al. (1998) and Favell, McGimsey, and Schell (1982) have shown that when items that match the oral sensory stimulation produced by pica are available, pica is reduced; however, when items that do not match the same sensory experience are available, there is no reduction in pica behavior. The idea that tobaccophagia arises from the effects of tobacco and not some other component of a cigarette was evaluated by Piazza et al. (1996). They recorded pica when various aspects of the cigarette butt (i.e., tobacco, filter, paper) were available and again when either cigarette butts with tobacco or cigarette butts with herbal ingredients were available. Tobacco was identified as the maintaining component based upon higher rates of pica when it was available than when other components were made available.

The argument that pica is a result of failed stimulus control suggests that individuals who engage in pica do not appropriately discriminate between food and nonfood items. More microscopically, properties of food (e.g., its appearance or smell), stimuli often associated with the delivery of food, times when food is likely to be available, and locations associated with eating food have failed to exert control over the eating behavior of some individuals. This argument has found support in research on discrimination training (Bogart, Piersel, & Gross, 1995; Finney, Russo, & Cataldo, 1982; Fisher et al., 1994; Johnson, Hunt, & Siebert, 1994). In these studies, individuals were often successfully taught to only eat food that was associated with specific stimuli, such as a placemat (Fisher et al., 1994). An argument in opposition to this account is that many individuals with pica have been described as having an obsessive pursuit of their respective pica items, but not for food items. Thus, if this theory were true, such individuals should display similarly obsessive pursuits for food items.

Treatment of Pica

Pica can be a difficult disorder to treat and may require thorough assessment to identify the most effective treatment approach. Research reveals preventive strategies, treatment strategies, and combination approaches to effectively reduce pica. Although much of the research has been focused on the use of behavior analytic tactics, biomedical treatments may also be considered, particularly for individuals who exhibit nutrient deficiencies. Although pica is occasionally observed in non-ID/DD populations, the following review reports on research exclusively using ID/DD individuals.

Behavioral Assessment

It is generally a good idea to conduct functional behavioral assessment of pica to determine what environmental variables may influence pica.

Functional behavioral assessments focus on identification of the environmental state preceding the behavior (i.e., antecedents), as well as the consequences that follow such behavior, with the goal of identifying a functional relationship between the behavior and the environment. Assessment methods vary in rigor, from those with limited validity (e.g., indirect measures) to those providing only correlational data (e.g., direct measurement) to methods that reveal causal relationships (i.e., experimental analyses). The more rigorous the assessment method, the more likely the results will lead to effective treatment outcomes (Hall, 2005).

A functional analysis (FA), which involves the manipulation of antecedent and consequence variables to determine function, requires baiting the environment with safe-to-consume items, such as uncooked beans, Play-Doh®, and candles (Piazza, Roane, Keeney, Boney, & Abt, 2002). Most research studies involving FAs of pica have indicated an automatic function, suggesting that this behavior does not tend to be sensitive to social contingencies (e.g., Hagopian, Rooker, & Rolider, 2011); however, this finding is not guaranteed. For example, Piazza et al. (1998) conducted functional analyses on three children with ID and found that pica was maintained by attention for one participant and may have been maintained, in part, by access to tangibles (i.e., cola beverage) for another participant.

Even when pica is likely to be automatically maintained, functional analyses can be beneficial in determining environmental variables that may increase or decrease the likelihood of pica. For example, in the first functional analysis of pica to be published, Mace and Knight (1986) varied the level of staff interaction and protective equipment (i.e., the use of a helmet, with and without a face shield) with a young adult with ID and pica. The analysis showed that frequent interaction and limited interaction consistently resulted in less pica than a no-interaction condition. In addition, a condition involving no protective equipment resulted in lower levels of pica than conditions where the participant was required to wear protective equipment. The assessment results were used to develop a treatment involving limited interaction and no protective equipment that ultimately led to substantial reductions in pica.

Behavioral Strategies to Reduce Pica

Much research has been conducted on strategies grounded in behavior analytic principles to reduce pica; however, for several reasons, behavior analytic studies can make it difficult to draw firm conclusions about the effectiveness of pica treatments and their generalizability. Most behavior analytic studies utilize single-case design and generally few participants. Additionally, many strategies developed using behavior analytic principles have included packaged treatments that consist of multiple treatment components, sometimes without isolating which treatment components were necessary for adequate behavior reduction.

Successful behavioral strategies can be broadly classified as prevention or treatment efforts, although a combination of prevention and treatment strategies may be optimal. Prevention strategies generally involve manipulating the environment in some fashion to reduce easy access to pica items, while treatment strategies focus on using behavioral procedures to reduce the likelihood that pica will recur, often through reinforcing the absence of pica, extinguishing attempts at pica, or punishing pica behavior. The use of restraint and response blocking may be considered preventive in that these strategies reduce the likelihood that an individual will access pica items; however, both of these strategies will be regarded as treatment strategies within the sections below.

Prevention

There are many justifications for the use of prevention strategies to reduce pica. Such strategies may be essential for individuals whose pica involves consumption of potentially lethal substances and for individuals with a long history of pica behavior. Preventive efforts may also be needed for individuals who do not have adequate supervision and in cases where treatments have not led to satisfactory reductions of pica behavior. For example, Goh, Iwata, and Kahng (1999) tried multiple treatment procedures in an attempt to reduce cigarette pica in an adult male with ID, but without sufficient reduction. As a result, they chose to forego treatment and settle for preventive efforts, including regularly cleaning areas surrounding the participant and increased supervision.

Although preventive strategies may stand alone, based upon a broad review of the research literature, Williams and McAdam (2012) suggest that prevention methods may be most beneficial when used in combination with treatment procedures. Additionally, they recommend that preventive efforts continue to be utilized until treatment strategies have been shown to be effective and generalized across people, settings, and time.

Prevention of pica is typically done in three steps: First, a comprehensive inventory is taken of the nonnutritive, nonfood substances that an individual may consume. This should include a fairly exhaustive survey, in some cases leading to a substantial list of items. Second, efforts are taken to eliminate the nonnutritive items (and other items with similar properties) from the immediate environment and/or to increase the response effort required to access such items. Finally, the third step involves regular monitoring of the environment for any items that may be considered a pica target and identification and removal of new pica items. A comprehensive management program for adults in group homes exhibiting pica was originally described by Williams, Kirkpatrick-Sanchez, Enzinna, Dunn, and Borden-Karasack (2009) and included several prevention components. This program, which effectively reduced pica for a large number of clients, included a *Pica-Safe Checklist* to be used in monitoring of pica items and pica behavior in the group home (see Sturmey & Williams, 2016, for a full description of the prevention efforts).

Pica-proofing strategies may be effective in private settings where it is easier to eliminate potential pica items, but in public places such strategies are difficult to implement and are unlikely to be effective in reducing access to pica items. Additionally, when employed as the sole strategy to address pica, prevention strategies are unlikely to produce successful long-term outcomes.

Treatment

Treatment Selection

Because pica can be a life-threatening disorder, the goal of treatment is generally to reduce pica behavior to zero (Williams & McAdam, 2012), which makes treatment selection critical. In much of the research on pica treatments, treatments deemed effective are often presented in "packaged" form with multiple treatment components required to attain sufficient reductions in pica. For example, Call, Simmons, Mevers, and Alvarez (2015) reviewed data on 11 patients who engaged in pica and were treated in an intensive day treatment program from 2001 to 2013. On average, clinicians tried more than 4 different treatment components for the 11 patients, and the final treatment for each patient, on average, consisted of nearly 2.5 different treatment components.

Deciding which treatment components to include in a treatment package may be challenging. When pica is maintained by social contingencies (e.g., caregiver attention), effective treatment will likely incorporate manipulation of the motivating operations for pica. For example, in a study by Piazza et al. (1998), a functional analysis indicated that pica was maintained by attention for a young boy with autism who exhibited pica with various items. This finding led Piazza and colleagues to develop a treatment using noncontingent attention and stimuli that matched the sensory consequences of pica, resulting in a substantial reduction of pica.

Given that pica behavior is most often automatically maintained, treatments are unlikely to be function-based, increasing the challenging of treatment selection. Such decisions require consideration of several important factors. For example, more severe or harmful pica, such as ingesting toxic substances or items that lead to intestinal blockages, may require treatments that reduce pica to zero, regardless of the intrusiveness of the intervention, whereas chronically consuming less toxic items (e.g., ice or small amounts of paper) may not necessitate the same absolute goal of reducing pica to zero and also may allow for less restrictive interventions to be tried first. Williams and McAdam (2012) raised the concern that treatments deemed "successful" because they substantially reduce rates of pica may not be sufficient, especially if pica continues to occur. They argue that evaluation of treatment effectiveness should consider both reduction in pica behavior over baseline and suppression of pica behavior to zero.

Considering suppression data is especially important for choosing treatments for life-threatening pica. McAdam et al. (2012) conducted a meta-analysis of nine behavioral treatments for pica, but considered both the effect size for pica reduction and the effect size for pica suppression (i.e., pica behavior at zero) for each treatment. Interestingly, several behavioral treatments, including negative practice, physical restraint, habit reversal, and the use of aversive stimuli, were considered moderately to highly effective at reducing pica, but showed questionable effectiveness for pica suppression. By contrast, response blocking, which only outperformed three of the other eight treatments evaluated in terms of pica reduction, was the most effective in terms of pica suppression. Thus, depending on the risk for safety, treatment selection will require consideration of the effects on pica reduction and pica suppression.

For pica that has been deemed low-risk, treatment selection should consider a hierarchical model, with the least restrictive interventions serving as the first-line option and more intrusive treatment strategies utilized when those fail (McAdam et al., 2012). When considering punishment-based approaches, clinicians must also weigh the ethics, permissibility, and acceptability of using such procedures. In addition, all treatment options must be evaluated for the practicality of treatment implementation, especially for treatments considered intensive (e.g., overcorrection).

As noted previously, nearly all published studies on treatments attaining successful reduction of pica incorporate some combination of reinforcement, punishment, and/or extinction components. However, in the following review of treatment strategies, treatments have been divided into classifications of those primarily involving strengthening of non-pica behaviors (i.e., reinforcement-based approaches) and those focused primarily on pica reduction procedures (i.e., punishment and/or extinction).

Reinforcement-Based Strategies

Differential Reinforcement

Differential reinforcement is the most popular reinforcement-based strategy used in pica treatments and in most cases is combined with other treatment components. Differential reinforcement procedures involve a combination of reinforcement for a response class or properties of a response class (e.g., an alternative behavior to pica), while withholding reinforcement for another response class (e.g., pica behavior). For pica, like many behaviors that are maintained by automatic reinforcement, a great challenge exists in withholding reinforcement for pica behavior as it may be inherently reinforcing immediately upon engaging in the act (Vollmer, 1994). Additionally, treatments for pica cannot simply differentially reinforce more acceptable behaviors while using the same maintaining putative reinforcer for pica. Thus, without adding treatment components that make it more difficult to engage in pica (e.g., response blocking) or components involving punishment procedures (e.g., contingent presentation of aversives), selection of the optimal alternative reinforcer requires that it compete with the reinforcement that results from pica.

Differential reinforcement of alternative behavior (DRA) requires that an individual engages in specific alternative behaviors to obtain reinforcement, while differential reinforcement of incompatible behavior (DRI) involves reinforcement of behaviors that are incompatible with pica behavior. Despite this difference, most studies using DRA procedures identify an alternative behavior to target for reinforcement that is incompatible with pica.

Pica treatments employing DRA and DRI procedures have targeted a variety of behaviors for reinforcement, including gum chewing (Donnelly & Olczak, 1990), toy playing (Mitteer et al., 2015), and vacuuming pica items (Schmidt et al., 2017). Smith (1987) chose to target a variety of incompatible behaviors for reinforcement for a young adult with ID who ingested dangerous inedible items. Using edibles and preferred activities as reinforcers, the behaviors programmed for reinforcement included keeping his hands on his work materials, staying in his work area, actively working, and keeping his mouth clear.

The alternative behaviors targeted for reinforcement in most studies have involved handing the pica items over to a caregiver (Donnelly & Olczak, 1990; Goh et al., 1999; Hagopian et al., 2011; Kern, Starosta, & Adelman, 2006) or discarding the items in the trash (Bogart et al., 1995; Ricciardi, Luiselli, Terrill, & Reardon, 2003; Slocum et al., 2017). Handing over a pica item to a caregiver for a tangible reinforcer has been dubbed “pica exchange.” One of the earliest demonstrations of the pica exchange procedure was by Goh et al. (1999), for four middle-aged adults with severe to profound ID who engaged in cigarette pica (tobaccophagia). All four participants were taught to hand cigarettes to a therapist in exchange for a preferred edible. The combination of pica exchange and response blocking for attempts at pica was successful in reducing pica for three of the four participants.

Treatment protocols using differential reinforcement of other behavior (DRO) also provide reinforcement for nontarget behavior; however, in contrast to DRA or DRI procedures, reinforcement is delivered for the absence of a behavior targeted for reduction over a period of time. Thus, in DRO procedures, if an individual engages in any non-pica behaviors over a specified period of time, reinforcement would be delivered. Clinically, DRO procedures are common as a treatment component for pica; however, few studies have chosen DRO over other differential reinforcement procedures in the treatment of pica. Exceptions include studies by Finney et al. (1982) and Paniagua, Braverman, and Capriotti (1986), both of which used DRO procedures, but required additional punishment components for successful reduction of pica.

Noncontingent Reinforcement and Environmental Enrichment

Noncontingent reinforcement (NCR) and environmental enrichment (EE) both involve the provision of known reinforcers, such as toys, activities, and snacks, on a noncontingent basis; however, they differ in that NCR, or time-based delivery of reinforcers, provides known reinforcers at fixed or variable intervals, while in EE these things are made available in the individual’s environment at all times. In treatments for pica, NCR and EE provide alternative sources of stimulation that, when successful, compete with the stimulation garnered from pica. These treatments, and particularly EE, may be relatively simple to implement, but there is one important caveat: In using strategies involving competing stimuli, frequent use of alternative sources of stimulation or providing access for long durations increases the possibility of satiation and likely a reduction in treatment effectiveness. This is especially true when foods serve to compete with pica and may be one reason that NCR and EE are often merely one component in effective treatment packages.

Effective NCR and EE components call for a mindful selection of stimuli to compete with pica. Stimulus preference assessments are commonly used to identify alternative sources of stimulation. It stands to reason that the more preferred an item or activity is to an individual, the more likely it will compete with the reinforcement that individual obtains through pica. For example, prior to implementing treatment for a young girl with autism who exhibited coprophagia, Ing et al. (2011) conducted preference assessments for food and nonfood items. Each item or snack was paired with a pica item (artificial feces), and the results suggested that only food items would effectively compete. Treatment, consisting of NCR with food, effectively eliminated pica when treatment was in place.

Preference assessments may be enhanced by the inclusion of items that are thought to match the stimulation accessed through pica. Piazza et al. (1998) developed an assessment to do just that. They hypothesized that pica was at least partially maintained by the oral stimulation it produced for three child participants. Stimulus preference assessments were used to evaluate preference and pica behavior for various items that would provide oral stimulation and various items that would not. For all three participants, items thought to match the oral stimulation of pica were more preferred (as measured by item interaction) and were associated with lower levels of pica. Treatments utilizing matched stimuli were shown to produce greater and more stable reductions in pica for all three participants.

Although EE and NCR are often paired with other treatment components, both may be used as a stand-alone strategy. In fact, several studies have been published showing substantial reductions in pica when employing EE as the sole treatment component for pica (Baker, Valenzuela, & Wieseler, 2005; Favell et al., 1982) or using NCR exclusively (Ing et al., 2011). Piazza et al. (2002) added an interesting twist to this line of research by varying the response effort required to access pica items and competing items in an EE context. For three teenage females with severe ID and pica, effort manipulations indicated the lowest rates of pica when (a) competing items required low effort to access, and (b) pica items required high effort. Thus, Piazza et al.'s study suggests that the most effective use of EE may require that competing stimuli are easily accessible and potential pica items require greater effort to obtain.

Discrimination Training

McAdam et al. (2012) conceptualized that pica may be due, in part, to a lack of stimulus control in which individuals poorly discriminate between proper food items and nonfood items. If this is the case, then training individuals who engage in pica to discriminate between those things they should not eat and those items that are appropriate for consumption would lead to reductions in pica. Discrimination training procedures for pica typically involve presentation of a discriminative stimulus (physical or verbal) associated with food items, followed by reinforcement of either selection or consumption of food under the presence of that stimulus, or by accurately identifying whether the item is food or nonfood. Examples of the discriminative stimuli used in published studies include placemats (Fisher et al., 1994; Johnson et al., 1994) and red dishware (Bogart et al., 1995) and questions, such as "Should you put this in your mouth?" (Finney et al., 1982). Although reinforcement of appropriate responding is essential in discrimination training, most studies also incorporate a punishment component, whereby selection of the nonfood item results in the presentation of an aversive. For example, in the Johnson et al. (1994) study, if the participant selected a food from a specific placemat, he was allowed to consume that item; however, if he chose a nonfood item, a therapist firmly said "no," "stand up," and "spit it out," followed by washing the individual's face with a cold washcloth.

Punishment-Based Approaches

The number of studies employing punishment-based treatment approaches for problem behavior reduced substantially following the introduction of a comprehensive functional analysis technology by Iwata, Dorsey, Slifer, Bauman, and Richman (1982/1994; Lydon, Healy, Moran, & Foody, 2015). The ability to identify functional relationships between environmental events and behavior has meant that treatments may target that relationship by identification and reinforcement of functionally equivalent alternative behaviors. Yet, for pica, which has consistently been found to be automatically maintained, this approach has reduced utility. Moreover, reinforcement-only approaches have rarely provided the necessary rapid reductions of pica that are desired. Thus, punishment-based approaches have long been an essential common component in behavioral treatments of pica. Successful treatment using punishment often owes to the fact that aversive environmental events (i.e., the punisher) can overpower the reinforcement garnered from the behavior being targeted for reduction (Azrin & Holz, 1966).

Successful reduction of pica through punishment procedures may be accompanied by a number of unwanted side effects. Increased aggression and emotional responding by the individual targeted for treatment have been suggested as possible side effects of punishment procedures; however, this finding is more ubiquitous in basic (nonhuman) studies than applied studies (Lerman & Vorndran, 2002). Punishment procedures may also produce escape/avoidance behavior in the presence of stimuli associated with punishment, including the individual administering the punishment (Cooper, Heron, & Heward). Lerman and Vorndran (2002) suggest that unwanted side effects of punishment procedures may be mitigated by using brief exposure to punishing stimuli and by utilizing potent reinforcers contingent upon alternative behaviors or the absence of the problem behavior.

The following is a brief description of punishment procedures that have been used to treat pica, albeit often in packages that include reinforcement-based approaches.

Response Blocking

Given the potential safety risks of pica, it should not be a surprise that many behavioral treatment packages for pica incorporate a response-blocking component. Response blocking rarely serves as a stand-alone treatment for pica (see LeBlanc, Piazza, & Krug, 1997, and McCord, Grosser, Iwata, & Powers, 2005 for exceptions). Some procedural variations exist, but response blocking typically involves placing a hand or arm between the pica item and the individual's mouth, with the greatest effectiveness when blocking is earliest in the pica chain (e.g., touching a pica item; McCord et al., 2005). It is possible that the reductive effects of this procedure are due to extinction (i.e., attempts at pica do not result in reinforcement), but more likely it serves to positively punish pica behavior (see Lerman & Iwata, 1996 for more information on distinguishing between extinction and punishment effects).

A major challenge in conducting effective response blocking is that it requires hypervigilance on the part of the person implementing it and it may require that these procedures be in place continuously for it to be effective. McCord et al. (2005) demonstrated the lack of generality of response blocking in a study involving three adult males with severe ID who all engaged in pica. After showing substantial reductions in pica using response blocking (contingent upon touching a pica item) for all three participants, McCord and colleagues had two participants return to an alone condition that previously resulted in high rates of pica for each. For both participants, rates of pica returned to levels observed in the alone condition prior to treatment.

Another problem common to response blocking, but also found with many punishment procedures, is the side effect of increased aggression (Lerman & Vorndran, 2002). Given that response blocking includes physically intervening, the implementer of treatment stands to be an easy target for aggressive behavior. Indeed, Hagopian and Adelinis (2001) conducted a treatment evaluation with a 26-year-old male with ID who exhibited high rates of aggression when a stand-alone response-blocking component was used to treat pica. Using a reversal design, Hagopian and Adelinis alternated between response blocking only and response blocking with redirection to a preferred food item. With the added redirection component, both pica and aggression were substantially reduced over the condition involving response blocking without redirection.

Time-out, Facial Screening, and Restraint

Unlike many of the punishment methods used to treatment pica, time-out, facial screening, and restraint have often been conceptualized as negative punishment procedures in that they employ removal of, or restriction from, reinforcing stimuli contingent upon pica behavior. The latter two could arguably be considered as positive punishers as well, but this distinction is an unnecessary argument for this discussion. These three procedures vary greatly in restrictiveness and acceptability.

Time-out from reinforcement is one of the most widely used and accepted parenting strategies to treat problem behavior (Barkin, Scheindlin, Ip, Richardson, & Finch, 2007), yet it has rarely been documented as a treatment strategy for pica. Kalfus, Fisher-Gross, Marvullo, and Nau (1987) conducted a unique study on the treatment of pica by using time-out without implementing additional restrictive procedures (i.e., facial screening or restraint). Using a combination of DRO with praise and tickles and a 15-s time-out from toys and attention contingent upon pica, they were able to obtain substantial reductions in pica for a 4-year-old boy with ID.

Facial screening, which involves creating a visual barrier for an individual to reduce visual stimulation, has been used extensively in treatment packages for pica (Bogart et al., 1995; Falcomata et al., 2007; Fisher et al., 1994; Mitteer et al., 2015; Singh & Winton, 1984; Williams et al., 2009). A variety of implements have been used to block visual stimulation, including blindfold (Singh & Winton, 1984), bib (Bogart et al., 1995), goggles (Williams et al., 2009), and hands (Fisher et al., 1994; Mitteer et al., 2015), most with a duration of less than 1 min. While facial screening has rarely been implemented without other treatment components (see Singh & Winton, 1984, for exception), Fisher et al. (1994) found facial screening contingent upon pica to be the most effective punishment component trialed for all three participants in their study.

In an effort to abide by the principal of least restrictiveness, physical and mechanical restraints should only be considered within a treatment package that includes reinforcement-based strategies and monitoring by a licensed professional or Board Certified Behavior Analyst trained in the treatment of problem behavior (Association for Behavior Analysis International, 2010). While such restrictive procedures are less common now than in the past, they may still be considered necessary in cases of pica that are life-threatening. Restraint may be mechanical or physical restraint, but the latter (sometimes referred to as protective equipment) has often been utilized on an antecedent basis to reduce the possibility of pica, while the latter has been used contingent upon pica behavior. Mechanical restraints range from a camisole (Rojahn, Schroeder, & Mulick, 1980) to canvas arm sleeves and a helmet with a facemask (LeBlanc et al., 1997). When mechanical restraints prevent or inhibit pica, the down side is that they may also inhibit more desirable behaviors, such as social interaction and toy play (LeBlanc et al., 1997).

Like mechanical restraint, brief physical restraint procedures have many variations. Physical restraint, in the form hand holding (Bogart et al., 1995), restriction of arms to the side or behind the back (Bucher, Reykdal, & Albin, 1976), and basket hold procedures (Fisher et al., 1994; Northup, Fisher, Kahang, & Harrell, 1997), has been an effective treatment component for pica. These studies have typically used a very brief duration for restraint (i.e., 30 s or less), which follows a finding by Winton and Singh (1983) that restraint duration as short as 10 s may be more effective than longer restraint durations (i.e., 30 s and 3 min). Although the physical demands of restraint protocols may make them impractical, Northup et al. (1997) demonstrated that even lean schedules of physical restraint (i.e., VR 2 and VR 4 schedules) may be sufficient to reduce pica to low levels.

Overcorrection

Few recent studies have incorporated overcorrection as a treatment component for pica despite strong evidence of its effectiveness. Williams and McAdam (2012) surmised that the decline in usage may be due, in part, to the physical demands and necessary oversight required on the part of the treatment implementer. A positive punishment procedure, overcorrection for pica, generally involves a contingent demand for pica behavior. The contingent demand typically is related to pica and requires the individual to either practice a more appropriate behavior or improve the environment where it happened. The most frequent corrective behavior documented has been oral hygiene tasks (Matson, Stephens, & Smith, 1978; Mulick, Barbour, Schroeder, & Rojahn, 1980; Singh & Bakker, 1984; Singh & Winton, 1985). Foxx and Martin (1975) published the first example of overcorrection for pica with four adults with ID who engaged in coprophagia or cigarette pica. Participants were required to complete an extensive overcorrection procedure that lasted up to 30 min to complete fully contingent upon pica behavior. Beginning with the discharge of any pica items from the mouth, the participant was expected to clean his or her mouth and gums with a toothbrush soaked in antiseptic cleaner, wash his or her hands in a bathroom sink, and clean the area where he or she engaged in pica (e.g., empty trashcans, flush toilets). This procedure has been noted for the large and rapid reduction in pica.

Aversive Presentations

Another positive punishment strategy regularly cited in pica treatment literature is the use of contingent aversive stimuli. It could be argued that many of the other punishment procedures described above involve contingent presentation of aversive stimuli; however, in these studies, a known aversive sensory experience, often in the form of a physical substance, is presented subject to pica behavior and is often accompanied by a reprimand (e.g., "No!"). Most studies using aversives have treated pica using a substance with an aversive taste, such as lemon juice (Paisey & Whitney, 1989), tapioca pudding (Ferreri, Tamm, & Wier, 2006), and hot sauce (Goh et al., 1999). Water mist sprayed in the face has been evaluated multiple times, but with mixed results (Fisher et al., 1994; Goh et al., 1999; Paisey & Whitney, 1989; Rojahn et al., 1987). Rapp et al. (2001) failed to obtain adequate reductions in pica for a young girl with autism using a variety of reinforcement- and punishment-based approaches, but were able to obtain suppression using contingent loud auditory tones presented for 2–3 s each time.

Many studies employing aversives have failed to report how they selected the aversive stimuli used for treatment. By not conducting an empirical evaluation of possible aversives, prolongation of treatment may occur when something believed to be aversive is not experienced as such by the individual engaging in pica. In some cases, what is believed to be aversive may turn out to be perceived as pleasurable (and thus potentially reinforcing). Fisher et al. (1994) used a two-step process to identify potential punishers for treatment of pica: First, a stimulus avoidance assessment was conducted to identify procedures that were highly, moderately, or minimally aversive as measured by negative vocalizations and escape/avoidance behaviors by the participant. This was followed by a punisher assessment using a multielement design to test stimuli from each level of aversiveness as a punisher for pica behavior. Through this assessment, the authors were able to identify effective punishers and avoid spending time using less effective or ineffective stimuli.

Biomedical Treatments for Pica

Behavioral treatments dominate the research on pica and especially for pica in ID/DD populations. Given the large number of studies demonstrating effective behavioral treatment of pica, it has been suggested that non-behavioral treatments may not be a worthy interest to clinicians based upon a paucity of research, poorly designed experimentation, and equivocal outcomes (Matson, Hattier, Belva, & Matson, 2013). Nonetheless, research on nutritional and pharmacological interventions exists and warrants further review and additional research, particularly for difficult-to-treat cases of pica. In the following sections, existing research on nutritional treatments is briefly reviewed, followed by pharmacological treatments of pica. It should be noted that in this review of biomedical treatments, no attempt has been made to distinguish between studies exclusively involving ID/DD populations and those that do not as most research on biomedical treatments does not clearly delineated these groups.

Nutritional Treatments

A number of studies have indicated that pica is more likely to occur in individuals with nutritional deficiencies, particularly involving the minerals iron and zinc (Lofts et al., 1990; Miao et al., 2015; Swift, Paquette, Davidson, & Saeed, 1999). As a result, research studies have evaluated nutritional supplementation as a treatment for pica. Unfortunately, most studies demonstrating reductions of pica using nutritional supplementation have had inadequate experimental design, and they rarely fully suppressed pica. Lofts et al. (1990) added zinc supplementation to the diets of adults living in an institution who exhibited pica and low zinc plasma levels. The added zinc resulted in substantial decreases in average pica over a 2-week period. Two controlled double-blind studies of iron supplementation on geophagy (Gutelius et al., 1962; Nchito et al., 2004) failed to show a significant effect on pica behavior.

The effects of supplementation with multivitamins on pica without respect to any specifically identified nutritional deficiency have been evaluated in two studies. Using a single-case design (i.e., BAB reversal), Pace and Toyer (2000) demonstrated that a liquid multivitamin resulted in decreased pica for a young girl with ID. Bugle and Rubin (1993) used a nutritional supplement with amino acids and other essential nutrients for three individuals with coprophagia. The results showed modest improvement in pica over baseline.

Pharmacological Treatments

Unlike treatments involving nutritional supplementation, pharmacological treatments require a prescription by a licensed physician and are more likely to be associated with unwanted side effects. Any medications prescribed for pica are done so "off label" as there is currently no FDA-approved drug for the treatment of pica. Many published accounts of successful treatment of pica with medication have been case reports with limited accompanying data for review and with participants exhibiting accompanying comorbid psychiatric diagnoses. Such reports have indicated some success with a range of medications, including central nervous stimulants (Hergüner & Hergüner, 2010), atypical antipsychotics (Harada, Yamamoto, & Saito, 2006), selective serotonin reuptake inhibitors (Bhatia & Gupta, 2009), and alpha-adrenergic agonists (Saddichha, Vibha, & Vishnuvardhan, 2012).

Interesting and sometimes conflicting results have come from case reports. For example, in one case report, olanzapine, an atypical antipsychotic, effectively treated pica in an adult woman with ID (Lerner, 2008), but the same drug was singled out as a possible cause of pica in an adult male with schizophrenia (Huang, Shiah, Lee, Tzang, & Chang, 2010) and an adult female with schizophrenia (Chawla, Charan, Kumar, & Pattanayak, 2016). In another case report, Brahm, Farmer, and Brown (2006) described successful treatment of cigarette pica in a 50-year-old male with profound ID with bupropion. Interestingly, bupropion, a norepinephrine-dopamine reuptake inhibitor, has been shown to be a highly effective component of smoking cessation programs (Jorenby, 2002).

One of the few rigorous studies on pharmacological interventions for pica was conducted by Singh et al. (1994). Using a double-blind, placebo-controlled single-case design, an evaluation was carried out on the separate effects of thioridazine (a dopamine antagonist) and methylphenidate (a stimulant that increases dopamine) on pica for three adolescents with profound ID. All three participants had previously failed to respond to "well-designed" behavioral treatments. The use of thioridazine led to the highest levels of pica for all participants, while methylphenidate usage was associated with the lowest levels of pica for all three. The authors hypothesized that decreased dopaminergic transmission leads to increases in pica in some individuals, which their data support.

Summary and Conclusions

Pica is a difficult-to-treat and potentially life-threatening disorder that is commonly observed in the ID/DD population. Thus, it warrants a great deal of attention from caregivers, treatment providers, and researchers alike. Caregivers of individuals with ID/DD must be aware of the relatively high prevalence rate of pica in this population and be vigilant of the signs and symptoms. For particularly dangerous pica, even momentary disregard may lead to tragic outcomes. The treatment provider should acknowledge possible biomedical underpinnings (e.g., nutrient deficiencies), but be inclined to develop treatments based upon behavior analytic principles. They are faced with the daunting task of choosing among a broad range of treatment components found in the research literature. Moreover, it is essential for treatment providers to consider the practicality of treatment and whether a potential treatment would be acceptable if it leads only to reduced pica behavior, but not full suppression. There are many knowledge gaps that researchers must fill. Of chief importance is ascertaining the cause(s) of pica. A number of theories have been proffered, but most give an incomplete account or fail to hold adequate supporting evidence. A definitive account for the basis of pica would likely contribute to preventive approaches and more effective treatments. Treatment must also be a focus of continued research. Despite a large number of published treatment studies, especially in the field of applied behavior analysis, the majority have been of the small-n variety and rarely with replication. Furthermore, many research studies have utilized treatment packages incorporating multiple treatment components and rely on punishment-based approaches, which are traditionally associated with weaker social validity.

Feeding Disorders

34

Mitch Fryling, Kimberley L. M. Zonneveld,
Aline Zaragoza, and Catherine L. McHugh

Introduction

Feeding disorders encompass a variety of behavioral topographies and affect a wide range of people. Prevalence rates for feeding problems vary across definitions and populations. While feeding problems occur among typically developing populations (e.g., Benjasuwantep, Chaithirayanon, & Eiamudomkan, 2013), feeding disorders are much more common with individuals with disabilities (see Kerwin, 1999, Munk & Repp, 1994; Volkert & Piazza, 2012 for overviews). Several authors have also noted an increased prevalence of feeding disorders with individuals on the autism spectrum specifically, with some estimates being as high as 90% (e.g., Kodak & Piazza, 2008; Schreck, Williams, & Smith, 2004; Twachtman-Reilly, Amaral, & Zebrowski, 2008). Importantly, feeding disorders are not limited to young children and may occur in various forms throughout the life span.

Feeding disorders are also complex and may be related to various medical conditions (Field, Garland, & Williams, 2003). For example, a child may begin to avoid eating as a result of painful experiences associated with eating caused by gastroesophageal reflux disease. Alternatively, an individual may have difficulty swallowing and avoid eating for reasons related to this. As these examples highlight, it is important that an interdisciplinary assessment be conducted to identify possible medical factors that may need to be considered prior to implementing a behavioral intervention. In addition to the complex range of factors that can be involved in feeding disorders, feeding disorders are also diagnosed in various ways, which can make it difficult to identify exactly when a problem exists (see Piazza, 2008). This chapter provides an overview of the behavior analytic literature on feeding problems. We begin by providing a brief overview of the behavioral position in general, followed by a consideration of common intervention components, and conclude with more detailed overviews of the literature on two relatively under-researched areas, packing and rapid eating.

Taking a Behavior Analytic Approach

A variety of disciplines and theoretical approaches have addressed feeding disorders. Several behavior analytic strategies have been demonstrated to be effective, with others showing promise (see Bachmeyer, 2009; Kerwin, 1999; Volkert & Piazza, 2012). In addition, a

small number of researchers have begun to compare behavior analytic strategies to those advocated for in other disciplines. For example, Addison et al. (2012) compared a behavioral intervention to sensory integration intervention with two children with feeding problems and found that the behavioral intervention was more effective toward improving food consumption and decreasing inappropriate mealtime behavior (IMB). Similarly, Peterson, Piazza, and Volkert (2016) compared a behavioral intervention to a sensory approach with six children with feeding problems and found that food consumption only increased when the behavioral intervention was implemented. While more research comparing different types of interventions is certainly needed, there is now considerable support for assessment and intervention strategies based on the principles of behavior analysis.

Consistent with behavioral approaches more generally, behavior analytic approaches to feeding problems focus on understanding how factors in the environmental context are functionally related to behaviors considered to be socially important. This sort of assessment, often termed *Functional Behavioral Assessment* in behavior analytic research and practice, is foundational to all intervention work in behavior analysis (more on this below). Behavioral approaches are also committed to objective measures of socially relevant target behaviors over time (Baer, Wolf, & Risley, 1968). For this reason, behavioral work in the area of feeding disorders involves the objective measurement of important dimensions of feeding behavior. Common targets within the feeding literature often include food acceptance (e.g., the number of times food passes the plane of an individual's lips), food consumption (e.g., the number of times the individual swallows a bite of food), and various topographies of IMB (e.g., throwing food items, yelling, hitting the spoon). A variety of other behaviors involved in eating have also been targeted, especially as prerequisite feeding skills are increasingly considered in the research literature. For example, recent research has targeted chewing as a dependent variable as this is indeed a critical skill involved in eating (Volkert, Peterson, Zeleny, & Piazza, 2014; Volkert, Piazza, Vaz, & Frese, 2013). Self-feeding has also been studied, which is an important step toward developing independence more generally (e.g., Rivas et al., 2014. Several behavior analysts have also conducted research on rumination (i.e., bringing up previously swallowed food; see Lang et al., 2011, Luiselli, 2015). As we will elaborate on below, behavior analysts have also focused on the time between taking bites when bites are taken too quickly (i.e., to reduce rapid eating) and packing or storing food in one's mouth. As these examples highlight, behavior analysts approach feeding problems with a focus on a range of objective measures of socially significant target behaviors. Again, such measurement is fundamental to the identification of meaningful target behaviors and the ongoing assessment of intervention effectiveness. In the following section we provide an overview of behavior analytic assessment and intervention research on feeding disorders. We begin by reviewing research on the functional assessment of IMB.

Functional Assessment

Indirect Assessments. As with the functional assessment of other topographies of problem behavior, the assessment of IMB takes three general forms: indirect assessments, descriptive assessments, and functional analysis. Indirect assessment of IMB typically involves questionnaires and rating scales in which respondents are asked to respond to questions related to numerous variables that may influence feeding problems. Several indirect feeding assessments have been developed to assess feeding problems in individuals with and without developmental and intellectual disabilities across the life span (see Seiverling, Williams, & Sturmey, 2010).

For example, the Behavioral Pediatric Feeding Assessment Scale (Crist & Napier-Phillips, 2001) is a 35-item questionnaire designed to assess the mealtime behavior of children. Caregivers rate 25 items on the child's mealtime behaviors and rate 10 items on their feelings or strategies to manage feeding problems using a 5-point Likert scale from never to always. The Brief Autism Mealtime Behavior Inventory (Lukens & Linscheid, 2008) is an 18-item questionnaire designed to assess the mealtime problem behavior among children with ASD. Parents rate each item using a 5-point Likert scale from never to always to measure the frequency of mealtime problem behavior, rote behavior characteristic of ASD (e.g., "My child is flexible around mealtime routines," "My child is willing to try new foods"), and preferences. The Screening Tool of Feeding Problems (Matson & Kuhn, 2001) assesses feeding problems in individuals, regardless of age, with developmental disabilities. It consists of 23 questions arranged into 5 categories: aspiration risk, food selectivity, feeding skills, food refusal behavior problems, and nutrition-related behavior problems. Respondents rate each question according to frequency and severity of the feeding problem. Finally, the Parent Mealtime Action Scale (Hendy, Williams, Camise, Eckman, & Hedemann, 2009) is a 31-item questionnaire designed to assess caregiver strategies to manage mealtime problem behavior (e.g., "You insisted the child 'try one bite,'" "You offered the child a toy or a favorite activity as a reward for eating"). Caregivers rate the frequency of their behavior on a 3-point Likert scale from never to always.

Descriptive Assessments. Although indirect assessments are relatively simple to conduct, they do not offer specific information regarding the nature, extent, or frequency of IMB. Conversely, descriptive feeding assessments involve the direct observation of typical mealtime routines and as such allow the observer to obtain more specific information on the topography, extent, frequency, and variables that may influence IMB in the natural environment. For example, Borrero, Woods, Borrero, Masler, and Lesser (2010) conducted descriptive assessments with 25 child-parent dyads during typical mealtimes and found that parents delivered attention, access to tangible items, and escape following their child's IMB. The researchers then compared the conditional probabilities of these common parent-delivered consequences given IMB and acceptance to the unconditional probabilities of each event and found that parents delivered escape and attention most frequently for food refusal. The authors did not conduct subsequent functional analyses to verify the results of their descriptive assessments; therefore, the extent to which descriptive assessments may provide information regarding the variable(s) influencing IMB could not be delineated.

To examine the extent to which the results of descriptive assessments of IMB predict those of functional analyses of IMB, Borrero, England, Sarcia, and Woods (2016) compared descriptive assessment and functional analysis of IMB outcomes for 10 child-parent dyads. The researchers compared the conditional probabilities of the descriptive assessment data to the functional analysis outcomes and found that these assessment outcomes corresponded on 71% of cases. Because this is the first study to examine correspondence between descriptive assessments and functional analyses of IMB, more research is needed to replicate these effects and perhaps to refine the descriptive assessment procedures to produce higher correspondence rates. At the same time, these preliminary data seem promising and may suggest that descriptive assessments may be a viable alternative when a functional analysis of IMB is not feasible (Borrero et al., 2016).

Functional Analysis. Piazza, Fisher, et al. (2003) were the first researchers to demonstrate that the consequences commonly arranged in a functional analysis of IMB were observed in the natural environment. The researchers conducted a descriptive assessment of 15 child-parent dyads during mealtime and found that parents provided attention (coaxing, reprimands), escape, and access to preferred toys and food following IMB. The researchers then arranged these consequences using functional analysis procedures similar to those described by Iwata, Dorsey, Slifer, Bauman, and Richman (1994) by alternating control, attention, escape, and tangible conditions. To ensure the relevant establishing operation or discriminative stimulus was in place during each condition, the researchers instructed participants to take a bite of food every 30 s in all conditions. Piazza, Fisher, et al. found that escape was the most commonly identified function, attention was the second most commonly identified function, and access to tangible items was the least commonly identified function of IMB for their participants.

Najdowski et al. (2008) extended upon the study by Piazza et al. (2003) by using caregivers as therapists. Clear functions were obtained, and caregivers also conducted the functional analyses with a high degree of procedural fidelity. However, Najdowski et al. used alternative functional analysis procedures and only delivered prompts to take a bite of food during the escape condition. That is, during all other test conditions, the researchers placed a plate of non-preferred foods in front of the participant but did not instruct the participants to take a bite. These researchers found that all six participant's IMB was maintained by escape but noted that their procedural variation may have produced false-positive outcomes because the establishing operation or discriminative stimulus may not have been present during all other test conditions.

Bachmeyer et al. (2009) demonstrated that the identification and function-matched treatments of all possible functions of problem behavior are critical to successful treatment outcomes. The researchers first used the functional analysis procedure similar to that described by Piazza, Fisher, et al. (2003) to identify four children whose IMB was multiply controlled by escape and attention. The researchers then evaluated and compared the effectiveness of both function-based extinction procedures, individually and in combination. Results showed that (a) attention extinction alone did not increase acceptance or decrease IMB, (b) escape extinction alone produced an increase in acceptance and a decrease in IMB, and (c) attention and escape extinction combined produced the best treatment outcomes for all participants (i.e., 100% acceptance and near-zero levels of IMB). These results further emphasize the importance of assessment techniques that can accurately identify all possible functions of IMB.

While research on functional assessment has largely focused on IMB and certain factors that may influence its presence, functional assessment may be much broader than this. Researchers and clinicians alike are encouraged to consider functional analysis as a general framework for evaluating the extent to which different factors contribute to the presence of diverse types of feeding problems, skills deficits, and more. In the following section, we provide a brief overview of behavioral interventions for feeding problems. Our aim in doing so is to provide the reader with a broad look into the behavioral approach to intervention for feeding problems.[1] Also, while we categorize interventions to organize our discussion, we acknowledge that feeding interventions probably most often involve treatment packages comprised of several components. We begin by reviewing antecedent interventions.

Intervention

Antecedent Interventions. Antecedent interventions may be considered any intervention that aims to influence a target behavior prior to the behavior occurring. Process wise, these interventions are effective when they alter the aversive characteristics of the feeding context in some way, increase the value of reinforcement for food consumption, and/or reduce the response effort for engaging in the target behavior. For example, several researchers have studied an antecedent procedure known as simultaneous presentation (e.g., Ahearn, 2003; Piazza et al., 2002). This strategy involves providing non-preferred foods at the same time as preferred foods (e.g., by putting preferred condiments on the non-preferred foods). When this procedure works, it alters the aversive characteristics of the non-preferred food so as to increase consumption. A number of researchers have also studied a procedure known as the high-probability instructional sequence. In this procedure 2–3 responses which the individual has a high probability of complying with are presented just before the non-preferred food (e.g., Dawson et al., 2003; Meier, Frylíng, & Wallace, 2012; Patel et al., 2007). Others have manipulated the texture of the target food as a means to improve food consumption and have found that this may also be an important variable to consider (e.g., Patel, Piazza, Layer, Coleman,

---

[1] More exhaustive reviews of feeding intervention are available (e.g., Bachmeyer, 2009; Fernand, Saksena, Penrod, & Fryling, in press; Sharp, Jaquess, Morton, & Herzinger, 2010; Silbaugh et al., 2016).

& Swartzwelder, 2005). Additional research has examined different ways of presenting bites of food, such as using a flipped spoon or Nuk brush (Sharp, Harker, & Jaquess, 2010). Demand fading has been examined as well, where the amount or number of bites of food is initially decreased and later increased systematically contingent upon food consumption (e.g., Najdowski et al., 2010). While a large number of antecedent interventions have been studied, less information is known about exactly when such interventions are more or less likely to be effective, both in isolation and in combination with other interventions (Seubert, Fryling, Wallace, Jimenez, & Meier, 2014). It is possible that antecedent interventions are more likely to be effective in isolation when they are used with individuals who engage in little or no IMB. In addition, in circumstances where antecedent interventions are not effective in isolation, they may enhance the effects of other interventions (e.g., further reducing IMB; Patel et al., 2006). Additional research is needed to explore these possibilities.

Reinforcement Procedures. Behavior analysts have also explored the use of reinforcement procedures in the treatment of feeding disorders. For example, differential reinforcement of alternative behavior (DRA) procedures have been evaluated in the treatment of feeding problems. In a typical DRA procedure, reinforcers such as toys, attention, and/or preferred foods are provided contingent upon a particular target behavior (in this case food consumption), and not at any other time. Feeding researchers have evaluated DRA for some time, with early studies on the topic being published nearly 40 years ago (e.g., Riordan, Iwata, Wohl, & Finney, 1980) and continuing to more recent times (e.g., Brown, Spencer, & Swift, 2002). Variations of DRA have also been evaluated, including differential negative reinforcement (i.e., providing a break from the meal contingent upon engaging in the target behavior; Kahng, Tarbox, & Wilke, 2001). DRA has also been examined in conjunction with other procedures (e.g., Najdowski et al., 2010), and the extent to which DRA contributes to treatment outcomes relative to extinction procedures has also been considered (e.g., Piazza, Patel, Gulotta, Sevin, & Layer, 2003). Noncontingent reinforcement (NCR) has also been examined in the treatment of feeding problems. Wilder, Normand, and Atwell (2005) examined the effects of an NCR procedure, which consisted of providing continuous access to a preferred video during mealtimes and found that this reduced self-injurious behavior and increased acceptance of bites. Like DRA, NCR has also been evaluated in combination with other interventions (e.g., Reed et al., 2004). Others have compared variations of reinforcement procedures (e.g., Allison et al., 2012; Patel, Piazza, Martinez, Volkert, & Santana, 2002). Similar to antecedent interventions, more research is needed to identify when reinforcement-based interventions are more or less likely to be useful in isolation and in combination with other interventions.

Extinction Procedures. There is considerable support for the use of extinction procedures, particularly escape extinction (EE), in the treatment of feeding disorders (see Piazza, 2008; Volkert & Piazza, 2012). Two of the most utilized extinction procedures include non-removal of the spoon (NRS) and physical guidance (PG) (Piazza, 2008). In NRS, the feeder holds the feeding utensil at the child's lips until the child accepts or consumes the presented food while IMB is ignored. During PG, the feeder gently presses the jaw (or mandibular joint) of the child to prompt the mouth to open and then deposits the food.[2] Importantly, however, extinction procedures may also be associated with extinction bursts, whereby challenging behavior may initially increase or worsen when they are initially implemented. These initial struggles may increase the probability of integrity failures, which could ultimately worsen an individual's feeding problem (see Bachmeyer, 2009). Given the nature of feeding problems, this could be dangerous, and therefore it is very important that extinction procedures be used with caution and only with professionals with experience using the procedure and in settings which are equipped and prepared for possible challenges. Related to

[2] See Fernand et al. (in press) for a more detailed overview of extinction procedures, variations, etc., in the treatment of feeding problems.

this, parents may find other interventions more acceptable than extinction procedures (e.g., Vazquez, Fryling, & Hernandez, in press), again suggesting that such procedures should only be used in certain situations and with therapists with very specialized training.

While a wide range of behavioral procedures have been evaluated in the feeding literature, we are yet to develop a systematic approach to matching particular interventions to particular individuals. For this reason, additional attention should be given to pre-treatment assessment by both clinicians and researchers alike. More specific participant information will help guide treatment selection, as there is a need for the field to further understand *when* different interventions are more or less likely to be successful with different populations. The majority of behavior analytic studies on the topic of feeding disorders have focused on food selectivity and food refusal, with relatively less attention being given to several other important behaviors. Given this the remainder of the chapter will focus on two important target behaviors that are common among individuals with disabilities and feeding problems, packing and rapid eating.

Packing

Packing involves storing foods or liquids in one's mouth (e.g., pocketing food on the side of one's mouth without swallowing). Packing may emerge for various reasons, including physical abnormalities, oral-motor skills deficits, and positive and negative contingencies of reinforcement. Packing is important for a variety of reasons; it may lead to choking, aspiration, decreased caloric intake, extended meal times, and parental stress. If left untreated, packing can result in dental problems, dehydration, malnutrition, and failure to thrive (see Silbaugh, Swinnea, & Penrod, 2018 for an overview). Despite the numerous health and safety risks associated with packing, researchers have not widely addressed this issue in the literature—a situation that may have arisen because researchers often consider packing a *collateral response* (e.g., Levin, Volkert, & Piazza, 2014; Sevin, Gulotta, Sierp, Rosica, & Miller, 2002; Vaz, Piazza, Stewart, Volkert, & Groff, 2012). In fact, several researchers reported that packing emerged only after they observed improvements in the target dependent variable (e.g., acceptance [Levin et al., 2014; Riordan et al., 1980; Sevin et al., 2002; Vaz et al., 2012] and expulsion [Sevin et al., 2002]). For example, Sevin et al. (2002) used NRS to increase acceptance in one child who presented with food refusal. As acceptance increased, the researchers observed a concomitant increase in expulsion, which they treated with representation of expelled bites. As expulsion decreased, the researchers observed a concomitant increase in packing, which they subsequently treated with redistribution. The authors noted that these findings indicate that packing may belong to the same response class as the other food refusal behaviors (Sevin et al., 2002). The following section provides an overview of some of the behavior analytic intervention research on packing.

Intervention

Researchers have evaluated the efficacy of several treatments of packing in isolation or in combination: differential reinforcement of acceptance (Buckley & Newchok, 2005; Riordan et al., 1980), response cost (Buckley & Newchok), simultaneous presentation (Buckley & Newchok), food redistribution (Gulotta, Piazza, Patel, & Layer, 2005; Levin et al., 2014; Sevin et al., 2002; Volkert, Vaz, Piazza, Frese, & Barnett, 2011), swallow facilitation (Volkert et al., 2011), a chaser (Vaz et al., 2012), and food texture manipulation (Patel et al., 2005). We first review seminal behavioral studies on each of these treatments for packing, followed by suggestions for future research and clinical practice.

Differential Reinforcement of Alternative Behavior. In one of the first reports of packing in the behavioral literature, Riordan et al. (1980) evaluated the effects of DRA on the acceptance of non-preferred foods in two children (ages 6 and 9) with developmental disabilities. Initially, the researchers arranged the contingency on acceptance of non-preferred food or drink (i.e., researchers provided a bite of preferred food contingent on the child's acceptance of a non-preferred food or drink). Researchers found that DRA not only produced an increase in acceptance, but they also observed in a collateral increase in packing. Therefore, they added swallowing to the existing contingency such that they required children to consume the non-preferred food or drink prior to delivering reinforcement. After the researchers revised the contingency, they observed an increase in consumption of all target foods for both children. It should be noted that the researchers did not collect data on packing; therefore, it is unclear if the revised DRA contingency was responsible for the observed decrease in packing. Regardless, these findings (a) provide a demonstration of the emergence of packing following successful treatment of acceptance of food and (b) seem to suggest that simply arranging a contingency on the consumption of food—at least for some individuals—can decrease packing and may actually circumvent the emergence of packing altogether.

Differential Reinforcement with Response Cost and Simultaneous Presentation. In another study involving differential reinforcement, Buckley and Newchok (2005) compared the effectiveness of differential reinforcement with response cost, differential reinforcement with response cost and simultaneous presentation, and simultaneous presentation alone on the packing of a 9-year-old girl with autism spectrum disorder. During differential reinforcement with response cost, researchers presented the child's preferred movie at the start of the session, terminated the movie clip contingent on packing, and provided praise for a clean mouth (consumption). When researchers evaluated simultaneous presentation, either within the context of differential reinforcement plus response cost or in isolation, they presented a spoon that contained a bite of cookie placed behind the target food. Researchers found that all three treatments were effective, but that simultaneous presentation alone was the most effective. However, because simultaneous presentation was not implemented alone prior to being combined with differential reinforcement and response cost, it is unclear if simultaneous presentation alone would have been effective if it had been implemented prior to it being combined with differential reinforcement and response cost.

Texture Manipulation. Patel et al. (2005) assessed the influence of food texture on the packing and caloric consumption in three children between the ages of 3 and 4 years diagnosed with a feeding disorder. The researchers developed individualized treatments for each child based on previous assessment outcomes and used textures recommended by an occupational therapist. All treatments involved several of the same components: (a) fixed time bite presentations (15 s or 30 s), (b) NRS, (c) representation of expelled bites, (d) prompts to swallow packed bites (for one participant, the researchers also used redistribution with bristle massaging toothbrush), and (e) brief praise or brief access to preferred toys contingent on a swallow response. The researchers observed lower levels of packing and greater calorie consumption with lower textures of food relative to higher textures of food. Because the researchers included NRS, it is unclear if manipulating texture alone would have produced the same decrease in packing. However, because NRS was present during baseline and treatment phases, it is unlikely that NRS was responsible for the differentiated levels of acceptance across textures for all participants. In addition, although Patel et al. (2005) did not identify the mechanisms responsible for the effectiveness of the lower food textures, they suggested several potential rationales for observed decreases in packing with lower food textures: (a) lower food textures may simply be easier to swallow, (b) higher food textures require more advanced oral-motor skills, and (c) higher food textures may be a conditioned aversive stimulus such that individuals avoid swallowing foods at higher textures as opposed to lower textures. Because these possibilities can have different implications for treatment (e.g., treatment may consist of teaching prerequisite oral-motor skills or reconditioning higher-textured food), researchers should identify the exact mechanism(s) responsible for the effectiveness of lower textures on packing.

Chaser. Vaz et al. (2012) used a chaser (a food or liquid each child consistently accepted and swallowed) to decrease the packing of three children between the ages of 24 months to 10 years. As in Patel et al. (2005), the researchers arranged NRS for food refusal, representation for expulsion, and brief praise for acceptance and consumption in all phases. Due to individual participant characteristics, the chaser treatment was procedurally different for each child. For one child, researchers presented the chaser (4 ml of liquid) immediately following acceptance of the target food by holding a nosey cup at the child's lips, instructing the child to "take a drink," and depositing the liquid in the child's mouth. For another child, researchers waited to present the chaser after initial acceptance and conducted a clean-mouth check 15 s after the child accepted the target food. If the child packed the food, they presented the chaser (a bite of fruit) on a spoon on a plate in front of the child. If the child did not feed himself the chaser within 5 s, the researchers used a Nuk brush to roll the chaser on his tongue. For the final participant, the researchers presented the liquid chaser in a cup with a straw and instructed the child to "take a drink" immediately after he accepted the target food. The authors noted that although the children in their study consistently accepted at least one liquid or food and accepted the chaser during the evaluation, this may not be the case for all individuals who pack food. As such, a chaser may not be a viable treatment alternative for those individuals who do not consistently accept the chaser inside or outside of the treatment protocol. The authors also noted that a chaser may not be a viable treatment alternative for those children whose medical evaluations indicate that they are at risk for aspiration—or if their risk of aspiration is unknown. Finally, although the authors provided the chaser immediately after acceptance for two of three participants, they stated that it may be important to provide participants an opportunity to chew the target food before presenting the chaser to avoid situations in which participants would have mixed textures in their mouths (e.g., solid food plus liquid chaser), which may increase the risk of aspiration for some individuals. The exact reason for the effectiveness of the chaser remains unclear; though, several researchers have suggested that it may facilitate the swallow response by (a) addressing oral-motor deficits (e.g., Levin et al., 2014; Vaz et al., 2012) or (b) decreasing response effort associated with swallowing. In addition, the chaser may function as escape extinction (Vaz et al., 2012).

Food Redistribution. Gulotta et al. (2005) used food redistribution to decrease the packing and latency to clean mouth in four children with feeding disorders. Throughout all phases, the researchers arranged NRS for food refusal, representation for expulsion, and reinforcement (a token, brief access to a toy, or brief praise) for acceptance and swallowing. During redistribution, researchers used a brush to scoop any remaining food in the mouth and turn the brush to place the food in the middle of the child's tongue. Researchers either implemented the redistribution procedure immediately (1 child), after 15 s (2 children) or after 30 s (1 child) of the children accepting the target food in the mouth. Although the researchers only observed clinically significant decreases in packing for two of four children, they observed a mean decrease in latency to clean mouth for the two children for whom redistribution only produced a small decrease in packing (these children packed food on 50% or more of trials). This posttreatment decrease in mean latency to clean mouth may be considered a clinically significant treatment outcome because these children were holding food in their mouths for less time after treatment than they were prior to treatment. In addition, all children consumed more grams of food following treatment. Given these findings, the authors noted that it may be important to collect data on multiple measures to accurately capture the effects redistribution has on packing.

Packages Involving Redistribution

Redistribution + Swallow Facilitation. Volkert et al. (2011) used redistribution and swallow facilitation to reduce the packing behavior in two children with feeding disorders. During all phases, researchers arranged NRS for food refusal, representation for expulsion, and brief praise for acceptance and mouth clean (consumption). During treatment, researchers implemented redistribution with a flipped spoon and swallow facilitation in which the researchers collected packed food on the spoon, rotated the spoon 180°, placed the flipped spoon behind the middle of the child's tongue, and applied slight pressure while pulling the spoon toward the lips. The swallow facilitation component involved the placement of the food toward the posterior of the tongue, as opposed to the middle of the tongue, along with the application of slight pressure to the tongue while pulling the food toward the lips. These components appear to be the critical components involved in swallow facilitation because the combination of placing the bolus toward the posterior of the tongue plus the application of slight pressure may act as an eliciting stimulus that elicit the swallow response.

Redistribution + Swallow Facilitation + Chaser. Levin et al. (2014) found that redistribution, swallow facilitation, and a chaser decreased the packing behavior in two children with autism spectrum disorder. During all phases, researchers arranged NRS for food refusal, representation for expulsion, and brief praise for acceptance and clean mouth (consumption). During treatment, the researchers presented the liquid chaser immediately after the child accepted the target food. If the child packed the bite, researchers collected and removed the packed food with a Nuk brush (1 child) or a spoon (1 child), re-inserted the food on the Nuk brush or spoon back into the child's mouth, placed the Nuk brush or spoon onto the posterior (1 child) or middle (1 child) of the child's tongue, rotated the Nuk brush or spoon 180°, and applied slight pressure while dragging the brush or spoon toward the child's lips. For one child, the swallow facilitation component involved both the posterior placement of the food on the tongue and the application of slight pressure while dragging the spoon toward the lips. For the other child, the swallow facilitation component only involved the application of slight pressure while dragging the spoon toward the lips (i.e., food was placed mid-tongue). Because this study involved numerous procedural variations within and across participants, treatment components, and combinations of treatments, the necessary and sufficient treatment components are unknown.

Given the limited number of studies on redistribution, researchers have ample opportunities to contribute to this literature. For example, it may be the case that redistribution is more or less effective when implemented at different latencies from initial acceptance. Gulotta et al. (2005) implemented redistribution either immediately, after 15 s, or after 30 s of initial food acceptance with their participants; however, they did not compare this procedural variation on the level of packing behavior; therefore, researchers should investigate the effects of the latency from initial acceptance with which redistribution is implemented on packing. Researchers may also consider evaluating the effects of other procedural differences within the redistribution procedure (e.g., type of instrument used to redistribute food [e.g., upright spoon, flipped spoon, Nuk brush], position of food on the tongue, application of pressure on the tongue). Researchers can compare the effectiveness of redistribution when implemented alone or in combination with other treatment components (e.g., swallow facilitation, texture manipulation, or the addition of a chaser).

Recommendations for Clinical Practice

Because packing behavior can be influenced by physical abnormalities, oral-motor skill deficits, operant processes, or some combination of these causes, it is imperative that an interdisciplinary assessment be conducted to obtain a comprehensive understanding of an individual's disordered feeding. This is a particularly important consideration in the treatment of packing given that unmatched treatments can increase safety risks such as choking or aspiration. For example, if an individual's tongue lateralization is deficient such that he or she cannot form or bolus, using regular-textured foods within a differential reinforcement of consumption contingency will likely prove ineffective and may present safety risks.

Several researchers observed that packing increased following the treatment of acceptance (e.g., Riordan et al., 1980; Sevin et al., 2002; Vaz et al., 2012) and expulsion (e.g., Sevin et al.).

Clinicians should be sensitive to this possibility and conduct clean-mouth checks during feeding intervention to assess concomitant increases in packing. Clean-mouth checks also allow the clinician to identify the amount of packed food in client's mouth such that he or she can determine if it is safe to provide another bite of food. Conversely, the interdisciplinary team may determine that any amount of food in the mouth poses a safety risk to the individual such that he or she must swallow all food in the mouth before the clinician presents additional food. Finally, after the physician, speech therapist, or occupational therapist identifies the client as a safe oral feeder (this should be established before a behavioral intervention is implemented), clinicians should consider arranging the reinforcement contingency on *consumption* of food rather than on the *acceptance* of food. This may circumvent the emergence of expulsion, packing, or both following the treatment of acceptance, which may subsequently lead to more rapid treatment of food refusal.

Rapid Eating

Rapid eatingis a relatively understudied behavior that also falls under the broad umbrella of feeding problems. Rapid eating is distinct from other areas of the feeding literature in that it does not easily fit into either the skills deficit (e.g., chewing skills) or behavioral excess (e.g., throwing food, yelling) categories in the traditional sense. Rather, it is the amount of time between the behavior, in this case taking bites of food, that presents concerns. The problem of rapid eating is not only concerning for social reasons (e.g., it prevents one from contacting the reinforcers associated with sitting down and eating with others over a period of time), but it also presents threats to one's safety and health, in both the short- and long-term. Immediate threats include the possibility of choking and/or throwing up food, whereas more long-term threats may include obesity and all of the challenges that are associated with that. Interestingly, rapid eating is a concern across populations of individuals, with several researchers noting concerns with rapid eating in typically developed adults (e.g., Azrin, Brooks, Kellen, Ehle, & Vinas, 2008; Britt & Singh, 1985). At the same time, individuals with developmental disabilities may be especially at risk for rapid eating, and for this reason, rapid eating warrants specific attention from clinicians working with this population. While rapid eating is clearly a socially important area for research and practice, it has been given relatively little attention by behavioral researchers, especially when compared to other feeding problems. Given this, the final section of this chapter will focus on the behavior analytic research on rapid eating.

One of the earliest behavior analytic studies on rapid eating was conducted by Favell, McGimsey, and Jones (1980). This study involved four individuals with developmental disabilities (three males and one female), ranging from 9 to 21.5 years of age. Each of the individuals had difficulties related to their rapid eating which prevented them from accessing less restrictive environments. Specifically, the participants ate an average of 10.5 bites of food every 30 s. Before the experiment, the researchers were curious as to whether or not access to additional food would slow down the participants eating. In other words, the researchers wondered if the individuals ate rapidly simply because they were hungry. However, permitting the individuals to eat additional servings of food did not impact rapid eating in any meaningful way; the individuals simply ate more food. Favell et al. then examined a behavioral treatment package comprised of reinforcing pauses between bites of food, shaping longer pauses, and preventing attempts to eat rapidly by prompting the participants to wait. The reinforcement schedule was thinned contingent upon reductions in rapid eating.

The results of this treatment package demonstrated that the number of bites per 30 s decreased for each of the four participants. Specifically, during baseline participants took an average of 10–12 bites per 30 s, whereas during intervention participants took an average of 3–4 bites per 30 s. Moreover, the staff working in the participant's residential units were easily taught how to implement the procedure and were able to continue using the procedure while they were carrying out their other job duties. As a result of this, the results of 3–4 bites per 30 s maintained for 3 months, leading to the participants being moved to less restrictive settings. There were also number of indirect effects of the intervention; one participant who was initially rather messy during mealtimes was no longer messy, and another participant, who vomited during 15% of the baseline meals, no longer vomited during intervention. Finally, although not measured formally, the researchers reported that none of the participants engaged in challenging behavior during the intervention, suggesting that the intervention was not unpleasant for the participants. This study represents an important initial effort for behavior analysts to help individuals who struggle with rapid eating.

Lennox, Miltenberger, and Donnelly (1987) evaluated three treatments to reduce rapid eating. Three adults with developmental disabilities participated in the evaluation: a 32-year-old female, a 44-year-old male, and a 28-year-old male. Researchers selected a target inter-response time (IRT) of 15 s by observing two individuals who were considered to be socially appropriate eaters. Three intervention conditions were evaluated: (1) fixed-interval response blocking, (2) differential reinforcement of low rates of behavior (DRL), and (3) DRL + prompting. In the fixed-interval response blocking condition, eating responses that occurred 15 s after the previous eating response were reinforced with access to food, whereas eating responses before the 15 s interval were blocked (i.e., the first response that occurred after the 15 s IRT was reinforced). During the DRL condition, attempts at eating before the 15 s IRT had passed continued to be blocked, and attempts to eat prior to the passing of 15 s also resulted in the resetting of the 15 s interval (i.e., participants had to wait an additional 15 s; they were not permitted to take a bite until 15 s without any attempts at eating had passed). During the DRL + prompting condition, a competing response was prompted immediately after participants took a bite of food. Specifically, participants were prompted to put their utensils on their plates and their hands on their laps, with less and less prompting being required as participants were more independent. For one of the participants, an additional time-out from food was added to the DRL + prompting condition due to challenging behavior. This meant that attempts to eat before the 15 s interval had passed resulted in the tray of food being removed for 15 s, followed by the participant waiting for an additional 15 s when the food tray was represented.

Results of the evaluation showed that for two of the participants, mean IRT's did not reach the 15 s target level until the DRL + prompting condition was implemented. For a third participant, the 15 s target IRT was not met in any of the conditions, and despite the addition of a time-out procedure to the DRL + prompting condition, this participant engaged in challenging behavior throughout the evaluation. At the same time, it should be noted that while the 15 s goal was not met with this third participant, a mean IRT of 11.5 s was achieved, representing a substantial increase over baseline levels. This study underscored the importance of considering challenging behavior when evaluating intervention for rapid eating.

Wright and Vollmer (2002) conducted a systematic replication of the study by Lennox et al. (1987) with a 17-year-old female with profound developmental disability and cerebral palsy. Remember, the DRL procedure evaluated by Lennox et al. was always set at 15 s, regardless of the participant's performance, and the 15 s interval was reset upon each attempt to take a bite prior to the 15 s interval. This meant that it was possible that participants would never contact the reinforcer and that the interval could be continuously reset. In an effort to be more sensitive to this possibility, Wright and Vollmer evaluated an adjusting DRL procedure, whereby the length of the DRL interval depended upon the participant's average IRT across the previous five sessions. After rapid eating remained unchanged during baseline conditions and an initial fixed DRL condition, rapid eating decreased during the adjusting DRL condition, suggesting that it is important to continue to adjust the DRL interval based upon participant's behavior. Moreover, while challenging behavior (specifically self-injurious behavior) occurred during the initial intervention conditions, challenging behavior decreased over time, suggesting that increases in challenging behavior during intervention for rapid eating may be temporary. From a practical standpoint, it is important for clinicians to recognize that challenging behaviors may be temporary. From a research standpoint, it is important that future research further consider strategies that might reduce the occurrence or severity of challenging behavior during behavioral treatment as this may compromise safety and caregiver fidelity.

Technology-Enhanced Interventions

While the aforementioned studies represent important steps toward understanding effective interventions for rapid eating, they all require the presence of a therapist during mealtimes, especially during the early stages of treatment. It is possible that prompts, typically provided by therapists, could also be provided through the use of technology. To evaluate this possibility, Anglesea, Hoch, and Taylor (2008) evaluated the use of a pager prompt in treatment of rapid eating with three teenagers with autism. Each of the participants had a history of rapid eating, and two of them also had a history of gastroesophageal reflux and rumination. Two types of pagers were used in the intervention, depending on their availability in the participant's classroom (i.e., they either used one or the other throughout the study). One of the devices could be programmed to vibrate at specific intervals and stopped automatically after 3 s, and the other vibrated at programmed intervals and continued until someone pressed any button on the device (each pager vibrated at set intervals regardless of this difference in how the vibration stopped). To set specific intervals for each individual and target food, the authors first timed a typically developed adult eating one of the target foods. As such, the length of vibration intervals varied across participants and their respective target food.

The effects of the pager on rapid eating were evaluated in three reversal designs, one for each participant. During baseline sessions participants were presented with the target food while wearing a pager that was not activated. Sessions were conducted during lunchtime, and participants were first presented with the target food, and after they consumed it, the rest of their lunch was presented. During training, pagers were set to vibrate at varying interval lengths, in order to avoid developing time-based responding and to increase the chances of the vibration itself developing stimulus control. The trainer (a teacher) first prompted the participants to touch the pager and blocked any attempts to eat before the pager vibrated. After this, the participants were no longer required to touch the pager, while attempts to eat before the pager vibrated continued to be blocked. Participants were only permitted to take a bite of their food when the pager vibrated and were prompted to do so, if needed. After eating a bite of food, participants were prompted to put their hand back on the pager and were praised for waiting until the pager vibrated. Training sessions consisted of 10 trials, and training continued until participants only took bites after the pager vibrated for 100% of the trials for two consecutive sessions. After training the participants entered a pager-activated phase, which was the same as baseline with the exception that the pager was turned on. Participants then completed an additional baseline phase and a final intervention phase to complete the ABAB reversal design.

The results demonstrated that the total number of seconds eating the target food item increased only during the pager-activated condition and not during either of the baseline conditions, suggesting that the pager was likely to be responsible for the change in behavior. Importantly, the authors of the study also measured the total number of bites taken during each session and found that the total number of bites did not vary across baseline and intervention conditions. This confirmed that it was indeed the time between bites that increased during the intervention condition (i.e., and not the amount of food consumed during each bite). Finally, researchers conducted an additional probe condition with one of the participants, with no adult present, and found that the length of time between bites continued at target levels.

Echeverria and Miltenberger (2013) further evaluated the use of pager prompts, alone and in combination with other interventions, to reduce the rapid eating of two adults with developmental disabilities. Two adults (51 and 32 years old), living in group homes, participated in the study; both participants had a history of rapid eating and choking prior to participating in the study. Sessions were conducted during lunch or dinner times, at the participant's regular mealtime setting. Staff members sat next to the participant in order to provide prompts as needed. Using a multiple-baseline and reversal designs, the effects of a pager, alone and in combination with verbal prompts, were evaluated.

After baseline conditions participants went through a training session aimed at establishing the pager vibrating as a discriminative stimulus for taking a bite of food. Training involved the trainer providing instructions to the participant to only take a bite after the pager vibrated and then setting the pager on the table. To start, the trainer modeled this by placing their hand on the pager, and, when the pager vibrated, the trainer pretended to take a bite of food (with no food or other materials present). Following this model trial, the participant was instructed to try. Praise was provided by the trainer when the participant also engaged in the behavior after the pager had gone off. Upon engaging in three correct responses, the participant was instructed to put the pager on his belt and was provided with an empty plate and silverware. When the participant again engaged in three correct responses, the participant was provided with a plate with food and was instructed to wait before taking a bite. Once the participants engaged in three consecutive correct responses with food present, training was considered to be complete. Praise was provided throughout training for correct responses, and if the participants attempted to take a bite prior to the pager vibrating, these attempts were blocked while the trainer instructed them to "wait."

After training participants were exposed to a pager plus verbal prompts treatment condition. This involved the participants wearing the pagers that were set to vibrate at 15 s intervals (the interval being based upon the previously described Lennox et al. study). Before sessions, the trainer reminded the participants not to take a bite until the pager went off, and additional verbal prompts to "wait" were provided whenever participants attempted to take a bite too early. In addition, praise was provided when the participants waited the length of the interval. This condition was followed by a condition with the pager alone, which was similar to the pager plus verbal prompts condition with the exception that there were no prompts to "wait" contingent upon attempts to take bites before the pager went off. Finally, a verbal prompts alone condition was implemented with one of the participants, which involved providing reminders to eat slowly, chew, etc., and praise each time the participant chewed his food before taking another bite (no pager was used in this condition). Follow-up data were also collected; participants were wearing pagers during the follow-up probe, and one of the participants was also receiving verbal prompts. Two measures of social validity were obtained. One group of staff who did not work with the participants was shown videos of the participants at the end of treatment, and they were asked to evaluate the participants' behavior. Additional social validity assessment involved asking three individuals who had experience working with the participants to evaluate their progress.

Results of the evaluation demonstrated that both the pager plus verbal prompts and pager alone conditions decreased the number of bites per minute for both participants. Of note, while the number of bites per minute decreased across both conditions, there was a slightly larger decrease in the pager + prompts condition (i.e., the pager alone was just slightly less effective). Given that the difference between these conditions was slight, and given the practical benefits associated with the pager alone condition (i.e., that a staff member does not have to consistently prompt), it is possible that the pager alone condition would remain preferred. Finally, the results of the social validity assessment, from both unfamiliar and familiar caregivers, were positive, indicating that the behavior change had at least some degree of social significance. Importantly, both of the social validity evaluations suggested that the behavior change achieved was appropriate for community settings.

More recently, Page, Griffith, and Penrod (2017) evaluated the use of a treatment package including a pager prompt, rule, and verbal prompts to decrease rapid eating with a 12-year-old female diagnosed with autism spectrum disorder. Using a multiple-baseline and reversal design, sessions were conducted in both a university-based feeding clinic and home-based setting. Each setting was similar in that sessions were conducted at a dinner table with typical items present. The participant's family and researchers sat at the table during all sessions and engaged in conversation unrelated to the participant's food consumption throughout all sessions. During baseline conditions the participant wore an inactive pager, and the researcher presented the meal by stating "Here's your dinner." There were no consequences related to food consumption. During the active pager with rule condition, the pager was activated (with the interval being set at 20 s), and the participant was given the following rule "Here's your dinner. When you take a bite, chew 20 times, and wait for the buzz to take another bite." (p. 89). There were no consequences related to the participant's compliance with the rule. The active pager with rule and vocal prompt condition was the same as the pager with rule condition with the exception that attempts to take a bite before the pager vibrated resulted in the researcher prompting the participant to "wait." Results demonstrated that the participants' mean IRT between bites did not increase during the active pager plus rule condition but did increase during the pager plus rule plus prompts condition. This effect was replicated in a reversal design in the clinic setting and in a multiple-baseline design in the home setting.

Finally, Valentino, LeBlanc, and Raetz (2018) recently evaluated strategies to fade the use of pagers in the reduction of rapid eating with a 10-year-old child with autism. After collecting baseline data, conducting pager training (similar to that described by Anglesea et al. (2008), and demonstrating the effectiveness of the activated pager, the researchers compared different strategies to fade the pager prompt to transfer stimulus control to the natural environment. Specifically, the researchers evaluated the extent to which the pager could be faded by reducing the intensity of the pager (i.e., by having it vibrate more softly) and the number of times the pager prompt was used (i.e., the frequency of prompts). Specifically, the authors evaluated a low intensity 100% condition (where the pager was used at regularly programmed intervals but at a lower intensity), lower intensity 50% of the intervals (where the pager was used at a lower intensity but only vibrated for half of the intervals), a muffled 100% condition (where the pager was at the lower intensity and also wrapped in bubble wrap and a kitchen dishtowel), and finally a no intensity, 0% condition (i.e., the pager was not activated).

Results indicated that the target IRT maintained during the lower intensity 100% conditions but that the IRT increased significantly during the lower intensity 50% conditions. The IRT maintained at the target level during the muffled condition and also during the final no intensity, 0% condition. The researchers hypothesized that it may be more difficult to pursue fading by reducing the frequency of the pager prompt because the participant learned to take bites after the pager vibrated. In other words, the participant learns to wait for the prompt and will simply wait longer. However, reducing the intensity of the prompt does seem like an option worth exploring further, as this method was associated with maintaining eating at target levels throughout the study, and these prompts were eventually faded entirely.

Recommendations for Research and Practice

Rapid eating is a socially important target behavior and warrants the attention from both researchers and clinicians alike. A number of interventions have been evaluated to reduce rapid eating within the behavioral literature, though the body of research on this topic remains small and is ripe with opportunities for further investigation. Of particular importance are studies that evaluate the long-term maintenance of interventions aiming to reduce rapid eating. While maintenance is always desirable, it may be particularly important with rapid eating given the many hazards associated with the persistence of this behavior. The study by Valentino et al. (2018) is an important step in this regard. More research is needed to better understand how to fade other prompts, such as the verbal prompts employed in some of the studies reviewed here. Similarly, systematic attempts at understanding caregiver preference for different interventions for rapid eating may also be useful, as it seems possible that caregiver's will need to make prolonged efforts to change rapid eating over time. Finally, it is possible that mindful eating interventions (e.g., Hanh & Cheung, 2011), or some components of them, will be useful for some individuals with intellectual disabilities. More research is needed to even begin to explore these possibilities.

Conclusion

Eating is a fundamental activity; it is needed for healthy growth and development, provides a context for social opportunities, impacts family dynamics, and more. We have provided a brief overview of the behavior analytic approach to feeding problems in general and to the areas of packing and rapid eating in particular. There are a number of interesting avenues for continued research and practice, and we hope we have highlighted some of these areas throughout. In particular, we note the need to continue to relate particular participant characteristics and unique contexts to the effects of various interventions. More refined pre-treatment assessment efforts will assist in this effort, and additional research in this area is also called for. Finally, as feeding problems impact families in general (e.g., Craig, Scambler, & Spitz, 2003; Didehbani, Kelly, Austin, & Wiechmann, 2011; Greer, Gulotta, Masler, & Laud, 2008), future research should consider incorporating assessment of parental stress before and after intervention to better understand the extent to which parental stress decreases after behavioral intervention.

Psychological and Educational Approaches to the Treatment of Aggression and Tantrums in People with Intellectual Disabilities

Russell Lang, Tonya Davis, Katherine Ledbetter-Cho, Laurie McLay, Patricio Erhard, and Mac Kenzie Wicker

Aggression and tantrumming are relatively common topographies of challenging behavior. Aggressive behaviors are acts with the potential to do physical harm to another person such as hitting, kicking, and biting. In some cases, verbal threats of harm and aggressive language – even when not accompanied by violent physical acts – may also be considered aggression (Crotty, Doody, & Lyons, 2014). The term tantrum can be used to describe some combination of screaming, crying, thrashing body on the floor, property destruction, and other similar behaviors that tend to be loud, disruptive, and potentially dangerous. Tantrums may include aggressive behavior: for example, a child may flail on the ground, scream, and attempt to hit caregivers when they approach.

Most people will engage in minor aggression or tantrumming at some point in life, probably during childhood. In people without intellectual disability (ID), however, these behaviors are more common, more likely to persist over time, and more likely to cause serious harm (Cooper et al., 2009; O'Dwyer et al., 2018; Ruddick, Davies, Bacarese-Hamilton, & Oliver, 2015; Schroeder et al., 2014). Indeed, severity of ID appears to be among the more reliable early predictors for the emergence of aggression and tantrumming (e.g., Arias, Gomez, Moran, Alcedo, Monsalve, & Fontanil, 2018; O'Dwyer et al., 2018; Powis & Oliver, 2014). Estimates of the percentage of individuals with ID that present with challenging behavior vary a great deal depending on sample characteristics (e.g., age, disability severity, gender), definitions of challenging behavior, and how challenging behavior is measured (e.g., direct observation or parent report) (Davies & Oliver, 2013; Powis & Oliver, 2014; Ruddick et al., 2015). For example, Hardiman and McGill (2018) completed a systematic review of 28 studies that estimated the prevalence of challenging behaviors – including aggression and tantrumming – in people with

fragile X syndrome (i.e., the leading genetic cause of ID; Mazzocco, 2000) and reported a range from 12.5% to 60.9%. Davies and Oliver (2013) conducted a meta-analysis of 11 studies wherein the prevalence of aggression was measured in samples of adults and/or children. They reported that the risk of aggression appears to increase with age until sometime between the late teenage years and early twenties, when prevalence tends to level off on average. Adults with ID and a history of sexual or physical victimization and comorbid mental illness appear to be at particular risk for emergence of aggression (Clark, Crocker, & Morin, 2016). In childhood, deficits in language and communication also appear to be notable risk factors for aggression, tantrumming, and other challenging behaviors (McClintock, Hall, & Oliver, 2003; Schroeder et al., 2014; Wacker, 1998).

Persistent severe aggression and tantrumming may limit a person's opportunities for social inclusion and detract from quality of life (Brosnan & Healy, 2011; Lloyd & Kennedy, 2014; Tranfaglia, 2011). Quality of life is conceptualized as a collection of factors including the extent to which a person is able to (a) exercise self-determination (e.g., set their own goals and make choices), (b) access typical social and community settings, and (c) achieve physical and emotional well-being (Schalock & Verdugo, 2002). All of these areas may be impeded by aggression and tantrumming at any point across an individual's life-span. Additionally, severe challenging behaviors – particularly aggression – may result in (a) injury to the individual with ID and their family or service providers, (b) higher rates of turnover and job dissatisfaction in teachers and direct care staff, and (c) increased family member stress (Hensel, Lunsky, & Dewa, 2012; Knotter, Stams, Moonen, & Wissink, 2016). Children who engage in these behaviors have an increased risk of poor educational outcomes in school, and, if unresolved by adulthood, adults with ID face an increased risk of incarceration (Taylor, 2002).

Given the prevalence of aggression and tantrumming among people with ID and the associated adverse outcomes, it is not surprising that parents, teachers, and others who work to educate and care for people with ID tend to identify the reduction of these behaviors to be among the more important treatment goals (e.g., Pittenger, Barahona, Cavalari, Parent, Luiselli, & DuBard, 2014). Fortunately, there are several intervention options for treating challenging behavior with a notable amount of support in the research base. This chapter covers the psychological and educational treatments for aggression and tantrumming in people with ID with the most supportive and robust evidence. Specifically, this chapter focuses on behavioral intervention consisting of functional assessment followed by a function-matched treatment.

Applied Behavior Analysis-Based Treatment Approaches

Applied behavior analysis (ABA) involves the application of findings from the experimental analysis of behavior to address problems of social significance (Baer, Wolf, & Risely, 1968). ABA-based intervention approaches emphasize the interaction between the individual and their environment as opposed to psychopharmacological approaches that can be said to focus on a person's internal biology. There have been a number of reviews and meta-analyses focused on the treatment of challenging behavior in general and of aggression specifically, but none focused exclusively on the treatment of tantrums. Taylor (2002) conducted a narrative review of studies related to the treatment of anger and aggression in adult offenders with ID and concluded that behavioral interventions appeared to be more effective than psychotropic medication. Brosnan and Healy (2011) reviewed 18 studies wherein behavioral interventions were used in an effort to reduce aggression in people 3 to 18 years old with ID and reported that all 18 studies resulted in a decrease in aggressive behavior. Similarly, Fossum, Handegard, Adolfsen, Vis, and Wynn (2016) conducted a meta-analysis of 56 studies involving the treatment of aggression in people with and without ID and found that a majority of studies ($n = 34$) utilized behavioral intervention approaches and that corpus of studies yielded a medium effect size for the reduction of aggression. Although there are no reviews or meta-analyses focused exclusively on tantrumming, reviews focused on challenging behavior in general have reached similar conclusions regarding the effectiveness of behavioral intervention for people with ID (e.g., Lloyd & Kennedy, 2014).

Operant Learning Theory

ABA arose from a translation of basic operant learning research, which is typically conducted in laboratory settings, to applied research conducted in naturalistic settings (Sidman, 2011). Specifically, the underlying basic research elucidated how a change in a behavior's probability is influenced by past consequences in the context of an individual's current environment (Skinner, 1953). Consequences that increase the probability of a behavior's future occurrence are referred to as reinforcers, and consequences that reduce that probability are termed punishers. Elements of the environment that signal when reinforcement is available are called discriminative stimuli (Cooper, Heron, & Heward, 2007). According to operant learning theory, behaviors persist when the immediate result is at least occasionally a reinforcing consequence (Skinner). In terms of challenging behavior, ABA-based interventions alter the antecedent environment and/or the reinforcement contingencies (i.e., consequences) associated with targeted challenging behaviors. Therefore, function-based treatment is a two-step process wherein the first step is to identify relevant interactions between the individual and their environment via functional behavioral assessment (FBA). The second step is to design an intervention that incorporates this information in an effort to eliminate the challenging behavior (Hurl, Wightman, Haynes, & Virues-Ortega, 2016; Lang et al., 2013).

Consequences that may function as reinforcement for challenging behavior can be grouped into three categories: (a) socially mediated positive reinforcement, (b) socially mediated negative reinforcement, and (c) automatic reinforcement. Socially mediated functions include all of the ways people respond to another person's challenging behavior. For example, a teacher may approach and reprimand a child who hits a peer in the classroom and, if that consequence (i.e., obtaining teacher attention) is reinforcing, then the likelihood of the child hitting again the next time he wants teacher attention increases. In such a case, aggression is maintained by the contingency between hitting and obtaining socially mediated positive reinforcement in the form of teacher attention. Even though the intent of the reprimand was to decrease aggression, the behavior will increase if the reprimand (a form of attention) is reinforcing (Piazza et al., 1999). Several types of social consequences like praise, reprimands, physical contact (e.g., hugs, high fives), delivery or removal of tangibles, and even closer physical proximity have the potential to function as reinforcers or punishers, and individualized FBA is often necessary to determine how specific contingencies influence behavior for a given individual.

Lang et al. (2014) provide an illustrative example in the treatment of tantrum behavior in two children between 4 and 5 years of age with ID and autism spectrum disorder. A modified pairwise preference assessment (Fisher et al., 1992) was conducted wherein picture cards depicting various forms of social interaction were presented to participants who then indicated their preference for a form of social interaction by touching the corresponding picture card. This process identified a high- and low-preferred form of social interaction for each child. The different topographies of contingent attention (e.g., "high five" and praise) where then compared during an educational intervention (i.e., discrete trial training) using an alternating treatment design. When the high-preferred form of attention was made contingent on appropriate behavior, correct responding on instructional tasks increased, and tantrumming behavior decreased relative to a condition where the lower-preferred topography of attention was contingent.

Socially mediated contingencies are referred to as positive reinforcement when behavior results in obtaining or accessing preferred stimuli (people, objects, activities) which in turn causes the behavior to occur more often in the future (Cooper et al., 2007). For example, a challenging behavior that results in obtaining a snack from mom or being allowed to sit near a preferred peer in school may be maintained by positive reinforcement. Socially mediated contingencies are referred to as negative reinforcement when undesirable stimuli are removed or reduced and the behavior increases. The term "negative," in this context, refers to the removal of stimuli, not a reduction in behavior. For example, a child who has a tantrum because she does not want to clean up, a man who hits staff in order to escape a noisy room, and a teenager who destroys their book to avoid homework are engaging in challenging behavior with a negative reinforcement function.

Automatic reinforcement differs from social-mediated reinforcement because other people are not involved in giving or removing of stimuli (Vollmer, 1994). Specifically, automatic reinforcement does not require action from another person because the behavior directly produces reinforcement. Automatic reinforcement may be in the form of a pleasant sensation or reduction of an aversive sensation. Although automatic reinforcement has been shown to have the potential to maintain self-injurious behavior (Iwata, Dorsey, Slifer, Bauman, & Richman, 1994, Iwata et al., 1994), there are far fewer instances of aggression and tantrums being maintained by automatic reinforcement contingencies in the research base (Brosnan & Healy, 2011; Kurtz, Chin, Robinson, O'Connor, & Hagopian, 2015). For additional discussion of challenging behaviors more likely to involve automatic reinforcement (e.g., stereotypy and self-injurious behavior), see Chapters 32 and 33. In the following sections of this chapter, approaches to assessing the functional properties of aggression and tantrums are presented. Next, a range of behavioral intervention options will be identified with emphasis on how interventions should be aligned with identified function(s).

Functional Behavior Assessment

The first step of a function-based approach to the treatment of aggression and tantrumming involves conducting a FBA. This is an essential first step because FBA results inform the selection and adjustment of specific treatment procedures (Anderson, Rodriguez, & Campbell, 2015). For example, a child with an FBA suggesting he hits peers in order to obtain attention (i.e., socially mediated positive reinforcement) would not receive the same intervention as a child with FBA results suggesting he hit peers in order to be removed from the classroom (i.e., socially mediated negative reinforcement). In the former case, some examples of function-matched treatment include (a) teaching the child other more appropriate ways to obtain attention (i.e., replacement behavior), (b) withholding teacher attention following aggression (extinction), (c) providing attention following periods without aggression, or (d) providing attention before the child hits (antecedent intervention). However, in the case of hitting maintained by escape from the classroom, examples of function-matched treatment might include (a) teaching a more appropriate way to request a break (replacement behavior), (b) not allowing the child to leave the room following hitting (escape extinction), (c) scheduling more work breaks, and (d) reducing the averseness of tasks to reduce motivation to escape. Although both cases involved the same topography of aggression (hitting), intervention procedures are tailored by alignment with the behavior's function.

There are a number of techniques for identifying function, and there is no standardized FBA process agreed to be best practice. Practitioners must select FBA procedures by considering characteristics of the individual being assessed and their specific context (e.g., assessment environment, type of challenging behavior, available resources). FBA assessment methods fall into three categories: indirect methods, direct observation methods, and experimental methods. Most FBAs will include a combination of these methods because each has specific strengths and limitations.

Indirect methods. Indirect FBA methods gather data from informants rather than via direct observation of the person engaging in challenging behavior (Anderson et al., 2015). Indirect methods include interviews, questionnaires, and rating scales that are completed by teachers, parents, and other caregivers who know the individual well. Specifically, the informant is asked to consider instances when they observed the person engaged in aggression, tantrumming, or some other challenging behavior and then endorse a degree of agreement or disagreement with statements on Likert scales. For example, a teacher might endorse strong agreement with a statement indicating the person "engages in the behavior to get attention" and strong disagreement with "engages in the behavior to escape work or learning situations" which would suggest that social-mediated positive reinforcement may be maintaining aggression. Advantages of indirect approaches are that questionnaires and similar tools are typically easy to administer and can be completed in a relatively short amount of time. These factors may be particularly appealing to professionals who lack the resources, expertise, or time to implement direct methods (Floyd, Phanuef, & Wilczynski, 2005).

Although research evaluating the technical adequacy of these instruments is somewhat scant (Dufrene, Kazmerski, & Labrot, 2017; Floyd et al., 2005), three semi-structured interviews have accumulated a notable amount of research support: the Functional Assessment Interview (FAI; O'Neil et al., 1997), the Functional Assessment Checklist: Teachers and Staff (FACTS), and the Functional Assessment Interview Record for Teachers (FAIR-T; Edwards, 2002). For school-age children, in particular, The FACTS and FAIR-T may be most appropriate because they were designed for school settings with teachers and school staff serving as informants. The FAI can be implemented across settings and, in addition to school personnel, other direct service staff and family members have served as informants (O'Neil et al., 1997). The FACTS and FAIR-T have been evaluated more extensively with typically developing children, while the FAI has been evaluated with people with and without an ID (Dufrene et al., 2017).

Similar to interviews, a variety of questionnaires and rating scales with empirical support are available. Options with the most research support include the Motivation Assessment Scale (MAS; Durand & Crimmins, 1988), the Questions About Behavioral Function (QABF; Matson, Tureck, & Rieske, 2012), and the Contextual Assessment Inventory for Problem Behavior (CAI; McAtee, Carr, & Shulte, 2004). All three of these rating scales were designed for individuals with intellectual and/or developmental disabilities (Dufrene et al., 2017). The MAS and QABF have the best available evidence, demonstrating sufficient, inter-rater reliability, internal consistency, and temporal stability (Dufrene et al., 2017).

Whenever possible, indirect methods should be utilized in combination with other FBA procedures, including both direct observations and experimental methods, because the likelihood of successfully identifying the function of aggression from a single indirect assessment is lower (Alter, Conroy, Mancil, & Haydon, 2008; Fee, Schieber, Noble, & Valdovinos, 2016). Although indirect methods alone may not be sufficient in some cases, they are still useful early in the overall FBA process. Specifically, responses from informants who know the person well (e.g., parents, direct care staff, and teachers) may inform timing and procedures used during direct observations and experimental analysis methods conducted later in the FBA process (Dufrene et al., 2017; Fee et al., 2016; Hall, 2005; O'Neil et al., 1997).

Direct observation. Direct observation involves watching the person in environments where aggression or tantrumming occurs and collecting data on (a) events that tend to precede occurrences of the challenging behavior (antecedents), (b) changes that occur contingently and immediately after the challenging behavior (consequences), and (c) frequency of occurrence (Anderson et al., 2015). Common direct observation methods include antecedent-behavior-consequence (ABC) recording, structural analysis, and scatterplots. ABC recording involves noting antecedent events observed immediately before and consequence events occurring immediately after the occurrence of challenging behavior. Practitioners then review this running record to identify potential patterns related to antecedents and consequences that suggest a specific function (Bijou, Peterson, & Ault, 1968). The ABC recording method is among the most frequently implemented direct observation FBA approaches (Anderson et al., 2015).

Another common direct observation method is a structural analysis (Anderson et al., 2015). To conduct a structural analysis, practitioners observe the targeted behavior in two or more predetermined, but naturally occurring, contexts (e.g., group work versus independent work). Similar to the ABC recording, practitioners then evaluate patterns arising from the data in an effort to identify the behavior's function (Anderson et al., 2015; Stitcher, Lewis, Johnson, & Trussell, 2004). Finally, a scatterplot involves recording occurrences of the behavior across time by dividing an observation time into equal intervals (e.g., 48 30-min intervals per day). The frequency of challenging behavior per interval can then be used to highlight the times of day challenging behavior is most common. The activity scheduled at that time of day, staff on duty, and other schedule and environmental factors can then be compared across intervals where challenging behavior is most frequent and when it is least likely. This approach may help inform the scheduling of future ABC recording observations, provide a baseline measure of the behavior's frequency, and, by noting environmental correlates with challenging behavior, provide clues regarding function (Touchette, MacDonald, & Langer, 1985). For example, a scatterplot that reveals tantrumming occurs most often right before dinner but is rare after meals would suggest that challenging behavior is maintained by access to food. To further explore that possibility, the practitioner could conduct ABC recording before and after dinner to note whether access to food may be the function. In such a case, the practitioner might note that the group home's cook began taking food from the refrigerator right before the tantrum started (discriminative stimuli) and, upon seeing the tantrum, gave the individual a snack (reinforcing consequence). Treatment for challenging behavior with this pattern of antecedent and consequence could include teaching the individual how to request food appropriately (i.e., functional communication training) and/or modification of the antecedent environment (e.g., increasing availability of snacks or moving dinnertime to earlier in the evening).

Direct observation methods require more time and expertise than indirect methods, but they tend to lead to more accurate conclusions than indirect methods, which are more susceptible to informant bias (Anderson & Long, 2002). However, beyond additional expertise and time, there are several other limitations associated with direct observation. Most importantly, direct observation alone can only provide correlational data, precluding practitioners from making causal statements regarding the environment-behavior relationship (Mace, Lalli, & Shea, 1992). Further, targeted challenging behavior may occur infrequently during observations, making correlational hypotheses difficult to develop (Lerman & Iwata, 1993). In many cases, a combination of indirect interviews and questionnaires in tandem with direct observation is sufficient to design a successful treatment for challenging behavior. However, when these approaches are insufficient or impractical due to resource constraints (e.g., limited time) and in cases where these methods do not produce clear results or when intervention fails to reduce the challenging behavior, a more rigorous FBA protocol that includes a functional analysis is indicated (Beavers, Iwata, & Lerman, 2013; Hanley, Iwata, & McCord, 2003).

Functional analysis. Instead of merely observing and attempting to identify patterns that hint at behavioral function, a functional analysis involves systematically programming conditions with contrived antecedents and contingencies and then measuring changes in behavior across these predetermined conditions (Anderson et al., 2015; Hanley et al., 2003). Iwata and colleagues (1982/1994) developed the most widely cited functional analysis procedures. Iwata et al.'s method involved a control condition (unstructured play) and three test conditions (i.e., attention/social disapproval, academic demands, alone). Although many variations and modifications to these conditions have been evaluated, those options are based on the conditions originally described by Iwata et al. and preserve the underlying operant logic (Lydon, Healy, O'Reilly & Lang, 2012). Procedures for each of Iwata et al.'s original FA condition are summarized in Table 35.1.

The procedures described in Table 35.1 have been modified in a number of ways in order to improve functional analysis efficiency or suitability for a specific individual (Lydon et al., 2012). For example, Iwata et al.'s (1982/1994) conditions were 15 min each, and the process involved running each condition multiple times. The overall duration of the functional analysis process can be decreased by reducing the duration of conditions (e.g., 15 min to 5 min) and is then referred to as a brief functional analysis (MacDonald et al., 2002; Northup et al., 1991). Other variations of functional analysis procedures include delivery of additional test conditions (e.g., tangible condition where preferred items are provided contingent on challenging behavior) and the use of protective equipment to prevent injury during assessment of aggressive or self-injurious behavior (see Beavers et al., 2013 and Lydon et al., 2012 for reviews of functional analysis procedural variations).

Unlike indirect and observation-only methods, a functional analysis allows for causal inferences regarding the function of a targeted behavior and is therefore more likely to yield accurate results (Didden, Duker, & Korzilius, 1997; Hurl et al., 2016). Although a large corpus of rigorous single-case design studies have demonstrated the success of treatments based on functional analysis results (Beavers et al., 2013), functional analysis methods are not without criticism. For example, they may be time-consuming and require rare expertise, and there is concern that occasioning and reinforcing targeted aggression during test conditions could pose additional risk of harm to the individual being assessed or the assessor. As with any such assessment, practitioners must weigh the risks and benefits when determining whether a functional analysis should be included in the FBA process for their client (Mueller & Nkosi, 2007). More recent approaches such as trial-based functional analyses (Sigafoos

Table 35.1 Overview of the functional analysis test and control conditions from Iwata et al. (1982/1994)

Condition	Purpose	Antecedent arrangement	Contingent consequence
Social disapproval	To measure the rate of challenging behavior that occurs when the contingency is socially mediated positive reinforcement	Assessor pretends to ignore the individual (withhold attention) by engaging in some other activity (e.g., reading a magazine)	Social interaction is made contingent on challenging behavior. Specifically, if the individual engages in challenging behavior (e.g., begins tantrumming), the assessor moves closer and reprimands. All other behavior is ignored
Academic demands	To measure the rate of challenging behavior that occurs when the contingency is socially mediated negative reinforcement	Assessor instructs the individual to complete a task that has been reported or observed to be non-preferred (e.g., doing homework)	The task materials and request to do the task are removed, and the assessor turns or moves away from the individual contingent on challenging behavior. All other behavior has no influence on requirement to complete task
Alone	To measure the rate of challenging behavior that occurs when there is no socially mediated reinforcement available	Assessor is not in the room, and the individual is alone	There are no socially mediated contingencies programmed for this condition. If the behavior occurs at high rate, it is likely maintained by automatic reinforcement
Unstructured play	Serves as a control condition to empower comparison of rates of challenging behavior across conditions	Assessor provides pleasant social interaction, does not make any demands, and provides free access to preferred items (e.g., toys)	There are no socially mediated contingencies programmed for this condition. If the behavior is maintained by socially mediated reinforcement, then challenging behavior should be low or absent in this condition

& Saggers, 1995) and interview-informed synthesized contingency analyses are appearing more often in the literature and may offer additional advantages, particularly for practitioners in complex applied settings (e.g., Slaton & Hanley, 2018). Regardless of FBA components utilized, an accurate and thorough assessment of a behavior's operant function is often critical to successful intervention to reduce aggression and tantrumming (Hurl et al., 2016; Mace, 1994).

Function-Based Intervention Components

After operant functions maintaining aggressive or tantrumming behavior are identified via FBA, behavioral intervention components aligned with the FBA results are selected (Smith, 2011). Therefore, in terms of selection of intervention components, a behavior's operant function is a more important consideration than the behavior's form or appearance (Dunlap & Carr, 2007; Petscher, Rey, & Bailey, 2009; Pinkelman & Horner, 2017). In general, function-based interventions can effectively reduce challenging behavior by (a) altering the antecedent environment to reduce motivation to engage in challenging behavior, (b) removing discriminative stimuli that signal reinforcement for challenging behavior, and (c) altering reinforcement contingencies such that people respond to challenging behavior differently (Dunlap & Fox, 2011).

Antecedent-Based Intervention Components

Antecedent interventions involve making changes to the environment where challenging behavior typically occurs in order to reduce the individual's motivation for reinforcers maintaining challenging behavior and remove or alter discriminative stimuli that occasion challenging behavior. When possible these changes are aligned with the results of the FBA process such that the function of the challenging behavior is incorporated. For example, Rispoli et al. (2011) conducted a functional analysis of tantrumming behavior (i.e., throwing work materials) of a 5-year-old boy with autism and ID and found that access to specific tangibles (crayons and paper) was the maintaining contingency. An alternating treatment design was then used to compare a condition in which the child had free access to those items prior to receiving academic instruction to a condition in which access was restricted. When the child had access to the items in the antecedent condition, the frequency of tantrumming was lower and rates of academic engagement were higher than in sessions following the restricted access condition.

Noncontingent reinforcement. Noncontingent reinforcement (NCR) involves the delivery of the reinforcer maintaining a challenging behavior on a time-based, response-independent schedule such that the individual is less motivated to engage in challenging behavior in order to access the reinforcer and the contingency between behavior and reinforcement is broken (Richman, Barnard-Brak, Grub, Bosch, & Abby, 2015; Vollmer, Iwata, Zarcone, Smith, & Mazaleski, 1993). Specifically, because the reinforcer is no longer contingent on the occurrence of the behavior, the behavior is rendered less useful to the individual, and the scheduled access may reduce the value of the reinforcer and abate behavior maintained by that reinforcer (Carr, Bailey, Ecott, Lucker, & Weil, 1998; Rispoli et al., 2011). In terms of aggression, the schedule of reinforcer delivery may need to be denser in the beginning of intervention and then gradually faded over time as aggression is reduced (Richman et al., 2015), particularly for older individuals capable of doing more physical damage.

Britton, Carr, Kellum, Dozier, and Weil (2000) implemented NCR with a 41-year-old male who engaged in grabbing, hair pulling, and biting. A functional analysis indicated Victor's aggression was maintained by provision of attention in the form of physical contact (e.g., hand-holding). Forms of physical contact identified as appropriate and reinforcing for Victor were provided at set time intervals independent of the occurrence of aggression. Initially, the NCR schedule was based on the mean latency to the first occurrence of aggression during baseline. However, after three consecutive sessions in which aggression occurred in less than 5% of intervals, the NCR schedule was thinned from every 50 s to delivery every 6 min. Results indicated that NCR successfully reduced aggression, and the schedule thinning procedure maintained low levels of aggression over time.

NCR can also be applied to challenging behaviors maintained by escape or avoidance of unwanted or unpleasant stimuli. For example, NCR to treat aggression maintained by socially mediated negative reinforcement involves removing the undesired stimulus or aversive demand on a time-based schedule. For example, scheduled breaks from undesired tasks (e.g., academic work, clean up, work demands) can be provided. This approach is potentially effective regardless of whether the individual engages in aggression or tantrumming as long as the challenging behavior's function is to avoid or escape.

Altering antecedent environments and discriminative stimuli. In addition to NCR, there are other antecedent approaches to reducing aggression or tantrums with notable support in the research base. Langthorne, McGill, and Oliver (2014) conducted a systematic review of 59 studies involving challenging behavior maintained by negative reinforcement. In terms of intervention studies targeting aggressive or tantrumming behaviors in people with ID, several antecedent-based strategies were identified including (a) adding discriminative stimuli associated with positive reinforcement to the antecedent environment, (b) reducing the difficulty or averseness of task demands, (c) offering choices for how or when to complete task demands, and (d) altering the mode of demand presentation.

McComas, Hoch, Paone, and El-Roy (2000) provide an example of reducing the disruptive tantrumming of an 8-year-old boy with autism and ID. In that study, the presentation of an academic task demand was found to occasion the occurrence of the challenging behavior, and escape from that task demand was identified as the maintaining consequence. The disruptive tantrums were then reduced, and compliance to task demands increased by offering more effective instructional strategies and academic supports (e.g., provided with calculator and number line). Improved academic instruction has also been found to reduce aggression maintained by negative reinforcement for older children with mild ID (Lali, Kates & Casey, 1999). An example of the potential benefit of altering schedule to include additional breaks is provided by Aikman, Garbutt, and Furniss (2003) who reduced the tantrumming (i.e., screaming and throwing materials) of an 8-year-old boy with severe ID by providing breaks for the child to play as opposed to a more continuous expectation for academic work. Crockett and Hagopian (2006) provide one of the few examples of this approach with an adult. Specifically, the disruptive tantrumming of a 19-year-old with mild ID and Nager's syndrome was reduced by providing a wider range of prompts.

Consequence-Based Intervention Components

Instead of focusing intervention procedures on the antecedent environment before aggressions or tantrumming occurs, consequence-based intervention components alter how the environment responds after challenging behavior occurs. Typically, these approaches involve some combination of ensuring reinforcement is not provided for challenging behavior (i.e., extinction) while also providing reinforcement contingent on an appropriate replacement behavior.

Extinction. Extinction is the discontinuation or withholding of reinforcement following a target behavior, and, when applied with fidelity, extinction can be used to reduce the frequency of the preceding behavior (Keller & Schoenfeld, 1950/1995). In order to be function-matched, extinction procedures differ based on the challenging behavior's socially mediated function. Aggression maintained by socially mediated positive reinforcement can be treated with extinction because practitioners and caregivers can control access to delivery of attention or tangibles. O'Reilly, Lancioni, and Taylor (1999) implemented extinction for aggression in a 10-year-old boy with ID who engaged in a variety of aggressive behaviors including biting, scratching, and hitting. A functional analysis indicated these behaviors were all maintained by provision of attention; therefore, treatment involved withholding attention; specifically no eye contact or verbal interactions were provided following aggression. During the first two sessions, aggression increased above baseline levels, but in subsequent sessions quickly decreased to zero levels.

Aggression maintained by socially mediated negative reinforcement can also be treated with extinction when the practitioner can control the presence of the aversive stimulus. This form of extinction is typically referred to as escape extinction (Cooper et al., 2007). To implement escape extinction, a practitioner would no longer remove or reduce task demands contingent upon aggression. Anderson and Long (2002) demonstrated escape extinction to reduce several problem behaviors, including aggression in an 8-year-old boy with autism and moderate to severe ID. Problem behaviors were maintained by escape and were highest during educational tasks with a speech pathologist. Escape extinction was therefore implemented within this context. Specifically, when the child engaged in aggression during the educational tasks, the speech pathologist continued to prompt him to complete the task and did not reduce or remove the demand. Escape extinction (i.e. persisting with the task demand) resulted in reduction of challenging behavior from three to four times per minute on average to less than once per minute across the last four sessions.

Several characteristics of a behavior's response to extinction have been discussed in the literature. These include concerns regarding extinction burst, spontaneous recovery, and undesirable indirect effects (Lerman & Iwata, 1996). An extinction burst is a temporary increase followed by a decrease in the frequency of a behavior when exposed to extinction (Lerman, Iwata, & Wallace, 1999). Although practitioners should consider the possibility of an extinction burst when using extinction to treat aggression, it is worth noting that extinction bursts do not occur in all instances of extinction (Lerman & Iwata, 1995). Further, when an extinction burst does occur, it is typically brief, lasting only a few sessions (Lerman & Iwata, 1996). Spontaneous recovery is the temporary reappearance of a behavior that has been previously reduced by extinction. Although spontaneous recovery has been demonstrated in basic research, much less evidence of spontaneous recovery is evident in the applied literature. In fact, instances of potential spontaneous recovery may actually reference other phenomena such as treatment that failed to generalize across other individuals or settings (Lerman & Iwata, 1996). Finally, indirect undesirable effects on non-targeted behaviors may occur. These other behaviors have been described as *agitated* or *emotional* behaviors and include topographies such as crying, disruption, and complaining. Although such side effects of extinction are possible and should be considered when planning treatment, these undesirable outcomes also tend to decrease with continued exposure to extinction (e.g., Goh & Iwata, 1994). Moreover, these phenomena may be mediated if extinction is utilized as a component of a treatment package, rather than a stand-alone treatment. Extinction is rarely utilized in isolation and is typically included within a multicomponent treatment package that also programs novel reinforcement contingencies (Vollmer & Athens, 2011).

Reinforcement Procedures

Differential reinforcement. Differential reinforcement is a two-component process in which the practitioner (a) provides reinforcement contingent upon an appropriate behavior targeted for increase but (b) withholds reinforcement for challenging behavior (i.e., extinction) with the same function. When used to decrease aggression, for example, differential reinforcement involves reinforcing occurrences of an alternative to aggression while placing aggression on extinction. If the behavior targeted for increase is physically incompatible with aggression such that the two behaviors cannot co-occur, the procedure is referred to as differential reinforcement of incompatible behavior (DRI). Friman and Altman (1990) treated high-rate disruptive behavior (tantrumming) in a 4-year-old boy with severe ID by teaching his parents to implement DRI. The child's tantrums included elopement and throwing objects. Therefore, reinforcement (i.e., praise and small edibles) was delivered contingent on the child staying in his seat for specified periods of time that gradually increased across intervention sessions. When the child left his seat, he was redirected back to the chair, and no programmed reinforcement was provided. Tantrumming (i.e., out of seat and throwing objects) reduced from multiple occurrences per minute in baseline to less than once per minute during initial intervention sessions and then eventually to zero in the last two sessions.

Differential reinforcement of alternative behavior (DRA) is similar to DRI except the behavior selected for increase is not physically incompatible with the targeted challenging behavior, and the behavior targeted for increase is aligned with the function of the challenging behavior. For example, if FBA results suggest that aggression is maintained by socially mediated positive reinforcement, the DRA procedure will involve teaching the individual to gain access to that consequence (e.g., tangible items, attention) via an alternative behavior. Roane, Fisher, Sgro, Falcomata, and Pabico (2004) implemented DRA with Carl, an 11-year-old boy with autism and ID who engaged in pinching, biting, and grabbing others. After a functional analysis concluded Carl's aggression was maintained by access to tangibles, the therapist taught Carl to give him a picture card as a replacement behavior to access preferred items while aggression was placed on extinction. This resulted in decreased rate of aggression and increased rate of picture card exchange.

If FBA results indicate aggression is maintained by socially mediated negative reinforcement (e.g., escape from undesired activities) a DRA may involve teaching the individual to emit a socially acceptable behavior to access a break. This is referred to as differential negative reinforcement of an alternative behavior (DRNA; Vollmer & Iwata, 1992). Vollmer, Roane, Ringdahl, and Marcus (1999) implemented DRNA with two participants with ID that engaged in aggression maintained by escape from demands. During DRNA, if the participant complied with a task demand (i.e., replacement behavior), the therapist provided a 30-second break from the task. During that 30-s break, the therapist moved away from the table and discontinued any prompts to engage in work. Aggression was placed on extinction. The DRNA procedure resulted in decreased aggression and increased task demand compliance.

When selecting replacement behaviors for differential reinforcement, practitioners should consider several factors (Dwyer, Rozewski, & Simonsen, 2012). First, the practitioner should select a replacement behavior that is already within the individual's repertoire, if possible. If not possible, then the replacement behavior should be one that is easy to teach. Similarly, the replacement behavior should require less effort than aggression. In other words, it should be physically easier for the individual to engage in the replacement behavior than to engage in aggression or tantrumming. Finally, the practitioner should select a replacement behavior that is likely to be reinforced in the natural environment. For example, hand raising is a behavior that is likely to be reinforced with attention in the classroom.

Functional communication training. Functional communication training (FCT) is a type of DRA in which the replacement behavior is a form of communication (Tiger et al., 2008). The communicative response may involve speech but may also involve augmentative or alternative communication (AAC) such as manual signs, picture exchange, or speech-generating devices (Tiger, Hanley, & Bruzek, 2008). Carr and Durand (1985) taught children with ID to produce vocal requests to access consequences maintaining challenging behavior. Specifically, children with challenging behavior maintained by attention were taught to request attention by asking the teacher, "Am I doing good work?" and children with challenging behavior maintained by escape from demands were taught to tell the teacher, "I don't understand". Praise and additional assistance with the task was then provided following these requests. Similarly, Hanley, Iwata, and Thompson (2001) implemented FCT with a 34-year-old man with an ID who engaged in several topographies of aggression: biting, pinching, and twisting limbs, along with self-injurious behavior. A functional analysis concluded these behaviors were maintained by access to preferred items. Experimenters successfully taught Jake to access those preferred items utilizing a manual sign while placing challenging behavior on extinction.

Radstaake et al. (2013) assisted a classroom teacher in implementing FCT with Amy, a 7-year-old girl with Angelman syndrome and an ID. Amy pinched others among other topographies of challenging behavior. A functional analysis concluded that these challenging behaviors were maintained by escape from tasks. As a result, the teacher successfully taught Amy a form of picture exchange communication (Bondy & Frost, 2001) to request a time-out from undesired tasks. In all of the above examples, challenging behavior decreased as the communicative replacement behavior increased. After replacement behaviors have been acquired and the aggression and tantrumming reduced, effort to thin reinforcement schedules such that the behavior is supported by natural reinforcement contingencies is necessary (for review of schedule thinning, see Hagopian, Boelter, & Jarmolowicz, 2011).

Conclusion

Aggression and tantrumming behaviors are common topographies of challenging behavior identified in samples of people with ID across the life-span. These behaviors pose considerable risk to the individual's quality of life, physical safety, and future opportunities. The psychoeducational treatments with the most support in the research base involve first conducting a FBA that includes some combination of indirect as well as direct measures and observations of how the individual interacts with their environment. After the function (reinforcing consequence) of challenging behavior is identified, intervention components are individualized accordingly. This two-step process has been found effective with individuals with a range of ID severity during childhood, adolescence, and adulthood. Although other educational and psychological approaches have been investigated and can be said to have a promising body of emerging evidence, interventions based on ABA are the only options that have accumulated sufficient scientific evidence to be considered evidence-based practices. Future research in this area should include replication and extension studies focused on older individuals because the overwhelming majority of studies have included participants in early adulthood or younger. Further, interventions that have been found effective with other populations but that lack sufficient evidence for people with ID (e.g., cognitive behavioral therapy, relaxation, and mindfulness) warrant additional consideration.

Use of Medications in the Treatment of Aggressive Behavior

Lauren Charlot, Rory Sheehan,
and Angela Hassiotis

Introduction

Psychotropic medications have been used to treat aggression in various populations, including youth with antisocial behaviors, people with traumatic brain injury, and elderly patients with dementia (Maher et al., 2011). However, individuals with intellectual and developmental disabilities (IDD) including people with an autism spectrum disorder (ASD) are perhaps the most medicated group of all of these populations (Esbensen, Greenberg, Seltzer, & Aman, 2009). The extensive use of psychotropic medications, especially antipsychotic medications, has been linked to the frequency with which aggressive and other challenging behaviors are part of the presenting problem that brings individuals with IDD to clinical attention (Tsakanikos, Costello, Holt, Sturmey, & Bouras, 2007). The topic is important given that aggressive behavior is associated with poor quality of life, can lead to out of home placement, and in general limits independence and the ability to be integrated into one's community (Koch et al., 2015). In this chapter, following a brief review of the general topic of aggressive behaviors of people with IDD, the use of psychotropic medications to treat aggressive challenging behaviors (ACB) is described including prescription patterns, research regarding efficacy, side effects, and major findings informing best practice guidelines.

Definition and Epidemiology of Aggressive Behavior

Aggressive behavior can take many forms, from self-directed aggression, i.e., self-injurious behavior, to outwardly directed behavior such as aggressive behavior aimed at people or destructive behavior toward objects. While not currently a diagnostic entity in the DSM-5 (American Psychiatric Association, 2013), it is nonetheless considered a potential comorbidity in people with IDD, and the ICD-10 does provide a diagnostic code for both "repetitive self-injury" and "aggression toward others" (World Health Organization, 1993). By definition challenging behavior "may threaten the quality of life and/or the physical safety of the individual or others and is likely to lead to responses that are restrictive,

aversive or result in exclusion" (Banks, Bush, & Baker, 2007), which is perhaps never more applicable than in the case of aggressive behavior. In addition to the personal, emotional, and quality of life costs, challenging behaviors and especially aggressive behaviors are associated with more expensive forms of care.

A few studies have attempted to establish the prevalence of challenging behavior and aggressive behavior specifically. Prevalence rates of overall challenging behavior lie at 10–15% (Emerson et al., 2001). In the community, in a population-based investigation, the prevalence of aggressive challenging behavior was reported as 9.8% and the 2-year incidence as 1.8% (Cooper et al., 2009). However, figures vary with the setting and specific clinical picture of the population observed. A Canadian study of 3165 clinically referred adults with intellectual disabilities receiving rehabilitation services in Canada provided a 12-month prevalence of 51.8% for overall aggressive challenging behavior as well as the prevalence of five subtypes of aggressive behavior: property damage (24%), verbal (37.6%), physical (24.4%; 4.9% leading to injury of another person), self-injurious (24.4%), and sexual aggression (9.8%) (Crocker et al., 2006). For people with multiple disabilities and profound ID, figures have been reported to be as high as 45% for destructive or aggressive behavior and 82% for self-injurious behavior (Poppes, Van der Putten, & Vlaskamp, 2010). In a more recent study, Crocker, Prokić, Morin, and Reyes (2014) reviewed the cases of 265 adults with IDD and found that a prevalence of overall challenging behavior was 18.1%, self-injurious behavior 7.5%, aggressive-destructive behavior 8.3%, and stereotyped behavior 10.9%.

Unfortunately, persistence levels for challenging behavior are high for adults, particularly those with comorbid autism spectrum disorder (Totsika & Hastings, 2009). This is particularly true for physical aggression where in a study population which is not known to have received any intervention, it remained stable at a persistence percentage of 70% over 11 years (Totsika, Toogood, Hastings, & Lewis, 2008). In children persistence of challenging behavior is moderate to high (Totsika & Hastings, 2009), and the presence of earlier challenging behavior, as reported by parents, represents a significant risk for ongoing behavioral problems (de Ruiter, Dekker, Verhulst, & Koot, 2007). When considering the wide-reaching potential consequences in the context of the above figures on the pervasiveness and chronic course of aggressive behavior in people with intellectual disability, the importance of fully understanding associations and the possible underlying root causes becomes clear.

Predictors of Aggression

Factors that appear to predict risk for aggressive behavior in neurotypical youth are not the same as those identified in studies of children with IDD (Hill et al., 2014). Hill et al. (2014), for example, concluded that "Sociodemographic correlates of aggressive behavior in typical populations such as gender, parent education, race, and ethnicity tended to be weaker or absent in children with ASD." This suggests that root causes of aggression may differ for individuals with and without IDD.

Matson and Hess (2011) conducted a large review of studies that had examined causes for aggression and noted that most of the time, an environmental cause can be established. Cooper et al. (2009) reported that factors independently associated with aggressive behaviors in their population-based survey included lower ability, female gender, living away from home, cause of ID other than Down syndrome, presence of ADHD, and urinary incontinence. Several risk factors for aggression were identified in a meta-analytic study of individuals with IDD: male gender, severe/profound intellectual disability, communication deficits for self-injurious behavior, as well as autism spectrum disorder for self-injurious, aggressive, and disruptive behavior (McClintock, Hall, & Oliver, 2003). Risk factors for aggression displayed by children and adolescents with ASD include self-injury, sleep problems, gastrointestinal problems, communication challenges, and challenges in social functioning (Mazurek, Kanne, & Wodka, 2013).

Other factors include comorbid mental conditions such as dementia, sensory impairment, physical health problems, and abusive or restrictive environments (Citation? – from text sent to LC). Anxiety likely plays a significant role in childhood aggression (Granic, 2014) and may be an important and frequently overlooked influence for both children and adults with IDD. Specific deficits in executive functioning, for example, challenges in set shifting, may be predictive of aggressive behavior through influence on mental flexibility and need for sameness seen in many children and adults with ASD (Visser, Berger, Prins, Lantman-De Valk, & Teunisse, 2014). A number of recent studies have demonstrated that subtypes of deficits in executive function may occur more frequently in association with specific syndromes seen in conjunction with intellectual disability such as Prader-Willi syndrome (PWS) and Fragile X syndrome (FRA-X). These limitations, in turn, may impact pathways to aggressive behaviors. Individuals with PWS, for example, become angry and aggressive related to changes in routines, and this correlates with lower ability to set shift more so than measures of overall cognitive ability. Though set-shifting challenges correlate with challenging behavior in individuals with FRA-X, in this case, anxiety is a critical associated feature.

Other genetic syndromes predispose to specific health problems, such as Cornelia de Lange syndrome (CdLS). Individuals with CdLS display self-injurious behavior at elevated rates compared to counterparts who also have IDD and with other genetic causes. Frequently this is secondary to pain associated with GERD (gastroesophageal reflux disease) (Oliver, Sloneem, Hall, & Arron, 2009). Numerous studies have linked pain to aggressive behaviors displayed by people with IDD (Carr & Owen-DeSchryver, 2007; Gardner & Whalen, 1996; Kennedy et al., 2007). In general, certain genetic syndromes are associated with higher reported rates of aggressive behavior. For example, Cri du Chat, Smith-Magenis, Prader-Willi, Angelman, Cornelia de Lange, and Fragile X syndromes have rates reported of about 70%, while other syndromes, such Williams and Down syndromes, have much lower associations (less than 15%) (Powis & Oliver, 2014).

Research to date clearly indicates that a wide array of factors may influence the occurrence of aggressive behavior in people with IDD; therefore, simple explanatory models are unlikely to be useful. Also, if there are multiple factors that contribute to the occurrence of aggression, there may be a need for multiple approaches to address them.

Aggression and Mental Illness

Various rationales are used to support treatment of challenging behaviors with psychotropic medication beyond the assertion that particular antipsychotic medications alleviate states of irritability and reduce aggression in children with ASD. Aggression and other disruptive behaviors are sometimes viewed as “behavioral equivalents” of mental illness symptoms or more accurately as actual symptom substitutes. For example, certain researchers have suggested that aggression could be an equivalent of depressed mood in the absence of sadness or anhedonia in classifications of psychiatric syndromes applied to people with IDD. However, in a detailed review of the topic, it was concluded that the practice is unsupported by the evidence base and should be avoided for a number of reasons (Sturmey, Laud, Cooper, Matson, & Fodstad, 2010).

The most critical reason is that externalizing behaviors, and even most signs of dysphoric mood, are diagnostically nonspecific and therefore unlikely to be due to mental illness (Matson & Konst, 2015).

Recent work by Melville et al. (2016) and Painter, Ingham, Trevithick, Hastings, and Roy (2018) presents evidence of current conceptualizations of challenging behavior as distinct from or equivalent with mental ill health. This is consistent with early investigations where irritability and aggression were found to be common to most mental health problems experienced by a person with IDD (Charlot, Doucett, & Mezzacappa, 1993). The finding that aggressive behaviors should not be used as symptom substitutes for people with IDD is supported by the above-reviewed findings that so many factors seem to contribute to the occurrence of aggression.

Most experts have agreed that the basic criteria from accepted classification systems should be retained with small adjustments, as seen in the DM-ID 2. In the DM-ID 2, for example, in reference to depressive disorders, it was emphasized that it is important to recognize challenging behaviors as nonspecific signs of distress and to determine if they are occurring in the setting of all of the other depressive disorder criteria (i.e., anhedonia, other signs of dysphoria such as crying, difficulty falling or staying asleep, appetite changes etc.) and have a history consistent with the syndrome. Psychiatric syndromes have a typical clinical course and history and do not generally arise abruptly or appear in only certain settings. When present, symptoms of depression co-occur and are persistent and clinically significant while representing a departure from usual functioning. Further, syndromes such as major depressive disorder and bipolar disorder are episodic. All of these factors need to be considered before a challenging behavior is seen as related to the psychiatric illness, and even then, the behavior itself would be the result rather than the cause of the illness. In addition, the DSM 5 suggests that developmental profile will impact the manifestation of the symptoms criteria in ways that clinicians should know, so as not to miss identifying syndromes when present.

Aggressive behavior can become a way to escape distressing situations when a person has a mental illness like depression or a phobia, especially when one is not able to otherwise convey that the situation is experienced as aversive (Lowry & Sovner, 1992). Many individuals have unique or individualized but characteristic displays of aggressive and disruptive behaviors. Caregivers will describe how the basic outburst is similar each time and that it is the frequency and intensity that primarily shifts. In behavioral terms, depression, anxiety, or even psychosis may be a form of a setting event that will increase the probability of occurrence of a targeted challenging behavior when present during exposure to a triggering factor (Hunter, Wilkniss, Gardner, & Silverstein, 2008).

Given the fact that many people with IDD demonstrate the same kind of agitated behaviors regardless of the source of distress or etiology of their challenging behaviors, it is conceivable too that the same rating on an aggression rating scale such as the *Irritability subscale* of the ABC might also be given in all of these different situations. Because of the lack of diagnostic specificity of surface features of challenging behaviors, a model to explain aggression must then consider multiple potential influences each time there is a "flare-up" or significant change in the frequency or intensity of aggressive behavior. It would not be sufficient to have previously found one or even two factors having impact and then to assume that these factors caused the present problem. This is why functional assessments tend to extend over a long period of time and are repeated many times over the course of treating individuals using a positive behavior support plan.

Pathways to Aggressive Behavior

Complex models are needed to better understand pathways to aggression, as even the most robust predictors account for less than 50% of the variance found. The impact of factors identified as contributing risk at one time is diminished when followed longitudinally. Functional behavioral assessments, even the most structured and intense ones, also fail to account for all of the influences that seem to impact the frequency and intensity with which a challenging behavior will occur (Charlot, 2016; Unwin, 2014). Though the identification of psychiatric syndromes in people with IDD may have improved, most agree there is a large gap between research-based diagnoses and that which occurs in practice. Further, irritability and aggression have been identified as occurring in the context of every type of psychiatric disorder, so that it has virtually no diagnostic specificity. In fact, the most suitable manner of conceptualizing aggressive and other challenging behaviors in people with IDD may be that it acts as final common pathway for distress among people who have fewer ways to demonstrate this than counterparts with neurotypical developmental histories. Additionally, and for similar reasons, aggressive acts may be the most effective means available to some people, to exert control over one's environment. The motivation to try to control one's environment is a universal and healthy human drive with only the means being the true problem, when negative or dangerous patterns of behavior develop over time.

As the result of the complexity of the causes of aggression, unsurprisingly, the most promising of approaches seems to be the one that requires the most "up-front" investment of resources and time. This would be the use of comprehensive multidisciplinary assessment in which attention is paid to environmental and contextual influences on probability of occurrence of aggression (Charlot, 2016; Hunter et al., 2008). In this type of model, "internal" person factors, sometimes referred to as vulnerabilities, transact with a large array of individually significant experiences to produce outcomes. Outcomes might include the development of specific psychiatric syndrome or the emergence of a pattern of behavior (Unwin, 2014). The model is actually similar to that applied in research in developmental psychopathology regarding pathways to psychopathology in general population studies of youth (Rutter & Sroufe, 2000).

Unlike a psychiatric or medical approach, a comprehensive multidisciplinary assessment yields a case formulation that includes a broad-based functional assessment, and not simply a diagnosis. The formulation includes description of what the person brings to a given situation and then all of the varied factors that have an impact on how the person responds to his or her environment. Individuals with IDD often have a variety of genetically associated or biologically influenced challenges to health, cognitive capacities, and psychological and social domains of functioning that will affect responses. At the same time, the environments and experiences to which a person is exposed will also exert influence. In the study of aggression of people with IDD, it is widely accepted that there are multiple pathways to aggressive behavior. There is therefore unlikely to be a universal set of influences or a single form of treatment that will address the causes of aggressive behavior of individuals with IDD. There are interventions that can reduce aggressive behavior without treating its causes at all, such as any intervention, for example, that induces fatigue or slows a person down or any intervention that restricts a person's actions. Clearly, short-term safety can be an important and necessary goal in responding to severe aggression, but in the longer term, the goal must be to identify critical influences and corresponding treatments. Treatments derived from application of a transactional multifactorial model will most always involve multiple modalities including interventions aimed at the system of care, and not just the individual. The latter is in recognition of the finding that in many cases, aggression is a response to ineffective or even abusive caretaking. There may be common contributing factors as suggested by Unwin, so that performing assessments that reveal what are the specific ones affecting a given individual is a critical component of a comprehensive assessment. For example, functional communication challenges and sensory sensitivities are often identified factors influencing distress-driven agitated behaviors in people with IDD. Assessments that seek to identify possible psychiatric syndromes using classification systems with guidelines for use with people with ID are also a component. Anxiety, as another example, is probably underdiagnosed as a factor that influences aggressive responding in people with IDD. Evaluation for all possible medical irritants and medication side effects are also critical. If a genetic syndrome can be identified, clues to frequently associated features may be helpful in guiding both assessment and treatment. Cognitive assessments that include evaluation of executive functions and social cognition will also often reveal factors that act as setting events for challenging behaviors, such as EF deficits associated with rigid patterns of thinking and resistance to change or biologically mediated tendencies which seem to cause heightened seeking of social interactions.

Treatment

Multiple forms of treatment for aggressive behaviors have been reported in the literature, and several major review studies provide information to clinicians regarding the evidence base for a number of these various interventions (Fitzpatrick, Srivorakiat, Wink, Pedapati, & Erickson, 2016). ABA-based interventions for aggressive behavior have been the most studied and have the largest evidence base (Matson & LoVullo, 2008). Much of the literature on ABA focuses on children with ASD but has been reported as also helpful when applied in treating aggression in children and adults with other IDD (see Ali, Blickwedel, & Hassiotis, 2014 for an excellent overview of treatments for individuals with IDD and challenging behaviors). The main focus in this chapter is specifically the use of medication for treating aggressive challenging behavior and is reviewed in detail below. Special attention is given to the risks as well as reports of benefits of pharmaceutical interventions aimed at reducing challenging behavior.

Rates of Psychotropic Medication Use

Increasing numbers of people with IDD are treated with psychotropic medications, and polypharmacy appears to be common (Esbensen et al., 2009; Häβler, Thome, & Reis, 2015; Lott et al., 2004; Mandell et al., 2008; Spina & Leon, 2017; Valenza et al., 2017). Community samples show that large numbers of both children and adults with IDD receive psychopharmacologic treatment, whether they have any psychiatric indications for these prescriptions or not (Brophy et al., 2018; Esbensen et al., 2009; Lunsky & Modi, 2017; Thalitaya, Reynolds, & Ismail, 2017). Unlike other patient groups, people with IDD are generally referred for acute mental health care when they display aggressive or other externalizing behaviors, and their pharmacotherapy is often aimed at its reduction. This is true (that medication is targeting reduction of aggression) even when a psychiatric disorder is diagnosed (de Kuijper & Hoekstra, 2017; Matson & Neal, 2009; Sheehan & Hassiotis, 2017; Tsakanikos et al., 2007; Valenza et al., 2017). Sheehan et al. (2015) reported that only 21% of a large cohort they reviewed including over 33,000 individuals with IDD had a record of mental illness at study entry, while 25% had a record of challenging behavior. Forty-nine percent of adults without a psychiatric illness documented in their records were, however, treated with psychotropic medications (Sheehan et al., 2015).

Antipsychotic drugs are usually the most frequently prescribed class of medications in studies of people with IDD taking psychotropic drugs (Bowring, Totsika, Hastings, Toogood, & McMahon, 2017; Mandell et al., 2008). Brophy et al. (2018) noted that youth with an ASD and ID were prescribed antipsychotic medications more often, at a younger age, and for longer periods of time than a neurotypical control group. De Kuijper et al. (de Kuijper & Hoekstra, 2017) reviewed the care of individuals with IDD in the Netherlands and concluded that the prevalence of antipsychotic drug use for off-label indications in people with IDD "remains high." More and more specialists are raising concerns specifically about the extent of antipsychotic drug prescriptions for challenging behavior in both children and adults with IDD (Brophy et al., 2018; Matson & Hess, 2011). Various best practice guidelines have been outlined, but apparently, having professional or best practice guidelines does not seem to alter the actual practice (Matson & Williams, 2015). In the United Kingdom, this has prompted centralized, government-supported actions aimed at addressing the problem though no similar activity seems to be occurring in the United States (US) (England, 2015).

Recent reviews show major increases in the number of antipsychotic drugs prescribed to youth with ID and ASD particularly since 2011 (Park et al., 2016), following the introduction of new or atypical antipsychotics over the preceding two decades. Adults have been affected by the trend as well. Bowring et al. (2017) found high doses and polypharmacy to be common in their review of the prevalence of psychotropic medication use for challenging behaviors in 265 adults with IDD. These individuals were treated with an average of 2.62 medications per person, with antipsychotic medications being the most frequently prescribed class. Factors influencing prescription of antipsychotic medication included presence of a psychiatric diagnosis, challenging behavior, older age, male gender, and type of residence (Bowring et al., 2017; Lunsky & Modi, 2017; Sheehan et al., 2015). Individuals with ASD may be more likely to receive psychotropic medications if they have a psychiatric diagnosis, ADHD diagnosis, or epilepsy (Houghton, Ong, & Bolognani, 2017). Other investigations have identified factors associated with medication use to include older age and type of residence, as well as gender (males usually receiving more antipsychotic medication in some but not all studies) (Bowring et al., 2017; Lunsky & Modi, 2017).

A recently published *Autism Treatment Network* sponsored study regarding youth with ASD and antipsychotic drugs (Lake et al., 2017) reviewed the care of over 5000 children, and among the children taking antipsychotics to treat externalizing behavior challenges, one third were not receiving any behavioral therapies. Autism Speaks sponsors for the research concluded that the drugs should not be used in isolation of other forms of intervention nor as first-line treatments. Risk factors contributing to antipsychotic drug use included older age (teens versus younger children), use of multiple psychotropic medications, prior ASD diagnosis, non-white Hispanic race/ethnicity, oppositional defiant problems, and physical health conditions such as gastrointestinal and sleep problems. They emphasized the need for thorough behavioral and medical assessment for children with ASD who have co-occurring challenging behaviors, prior to attempting medication interventions.

Factor Associated with Polypharmacy

Polypharmacy appears to be on the rise (Bowring et al. 2017) and is associated with higher rates of drug side effects (Matson & Neal, 2009). O'Dwyer et al. (2017) examined polypharmacy in a group of older adults with IDD. Factors found to be influencing polypharmacy included living in a residential institution, having a history of reporting a mental health condition and sleep problems. Older individuals with IDD may be taking more medications than younger peers, and longitudinal studies find that more drugs seem to be added over time once pharmacotherapy is initiated (Esbensen et al., 2009; Valenza et al., 2017). Schoufour et al. (2018) looked at 1050 older adults with ID. Individuals taking 5 or more medications and who had 4 or more health conditions were 2.3–2.6 times more likely to die during a 5-year follow-up study period than peers with fewer of these risk factors. They concluded that efforts must be made to reduce the occurrence of polypharmacy and to prevent "multimorbidity." Lunsky and Modi (2017) found polypharmacy of psychotropic medications among outpatients with IDD was associated with female gender, residing in a supervised living situation and multiple psychiatric diagnoses. Spina and Leon (2017) suggested that clinicians need to familiarize themselves with the potential for adverse events and especially, the "potential for dangerous combinations of the increasingly frequent co-prescription of AEDs and psychotropic agents."

A large number of the 198 psychiatric inpatients in a study by Charlot et al. (2011) suffered from constipation and GERD. About 40% of admissions that were primarily due to challenging behaviors were eventually found to have a major contributing factor that was medical in nature. This included a number of problems that were associated with medications. In general, the inpatients had both high rates of medical problems and high rates of medication use, taking about three psychotropic drugs per person and a total of an average of five drugs per person for physical and mental ill health combined. Frequent goals during the admissions to the unit were to simplify complex medication regimens while treating medical problems and introducing non-drug interventions (Charlot, 2016).

Evidence Base

Treatment with antipsychotic drugs targeting challenging behavior in adults with ID is considered "controversial"… "because of inconclusive evidence for efficacy in the absence of a comorbid psychiatric condition, and substantial concerns about adverse effects" (Lunsky & Modi, 2017). A small number of studies contributed to risperidone and aripiprazole receiving FDA approval for treating "irritability" in youth with an ASD (Hirsch & Pringsheim, 2016; Research Units on Pediatric Psychopharmacology Autism Network, 2005). Irritability in these studies is defined as a score on the Aberrant Behavior Checklist Irritability subscale. The ABC is a factor-derived instrument normed for use with people with IDD, and it includes an array of items rated by caregivers. Many items on the Irritability subscale are related to externalizing behavior challenges, and very few items actually address mood states. The ABC has proven to be an excellent outcome measure for assessing the impact of interventions aimed at challenging behaviors. The majority of studies that supported the antipsychotic drug indication for treating "irritability" in children with ASD were short term, and the evidence for longer-term use of such treatment and use *not* occurring with other proven nonmedical assessments and interventions is questionable though common (Matson & Hess, 2011). There was one 6-month-long study of risperidone in which the risperidone was stopped over a very short taper and placebo started during the crossover component of the investigation. However, it should be noted that some individuals who have sudden or brief taper of antipsychotic medication display irritability initially which might account for the apparent relapse when individuals are taken off the study drug and placed on a placebo (see discussion below).

It remains unclear whether or not sedation contributes to a slowdown of challenging behaviors reported in the studies cited above. Sedation was reported to occur frequently in children in investigations regarding both aripiprazole (72% in the Marcus et al., 2011 study) and risperidone (51% rate in the Aman, De Smedt, Derivan, Lyons, and Findling (2002) study). There may be some constraints in terms of how generalizable these findings are as well. In many controlled drug studies, a very significant component of the target population was excluded for a variety of reasons, e.g., patients with seizure disorder who had any recent anti-epilepsy drug changes or a seizure any time in the past 6 months and any "significant" medical comorbidities. During the study, participants could not be taking any other psychotropic medications. About 1/3 or more of children with an ASD have a seizure disorder, and youth with ASD have high rates of medical comorbidities. In fact, a follow-up study of children in the RUPP (Research Units in Pediatric Psychopharmacology) investigations demonstrated that the youth who had constipation or diarrhea were less responsive to the treatment drugs (either risperidone or methylphenidate) and that about 1/3 of participants in these studies had these medical problems (CHECK and CITE). Both of the FDA-approved antipsychotic drugs were approved only for short-term use in children with an ASD. In a Cochrane review, the one long-term, placebo discontinuation study of aripiprazole found no differences between placebo and drug conditions in terms of relapse after discontinuation, "suggesting that re-evaluation of aripiprazole use after a period of stabilisation in irritability symptoms is warranted" (Hirsch & Pringsheim, 2016). It should be noted that placebo effects are generally reported to be very high in studies including children with IDD.

It has been well established that despite reports of reduced aggression in short-term use with risperidone, core features of ASD are not improved with this or any other similar medications. A recent investigation addressing this topic with a sample of 184 children with ASD who had reports of behavioral benefit concluded that core ASD symptoms "failed to improve, and in fact subtly worsened over time" (p.516) (Marrus, Underwood-Riordan, Randall, Zhang, & Constantino, 2014).

A number of review papers examine the efficacy of using medications to treat challenging behaviors or aggression in individuals with IDD with similar findings but sometimes different conclusions. The most comprehensive reviews can be found through the National Institute for Health and Care Excellence (NICE) in the United Kingdom and in the Cochrane Library of systematic reviews and meta-analyses. NICE reviews of research regarding antipsychotic drugs, antidepressants, and other psychotropic medications have concluded that the quality of evidence in support of these medications in treating challenging behaviors in people with IDD is low to very low or insufficient. In a study that reviewed the use of psychotropic medications in children with IDD, evidence for use was considered to be low with only short-term benefit for the use of risperidone, with cautious use being advised following best practice guidelines in terms of first exhausting less intrusive non-drug approaches (McQuire, Hassiotis, Harrison, & Pilling, 2015). However, as Matson and Williams (2015) warned, parents may be making decisions about what forms of intervention they choose for their children with ASD based on very different rationales than that applied by researchers, and a wide array of variables likely impact this.

An important study published in the Lancet reported on the clinical effectiveness of antipsychotic drugs in treating challenging behaviors in adults with IDD (Tyrer et al., 2009). The methodology used mirrored that of the CATIE studies (Caroff, Hurford, Lybrand, & Campbell, 2011), investigating "real-world" patients in treatment at multiple sites in Europe. The impact of haloperidol was contrasted with risperidone and placebo. Placebo was found to be as effective in the reduction of challenging behaviors as either of the antipsychotic drugs in the study.

Weighing Risks Versus Benefits

Even in research regarding the use of drugs such as antipsychotic medications for treating actual psychosis, data from recent investigations suggest that findings of efficacy are not particularly robust. There is debate as to whether long-term antipsychotic drug use increases mortality rates in general, but it has been determined that using these agents in elderly dementia patients does and significantly so (reported rates almost three times that of controls). Another worry is that in crossover designs, when there is a switch to placebo or even when a trial is started following an abrupt discontinuation of a current medication, withdrawal effects likely amplify the positive response attributed to the intervention drugs' effects (Beumer & Maes-Festen, 2017). Rather, getting the medication probably mitigates withdrawal effects if you recently stopped taking it, and suddenly stopping an antipsychotic and then getting a placebo would likely uncover withdrawal-related effects in those prone to these (not all people seem to experience such effects). See additional discussion regarding placebo effects below.

There are no randomized clinically controlled trials demonstrating efficacy of polypharmacy in the treatment of challenging behaviors in people with IDD, despite this being quite a common practice. The risk of side effects rises with the addition of medications. It is then especially difficult to see any rationale for this practice, especially when patients are not given access to other forms of intervention that carry much less risk such as ABA-related interventions. Studies in which a drug trial is conducted and there is a direct comparison with an established non-medication intervention seem completely absent from the literature. One investigation contrasted findings from studies reporting on effects of various interventions for challenging behaviors in individuals with IDD (Heyvaert, Maes, & Onghena, 2010). No one form of treatment was superior, including methodologically rigorous investigations of medications and behavioral and other therapeutic strategies. The authors suggested that if these various interventions are equally efficacious, consideration of associated risk should become the focus in treatment selection.

Another consideration in the risk benefit analyses of the use of antipsychotic and other psychotropic medications to treat challenging behaviors is that individuals with IDD rarely control their own pharmacotherapy (Kroese, Dewhurst, & Holmes, 2001). Individuals with IDD often struggle to report internal states, including not only feelings but also physical effects. For example, one of the authors worked with a patient with ASD who reported that he had swallowed batteries.

It was eventually shown that he suffered from GERD, but did not know how to explain it. This was true even though he had only a mild degree of ID. His associated increased challenging behaviors at the time were seen as "treatment resistant" when evident during treatment with atypical antipsychotic medications. At the same time, he was having problems related to both weight gain and daytime sedation.

In addition to challenging behaviors, changes in eating and motor behavior may also be provoked by a physical source of distress, including medication side effects (Charlot et al., 2011). Mistaking surface features of distress such as irritability and aggression as evidence of an acute mental illness episode or as a condition that requires medication in the absence of a comprehensive assessment may inappropriately elevate risk for adverse drug events (Charlot, 2016; Mathews et al., 2005). As an example, it seems clear that antipsychotic drugs prescribed to treat irritability (manifested as negative mood coupled with externalizing behaviors) that is provoked by constipation may reduce the associated externalizing behavior transiently because of sedative effects. However, everyone would agree that this approach is likely to be ineffective over time and potentially harmful, and it would be best to treat the constipation. One strong indicator that the longer-term use of antipsychotic drugs to treat aggression and irritable mood states is ineffective is how often children are started on drugs like risperidone but eventually end up on three or more medications for the same problems that the antipsychotic was prescribed (Esbensen et al., 2009). The drugs may only be effective until the patient has fully accommodated to sedative effects, since there is no evidence that core features of ASD or the symptoms of irritability are diminished because of specific drug actions of antipsychotic medications (Marrus et al., 2014).

There may be differences related to psychotropic medication prescription practices in different countries. Despite the likelihood that rates of challenges are similar, more children and adolescents in the United States are prescribed psychotropic medications than their counterparts in the United Kingdom (Murphy, McCarthy, Baer, Zima, & Jellinek, 2014). One interesting observation is that European, Canadian, and Australian reviews of psychotropic medication use in people with IDD for challenging behaviors tend to advise caution in their use for treating CBs (in line with NICE findings and guidelines), while US reports seem to suggest drugs are not only helpful but that some should be seen as a first-line intervention (Matson & Hess, 2011). One group from the United States, for example, based their recommendation that using two antipsychotic drugs together provides clinical benefit and is "generally well tolerated" on a retrospective chart review at one clinic including 61 individuals with ASD (Wink, Pedapati, Horn, McDougle, & Erickson, 2017). One comprehensive review from the United Kingdom, in contrast, concluded there was a limited evidence base, expressed concern regarding adverse effects of antipsychotic drugs used to treat behavioral challenges, and offered suggestions more in line with best practice guidelines such as those provided by NICE (Sheehan et al., 2015). The view presented was balanced, as the authors noted that there are some individuals who benefit from short-term use of the drugs under specific conditions. In an Australian review of the subject, it was also concluded that evidence for the use of psychotropic medications to treat challenging behavior is weak, with the authors suggesting that such use should be "avoided unless the behaviour is severe and non-responsive to other treatments" (Trollor, Salomon, & Franklin, 2016). Canadian guidelines for children with disruptive behavior disorders endorsed conditional use of risperidone for severe challenges only after psychosocial interventions failed and then only after medications for ADHD also failed. These authors warned consumers of this area of research to cautiously interpret results, due to industry sponsors influencing much of the research on the topic (Gorman et al., 2015).

In another US-based review, the authors suggest that lithium and risperidone "may have efficacy for use in management of aggression in patients with ID," immediately after concluding that evidence for psychotropic medications treating aggression in the population is limited

(Roy, Hoffman, Dudas, & Mendelowitz, 2013). LeClerc and Easley (2015) concluded that "risperidone and aripiprazole remain the mainstays of ASD treatment…" (p. 41). It is unclear if these varying conclusive suggestions impact practice differences, though it is evident that concerns about overuse are more evident in research and review papers coming out of the United Kingdom, the Netherlands, and Canada compared with the United States with few exceptions. Papers providing summary reviews of psychotropic medication use for aggressive behavior of individuals with ASD and other developmental disabilities tend to downplay side effects, despite the large numbers affected by them in studies of antipsychotic medication use. Placebo rates in many studies are significantly high, and studies with children with disabilities are likely exquisitely open to such effects for several reasons (Sandler, 2005). First, parents and other caregivers may be extremely motivated to find help related to family stress. Second, in addition to expectancy effects, ratings that are subjective (such as the ABC scoring) done by the caregivers who are hopeful that an intervention will work are very subject to bias. Newer research suggests that placebo in developmental disability studies is a significant issue and a powerful factor that impacts medication intervention and other investigations using RCT formats (Curie et al., 2015). This may mean that efficacy of a medication that reaches statistical significance might be clinically relatively small (a few points on subscale that could be due to nonspecific drug effects like slowing people or making them tired). These considerations in turn amplify the importance of weighing the associated risks of interventions carefully, as well as adding objective measures of outcomes (actual frequency counts versus rating scales).

Another issue with significance in weighing risks versus benefits of medication use for aggressive behavior relates to the patient's role in treatment. When a patient has IDD, decisions are often made by others (not the patient) to continue medications or add medications and whether any apparent side effects are "well tolerated." In fact, individuals who refuse their psychotropic medications may be characterized as "non-compliant," without considering whether or not medication refusal is actually a wise choice at the time. This should be a very significant concern for anyone treating a person with IDD with psychotropic medications for off-label indications, given the finding from the CATIE studies indicating that even people who have psychosis will quit taking antipsychotic drugs more often than not for a variety of reasons, including the perception that the benefit is not worth the negative effects (Caroff et al., 2011). It is unknown how often people with IDD have long-term exposure to medications that have caused them to feel uncomfortable or unwell, because of a difficulty in conveying this to caregivers who are making decisions on their behalf.

Rationale for Use of Psychotropic Medications to Treat Challenging Behaviors

The concerns described above beg the question, why are the prescription rates for psychotropic medications so prevalent in this population? As noted by Matson and Williams (2015), availability of research and best practice guidelines for treatments in ASD suggest medications have a very limited role, yet the use has continued to be very high. Bhaumik and Michael (2004) speculated as to why psychiatrists may be prescribing antipsychotic drugs for challenging behaviors at such high frequencies, including limited availability of resources, "lack of clinical psychology input, inability to change environment meaningfully, lack of suitably trained staff to manage private residential homes, pressure from nursing staff and other professionals for immediate resolution of problems, lack of meaningful employment or day care opportunities." Thalitaya et al. (2017) emphasized that many people with IDD can be helped to come off of what may be unnecessary psychopharmacologic therapies, but adding this can likely only happen if "there are the right clinical supports in place." The latter suggestion is supported by studies that examined drug withdrawal.

De Kuijper and Hoekstra (2017) examined physicians' decisions to discontinue antipsychotic medications. An unexpected result was that their rationales not only depended on characteristics of their patients such as the presence of emotional or behavioral challenges "but also on environmental factors, such as inappropriate living circumstances, and on attitudes, knowledge and beliefs of staff, clients and their representatives towards the effects of antipsychotic drug use...". They summarized that the primary reasons given for not trying to eliminate antipsychotic medications are related to concerns about restlessness, ASD diagnoses, prior failed attempts to discontinue the medication, and the objections to discontinuation voiced by legal representatives.

Matson and Hess (2011) pointed to the absence of equivalent attention to the use of well-established and less risky interventions for challenging behaviors compared with reports about drugs and argued that there are no data supporting the view that medications aimed at treating irritability (operationalized as the ABC subscale score) are an evidence-based treatment for challenging behavior. Medication side effects and other medical problems may be one of many possible irritants that are often missed because people with IDD may not reliably report their own symptoms (Charlot, 2016). In behavioral terms, these and other factors are setting events that operate to increase the probability of occurrence of a targeted challenging behavior when they are present. Akathisia, muscle stiffness, constipation, or acid reflux may exacerbate a negative response even to a small triggering event.

Discontinuing Antipsychotic Medications

There are a number of studies in recent years that have examined efforts to reduce antipsychotic medications. Sheehan and Hassiotis (2017) reviewed studies in which attempts were made to discontinue the use of antipsychotic medications when prescribed for challenging behaviors. A significant proportion of people who were treated with antipsychotics for externalizing behaviors had successful tapers or complete discontinuation, with subsequent behavioral functioning that was either better or the same. Improvements in cognitive and adaptive functioning have been reported as the result of removing an antipsychotic drug, as have improvements in metabolic syndrome parameters. In one small case series cited by Sheehan and Hassiotis, individuals diagnosed with dementia were no longer presenting with symptoms of the syndrome after antipsychotic drug discontinuation.

Withdrawal-emergent movement symptoms were reported in a few studies, appearing or worsening when antipsychotic drug doses were reduced. In one discontinuation study, the emergence of withdrawal-related movement side effects was a factor predictive of reinstatement of antipsychotic drug treatment (or a lack of successful discontinuation). In another investigation, these types of symptoms appeared to be diminished at 6 months of follow-up, and Sheehan and Hassiotis speculated that over time, some movement disorders may remit. An older study of individuals with severe IDD actually identified this as occurring for a subset of individuals successfully taken off of antipsychotic drugs (May et al., 1995). These authors concluded that "working conditions, staff experience, and attributions about challenging behaviour can influence how behaviour is reported and how it is managed" (p. 8). Caregivers may need support and education to be open to drug tapers when patients present with aggressive behavior, given that their anxiety seems to contribute to an inability to complete efforts to remove the medication. It seems critical to raise awareness and knowledge of side effects, particularly movement disorders, among those treated with antipsychotic medications. It should be noted, however, that movements have been reported having been provoked by other classes of medication in addition to antipsychotic medications, including antidepressants and anti-epilepsy drugs, medications that individuals with IDD are prescribed often with an antipsychotic drug (Mahan et al., 2010).

Rates of tapering were contrasted with trials including 14 and 28 week protocols. Kuijper, Evenhuis, Minderaa, and Hoekstra (2014) found no advantage of a longer tapering period. However, people who could not tolerate the reduction of the drug included a disproportionate number of individuals with withdrawal-emergent movement disorder symptoms. This would indicate that the drug still may not have been needed to manage challenging behaviors, but more simply, that it was difficult to eliminate it. This is important since psychiatrists report past failed attempts to eliminate an antipsychotic medication is a reason they will not try to do this again. Though the de Kuijper group concluded that 14 weeks was adequate for a taper, it might be that a much lengthier one (more than 28 weeks) would help individuals who were experiencing uncomfortable emergent movement symptoms. In a similar finding, the individuals in an open clinical trial conducted by Ahmed et al. (2000) who were unable to complete a taper of antipsychotic medications had higher scores on a measure of drug-related movement disorder symptoms. Many people in the Ahmed group's study were successful in completing an antipsychotic drug taper, demonstrating improved activity levels and increased engagement. Staff and environmental variables also seemed to have a significant impact on outcomes in this investigation. The McNamara group (McNamara et al., 2017), however, used a 6-month tapering protocol, and although this RCT study of antipsychotic drug discontinuation had a small sample of adults with IDD, a 100% success rate in tapering risperidone was achieved without any behavioral decompensation. This may be because a very conservative taper is useful for individuals with movement disorder side effects, something that has received little attention but has been observed by others (Charlot, 2016; Silka & Charlot, 2002). Hypothetically, a long tapering period would allow more time for downregulation of previously sensitized receptors affecting neuromotor circuits, if in fact a pathway to developing dyskinesias and other movement problems is through upregulation of D2 receptors over the course of prolonged blockade. "The hypersensitivity of D2 receptors may cause them to respond abnormally to the dopamine reaching them," when the blockade ceases (Mathews et al., 2005).

Psychotropic Medication Side-Effect Ascertainment

Given all of the above, the small number of investigations focused on the occurrences of medication side effects of people with IDD is worrisome (Matson, Fodstad, Neal, Dempsey, & Rivet, 2010). There are some reports, but these are limited in frequency and scope. On a positive note, a screening tool was developed for use with individuals with IDD, the Matson Evaluation of Drug Side Effects or the MEDS (Matson et al., 1998). Its psychometric properties are sound, and it is easy to administer. The screen consists of subscales that include items representing common side effects of psychotropic medications. Some of the research noted here included use of the tool.

Individuals with IDD taking psychotropic medications, and specifically taking antipsychotic medications, are at elevated risk for extrapyramidal symptoms or EPS including acute dystonias, akathisia, Parkinsonism, and tardive dyskinesia (TD). TD was diagnosed in over 1/3 of children with ASD receiving haloperidol in one investigation cited by Matson and Hess (2011), who also noted that cases of TD have been reported with risperidone use as well. In an early study of the risk factors for TD in a population of individuals with IDD, Matson's group identified age, psychiatric diagnosis, level of ID, recent psychotropic medication use, lifetime exposure and duration of use, current treatment with an antipsychotic, and total daily dose were found significant predictors (Matson et al., 2010). In another investigation, the difference between treatment with atypical and typical antipsychotic on the MEDS movement disorder subscales was significant only for akathisia (Advokat, Mayville, & Matson, 2000).

In a retrospective review of a very large cohort of individuals with ID treated with antipsychotic medications, Sheehan et al. (2017) found that the recorded incidence rate of any movement disorder was 30% higher in people with ID compared with those without ID. This important study is the first large-scale investigation to demonstrate that ID confers elevated risk for these ADEs, confirming what many clinicians have observed in practice. Parkinsonism and akathisia showed the most elevation in risk comparatively. Neuroleptic malignant syndrome (NMS), a rare but potentially lethal side effect of antipsychotic drugs, was documented as occurring three times more often in the individuals with ID versus without who were taking antipsychotic medications.

Use of antipsychotic medications has also been found to be associated with increased risk for an epilepsy event, physical injury, diabetes, depression, and respiratory problems in children with ASD and ID (Brophy et al., 2018). Ramerman, Hoekstra, and de Kuijper (2018) found a measure revealing reduced health and wellness was associated with antipsychotic drug use, with specific effects related to occurrences of dysphagia, temperature regulation problems, and Parkinsonian symptoms. Individuals with IDD may be at an increased risk of experiencing EPS (extra pyramidal symptoms) (Matson et al., 2010). Risk factors for ADEs or drug side effects have been identified for people with IDD. Mahan et al. (2010) (using the MEDS screening tool) found that receiving medications from more than one class was associated with having higher MEDS scores. Scheifes et al. (2016) found that of the 103 individuals with IDD for whom a survey was completed, over 80% had at least one ADE reported while 46% had 3 or more. They also found that being on more medications was correlated with having more side effects.

Valdovinos and colleagues found that having multiple drug changes in a short period of time seemed to elevate risk for adverse events (Valdovinos, Caruso, Roberts, Kim, & Kennedy, 2005). Charlot et al. (2011) reviewed the care of 198 psychiatric inpatient adults with IDD who were prescribed close to three psychotropic medications per person on average and found that having more medical problems (including drug-induced symptoms and disorders) was associated with longer lengths of stay. These findings provide added support to the Schoufour's group's warning that more attention should be paid to "multimorbidity" (Schoufour et al., 2018).

Data trends indicate the increasing use of the newer or second-generation antipsychotics, though there is continued use of first-generation antipsychotics in the population. Since their release into the market, numerous published reports have suggested that atypicals confer less risk of extra pyramidal symptoms than typicals. However, studies looking more closely at this over time have asserted that early investigations were usually too short term (most lasting from only 6–12 weeks), while many side effects of antipsychotics emerge over the course of long-term treatment (Matson et al., 2010). In earlier studies, the side effects of risperidone, for example, were described as "well tolerated" and included mainly sedation and weight gain (de Kuijper et al., 2013; Pringsheim, Lam, Ching, & Patten, 2011). de Kuijper and colleagues concluded that "more recent evaluation of the evidence suggests that the initial enthusiasm for second-generation agents was misplaced and largely based on studies that made unequal comparisons between atypicals and high-potency typical antipsychotics (de Kuijper et al., 2013). In the Sheehan et al.'s investigation cited above, group differences in rates of movement disorder side effects were not found based on whether the individual took a typical or atypical antipsychotic drug (Sheehan et al., 2017). Divac, Prostran, Jakovcevski, and Cerovac (2014) note that atypicals differ in terms of their relative risk for drug-induced movement disorders, but "the fact is that these drugs have not lived up to the expectation regarding their tolerability" (p. 1). Reports from studies in schizophrenia have suggested that comparator selection and dosing likely impacted earlier findings of lower EPS rates in patients treated with atypicals (Caroff et al., 2011).

Bakker, de Groot, van Os, and van Harten (2013) predicted the rise of drug-induced movement disorders secondary to the extensive marketing of atypicals as indicated in the treatment of multiple disorders, beyond schizophrenia, and other psychotic disorders. Even if it is accepted that those drugs as a group may be associated with a somewhat lower risk of movement disorders, the absolute numbers of people now likely to develop them is much larger because more and more people are being prescribed antipsychotics. Ryu et al. (2015) who performed detailed chart reviews of 80 elderly patients with schizophrenia on antipsychotic medications noted that tardive dystonias as well as tardive dyskinesia will affect most patients who receive long-term antipsychotic drug therapy. These findings amplify the need for those of us in the field of IDD to be vigilant in regard to the assessment of neuromotor symptoms associated with medication and to keep in mind that cognitive disability itself is a risk factor for drug-induced movement disorder (Peluso, Lewis, Barnes, & Jones, 2012; Sheehan et al., 2017). These investigators, however, noted the rate of reported TD was lower than expected and speculated that drug-induced tardive dyskinesia "may be misinterpreted as part of the underlying ID and under-recorded, an example of 'diagnostic overshadowing'."

Differential diagnosis of drug-induced movement disorders can be complex (Burkhard, 2014). This is especially the case with patients who have an IDD who may not complain of subtle but uncomfortable problems like muscle stiffness or "inner restlessness." Ryu's group (2015) cited above conveyed that they were "surprised by the paucity of notes in the patient files about movement disorder side effects," supporting the contention that such problems may be overlooked by clinicians without special training or awareness of the frequency and seriousness of their occurrence in people with IDD. At the same time, a balanced approach or a rational psychopharmacology will be required so that people who are helped by certain medications and where the risk benefit demonstrates a medication is a good choice receive the treatment they need in the context of a multidisciplinary approach (Sheehan et al., 2017).

Sedation, one of the most commonly reported side effects of antipsychotic medications, can at times slow the rate or reduce the intensity of aggressive acts leading staff persons to view it as effective. In some cases, however, people are both irritable and tired, which may lower the threshold for (or in ABA terms "occasion") increased occurrence of externalizing behaviors. It is possible that the sedative side effects of risperidone and aripiprazole, for example, contributed to the difference between placebo and drug in some investigations, given a rate as high as 72% of subjects given these drugs reportedly experienced this side effect (Marcus et al., 2011). The onset of the metabolic syndrome (increased weight, hyperlipidemia, and hyperglycemia) and many of the attendant complications of obesity have been well documented in people with IDD receiving atypical antipsychotics (de Kuijper et al., 2013).

Summary and Suggestions for the Future

Given the extent of the use of psychotropic medications in the treatment of individuals with IDD who have mental health needs or challenging behaviors, it seems critical that more efforts be made to expand our knowledge base about the nature and correlates of side effects these individuals may be experiencing. It may be especially helpful to explore the extent of side effects reported for individuals in crisis who are exposed to polypharmacy and who are continuing to present with the same symptoms and challenges for which the medications they have been receiving were prescribed. In these cases, the presence and impact of side effects may be missed. Basch (2010) noted that clinicians may miss side effects that are then identified by patient self-report, noting that clinicians will "systematically downgrade the severity of patients' symptoms." This is a major concern for people with IDD who may not report their symptoms accurately or at all. López-Sendón et al. (2013) cautioned that clinicians need to be aware of and attend to the possible presence of drug-induced Parkinsonism, "particularly in the elderly, patients taking multiple drugs and those with genetic risk factors involved in Parkinson's Disease." The warning was based on their observations that these conditions were being overlooked despite being of significant clinical concern for many individuals. Some individuals with genetically mediated syndromes and who are born with challenges such as cerebral palsy have elevated risk for abnormal movements and may be especially vulnerable to medications that might worsen existing conditions involving neuromotor circuits in the brain and related to diminished neural plasticity (Ravin, 2016).

The association of various types of physical discomfort to challenging behavior in people with IDD has long been recognized (Carr & Owen-DeSchryver, 2007; Gardner & Whalen, 1996). In many cases, however, the presence of externalizing behaviors does not lead to a search for possible medical irritants but rather seems to lead to adding medications, including offending agents. Individuals with IDD who have high levels of emotional and behavioral support needs, and who have a history of requiring emergency services, are probably at the most risk for having medication change and additions that can elevate the risk for ADEs. One study found that individuals with IDD were more likely than peers without IDD to be given psychotropic medications but less likely to be offered simple pain relievers such as NSAIDs when showing nonspecific signs of discomfort (Axmon, Sandberg, Ahlström, & Midlöv, 2017). This too may be secondary to the concern raised by Sheehan and colleagues with regard to diagnostic overshadowing. Diagnostic overshadowing, attributing the symptoms observed to the IDD or even to an existing psychiatric label and missing alternative causative factors for a clinical problem, may be especially important with regard to ADE detection in this population. Of interest was a study that explored quality of life, psychopathology, and medications in a group of adults with mild ID. Koch et al. (2015) found that "proxy" or staff reports of quality of life were impacted by the presence of behavioral and psychiatric symptoms, while taking more psychotropic medications correlated with lower reported quality of life based on self-report of the individuals themselves.

The research reviewed here has many limitations and is varied in design. It is very challenging to design studies to provide clear evidence of cause and effect when looking at things such as the use of psychotropic medication subtypes or polypharmacy. It has been difficult for researchers in some countries like the United States, to secure major funding to support studies of variables such as drug side effects, while the studies that do receive the most support are RCTs that examine intended drug effects as part of the harms/benefits from the intervention. Even with these investigations, few include adults with IDD. There does seem to be more activity in this area in other countries, especially in Canada, the Netherlands, and the United Kingdom.

Future investigations that further examine side effects and their relationship to medications would be helpful. Also, RCTs in which medications are evaluated head to head with behavioral or other non-drug interventions would be informative, though design challenges would be significant. Despite the drawbacks to real-world studies, these seem important in improving our understanding of medication effects on challenging behavior. Since best practice guidelines seem to be ineffective in changing actual prescribing, other initiatives will be needed if there is a will to change what clearly seems to be an over-reliance on psychotropic medications to control behavior in the population such as current efforts in the United Kingdom. Examination of policies in places like the United States would be necessary, since there is currently no national approach nor funded initiatives that insure people with IDD who are given drugs for behavior have access to multidisciplinary assessment and alternative therapies. Research reviewed here would suggest many do not.

Acknowledgment We would like to thank Miss Jessica Blickwedel for having contributed to the initial draft of the introduction.

Skill Building and Intellectual Disabilities

Social Skills

37

Steven G. Little, Angeleque Akin-Little,
Margaret Gopaul, and Tom Nicholson

Libet and Lewinsohn (1973, p. 311) defined social skills as the "complex ability to maximize the rate of positive reinforcement and to minimize the strength of punishment elicited from others." Such a definition, while fundamentally accurate, is rather broad and does little to increase our understanding of the specific behaviors that are understood as comprising social skills. While current social skills definitions may vary somewhat, there is some basic agreement as to how social skills are developed. Specifically, social skills involve specific learned behaviors, are comprised of both initiation and response behaviors, and entail interactions with others. These skills are also socially reinforced and denote skills that are context specific (Little, Swangler, & Akin-Little, 2017). Basically, social skills are those skills that enable individuals to function competently at social tasks (Cook, Gresham, Barreras, Thornton, & Crews, 2008).

Gresham (1986, 1997) categorized social skills into three definitional areas: peer acceptance, behavioral, and social validity. Peer acceptance defines social skills by how readily an individual is accepted by his or her peers. In other words, it refers to an individual's popularity among peers (Oden & Asher, 1977). Such a definition defines social skills by their outcome and fails to identify the specific behaviors that lead to peer acceptance. In addition, while useful in a context such as a regular school classroom, it is less useful when applied to the ID population. The behavioral definition focuses on situation-specific behaviors that maximize the probability of reinforcement while decreasing the probability of punishment (Libet & Lewinsohn, 1973). This definition has greater relevance to ID as it allows social behavior to be specified and operationalized for measurement and intervention. It does not, however, ensure that the identified social behaviors are socially significant or socially relevant. The social validity definition defines social skills as exhibiting behaviors that predict important social outcomes in particular situations (Gresham, 1983; Kazdin, 1977; Wolf, 1978).

Related to social skills is the term social competence. While social skills consist of specific skills that form the basis for socially competent behavior, social competence reflects social judgment about the quality of an individual's performance (Hops, 1983). Social skills are considered to be the "most malleable of the components of social competence" (Elliott & Busse, 1991, p. 64). Semrud-Clikeman (2007) described social

competence as consisting of social, emotional, cognitive, and behavioral components needed for successful social adaptation. Social skills can be thought of as the behavioral component of Semrud-Clikeman's definition. Greenspan (1981) provided an interesting analogy that helps clarify the distinction between social skills and social competence. Competence as a golfer is usually defined by the outcome, the final score. This is analogous to social competence. The golf score, however, tells us nothing about the skills (e.g., driving, approach shots, putting) and how these contributed to the final score. These are analogous to social skills. As this chapter focuses on the ID population, attention will deal primarily with social skills and interventions directed at improving specific social behaviors.

Gresham (1986) categorizes social skills difficulty into four types: skills deficits, performance deficits, self-control skills deficits, and self-control performance deficits. Skills deficits are manifested when the individual lacks the skills needed for appropriate social interaction. Performance deficits are those where the individual possesses the capability of performing the behavior but is not performing the behaviors at an acceptable level due to factors such as motivation or lack of opportunity. Self-control skills deficits are identified when an individual has not learned a social skill. For example, in individuals with ID, their cognitive deficits may interfere with learning the social skill. Finally, self-control performance deficits also involve interference, but in this case it has not interfered with the acquisition of the behavior but rather with its performance. It is important to identify the type of social skill deficit when developing an intervention.

Constantino, Przybeck, Friesen, and Todd (2000) defined social skills as involving five components: social awareness, social cognition, social communication, social motivation, and autistic mannerisms. Social awareness involves the ability to recognize social cues. Social cognition is the ability to interpret social cues once they are identified. Social communication includes behaviors such as expressive social communication. Social motivation incorporates factors such as social anxiety, inhibition, and empathic orientation that influence the individual's motivation to respond in a socially responsive manner. Finally, autistic mannerisms include aspects of ASD and ID (e.g., stereotyped behaviors, highly restricted interests) that, while idiosyncratic, need to be addressed in any intervention designed to improve social functioning.

Social Skills and Intellectual Disability

The American Association on Intellectual and Developmental Disabilities (AAIDD) definition of ID states that "Intellectual disability is characterized by significant limitations both in intellectual functioning and in adaptive behavior as expressed in conceptual, social, and practical adaptive skills. This disability originates before age 18" (Schalock et al., 2010, p. 5). The DSM-5 (APA, 2013) definition includes three criteria: (a) deficits in intellectual functioning, (b) deficits in adaptive functioning that result in failure to meet developmental and sociocultural standards for personal independence and social responsibility, and (c) onset during the developmental period. The ICD-10 continues to use the term mental retardation and defines it as "A condition of arrested or incomplete development of the mind, which is especially characterized by impairment of skills manifested during the developmental period, skills which contribute to the overall level of intelligence, i.e. cognitive, language, motor, and social abilities" (World Health Organization, 2010). Adaptive behavior, which includes social skills and social functioning, is a fundamental component of each. Parmenter (2011) emphasized that social competence is the key factor for ID students making a successful transition into adult living, including successful employment. Without a doubt, individuals with ID have significant deficits in social skills, social skills are critical for effectively interacting with others, and the failure to acquire appropriate social skills can result in a multitude of other deficits (Matson, Dempsey, & LoVullo, 2009). The importance of social skills therefore cannot be underestimated.

Research has consistently supported the contention that social skills delays are a central component of ID. For example, de Bildt et al. (2005) examined social skills in 510 children with mild and moderate ID and found that all children in this study were delayed in their basic social skills, including communication skills, and the lower the level of ID, the larger the delay. De Bildt and colleagues, however, believe it is important to discriminate between limitations in social skills related to ID as opposed to social skills limitations in autism spectrum disorder (ASD) or other disorders with social skills deficits. Specifically in ID, the level of social skills functioning is usually commensurate with other areas of development and functioning with a relatively homogeneous profile (i.e., few relative strengths or weaknesses). In ASD, and with other disabilities with characteristic social skills deficits (e.g., ASD, attention–deficit/hyperactivity disorder, social anxiety disorder), limitations in social skills are often greater than in other areas of function, and there is greater heterogeneity in areas of social skills functioning.

Deficits in social functioning have been an essential component of ID/MR definitions as early as Doll (1941) where he defined ID as including "a state of social incompetence" (p. 215) and Greenspan (1999) has argued that social intelligence is the most important factor in ID. Greenspan makes it clear, however, that MR is not a global disorder of social competence, but involves significant deficits in social intelligence. He further elaborates that adaptive behavior instruments measure more "practical intelligence" (e.g., daily living skills) than social skills which are a component of social intelligence.

Specific Social Skills Deficits. It can be said that social skills involve specific learned behaviors, are comprised of both initiation and response behaviors, and entail interactions with others (Little et al., 2017). The Social Skills Scale of the *Social Skills Improvement System Rating Scales* (*SSIS*, Gresham & Elliott, 2008) provides a good framework for understanding the behaviors that comprise social skills. Social skills, as defined by the Social Skills Scale, consist of seven domains: communication, cooperation, assertion, responsibility, empathy, engagement, and self-control. Communication behaviors include making eye contact when talking and saying "please" and "thank you." Cooperation involves behaviors such as rule following and task completion. Assertion consists of behaviors such as asking for help and indicating when there is a problem. Examples of responsibility behaviors include respecting the property of others and acting in a well-behaved manner when unsupervised. Empathy involves behaviors such as trying to comfort others and feeling bad when others are sad. Engagement includes inviting others to join in activities, making friends easily, and introducing oneself to others. Finally, examples of self-control behaviors include staying calm when teased and acting appropriately when upset.

Communication. Communication skills are a frequent deficit in individuals with ID (Kurtz, Boetler, Jarmolowicz, Chin, & Hagopian, 2011). This is especially true for individuals at the lower end of the distribution (Matson, Terlonge, González, & Rivet, 2006). There is, however, a wide range of variability in communication skills in people with ID at all levels (van der Meer, Sigafoos, O'Reilly, & Lancioni, 2011). Light (1989) offered a definition of communicative competence as "… a relative and dynamic, interpersonal construct based on functionality of communication, adequacy of communication, and sufficiency of knowledge, judgment and skill in four interrelated domains: linguistic competence, operational competence, social competence, and strategic competence" (p. 137). The International Classification of Functioning, Disability and Health (ICF) divides communication into three areas: receiving communication (receptive communication), producing communication (expressive communication), and conversation (Schindler, Ruoppolo, & Barillari, 2010). This is very similar to the common communication subdomains of expressive, receptive, and written communication (Belva, Matson, Sipes, & Bamburg 2012) with written communication including expressive and receptive communication specific to reading and writing.

Cooperation. Cooperative behavior has been defined as involving both collaboration and prosocial behavior. Collaboration is usually defined as two or more individuals working together to achieve benefits and prosocial behavior defined as any behavior that benefits another, regardless of the benefit to the individual (Cronin, 2017). Lane, Givner, and Pierson (2004) surveyed elementary teachers utilizing items on the Social Skills Rating System and found that they viewed cooperation and self-control skills as the most important variables for success in school. Meier, DiPerna, and Oster (2006) confirmed Lane et al.'s research and found that specifically ignores peer distractions, follows directions, attends to instructions, uses free time acceptably, and uses time appropriately were all cooperation items identified critical for classroom success by a majority of elementary school teachers.

Assertion. This dimension is dominated by social skills that reflect a child or youth who might be called "outgoing or extroverted" by others. Skills such as initiating conversations with others, acknowledging compliments, and inviting others to interact are examples of assertion-based social skills (Caldarella & Merrell, 1997).

Responsibility. In the English language, "responsibility" can have multiple definitions including (a) the state or fact of having a duty to deal with something or of having control over someone, (b) the state or fact of being accountable or to blame for something, and (c) the opportunity or ability to act independently and take decisions without authorization. Operationalized on rating scales, responsibility includes behaviors such as respecting the property of others and being well-behaved when unsupervised.

Empathy. Empathy has been defined as sharing the emotional state or context of another (Eisenberg & Strayer, 1987). It has not, however, been used or measured in a consistent way, leading to confusion in exactly what it means (Cuff, Brown, Taylor, & Howat, 2016; Ralfs & Beail, 2012). In people with ID, the evidence on empathy is also equivocal with studies inconsistent about whether individuals with ID differ from individuals with higher levels of cognitive functioning on emotional and behavioral aspects of empathy (Kasari, Freeman, & Bass, 2003).

Engagement. In the context of social skills, engagement is usually defined as the time a child spends interacting with his/her environment in a developmentally and contextually appropriate manner (Nelson, Paul, Johnston, & Kidder, 2017) and is considered to be an important component of learning (Raspa, McWilliam, & Ridley, 2001). Engagement includes behaviors such as inviting others to join in activities, making friends easily, and introducing oneself to others.

Self-Control. Self-control can be conceptualized as "a set of goal-directed skills that develop from birth onward, enabling humans to act upon their personal and interpersonal aims; overcome difficulties relating to thoughts, emotions, and behaviors; delay gratification; and cope with distress, pain, and disturbing emotions while targeting both internal and external disturbing situations" (Orkibi, Hamama, Gavriel-Fried, & Ronen, 2018, p. 6). According to Gilbert (2006), people find it gratifying to exercise control, whereas the loss of control leads to unhappiness, helplessness, hopelessness, and depression. It has been operationalized by rating scales items such as "inviting others to join in activities," "making friends easily," and "introducing oneself to others." Research indicates that individuals with ID engage in meaningful activities or relationships to a lesser extent than the general population (Qian, Tichá, Larson, Stancliffe, & Wuorio, 2015).

Social Skills Training

Social skills training (SST) teaches specific skills that are targeted to improve social development and reduce behavioral problems (Gresham, Van, & Cook, 2006). In selecting a social skills intervention, it is best to ask a series of questions. First, does the child know how to perform the social skill in question? In other words, do they possess the prerequisite skills to be taught and/or the physical capability of engaging in the behavior? In addition, are there interfering responses present? Interfering responses consist of cognitive and verbal variables such as depressive thoughts, poor problem-solving ability, inadequate role-taking skill, or low self-efficacy. In planning interventions for individuals with ID, it is essential to adequately assess their cognitive functioning with particular focus on problem-solving and role-taking skills. It is also important to evaluate the overt and motoric variables such as disruptive behavior, aggressive behavior, excessive motor movement, or impulsive behavior. It is possible that interventions for these behaviors may need to be built into the social skills training package you plan on using or be dealt with prior to initiating direct social skills training. Similarly, if there are any emotional variables (e.g., anxiety, anger, depression, fear), these may need to be addressed before social skills training is initiated, or they need to be incorporated into the social skills training system.

In developing a social skills intervention program, it is also important to determine if the individual has skills acquisition or performance deficits (Gresham, 2016). Children with social skills deficits do not have the necessary social skills in their repertoires, or they may not know a critical step in the process. For example, a child may not know how to initiate a conversation. This is due to not having an appropriate model or never having the behavior shaped and reinforced. The test of whether this is the problem is to determine if the child has any history of performing the behavior. If there is no history of performing the behavior, it is likely a skill deficit. A subcategory of skills deficits is self-control skills deficit. This is when a child never learned a social skill because some type of interfering response was present which prevented skills acquisition. An example would be anxiety. A child may never learn peer interaction skills because social anxiety prevents social approach behaviors. Aggression also frequently interferes, as others avoid that child and he never has the opportunity to acquire social interaction skills. Performance deficits are when an individual knows how to perform a given behavior but does not perform the behavior at an acceptable level due to some form of interference. If an individual once performed a skill and does not now, or they are performing the behavior but at a very low rate, it is a performance deficit. Self-control performance deficits are a subcategory of performance deficit. Individuals with these have the social skill in their repertoire but do not perform the skill due to antecedent or consequent control. Here the child knows what to do and may even have intentions of doing it, but something gets in the way such as impulsivity (Gresham, 2016).

Gresham (2016) reports that since 1986, there have been 12 narrative reviews of social skills intervention literature with the following conclusions being derived: (a) a combination of modeling, coaching, behavioral rehearsal, and applied behavior analysis procedures appears to be the most effective approaches; (b) cognitive behavioral approaches are not as effective as the procedures mentioned above; and (c) a lack of generalization and maintenance of social skill gains are the greatest weakness of these interventions.

A number of meta-analyses focusing on social skills interventions (SSI) have been conducted over the past three decades. None, however, focused solely on an ID population. Gresham (2016) reviewed nine meta-analyses conducted between 1985 and 2011 and concluded that "approximately 65% of participants in social skills interventions improve relative to only 35% of individuals in control groups" (p. 329).

One meta-analysis that did include individuals with ID was conducted by Park, Kim, and Kim (2016). They conducted a meta-analysis on the effect of job-related social skills training (SST) for secondary students across different types of disabilities, outcomes, settings, and instruction. Regarding disability, the effect of SST was not significant for students with Down syndrome and learning disabilities. Other disabilities, such as intellectual disabilities, autism spectrum disorders, and emotional/behavioral disorders, showed moderate effect sizes. The effect sizes by subgroup analysis indicated the following effect sizes: intellectual disabilities ($ES = 0.487$), Down syndrome ($ES = 0.159$), autism ($ES = 0.445$), no specific ($ES = 0.856$), emotional and/or behavior disorder ($ES = 0.505$), and learning disabilities ($ES = 0.495$).

Gates, Kang, and Lerner (2017) conducted a meta-analysis on group-based social skills interventions (GSSIs) with youth with autism spectrum disorder (ASD). While the study did not include individuals with ID (mean IQ was 102), the results are useful in understanding the efficacy of GSSIs. Results indicated that the overall effect size was medium (g = 0.51). Effects were largest on self-report measures (g = 0.92), smaller for parent- (g = 0.47) and observer-report measures (g = 0.40), and smallest for teacher-report measures (g = 0.11). The authors concluded that social skills interventions appear modestly effective for youth with ASD, but may not generalize to school settings or self-reported social behavior. Research has shown that individuals with average or higher IQ and better developed verbal ability tend to benefit most from GSSIs (Herbrecht et al., 2009). Therefore, individuals with ID who have more highly developed cognitive and verbal abilities may show greater improvements from GSSIs than those individuals who have less-developed skills. Another important conclusion that may be drawn from this research involves the type of measure. Self-report measures had a large effect size, parent and observer measures moderate effect sizes, and teacher measures a minimal effect size. It is possible that rater bias may be influencing the scores on self- and other-report measures. Rater bias is a form of nonrandom measurement error or systematic variance that is attributable to the rater (Hoyt & Kerns, 1999), and rater bias may artificially inflate or suppress assessment scores relative to the actual frequency of behavior (Shapiro, Kim, Accomazzo, & Roscoe, 2016).

Wang, Cui, and Parrila (2011) conducted a meta-analysis using hierarchical linear modeling (HLM) to examine the effectiveness of peer-mediated and video modeling approaches, for social skills training of children with ASD. Both interventions (mean effect size = 1.27) were similarly effective and found to significantly impact the social performance of children with ASD. While level of cognitive functioning was not examined in this analysis, age functioned as a significant moderator in the effectiveness of the intervention with the interventions being slightly more effective for younger children. Similarly, Wang and Spillane (2009) conducted a meta-analysis on interventions to increase social skills for children and adolescents with ASD and attempt to determine whether interventions met the criteria for evidence-based practice. A total of 38 studies with 147 total participants were examined. Types of interventions examined using percentage of non-overlapping data points (PND) were social stories (n = 6), peer-mediated (n = 9), video modeling (n = 11), cognitive behavior training (n = 3), and others (n = 9). Results indicated the following: social stories (mean PND = 67.21%), peer-mediated (mean PND = 60.69%), and video modeling (mean PND = 84.25); leading the authors to conclude that only video modeling meets criteria as an evidence-based intervention. Due to the small n for cognitive behavior training studies and the variability in the others category, the authors concluded that while promising, firm conclusions could not be made as to the efficacy of these procedures.

Bellini, Peters, Benner, and Hopf (2007) conducted a meta-analysis examining the effectiveness of school-based social skills interventions for children and adolescents with ASD. Results indicated that social skills interventions produce low treatment and generalization effects and moderate maintenance effects for children with ASD. Using the percentage of non-overlapping data points (PND) as the metric, results indicated that just over half of the reviewed studies (52%) produced mean intervention PND scores above 70%. The results also suggested moderate maintenance effects (mean PND = 80%) and low generalization effects (mean PND = 53%). The authors concluded that results “suggest that school-based social skills interventions are minimally effective for children with ASD” (p. 159).

Bellini and Akullian (2007) conducted a meta-analysis analyzing 23 single-subject design research studies using the percentage of non-overlapping data points with children with ASD. Results indicated that both video modeling (VM) and video self-modeling (VSM) are effective intervention strategies to improve social communication, behavior, and functional skills in children with ASD. Additionally, results showed that VM and VSM not only promote skills acquisition but also have a lasting effect. While this study focused on children with ASD, it appears that VM and VSM may be promising approaches for social skills training in children with ID, provided they possess the prerequisite skills for these procedures. Note, these will be addressed later in this chapter.

Magee Quinn, Kavale, Mathur, Rutherford, and Forness (1999) conducted a meta-analysis on social skills interventions for students with emotional or behavioral disorders (EBD). Examining the data from 35 studies, their database yielded a pooled mean effect size of only 0.199, reflecting only a small gain as a result of a social skills intervention. These results are comparable to a meta-analysis examining the effects of social skills interventions on students with learning disabilities (Kavale & Forness, 1996) which found a mean effect size of 0.211. Magee Quinn et al. conclude that because developing appropriate social skills is critical to functioning in our society, social skills training should be refined and not eliminated.

Höher Camargo et al. (2016) examined behaviorally based interventions to teach social interaction skills for children with ASD in inclusive settings. All studies included in their analysis used peer or adult modeling, different prompt hierarchies and types (e.g., most to least or least to most hierarchy and verbal, visual, written, or tactile prompt), and/or positive reinforcement (e.g., praise, tangibles, and/or edibles) with a combination of these techniques used across the studies. Results indicated an overall effect size of 0.88 indicating a high magnitude of change. The authors concluded that "behaviorally based interventions were highly effective for improving social interaction skills of young children with ASD (ages 2–10) included in general education" (p. 240).

Whalon, Conroy, Martinez, and Werch (2015) performed a meta-analysis to evaluate the impact of school-based interventions to facilitate the peer-related social competence of children with ASD. Using results from 37 studies, target behaviors generally fit into one of four categories: initiations, responses, interactions, and engagement. Results indicated that studies using an adult-mediated intervention had a mean of 93% for non-overlapping data points and an effect size (Tau-U) of 0.85 indicating a positive impact on the social interactions of children with ASD. Studies using social narratives produced mixed findings with a mean overall of non-overlapping data points of 83% and an effect size of 0.65 (Tau-U). Targeting engagement was high (mean non-overlapping data points = 99%, *Tau-U* = 0.94) but variable for interactions (mean non-overlapping data points = 80%, *Tau-U* = 0.60), initiations (mean non-overlapping data points = 64%, *Tau-U* = 0.42), and responses (mean non-overlapping data points = 67%, *Tau-U* = 0.34). Results from VSM/VM studies were mixed (mean non-overlapping data points = 86% *Tau-U* = 0.71), but there was a large range between studies (non-overlapping data points = 57%–99%, *Tau-U* = 0.13–0.97). These results led the authors to conclude that "peer-related social competence interventions delivered in school settings produced a moderate to high impact regardless of intervention type (i.e., child-specific, peer-mediated, multi-component, and collateral skill), child characteristics (e.g., social initiations prior to intervention, cognitive ability, age), or outcome measure" (p. 1526).

Sukhodolsky and Butter (2007) identify five main techniques used in social skills training (SST) for children with intellectual disabilities: instruction, modeling, rehearsal, corrective feedback, and reinforcement for appropriate performance. Some SSTs rely exclusively on operant conditioning techniques (e.g., positive reinforcement), but most also include social learning models to aid in skill development. The goal of most SSTs with children with ID is usually the development of specific social skills as opposed to broader social interactional constructs. Depending on the developmental level of the child, targeted skills may differ in complexity from simple responses such as saying hello, making eye contact, and smiling to more complex behavioral repertoires used in interpersonal and vocational settings.

Promoting Skills Acquisition. Skills acquisition is the first thing that must be done when the child lacks the skill and there are no interfering behaviors. Modeling is frequently used in promoting skills acquisition. It is based on Bandura's

(1969) social learning theory. The basic premise is that by observing the successful demonstration of a task, the viewer learns to perform the task effectively. Modeling has consistently been shown to be an effective and efficient way to teach social behavior. The behavior to be modeled can be a simple discrete behavior or can involve an entire sequence of behaviors involved in a social skill. Coaching is another technique that can be used in skills acquisition. This is just direct verbal instruction where you provide rules, have the child rehearse behavior, and they you provide feedback.

Enhancing Skill Performance. The goal with this approach is to increase the likelihood of the social skill in a child who is not performing it by increasing the strength of the social skill and not by targeting the interfering behavior. In other words, by increasing the strength of the social skill, you indirectly weaken the interfering behavior. Techniques that can be used to enhance skill performance include behavioral rehearsal, reinforcement, peer initiation strategies, and cooperation learning strategies. Behavioral rehearsal involves having the child rehearse the behavior until they feel comfortable with it. Reinforcement-based techniques involve using contingency management, particularly positive reinforcement, to reinforce appropriate social skills at home and in classroom. Peer-initiation strategies incorporate other children in the class to initiate social contact with the target child as a cue to trigger the desired social behavior in the target child. In other words, you are providing the child with appropriate antecedents in the environment to signal particular social behaviors. Cooperation learning strategies are generally implemented through a group format where you use many of the other techniques described above while working on cooperative interactions. Role-playing is also used as a technique in cooperative learning.

Removing Interfering Behaviors. Unfortunately, many people overlook interfering behaviors and just try to teach positive behaviors without attempting to lessen the extent of any interfering behaviors that may exist. An assumption many people make is that the child is engaging in the inappropriate behaviors because he/she lacks appropriate social skills. This may be true sometimes, but many times work needs to first focus on the interfering behavior. Techniques such as response cost procedures, group contingencies where the entire class is targeted for behavior change (Skinner, Skinner, & Burton, 2009), or overcorrection in the form of positive practice or restitution are used.

Facilitating Generalization. One of the greatest weaknesses in social skills training is a lack of generalization and maintenance (Gresham, 2016). If you want the behavior to generalize to the natural environment, you must incorporate it into training. To facilitate generalization it is recommended that you take advantage of natural reinforcement. In other words, recognize what naturally occurring reinforcement exists in the environment, and use that as much as possible. You should also train diversely. That is, do not just take just one approach. Train the individual that there are different ways to handle situations. Emphasize that things do not proceed in real world exactly the way they did in the training environment. Make the individual aware of problems they may encounter. Of greatest importance with individuals with ID is to incorporate functional mediators into their environment. The narrow confines of the SST training environment, be it school or other controlled setting, simply may not give the individual enough training opportunities. Adults (e.g., teacher, parent), or possibly siblings or peers, can act as a mediator and coach in the natural environment. They can provide antecedent cues for engagement in certain behaviors and provide reinforcement (both verbal and tangible) on the occurrence of prosocial behaviors.

Discrete Trials

Discrete trials training is a practical instructional method used for implementing social and academic skills to students with ID and ASD. DTT incorporates the principle of ABA by focusing on a systematic way to facilitate learning, prompting accurate responding, correcting response errors, and delivering positive reinforcement (Leblanc, Ricciardi, & Luiselli, 2005). Anderson, Taras, and Cannon (1996) identify four distinct parts to DTT: (1) the trainer's presentation, (2) the child's response, (3) the consequence (e.g., reinforcement), and (4) a short pause between the consequence and the next instruction (between interval trials). Cooper, Heron, and Heward (2007) define a discrete trial as "any operant whose response rate is controlled by a given opportunity to emit the response. Each discrete response occurs when an opportunity to respond exists" (p. 694). DTT has established a history of effectiveness as the primary method used in early intensive behavioral interventions for ID and ASD students (Eikeseth, Smith, Jahr, & Eldevik, 2007). The use of DTT programs for students in schools is rare (Peters-Scheffer, Didden, Mulders, & Korzillus, 2010), primarily due to requirements for one-to-one instruction and the training required of staff (Dart, Radley, Furlow, & Murphy, 2017). Dart and colleagues tried to overcome some of the difficulties encountered in using DTT in schools by training high school students to implement DTT. Results indicated that while brief didactic training was not sufficient to produce acceptable levels of treatment integrity, a more intensive behavior skills package of training did produce acceptable levels of integrity.

Social Stories

Social stories are a growing topic in the education field. They are a behavioral intervention to improve children's social skills through a combination of visual and verbal cues. Their use is primarily with children who have been diagnosed with mild to severe disabilities and have been to teach appropriate skills such as interacting with others, prompting, joining-in behavior, sportsmanship, maintaining a conversation, specific skills acquisition, responding to cues, and describing settings (O'Hara, 2010). Barry and Burlew (2004) describe social stories as including empirically validated components such as modeling, task analysis, visual aids, practice and corrective feedback, and priming. When using social stories, the child or someone with whom he/she identifies reads a story that describes the character's behaviors, thoughts, and feelings as he/she accomplishes the behavioral goals outlined in the story (Barry & Burlew, 2004). Other people's perspectives can also be included in the story. McGill, Baker, and Busse (2015) conducted a meta-analysis of 27 single-subject research studies ($n = 77$) on social stories and found moderate to large treatment effects ($ES = 0.79$). They appear to be a promising treatment option for children with ID although the totality of the research indicates future research is still needed.

Role-Playing/Behavioral Rehearsal

It may be difficult to teach complex social behaviors using a strictly rule- and instruction-based approach (Bilich & Ciarrochi, 2009), and experience is a needed component to learn most social skills. Role-playing provides a venue in which individuals can practice behaviors which are emerging, or which they may find difficult, in a relatively safe setting. Role-playing/behavioral rehearsal has been used extensively to teach basic social interaction skills as well as other more complex social skill-related behaviors. It is an effective approach to teaching social skills that allows for the positive practice of skills (Gresham, 2010). Role-playing involves acting out situations or activities in a structured environment to practice newly acquired skills and strategies, or previously learned skills that the child is having difficulty performing. Role-plays can be either scripted or less structured with built in prompts. An important consideration in determining whether to use role-play in an intervention with an individual with an intellectual ability is the level of functioning and their ability to pay attention and take the perspective of another.

Video Self-Modeling

Video self-modeling (VSM) is a cognitive behavioral technique that provides participants with visual images of themselves performing a target behavior, such as on-task behavior, or interacting appropriately with peers. While it has been used primarily with individuals with ASD, it should be equally effective with individuals with ID. A video modeling intervention typically involves an individual watching a video demonstration of a model engaging in specific a behavior and then imitating the behavior in the video. The model can be a parent, teacher, therapist, another adult, age-level peer, or in the case of VSM, the model is the child him/herself (Bellini & Akullian, 2007; D'Ateno, Mangiapanello, & Taylor, 2003; Dowrick, Kim-Rupnow, & Power, 2006). The model is video recorded within a certain context (e.g., the classroom or playground). The recording is then edited to remove all instances of inappropriate behavior. The result is a video clip displaying the individual behaving appropriately and displaying the correct, targeted behavior.

Video self-modeling is a technique where individuals view themselves performing a desired behavior on video in order to increase the occurrence of that behavior or behaviors. Participants view their own positive behavior on edited video clips where all evidence of inappropriate and maladaptive behavior is removed. Bandura's (1977) social cognitive learning theory provided the theoretical basis for VSM. His view of learning emphasized the ability to learn through observation. Gul and Vuran (2010) write that the theory suggests that individuals gain knowledge and skills by observing behaviors which are displayed. The main advantage of this type of learning is that it provides the learner with clear information on how best to perform the skill. Bandura (1977) identifies four steps in the process of learning through modeling: (1) the individual must attend to the events being modeled, (2) modeled behavior must be retained, (3) symbolic representation of the behavior is converted into appropriate actions similar to the originally modeled behavior, and (4) the individual must be motivated to replicate the modeled behavior. Bandura goes on to explain that the success of the model being observed depends largely on the similarities between the observer and the model. The higher the number of similarities, the higher the success of the observer engaging in desired behavior. Gul and Vulcan concluded that video modeling interventions, where participants took part as the model, acquired target skills in a shorter time compared to participants who were not the model. VSM maximizes its chance of success by using the observer as the model of the desired behavior (Gelbar, Anderson, & McCarthy, 2012). Buggey (2007) writes that self-efficacy is at the heart of VSM with VSM helping to promote self-efficacy by providing participants with visual evidence that they can succeed or achieve the target.

Conclusion

Social skill excesses and deficits are a defining aspect of intellectual disabilities. Intervention targeting improving areas of deficit and decreasing excesses can aid in normalization and improve quality of life. This chapter reviewed definitions of social skills both in general and in the context of intellectual disabilities. It further broke down social skills into seven specific domains, communication, cooperation, assertion, responsibility, empathy, engagement, and self-control, and discussed the importance of each. A number of approaches to social skills training were also discussed with specific emphasis placed on interventions for individuals with intellectual disabilities ranging from discrete trials training which has been used to teach specific social behaviors to individuals with more severe intellectual disabilities to role-playing and video self-modeling which can be valuable treatment approaches for those with a higher level of functioning. Regardless of the approach used for SST, it is important to recognize the importance of incorporating procedures to increase the likelihood of generalization and maintenance of the learned behavior.

Coping Skills Training in Individuals with an Intellectual Disability

Renae Beaumont, Amy Lemelman,
Jennifer Schild, and Karen Tang

Introduction

The mental health and well-being of individuals with an intellectual disability (ID) have received scant empirical attention until the past 20 years. This chapter provides an overview of therapy approaches that have been evaluated for children, adolescents, and adults with an ID, including cognitive behavioral therapy and mindfulness-based interventions. A critical analysis of contemporary research evaluating the effectiveness of these treatments for a range of mental health issues is presented, together with a description of how the content and process of therapy can be appropriately tailored to meet the needs of clients with an ID. Core principles for adapting therapy are also illustrated with a case example. The chapter concludes with recommendations for future research to improve the quality and accessibility of mental health services to this underserved population.

Until the twenty-first century, the mental health and well-being of individuals with intellectual disabilities (ID) received little empirical attention (Whitehouse, Tudway, Look, & Kroese 2006). Arthur (2003) largely ascribes this to institutionalization, which, for many, led to an attitude of "out of sight, out of mind" (p 26). More recent research shows that individuals with ID experience full emotional lives (Jones, Miller, Williams, & Goldthorpe 1997), have the ability to reflect on and describe their emotional states (Stenfert Kroese, Dagnan, & Loumidis 1998), and suffer from the same mental health problems as the general population, often at higher rates (Lunksky et al. 2012). Smiley (2005) reported the prevalence of mental illness in people with ID to be between 30% and 50%, with Cooper, Heron, and Heward (2007) reporting a 40.9% prevalence rate in a population study. However, "diagnostic overshadowing" often results in mental health issues being underdiagnosed in individuals with an ID (Hemmings, Deb, Chaplin, Hardy, & Mukherjee 2013). This refers to presenting concerns being attributed to patients' ID or clinicians' attention being focused on reducing overt challenging behaviors, rather than investigating and treating mental health issues that may contribute to them.

Historically, individuals with ID have had very limited access to interventions for psychological

problems (Dodd & McGinnity 2003; Lynch 2004). Bender (1993) attributes this to the reluctance of many mental health professionals to treat this client group, perhaps due to assumptions about these individuals being unable to effectively participate and collaborate in treatment due to their disability. Heifetz and Dyson (2017) also note a tradition in the ID field for professionals to overly rely on behavior modification techniques and medication to address patient psychological or behavioral issues. These methods appear to show limited concern for the client's well-being (Stenfert Kroese 1998) and, in many cases, may be more aligned with meeting the needs of service providers or carers (Waitman & Reynolds 1992).

Encouragingly, in more recent times, studies examining the effectiveness of psychotherapeutic interventions for individuals with ID have begun to emerge. These have predominantly included evaluations of psychotherapy for anxiety (e.g., Douglass, Palmer, & O'Connor 2007; Lindsay, Neilson, & Lawrenson 1997; Marwood & Hewitt 2012), depression (e.g., Hassiotis et al. 2013; Unwin, Tsimopoulou, Stenfert Kroese, & Azmi 2016), and anger (e.g., Nicoll, Beail & Saxon, 2013; Willner et al. 2013). Most studies have been conducted with adults who have mild-to-moderate ID and have involved evaluations of CBT and, more recently, mindfulness-based interventions. This chapter provides an overview of psychological intervention techniques that have some empirical basis for children, adolescents, and adults with an ID, together with a critical analysis of the evidence supporting these approaches. The chapter also describes how the content and process of therapy can be successfully adapted for clients with an ID, including a case example. Lack of clinician knowledge, skills, and confidence in how to effectively tailor therapy to meet the needs of individuals with an ID is purported to be a major contributor to the lack of service availability for this client population (Whitehouse et al. 2006). This handbook is an important step in bridging this professional practice gap.

Cognitive Behavior Therapy for Adults with an ID

A central premise of CBT is that psychological disorders are characterized by distorted or dysfunctional thinking (Beck 1976). As such, clients learn to develop more helpful thinking patterns and behaviors by changing their thoughts, attitudes, and beliefs, in addition to making more realistic or adaptive assessments of events that cause distress (Beck 1976; Willner 2009). Success in CBT requires the client to engage in cognitive and behavioral tasks, such as identifying automatic thoughts; cognitive monitoring; identifying relationships between thoughts, feelings, and behaviors; relaxation skills training; cognitive restructuring; and engaging in behavioral experimentation (Beck 2011; Cooney, Tunney, & O'Reilly, 2018).

Case studies, small sample trials, and systematic reviews evaluating CBT for adults with an ID have demonstrated successful outcomes in some individuals with mild-to-moderate ID with a comorbid diagnosis. These include those with anxiety (Douglass et al., 2007; Lindsay et al., 1997; Marwood & Hewitt, 2012; Willner, 2005), depression (James, 2017; McCabe, McGillivray & Newton, 2006; McGillivray, McCabe & Kershaw, 2008; Unwin et al., 2016), anger (Hamelin, Travis & Sturmey, 2013; Nicoll et al., 2013; Taylor, Novaco, Gillmer, Robertson & Thorne, 2005), post-traumatic stress disorder (Carrigan & Allez; 2017; Kroese et al., 2016), obsessive compulsive disorder (Willner & Goodey, 2006), and psychosis (Kirkland, 2005; Lindsay, 1999; Willner, 2005, 2009). Recently, a small number of between-group comparison studies and randomized controlled trials have also supported the effectiveness of CBT for individuals with mild-to-moderate ID who experience issues with anger (Willner et al., 2013), anxiety (Cooney, Jackman, Coyle & O'Reily, 2017), and/or depression (Hartley et al., 2015; Hassiotis et al., 2013; Lindsay et al., 2015; McGillivray & Kershaw, 2015). New research also suggests that computerized cognitive behavioral therapy is an engaging approach to increase the accessibility of effective CBT interventions for individuals with ID (Cooney et al., 2017; Cooney, Jackman, Tunney, Coyle & O'Reily, 2018).

Lindsay's (1999) work with adults with an ID demonstrated that the core techniques used in CBT, such as agenda setting and homework assignments, could be implemented with adults with an ID if clinicians made modifications in their delivery of treatment. Stenfert Kroese et al. (1998) stated that modifications to CBT for adults with an ID may also include facilitating valid self-reports and accommodating the client's level of comprehension and expression of abstract concepts. However, published studies typically do not provided details on how CBT was implemented (Prout, Chard, Nowak-Drabik, & Johnson, 2000; Prout & Nowak-Drabik, 2003), so it remains unclear to what extent modifications can be made while also maintaining the integrity of the original psychotherapeutic model (Flynn, 2012) and which elements of treatment are integral to treatment success (Whitehouse et al., 2006; Willner, 2005). Cooney, Tunney, et al. (2018) conducted a systematic review of 18 studies evaluating CBT skills for adults with an ID, including emotion regulation; discriminating between thoughts, feelings, and behaviors; connecting events to emotions; and cognitive mediation (i.e., recognizing the mediating role of a thought in the thought-feeling-behavior relationship). A description of their findings regarding the appropriateness and value of each of these skills for adults with an ID is provided below.

Emotion Regulation

Adults with an ID were more effective in identifying emotions if they had a larger receptive language vocabulary and were able to point to a visual depiction of an emotion rather than having to verbally describe it (Cooney, Tunney, et al., 2018; Willner, 2006). Cooney, Tunney, et al. (2018) recommend that clinicians use photographs of faces expressing emotions with context, rather than photographs without context or line drawings, to guide emotion recognition by adults with an ID (especially those with moderate cognitive impairment).

Discriminating Between Thoughts, Feelings, and Behaviors

Willner (2006) found that adults with an ID were able to identify their feelings and behaviors but struggled with identifying their thoughts in isolation, even with training. A study by Vereenooghe, Gega, Reynolds, and Langdon (2016) showed that although adults' ability to identify thoughts within the context of a thought-feeling-behavior relationship increased with training, this improvement did not translate to situations where they were asked to identify thoughts in isolation.

Connecting Events to Emotions

Willner (2006) found that adults with ID were able to make a connection between events and emotions. Moreover, as an individual's level of expressive language ability increased, so did their ability to make the connection between events and experienced emotions.

Cognitive Mediation

Cognitive mediation is the ability to identify the mediating role of a thought in a thought-feeling-behavior relationship (Beck, 1976). Cooney, Tunney, et al.'s (2018) systematic review showed that adult participants with an ID were better able to understand and engage in cognitive mediation when presented with a congruent scenario (i.e., situations, feelings, and behaviors were all positive or all negative) relative to an incongruent scenario, where a negative situation was paired with a positive emotion or belief or vice versa. Cognitive mediation ability in adults with an ID was also boosted when the stimulus was presented in pictures rather than verbally alone. A study by Richardson et al. (2016) also suggested that individuals with an ID may be better able to identify mediating cognitions in personally relevant situations, relevant to arbitrary scenarios.

Cognitive Behavior Therapy for Children with an ID

Much of the research evaluating CBT for children with ID has focused on the treatment of fears and anxiety. For example, early research (Obler & Terwilliger, 1970) used a modified version of systematic desensitization to address specific phobias (e.g., fear of using a public bus or fear of the sight of a live dog) in 15 “neurologically impaired” children aged 7–12. The authors noted that their modified version of systematic desensitization differed in that there was no training in relaxation provided to the participants, participants were not required to create a fear hierarchy, and the participants were not expected to verbally indicate their anxiety level during exposure sessions. Specifically, treatment involved having the participants look at pictures of the fear-inducing stimulus instead of using imaginal exposure paired with progressive muscle relaxation. Once it was determined that the participants could tolerate looking at pictures of the stimulus, they were exposed in vivo. Instead of the participants using relaxation methods while viewing the fear-inducing stimulus, the therapist would act as a buffer between the participant and the stimulus and would praise the participant for successfully tolerating the exposure. High-potency reinforcement (toys, candy) were provided to the participants for eventually tolerating the stimulus without the therapist present. All children with IQs 75 or lower, as measured by the Wechsler Intelligence Scale for Children, were at a minimum able to tolerate the feared stimulus in the presence of another individual, with some participants able to independently tolerate the stimulus by the end of treatment. This early study demonstrated methods for modifying systematic desensitization for use with children with ID.

Davis, Kurtz, Gardner, and Carman (2007) also examined the utility of CBT to treat specific phobia in children with ID through a case study. This case study examined the effectiveness of a variant of CBT, one-session treatment (OST; Öst, 1989), to address the specific phobias (i.e., fear of water and heights) of a 7-year-old verbal child with “mild cognitive delays.” OST was delivered without adaptations and consisted of a 3-h session of graduated, in vivo exposure. The OST incorporated participant modeling, verbal and physical praise for approaching the feared stimulus, psychoeducation, and cognitive challenging. The child was never forced to approach the feared stimulus; however, the child and therapist negotiated how to move up the steps in his fear hierarchy. By the end of treatment for each feared stimulus, the child was able to complete the last steps in his fear hierarchies. At follow-up assessments, the child no longer met diagnostic criteria for either specific phobia. This research presented preliminary evidence for the use of one type of CBT, OST, to treat specific phobias in children with ID. However, since the participant was verbal and had “mild cognitive delays,” it is unclear what the effectiveness of this treatment is for nonverbal, more cognitively impaired children.

Another variant of CBT, cognitive behavioral play therapy (CBPT) has been examined for its ability to improve self-esteem in children with an ID (Bana, Sajedi, Mirzale, & Rezasoltani, 2017). Specifically, Bana et al. (2017) compared children aged 8–12 with IQs between 50 and 70 who received CBPT to a control group that was age- and IQ-matched. CBPT consisted of 12 1-h sessions administered in groups of five children each. During each CBPT session, children played with toys and participated in group games targeting predetermined objectives. Each session had different objectives such as identifying feelings, communicating with body language, focusing on children’s personal strengths, increasing self-esteem, and improving communication and cooperation among children. For example, in one session, children played with Lego blocks to increase their imagination abilities. Following treatment, comparisons between the treatment and control groups revealed that children who received the CBPT made significant improvements on a self-report measure of their self-esteem. The authors noted that previous research (Baggerly, 2004) has shown that improvements in self-esteem after play therapy also led to reduced anxiety and depression in a population of homeless children, although no information was given regarding the intellectual functioning of these children. Therefore, conclusions cannot be drawn regarding the effectiveness of CBPT as a mood enhancement intervention for children with ID.

Other researchers have focused on adapting manualized CBT programs for children, such as the Coping Cat program (Kendall & Hedtke, 2006). This program is recommended for anxious youth aged between 7 and 13 years with an IQ of at least 80, although it has been noted that the treatment can be modified for children with ID (Beidas, Benjamin, Puleo, Edmunds & Kendall, 2010). An example of this is illustrated in a 2006 case study by Suveg, Comer, Furr, and Kendall (2006). The authors described the treatment of an 8-year-old female with cognitive abilities in the borderline range (Full Scale IQ = 78) and learning difficulties in most academic areas. Initial assessment indicated that she met criteria for three anxiety diagnoses, social phobia, generalized anxiety disorder, and selective mutism. Her treatment plan which was based on the Coping Cat program (Kendall & Hedtke, 2006) was individualized to ensure that CBT methods were compatible with her abilities. Additionally, treatment had a focus on physical movement, such as dancing or active games, and placed less emphasis on metacognitive content. Further, increased repetition and drawing activities helped the patient understand and retain concepts. Some concepts were emphasized, such as understanding the physical symptoms of anxiety, and some were deemphasized, such as identifying maladaptive cognitions. The patient participated in 20 sessions of this modified CBT treatment and showed significant improvement across multiple domains of anxiety posttreatment, including no longer meeting criteria for generalized anxiety disorder or selective mutism. Although only a case study, this publication is important as it describes the specific modifications made to a widely accessible manualized treatment that clinicians can use with their own clients.

Much of the recent research examining the effectiveness of CBT for children with ID has focused on children with comorbid autism spectrum disorder (ASD). Similar to the ID literature on children without ASD, researchers have used strategies such as systematic desensitization to address phobias in children with ASD and ID. For example, Luscre and Center (1996) used systematic desensitization paired with video modeling and reinforcement to decrease fear of the dentist in three children aged six to nine who were functioning at the "severely mentally retarded level." Another study (Ricciardi, Luiselli, & Camare, 2006) used contact desensitization procedures, which involved shaping of approach responses, to gradually expose an 8-year-old child with ASD and cognitive delays to his feared stimulus (i.e., electronic animated toys). Both of these studies provide additional evidence for the use of graduated exposure-based interventions to address phobias in children with ID. However, they, like so many studies in the ID literature, fail to provide a clear indication of the IQs and functional abilities of the participant sample.

A case study by Mullins and Christian (2001) utilized progressive muscle relation to reduce disruptive behaviors in a 12-year-old boy with ASD and "mild mental retardation." The authors used adapted progressive muscle relaxation procedures to create a training book for the child to use during sessions. The therapist provided a series of most to least intrusive prompts to encourage the child to practice the steps of the relaxation procedures in the book. After 11 sessions, the child was able to perform the steps of progressive muscle relaxation independently with only the use of the book as a guide. After this training phase, the child was cued to complete the progressive muscle relaxation prior to engaging in a leisure activity. The child's disruptive behavior (i.e., loud screams, other vocal sounds, repetitive statements, hand and toe chewing, nose picking, and finger picking) was monitored during the leisure activities, and results indicated that the child engaged in less disruptive behavior during leisure activities posttreatment as compared to pretreatment. However, the child's disruptive behavior was not completely eliminated, and the child still had to be cued to engage in the progressive muscle relaxation, limiting its generalizability to other settings when the child was not cued to use this strategy.

Moskowitz et al. (2017) described a combination of CBT and applied behavior analysis/positive behavior supports (ABA/PBS) therapy to treat anxiety in three children aged six to nine with adaptive or intellectual abilities in the "low" range. Each child's treatment package was individualized based on the parent's report of which strategies would best fit their child. The CBT components used were graduated exposure, psychoeducation, and cognitive restructuring, while the ABA/PBS strategies used were increasing predictability, visual schedules, social stories, priming/video priming, providing choices, reinforcement/counterconditioning, and incorporating perseverative interests. Additionally, consequence-based strategies used were positive reinforcement contingent on approach, differential reinforcement of alternative behavior, and escape extinction. Following the application of the intervention procedures, all three children had significant reductions in anxious behaviors, as coded by blind raters.

Similarly, Parent, Birtwell, Lambright, and DuBard (2016) combined CBT and behavioral techniques to address verbal and physical aggression in a 12-year-old boy with ASD who had cognitive abilities at the first percentile. CBT strategies taught included taking deep breaths, reaching out to a familiar adult for help, cognitive restructuring for maladaptive thoughts, identifying triggers for aggression, and asking for a break when upset. These strategies were taught using behavior analytic principles, such as creating a task analysis for each technique and teaching smaller steps until they were mastered. Additionally, visual materials were used to help teach these techniques. The child participant's rate of physical and verbal aggression significantly reduced following intervention. Additionally, at post-intervention, he was using coping skills more than 80% of the time without prompting.

Gobrial and Raghavan (2017) examined the effectiveness of a parent-delivered anxiety management program, the Calm Child Programme (Gobrial & Raghavan, 2017), for seven 5- to 14-year-old children with a diagnosis of ASD and mild-to-moderate ID. The program featured a manual that taught parents to use proactive strategies (e.g., visual schedules, talking and explaining, relaxation, and physical activities) to prevent their child's anxiety, communication strategies (e.g., anxiety thermometer) to help their child to self-regulate, and reactive strategies (e.g., distraction, quiet time, having fun, comfort strategies) to manage their child's anxiety. Children's anxiety scores from pre- to posttreatment significantly decreased based on a parent report questionnaire. However, as parents were both the program evaluators and deliverers, rater bias may have influenced these results.

Collectively, the findings from the studies described above suggest that CBT holds promise for children with ID (and comorbid ASD), especially when used to treat anxiety and when supplemented with other behavioral supports and teaching strategies. However, large-scale controlled studies are needed to evaluate the effectiveness of CBT for upskilling children with ID in how to cope with a range of emotions, beyond anxiety.

Cognitive Behavior Therapy for Adolescents with an ID

Research suggests that adolescents with mild-to-moderate ID have the potential to greatly benefit from CBT when appropriate adaptations are made (Hronis, Roberts, & Kneebone, 2017). Teens with mild-to-moderate ID often have more severe depression, anxiety, and antisocial behavior than teens with more profound ID (Einfeld & Tonge, 1996), which in part may be due to a greater awareness of the challenges that they face (White et al., 2010). However, this same insight can help them to optimally engage in and benefit from CBT. For example, Singh et al. (2013) demonstrated the effectiveness of 20 sessions of exposure with response prevention over 4 weeks in reducing the OCD symptoms of an 18-year-old man with mild intellectual disability. A differential

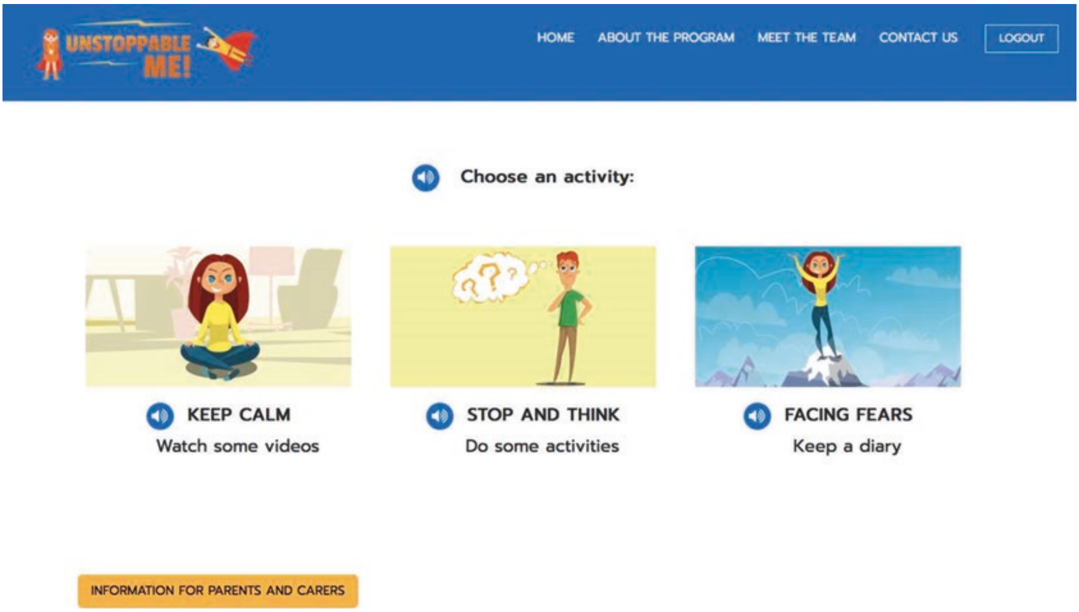

Fig. 38.1 Screenshot from Hronis et al.'s (2018) Fearless Me! online anxiety treatment program for youth. Reproduced with authors' permission

reinforcement system was used to motivate the patient to engage in therapeutic tasks, and his mother was trained as a co-therapist. Treatment gains were maintained at 1-year follow-up. However, as the patient was concurrently taking fluoxetine and clomipramine, the unique contribution that therapy made to his improved functioning could not be determined. Hronis, Roberts, Roberts, and Kneebone (2018) have also developed an online CBT anxiety treatment program (Fearless Me!) for 8- to 18-year-olds with mild-to-moderate ID (www.unstoppableme.com.au), which was being evaluated at the time of this publication. The intervention teaches relaxation strategies, helpful thinking approaches, and the importance of exposure in overcoming fears, as shown in the screenshot illustrated in Fig. 38.1.

Conclusions Regarding Cognitive Behavioral Therapy for Individuals with an ID

While there is a growing evidence base supporting the effectiveness of CBT for children, adolescents, and adults with an ID, the majority of studies have been uncontrolled and performed with small sample sizes and lack follow-up data examining the durability of treatment gains. Furthermore, it is not clear which ingredients in CBT treatment packages are the most powerful in producing positive change: the behavioral strategies, cognitive techniques, or both (Sturmey, 2006). More recently, empirical attention has turned to a third generation of behavioral therapies for individuals with ID: mindfulness-based approaches.

Mindfulness-Based Interventions for Individuals with an ID

Acceptance and commitment therapy (ACT) is a behavioral therapy model that focuses on changing one's relationship with the meaning of an event through psychotherapeutic strategies such as mindfulness, experiential engagement, and cognitive defusion (Hayes, Luoma, Bond, Masuda, & Lillis, 2006; Leoni, Corti & Cavagnola, 2015). In ACT, mental health issues are perceived to stem from avoiding unwanted internal thoughts and emotions. By distancing oneself from these thoughts and reconnecting people with their values, ACT aims to help clients to live the life they want to live, rather avoiding uncomfortable or unwanted aspects of it (Leoni et al., 2015). In one of the first studies examining ACT with an individual with an ID, Brown and Hooper (2009) found that CBT was not appropriate for an 18-year-old female participant with moderate-to-severe ID due to her limited language skills and poor verbal reasoning abilities. However, the participant was able to engage in experiential activities to learn to recognize and separate herself from anxious and obsessive thoughts, resulting in decreased functional impairment (Brown & Hooper, 2009).

Mindfulness is one of the fundamental techniques used in ACT. It refers to an individual's ability to nonjudgmentally pay attention to their thoughts, feelings, and perceptions as they occur (Hayes et al., 2006; Leoni et al., 2015). For individuals with ID, mindfulness-based therapies offer a way of accommodating new ways of seeing problems, thereby changing the relationship they have with unhelpful thoughts about themselves, and past, present, or feared future experiences of exclusion or rejection (Idusohan-Moizer, Sawicka, Dendle & Albany, 2015). Mindfulness aims to reduce experiential avoidance by helping individuals to become aware of and normalize unpleasant emotions and body sensations without engaging in futile efforts to avoid or escape them (Idusohan-Moizer et al., 2015). In contrast to CBT, which aims to change or challenge unhelpful thoughts, mindfulness focuses on being aware of these thoughts and letting them go without getting caught up (fused) with them (Idusohan-Moizer et al., 2015). Such concepts are simplified for individuals with ID through visual metaphors and analogies such as "dropping the rope" in a "tug of war" (Hayes, Strosahl & Wilson, 1999).

Emerging literature shows some evidence supporting the effectiveness of mindfulness-based procedures for individuals with an intellectual disability. For example, Singh et al. (2014) conducted a randomized controlled trial evaluating the effectiveness of a mindfulness-based smoking cessation program with 51 participants with mild ID. The program included basic concentration meditation, setting a daily intention, mindful observation of thoughts, and Meditation on the Soles of the Feet (shifting focus from emotionally arousing thoughts to the soles of one's feet). Results showed that participants in the mindfulness condition showed a significantly greater reduction in smoking relative to those in the treatment as usual condition, with gains maintained at 1-year follow-up.

Further evidence for the effectiveness of mindfulness techniques for individuals with ID, their parents, and paid carers is provided by a systematic review conducted by Chapman et al. (2013). An analysis of 11 studies showed improvements in aggression, sexual arousal, and psychological well-being in participants with mild-to-moderate IDs following mindfulness training, decreased use of physical restraint for aggressive behavior by care staff and improved parental well-being, parent satisfaction, and parent-child interactions (Chapman et al., 2013). Participants in the reviewed studies were predominantly adults with ID, although they did include individuals from White, African-American, and Hispanic populations, suggesting that mindfulness is acceptable and effective for people from diverse cultural backgrounds. Feedback from participants suggested that optimal mindfulness training involved clear instructions, regular practice, the use of concrete examples, and role-play.

Beauchemin, Hutchins, and Patterson (2008) demonstrated that mindfulness meditation can also be valuable for adolescents with ID. Following a 5-week intervention, adolescents aged 13–18 ($n = 34$) showed a significant improvement in their state and trait anxiety, academic performance, and social skills, based on teen and parent report measures. Adolescents also reviewed the program favorably. Furthermore, a case study by Singh et al. (2008) demonstrated that the Meditation on the Soles of the Feet program helped a 17-year-old with Prader-Willi syndrome and mild ID to self-manage his hunger to prevent overeating.

Idusohan-Moizer et al. (2015) examined the effectiveness of a 9-week group mindfulness-based CBT program for 15 adults with borderline, mild, or moderate ID who had recurrent depression and/or anxiety and a history of deliberate self-harm behavior. Results showed the intervention to be effective in improving participants' experience of self-reported depression, anxiety, self-compassion, and compassion for others, with improvements maintained at 6-week follow-up. However, there was a higher dropout rate among participants with a moderate ID relative to those with borderline or mild ID, and participant motivation appeared to be influenced by carer/support worker engagement in group sessions. A unique feature of Idusohan-Moizer et al.'s (2015) mindfulness-based CBT program was a focus on compassion and kindness. Specifically, the authors acknowledged the role that shame, self-loathing, and self-criticism can play in depression and anxiety in individuals with ID and taught participants how to develop self-compassion: to "let go" of self-blame and painful memories to ease their suffering.

Heifetz and Dyson (2017) also demonstrated the potential of mindfulness-based group therapy with a sample of eight adolescents with mild ID and their parents. Results showed that an 8-week mindfulness-based group program for teens (with intermittent joint and parallel parent sessions) resulted in improvements in teens' mood and social behavior, as reported by their parents. There was also a trend for adolescents to report feeling more happy, relaxed, and less worried at the end of each mindfulness session relative to the beginning. However, some adolescents were reluctant to practice mindfulness skills outside of sessions, despite parental support (which was sometimes resisted) and the introduction of a points reward system.

Conclusions Regarding Mindfulness-Based Interventions for Individuals with an ID

Much like the CBT literature, many of the studies examining the effectiveness of mindfulness-based treatments for individuals with ID consist of reports on single case studies or small group pre-/post-treatment evaluations. Therefore, while this class of interventions holds promise, it is premature to conclude that it is appropriate and effective for individuals with ID. Furthermore, the comparative effectiveness of mindfulness-based interventions relative to more traditional CBT approaches is unknown. Future research is also needed to identify predictors of treatment outcome for both CBT and mindfulness-based programs, in addition to determining which individuals with ID respond best to individual versus group therapy.

Treatment Modifications for Individuals with an Intellectual Disability

Irrespective of the treatment approach, it is important to understand common barriers to treatment engagement for individuals with an ID and how these can be overcome. Individuals with an ID have, to varying degrees, impairments in how they acquire and process information, as well as possible challenges in episodic and/or prospective memory, such as projecting the self into past or future scenarios (Willner, 2009). Moreover, these cognitive impairments may also be associated with sensory differences, impaired attention, and poor executive functioning (Willner, 2009; Willner & Goodey, 2006). Another potential treatment barrier is impaired verbal abilities. Individuals with ID may lack experience in reporting on their emotions, giving their opinions, or making decisions (Willner, 2009). Lastly, client motivation may be a treatment barrier, which may arise from the psychological presentation, maladaptive beliefs, and cognitively challenging framework of the psychotherapeutic treatment (Willner, 2009).

With a better understanding of common barriers to treatment for individuals with an ID, clinicians are better equipped to modify therapy to better meet their clients' needs. Hurley, Tomasulo, and Pfadt (1998), together with other researchers in this field, suggest the following modifications to psychotherapeutic treatment for individuals with an ID.

Simplification

When working with individuals who have an ID, it is recommended to simplify treatment by shortening activities and sessions, segmenting the intervention into smaller regular parts over a longer period of time, and using simple language during discussion of the client's thoughts and feelings (Hernadez-Halton, Hodges, Miller, & Simpson, 2000; Reddy, 2015). It is also advised that clinicians be more directive and less collaborative to reduce the executive functioning demands placed on clients (Hronis et al., 2017).

Language

The language abilities of clients with an ID should be considered when tailoring therapy to meet their needs. It is suggested that clinicians use shorter sentences and simpler words and be more succinct in sharing their thoughts and more concise when setting the agenda at the beginning of each session (Hurley et al., 1998; Lindsay et al., 1997; Willner, 2009). It is also recommended that supplemental tools such as photographs, video clips, and illustrations are used to facilitate the client's understanding of core concepts and ideas, rather than text-dense written materials (Morin, Cobigo, Rivard & Lepine, 2010). Clinicians need to provide explanations and interpretations at a level that matches the client's level of understanding (Hwang & Kearney, 2013).

Activities and Supports

It is highly recommended that clinicians include supplemental activities and supports to promote client learning, understanding, and change (Hurley et al., 1998). These activities should include experiential learning exercises such as practicing mindfulness in session with therapist support, role-playing new skills, completing interactive worksheets that provide simple visual illustrations of skills and concepts, and capturing details of how skills were used between sessions via drawings or smartphone voice memos, photos, or videos if writing is challenging. Digital calendar reminders can also be scheduled to prompt skill usage in daily life. Supplemental activities not only deepen the client's understanding and skill in applying therapeutic concepts but also help the clinician to gauge the client's comprehension and capacity to use these techniques (Summers & Witts, 2003).

Developmental Level

It is of the upmost importance that clinicians consider the client's developmental level when presenting topics and material in session (Hurley et al., 1998). If necessary, materials such as cartoon strips (hand drawn or computer-generated), emotion masks, dolls, and games can be used to provide concrete illustrations of emotions and event sequences to patients. Caution is warranted when using materials such as these, however, as some adolescents and adults may consider them to be developmentally inappropriate.

Directive Approach

Clinicians working with individuals with an ID often need to take a more directive than collaborative approach (Hronis et al., 2017). A directive approach typically includes outlining the goals of therapy, discussing treatment progress, and providing supplemental materials to guide sessions (Hurley et al., 1998; Lindsay et al., 1997). Moreover, Stavrakaki and Klein (1986) recommend that clinicians use more direct strategies, such as suggestion, persuasion, and reassurance, when working with individuals with an ID relative to typically developing clients.

Flexible Methods

Clinicians working with clients with an ID are encouraged to be flexible in their delivery of treatment, including flexibility in the structure and length of sessions and treatment, incorporating techniques from different treatment modalities, and a willingness to frequently repeat core concepts and ideas (Drury & Alim, 2014; Leoni et al., 2015). Being flexible and creative in the delivery of treatment allows therapy to be aligned with a client's level of cognitive and language functioning. Research conducted by Whitehouse et al. (2006) showed that flexibility was the most common treatment modification used by clinicians when delivering CBT to clients with ID.

Involve Caregivers

Caregiver involvement often supports treatment progress for individuals with an ID (Willner, 2006, 2009). Caregivers can function as co-therapists, prompting, modeling, and/or rewarding patients' use of emotion regulation skills when needed in daily life (Heifetz & Dyson, 2017; Hurley et al., 1998). While care must be taken to give clients the opportunity to discuss personal information with the therapist in private, caregivers also serve a vital role in providing therapists with feedback on patients' progress.

Transference/Countertransference

Hurley et al. (1998) argue that it is particularly important for clinicians working with clients who have an ID to establish firm boundaries and have consistent peer supervision, as stronger attachments often quickly develop with this clientele relative to typically developing patients. Clinicians also need to be cognizant of negative countertransference feelings that may develop from the client's sensitivity to nonverbal communication due to their impaired language abilities (Hernadez-Halton et al., 2000).

Disability/Rehabilitation Approaches

The disability experienced by clients with ID needs to be sensitively explored in therapy (Hurley et al., 1998). This includes the stigma that is oftentimes associated with having an ID (Haddock, Lobban, Hatton & Carson, 2004). It is recommended that clinicians help clients to accept limitations that cannot be changed and to focus on working toward goals that are important and achievable (Idusohan-Moizer et al., 2015).

Case Example

T was a 13-year-old Hispanic boy with mild intellectual impairment (Full Scale IQ = 71) who lived in a shelter with his mother and attended a school for special needs students. He presented to therapy with a diagnosis of oppositional defiant disorder. T was frequently irritable and angry at home and at school and refused to follow his mother's instructions to tidy his things and complete his homework. He also became frustrated in response to his teacher's requests to complete schoolwork at school. T would often complain about schoolwork being "boring" and "stupid." T's mother indicated that his oppositionality was causing significant distress to herself and other shelter residents. T's teacher believed that his noncompliance was contributing to him underachieving at school and being disliked by his peers.

T's mother and teacher reported that they had tried to use a points chart in the past to encourage T to follow instructions at home and at school. T's mother described this as being largely unsuccessful at home, as she did not have the financial resources to provide T with rewards that he was motivated to earn. T's teacher described some initial success with the points chart; however, she indicated that T quickly lost interest in it.

Individual therapy with T initially focused on rapport building. T was angry that his mother had forced him to come to therapy, insisting that there was "nothing wrong" with him. During the first four therapy sessions, the clinician informally chatted with T and enquired about his interests (basketball, soccer). During these conversations, the therapist took turns shooting hoops with T using a mini basketball set and kicked a mini soccer ball with him. She found this informal approach of talking with T while doing another activity helped him to relax and open up.

In Session 5, the therapist started exploring with T what life at home and at school was like. T indicated that he often didn't understand what his mom and teacher were asking him, which annoyed him. T and the therapist took a photo of T with the therapist's iPad and digitally drew body clues on the photo to illustrate what "annoyed" felt like for T (tightness in his stomach, feeling energetic, thinking "What are they talking about?", shouting, and swearing). The therapist printed this out and, with T's help and permission, discussed the picture with T's mother at the end of session. The therapist asked T and his mom to be on high alert for when these body clues occurred during the week and to make a voice memo on the mom's smartphone of what was happening when they spotted them.

At the beginning of the next session, T and his mom shared three voice memos with the therapist: one made by T's mom and two by T. Two of the voice memos described T's frustration when trying to do homework, and one related to him not getting ready to go to school when asked. To help address the homework issue, the therapist asked T for permission to contact his teacher to request him to complete homework after school at homework club with school staff support. T reluctantly agreed. The therapist also told T that she would talk to the teacher about simplifying his schoolwork and homework to make it easier for him to understand. The therapist spoke to both the teacher and T's mom about giving simple instructions to T, one step at a time. The teacher also agreed to provide T with handouts showing worked examples of concepts taught in class, rather than verbally describing them or writing them up on the whiteboard for him to copy.

T's mother agreed to set up a visual schedule for T at home with photos illustrating the daily tasks he needed to complete (e.g., getting dressed, brushing his teeth, etc.). A simple monitoring chart was set up at school, whereby if T tried his best to complete activities at school without complaining during three periods (morning, middle, afternoon), he was awarded 5-min increments of iPad time at the end of the school day. A response cost system was set up at home, whereby 5 min was deducted from T's 30 min per day iPad play time for each daily task that he did not complete (eating breakfast and dinner at the table, showering, dressing for the day and bed). T initially argued with his mother when this system was implemented. However, his mother was able to remove herself from him at these times and consistently use the response cost system. Over a period of 2 weeks, she started to see an improvement in his compliance with the daily routine tasks.

Over subsequent sessions, T reported that while things were "a bit better" at school, he still did not want to do schoolwork and found it annoying when he did. T indicated that he did not like asking for help when he didn't understand something, as the other kids would think that he was "stupid and a loser." As T and the therapist were shooting hoops in session, the therapist asked him how he was likely to perform if he thought "I'm stupid and a loser." He said he didn't know, so she suggested they test it out. She asked him to say "You can't do this. You're a loser at B-Ball" as she shot hoops. She didn't make any shots and showed an exaggerated disappointed face and body posture. The therapist asked T to identify how she was feeling. He laughed and replied, "Bad. Like a loser." She then asked him if she was likely to want to keep playing basketball when she had these thoughts, and he said no. Next, the therapist asked him what he could say to help her feel better and keep trying, and he said, "You've got this. Just practice." She said these helpful statements to herself (T joined in) and landed two of the next five baskets. She asked T what he learned from this activity, and he said, "You did better when I cheered you on." The therapist asked T if he could cheer himself on. She repeated the basketball activity, this time with T shooting hoops and initially saying unhelpful statements to himself and then being his own cheerleader. At the end of the activity, she asked him what he learned. He responded, "I feel better when I say nice things to myself." The therapist invited T's mother into the room at the end of the session and asked her to film him shooting hoops and being his own cheerleader with her smartphone. She asked both mother and son to review the video each day before school to remind T that he can also be his own cheerleader when doing difficult tasks at school.

The therapist reached out to T's teacher and asked if it would be possible for T to use an inconspicuous code word or card to signal when he needed help in class, so as not to draw peers' attention to him. The teacher agreed that if T was getting frustrated in class he could ask to go and get a drink (a maximum of five times per day), which signaled to her and the teaching assistant to offer him help. This was explained to T in the next therapy session, and he reluctantly agreed to give it a go. In this and subsequent sessions, T was asked to bring in schoolwork to session, and his mother filmed him saying helpful thoughts (e.g., "I'll give it a go. I'll get better with practice, like B-ball."), while he attempted it. T also practiced asking for a drink of water when he didn't understand something and walking to the other side of the therapy room and having a drink from his water bottle. T was initially encouraged to focus on the sensations in his body while walking as a mindfulness activity. However, this repeatedly made him agitated, so he was encouraged to squeeze a basketball-shaped stress ball in his pocket instead and to be receptive to help with his schoolwork when he returned to the desk. T was rewarded with NBA collector cards for calmly practicing this process over eight therapy sessions.

With his mother's support, T reviewed the filmed footage from therapy each morning before school, and over a period of 2 months, both his mother and teacher reported a marked improvement in his willingness to try his best at schoolwork and to ask for help. By the end of therapy, T's mother also reported that T completed his daily routine tasks with minimal prompting and that they were fighting a lot less at home. This case example illustrates how using a combination of environmental modifications, a behavioral reinforcement system, enlisting carer and teacher support, and promoting client skill building by taking therapy at a slower pace, using action-based learning, illustrating concepts with personally relevant examples, and consolidating skills through repeated roleplays, practice, and creating and reviewing video clips reduced the oppositional behavior and irritability of an adolescent client with mild ID.

Conclusion

CBT and mindfulness-based interventions appear to hold promise in improving the mental health and well-being of individuals with mild-to-moderate ID across the life span. However, as most of the research to date has involved single case study or uncontrolled evaluations with small sample sizes, large-scale randomized controlled trials are needed to conclude which interventions are most effective, for whom and in what format, and dosage. Future research is also needed to identify the active ingredients of different therapeutic approaches and what procedural modifications are optimal for different clinical populations who have an ID. Given the cognitive limitations of individuals with an ID, empirical attention should also be focused on the durability of treatment gains over time and the transferability of skills across settings. The dissemination of this knowledge to clinicians will help to improve their confidence and competence in working with clients who have an ID, enhancing service accessibility for this often-neglected sector of the population. The potential benefits of such efforts are far-reaching, including improved well-being, independence, and community and workforce participation for individuals with ID.

Early Intervention

39

Michael J. Guralnick and Mary Beth Bruder

Contemporary systems of early intervention are designed to provide a comprehensive and integrated array of resources and supports to families whose children are experiencing or are at risk for a wide range of delays in development during the early childhood period. The overarching objective of these systems is to help create an environment that fosters children's development as optimally as possible and to establish a trajectory that will ultimately enable them to carry out their goals within family, community, and cultural contexts. Ideally this would be accomplished in conjunction with necessary supports. As expected, such community-based early intervention systems are complex and diverse. Although often including preventive intervention programs for children at risk for delays, early intervention systems focus primarily on a heterogeneous group of children for whom a range of communication, motor, socio-emotional, sensory-perceptual, or adaptive concerns and behaviors are evident. But also central to early intervention systems are children experiencing substantial delays in cognitive development, although these children demonstrate delays in many of the domains noted above as well. Children with a diagnosed condition that is highly likely to result in cognitive delays are also eligible to receive early intervention services. The vast majority of young children with substantial cognitive delays will meet criteria for intellectual disability by the time they reach school age, and it is these children and their families that are the focus of this chapter.

During the early childhood period in particular, promoting children's development is realized through systems consisting of a network of early intervention professionals who develop collaborative relationships with families to generate as optimal a developmentally supportive environment for the child as possible. Among other features, this family-centered approach is designed to assist families to become advocates for their child, to ensure that family priorities are respected and supported, and to provide sufficient information to enable families to understand the complex influences on and features of their child's development. Together, it is anticipated that families participating in this process will be able to confidently and competently adjust to their child's ever-changing characteristics and develop relationships that will support their child's development as optimally as possible over time (Bailey Jr. et al., 2006; Bruder, 2010; Dunst, 2017; Guralnick, 2011, 2019a).

Principles

Centering early intervention on families constitutes an important principle for the field that has achieved international consensus (Guralnick, 2008). A corollary to that principle is the role developmental science plays in informing specific family-centered early intervention practices. For example, abundant evidence reveals that early intervention's focus on supporting parent-child relationships in numerous contexts, particularly relationships that constitute a discourse framework, an instructional partnership, and socioemotional connectedness, is a fundamental developmental mechanism that promotes a child's social and cognitive competence (Guralnick, 2011, 2019a). Other influential developmental processes consist of child experiences that are orchestrated by families. These include participation in community activities, diverse social networks, child care, preschool, and individual or group therapies, all of which constitute developmental pathways of considerable importance with respect to children's emerging competencies (Bruder, 2010; Dunst, Hamby, Trivette, Raab, & Bruder, 2000). Of course, family efforts to ensure a child's health and safety constitute mechanisms that can produce widespread effects on child development as well. In the context of developmental science, guidance to early intervention systems derived from these mechanisms of influence is provided with respect to assessment, intervention goals, corresponding intervention strategies, and their implementation and evaluation. In so doing comprehensive and integrated early intervention systems take advantage of the unusual levels of plasticity and sensitivity to environmental input characteristic of children during this developmental period (Bick & Nelson, 2017; Fox, Levitt, & Nelson III, 2010).

Early intervention principles that have also achieved international consensus address structural issues and values that can guide the system itself as well as related practices. Structural principles especially relevant include designing systems to ensure that early detection, surveillance, monitoring, and transition processes are in place; that evaluation procedures are embedded in all critical intervention goals, objectives, and activities; that the system can accommodate and attend to the complex and highly individualized needs of children and families; and that the system contains mechanisms for leadership capable of carrying out the overarching early intervention vision. Essential leadership functions must include the ability to achieve integration and coordination among components and service sectors at all levels to enable an early intervention system to function effectively. Principles related to values focus on the importance of providing intervention within a framework that maximizes full inclusion of children and families in community activities and programs and ensures that a meaningful partnership with families is established that includes an understanding of cultural differences and a recognition of their developmental implications and the importance of recommending intervention practices and strategies that have a firm evidence base embedded in a conceptually sound framework (Guralnick, 2008).

Vulnerable Children

These principles are incorporated to varying degrees into systems of early intervention in many countries throughout the world. In the United States, the systems of services for vulnerable children and their families are organized in the context of the Individuals with Disabilities Education Improvement Act (IDEA, 2004). This legislation, carried out through Part B of IDEA (Sect. 619), mandates services for preschool-age children in each state emphasizing educational interventions and is the responsibility of local school districts. In contrast, services for infants and toddlers (Part C of IDEA) center more directly on enhancing the capacity of families and providing individualized help-giving practices to meet children's needs (Bruder, 2005; Dunst, 2017; Hebbler, Greer, & Hutton, 2011). This program is administered by state designated agencies, and, although Part C programs are optional, all states continue to participate.

Eligibility to participate in the early intervention system for vulnerable children established by IDEA for Part C consists of three general categories. As suggested earlier, the first focuses on children demonstrating a substantial delay in one or more fundamental developmental domains (including cognitive development). Establishing the precise extent of the delay or delays required for eligibility varies from state-to-state and generally involves formal assessments, clinical opinion, and parental input. As expected, state eligibility definitions and assessment strategies have a major impact on the number and characteristics of the population that is served (Elbaum & Celimi-Aksoy, 2017; Rosenberg, Ellison, Fast, Robinson, & Lazar, 2013). Second, children are eligible if they have an established condition which indicates a high probability of exhibiting significant developmental delays during the early childhood period. This allows early intervention to commence prior to the appearance of those delays. Diagnosed conditions such as Down syndrome or fragile X syndrome are primary examples of children eligible in this category. Finally, although optional, states allow children to be eligible on the basis of biological risk factors. Extreme preterm birth, problems occurring during the perinatal period, or infectious diseases are among the most prominent biological risk factors that allow children with these risks to receive what is best conceptualized as preventive intervention; as they are provided services prior to the appearance of substantial delays should they emerge (see Guralnick, 2012). Children at risk due primarily to environmental factors, especially poverty and related concerns (see Evans & Kim, 2013), may also be included, but only a few states utilize this option as part of their eligibility criteria. Of course, many children in other delay categories are also at high risk due to environmental factors (Scarborough et al., 2004). Indeed, categories of environmental risk and delay overlap extensively (Halfon, Houtrow, Larson, & Newacheck, 2012). For children reaching preschool age (3–5 years), eligibility to participate in Part B can continue to be based on criteria related to developmental delay. Later-identified children, in particular, can also qualify for services by meeting categorical criteria including intellectual disability. Accordingly, early intervention systems, even those with relatively narrow eligibility requirements, must be prepared to address the complex and heterogeneous needs of children and families.

In this chapter, we focus on young children with substantial delays in cognitive development. For the most part, comparable delays in other developmental domains will also be apparent producing an overall pattern of general developmental delay despite characteristic unevenness of development (Shapiro & Batshaw, 2013; Shevell, Majnemer, Rosenbaum, & Abrahamowicz, 2001). Autism spectrum disorder, sensory and motor disorders, and especially clinically significant behavior problems (see Cheng, Palta, Kotelchuck, Poehlmann, & Witt, 2014; Crnic, Hoffman, Gaze, & Edelbrock, 2004) are among the conditions associated with substantial cognitive delay but will not be addressed directly in this chapter. We fully recognize the dynamic and changing nature of early development and corresponding difficulties achieving valid assessments and classifications specific to cognitive development at such young ages (Lobo, Paul, Mackley, Maher, & Galloway, 2014; Yang, Jong, Hsu, & Lung, 2011). Nevertheless, longitudinal studies indicate that, particularly during the preschool period, cognitive delays are highly likely to continue during the school years, qualifying children for services that meet criteria for intellectual disability (e.g., Keogh, Bernheimer, & Guthrie, 1997; Mangin, Horwood, & Woodward, 2017).

Information is provided in the next section with respect to the adjustments required to address the challenges encountered by families in their efforts to promote the development of their young child with a cognitive delay. As will be seen, challenges to development-promoting family patterns of interaction are considerable, and adjustments that are needed constitute an important framework to guide the design, implementation, and evaluation of early intervention systems.

Family Challenges and Adaptations

The extraordinary abilities of families with a child with a cognitive delay to modify their daily routines and to organize their home and community activities to accommodate to the developmental and behavioral patterns of their child, and to do so in a manner that supports their child's development, have been well documented (e.g., Bernheimer & Weisner, 2007). Many families, especially those with sufficient resources in terms of their own personal characteristics (e.g., mental and physical health, problem-solving abilities, coping style) and material resources (financial, social support network), have been able to display well-organized and integrated levels of sensitive responsiveness, affective warmth, and engagement in numerous situations with their child similar to that which occurs when parents interact with children without cognitive delays. For example, in the domain of parent-child interactions, compared to matched groups of typically developing children, studies have shown that parents of children with delays are able to appropriately scaffold and support their child in instructional and social play contexts, closely attune and adjust interaction strategies to children's changing ability levels over time, refrain from being highly directive, and find ways to support the autonomy of their child (de Falco, Venuti, Esposito, & Bornstein, 2009; Gilmore, Cuskelly, Jobling, & Hayes, 2009; Guralnick, Neville, Hammond, & Connor, 2008; Sterling, Barnum, Skinner, Warren, & Fleming, 2012; Venuti, de Falco, Esposito, & Bornstein, 2009). As in the case for children developing typically as well as those with other delays or risk factors, these and other adaptations of families are associated with advances in children's development (Guralnick, 2019a). Consistent evidence supports associations for these parent-child interactions with respect to cognition, social development, and various aspects of language and communication for heterogeneous groups of children with delays as well as those with specific etiologies (Feniger-Schaal & Joels, 2018; Fenning & Baker, 2012; Green, Caplan, & Baker, 2014; Hauser-Cram et al., 2001; Trivette, 2003; Warren & Brady, 2007; Warren, Brady, Sterling, Fleming, & Marquis, 2010; Zampini, Salvi, & D'Odorico, 2015). Moreover, these interaction patterns constitute the building blocks of parent-child and other relationships that are certain to support children's development throughout the early childhood period and beyond.

Child-Specific Challenges

The resilience of families of children with cognitive delays noted above can be appreciated further upon a close examination of the challenges posed to a family's ability to adjust to children's characteristics. To varying degrees, constraints imposed on children's developmental resources (cognitive, language, motor, social-emotional, and sensory-perceptual) and the processes that organize those resources (executive function, metacognition, social cognition, motivation, emotion regulation) result in a complex profile of social and cognitive competencies displayed in everyday goal-oriented activities (Guralnick, 2019a). General problems affecting a range of competencies, for example, with respect to seeking and organizing information about the physical and social world, or communicating needs and interests in an unambiguous manner, are common concerns (see Spiker, Boyce, & Boyce, 2002). Information obtained from cross-sectional and longitudinal studies of various etiologic-specific subgroups highlights many of the child characteristics that families must adjust to, find ways to organize the environment in a supportive and stimulating manner, and develop relationships that best facilitate their child's development. For example, for children with Williams syndrome, eye movement planning problems can create developmental consequences that adversely affect independent visual exploration and various aspects of attention (Brown et al., 2003; Landau, 2012). Similarly, developmental patterns affecting both developmental resources and organizational processes associated with children with Down syndrome have been well characterized and include special concerns with respect to executive function, task persistence and motivation, expressive language, and social cognition, among other developmental areas (e.g., Adamson, Bakeman, Deckner, & Romski, 2009; Cebula, Moore, & Wishart, 2010; Chapman & Bird, 2012; Daunhauer et al., 2014; Gilmore et al., 2009; Wishart, 1996). Constraints on competencies common to children with fragile X syndrome pose numerous problems for families due to their child's difficulties with respect to emotion regulation, social anxiety, working memory, gaze aversion, and effortful control; and many of these competencies are reflected in assessments of children's adaptive behavior (Abbeduto, Brady, & Kover, 2007; Kover, McCary, Ingram, Hatton, & Roberts, 2015; Roberts, Hatton, & Bailey, 2001; Robinson, Klusek, Poe, Hatton, & Roberts, 2018). Despite the higher probability that most of these child characteristics will be evident during the early childhood period, it is certainly the case that considerable variability (including minimal difficulties) in the developmental patterns of etiologic-specific and heterogeneous subgroups exists as a consequence of biological and environmental factors. Nevertheless, despite this variability in children's characteristics as well as a family's resources and their corresponding ability to adapt, considerable challenges to needed adjustments remain for many families. This circumstance may well require intensive and extensive involvement of an early intervention team.

Identifying Subgroups and Stressors

These constraints and others operate in the context of many child strengths, all contributing to the varying levels of children's social and cognitive competence evident at various points throughout the early childhood period and beyond (Burack, Russo, Flores, Iarocci, & Zigler, 2012). As a consequence, challenges to families to make adjustments to promote their child's development will differ in nature, scope, intensity, and timing as a result of current and changing child characteristics. Moreover, family resilience to meet these challenges varies as well, often linked to the availability of family resources (e.g., financial stability, social support, coping skills, or mental health status). These family resources are discussed later in a larger context. Taken together, as described below, subgroups of families emerge at various points in time in which challenges to adjust to specific child characteristics now constitute stressors that adversely affect the quality of various components of family patterns of interaction, particularly sensitive responsiveness. Similarly, child characteristics can create substantial challenges to a family's resources, with the resulting stressors also exerting an adverse effect on a family's pattern of interaction. The end result is a non-optimal environment that can potentially further constrain a child's development (Guralnick, 2001a, 2017a, 2017b).

Subgroups of families of children with cognitive delays susceptible to child-specific stressors can be identified through careful screening and assessment. As suggested, the consequences of these child-specific stressors take many forms. These include adverse effects on family patterns of interaction such as a lower quality of mother-child interactions, especially behaviors that are more negative and interfering, and providing language input not properly adjusted to children's ability levels (Blacher, Baker, & Kaladjian, 2013; Hauser-Cram et al., 2001; Thiemann-Bourque, Warren, Brady, Gilkerson, & Richards, 2014). More generally, these stressors can create circumstances that restrict relationships from forming between parents and children by adversely affecting processes related to establishing a framework in which extensive discourse can occur, by constraining the ability of children and parents to engage in mutual problem-solving actions (i.e., to form an instructional partnership), and by limiting activities that support the development of connectedness at the socioemotional level. Among other concerns, the limits imposed on socioemotional connectedness can affect the formation of a secure attachment and a cooperative pattern of relating (see Feniger-Schaal & Joels, 2018; Feniger-Schaal, Oppenheim, Koren-Karie, & Yirmiya, 2012). Addressing these relationship difficulties between parents and children (transactional processes) that result from a child's specific stressors that may emerge constitutes a critical task for the early intervention team.

Admittedly, it is not easy to predict or even identify those subgroups of families who are likely to have extensive difficulties successfully adjusting to their child's characteristics. Certain factors such as child behavior problems are predictive, but uncertainty remains, nevertheless, posing problems for an early intervention system from clinical, educational, and resource perspectives. Moreover, family resilience as reflected in the components of a family's resources also operates at a systems level, and it is often difficult to determine how the various components of a family's resources interact and work with one another in different situations to affect parent-child interactions as well as other family patterns of interaction. Consequently, a related but critical task for early intervention systems is to develop a process that is capable of identifying families most in need of support and then enabling them to access a family-centered intervention program that recognizes the interrelationships among children's characteristics, the various components of family patterns of interaction, and the resources available to families to support those interaction patterns. Ideally, such programs would operate in accord with the structural and values principles discussed earlier. Systems would also focus on the importance of relationships at all levels, ensure continuity of the program over time, and contain resources sufficient to comprehensively address the many stressors that may emerge capable of limiting optimal child development.

Community Involvement

In addition to child-specific effects on parent-child transactions noted above, it is also important to consider those community-based issues that often challenge a family's ability to maximize their child's development. Identifying high-quality and inclusive child care and school programs, assisting their child to form meaningful peer networks, finding a medical home with professionals knowledgeable and experienced in the care of children with cognitive delays, and engaging service providers with appropriate credentials and skills are among the community activities that parents must orchestrate to support their child's development and well-being (Dunst & Trivette, 2009). Combined with frequent negative societal attitudes and limited community resources, it is quite understandable how child characteristics can produce stressors restricting these development-enhancing community activities (Guralnick, 2019a).

Of considerable importance is the ability of families to maximize full participation in all community activities. This is especially the case for inclusive child care and preschool programs, as consistent evidence of developmental benefits has been found for those children participating in quality inclusive settings (Guralnick & Bruder, 2016; Justice, Logan, Lin, & Kaderavek, 2014). Once again, these issues highlight the importance of adopting a broader systems perspective in the context of early intervention and recognizing the importance of a comprehensive approach.

Family Resources

It is also the case that constant efforts to adapt to changing and challenging child characteristics create unusual problems that can affect many of the components of a family's resources throughout the early childhood period (Gallimore, Weisner, Bernheimer, Guthrie, & Nihira, 1993). For example, even at early stages, the emotional features of the diagnostic process can lead to many unresolved issues for parents which can adversely influence the quality of parent-child interactions over the long term (Barnett et al., 2006). Stress, often reaching clinical cutoff points, experienced by parents of children with delays directly related to child characteristics, is common and can be traced to child temperament, variations in mood, and especially behavior problems, with the latter elevating parent depressive symptoms (Gerstein, Crnic, Blacher, & Baker, 2009; Most, Fidler, Booth-LaForce, & Kelly, 2006; Neece, Green, & Baker, 2012; Woodman, Mawdsley, & Hauser-Cram, 2015; Zeedyk & Blacher, 2017). Periodic episodes of parent distress, including depression, can not only adversely affect parent-child interactions (Zeedyk & Blacher, 2017) but overall life satisfaction as well (see Nes et al., 2014).

Of importance, subgroup identification with respect to a family's resources for the purpose of early intervention remains critical, as most families demonstrate a remarkable degree of resilience. Indeed, ongoing adaptations rely extensively upon the personal characteristics of families, especially a positive coping style and the ability to engage their social support network (Minnes, Perry, & Weiss, 2015; Peer & Hillman, 2014). Social support can influence many components of a family's resources including parent mental health and the extent to which families feel competent and confident in their ability to parent a young child with a cognitive delay (Bailey, Nelson, Hebbeler, & Spiker, 2007; Guralnick, Hammond, Neville, & Connor, 2008; Kersh, Hedvat, Hauser-Cram, & Warfield, 2006).

Accordingly, a major task for early intervention systems with respect to supporting family adaptations is to accurately and sensitively monitor the various components of a family's resources, especially social support networks and levels of parent distress. The potential for these resources to be depleted at various points in time is considerable, especially for the many families with a child with a delay who also have extensive pre-existing environmental risk factors, particularly limited financial resources (Olsson & Hwang, 2008). These initial vulnerabilities in the form of higher environmental risk create a circumstance which can be exacerbated further such as by additional expenses related to child care responsibilities or lost income as a result of employment changes (Emerson & Hatton, 2009; Emerson, Hatton, Llewellyn, Blacher, & Graham, 2006). In view of the influence of these family resources on the quality of parent-child transactions, the extent of the child's involvement and participation in home, community, and educational activities as organized by parents, and on a child's health and safety, it is evident that the quality of the components of family resources has important consequences for a child's development (Guralnick, 2011, 2017a, 2017b).

As discussed more fully later, in view of the challenges and stressors to a family's resources and to a family's pattern of interacting with their child, effective systems of early intervention must be designed not only to address relationships but also to be organized in a manner that is comprehensive with an emphasis on continuity of services across the early childhood period. Taken together, the ability of the system to screen and then assess components relevant to children's characteristics, to family patterns of interaction that are linked to children's development, and to family resources that support those family interaction patterns are core elements of effective early intervention systems.

Systems and Effectiveness

Community-based systems of early intervention in the United States and many other countries have indeed been organized within a framework that reflects both a recognition of the diverse and complex needs of vulnerable children and the challenges facing families discussed above. Many of these community-based systems have also adopted the consensus principles governing the organization and operation of the system. This emergence and commitment to community-based early intervention systems as established by and modified through legislation and policy initiatives also reflect the expectation that both children and families will benefit substantially from a sophisticated array of well-organized and evidence-based interventions. Indeed, results from decades of intervention science involving diverse groups of families and children provided sufficient confidence to generate the political will to establish community-based early intervention systems and to continue to expand and refine the components of those systems. The relevant intervention science was summarized in 1997, during the period of rapid growth of early intervention programs just prior to and following the passage of P.L. 99–457 (Guralnick, 1997). This "first-generation" research included investigations involving children with cognitive delays and their families, demonstrating the ability of early intervention programs to reduce the decline in development that typically occurs over time in the absence of intervention and generate many other benefits (Guralnick, 2005, 2017a; Spiker & Hopmann, 1997). First-generation research also provided the foundation for subsequent "second-generation" studies that were designed to determine associations between well-defined family and child characteristics, emerging and innovative program features, and outcomes of relevance for both children and families. Findings from studies designed in this manner could form a database specifically organized to advance practice applications, with the potential for widespread implementation in community practice.

In the following section of this chapter, a brief history and description of the organization and practices of the early intervention system in the United States within the framework of the Individuals with Disabilities Education Act are discussed. This will be followed by a description of selected recent second-generation research designed to refine and enhance early intervention programs for children with cognitive delays and their families. In the final section, future directions intended to improve early intervention program quality and program effectiveness are discussed within a systems framework that is applicable to all young vulnerable children and their families.

Early Intervention: History, Organization, and Practices

In the United States, children under the age of 5 were not included in the federal mandate for special education under the Education of the Handicapped Act (EHA), passed in 1975 ("Education for All Handicapped Children Act of 1975, P.L. 94-142, 1977"). This law mandated that all school-age children with disabilities receive a free appropriate public education in the least restrictive environment under the direction of an Individualized Education Plan (IEP). States did receive incentive funds to enroll preschool-age children in public school programs and to provide training to preschool teachers under this Act. It was not until 1986, however, that Congress added several significant components to the EHA that specifically addressed the needs of eligible children under the age of 5. First, services for young children (ages 3–5) eligible for special education were mandated under the provisions of free, appropriate public education (Part B of P.L. 94–142). Second, these amendments created incentives for states to develop an early intervention program for children ages birth to three. This birth to three program was designed to establish a statewide system of interagency, multidisciplinary services available to eligible infants and toddlers and their families (as defined by each state through an agency also determined by each state). The name of the EHA was changed to the Individuals with Disabilities Education Act (IDEA) by the EHA amendments of 1991 (P.L. 102–119), and services for eligible infants and toddlers were made available in all states through IDEA amendments in 1997 (PL 105–17) under Part C of IDEA. This allowed states to receive funding for this age group if they implemented all assurances required under the subtitle. Part B, Section 619, addressed the preschool programmatic requirements of IDEA. Further, the IDEA amendments of 2004 required that services for infants and toddlers as well as preschool children be based on scientifically sound research findings, research that involves the application of rigorous, systematic, and objective procedures to obtain reliable and valid knowledge relevant to educational activities and programs. An added emphasis on the transition process between Part C and Part B (619) was also included in these amendments.

IDEA provides the guidance and structure for statewide systems of early childhood intervention for eligible infants, toddlers, and preschoolers and their families. While these two programs differ as a function of the age of the child and have different statutory requirements, both focus on structural and values components of early intervention to support children's development and family well-being. Some key elements of these two programs are described next.

Family Participation

Both Part C and Part B (619) address the civil rights of children and their parents through a system of procedural safeguards that are in place throughout the early intervention process. Part C, however, strengthens the role of the family by identifying it as a target of early intervention services. The preamble of the statute explicitly states a need for early intervention to enhance the capacity of families to meet the special needs of their infants and toddlers with disabilities. As a consequence, early intervention services for infants and toddlers are delivered in accordance with an Individual Family Service Plan (IFSP). Additionally, the IFSP outcomes must be based on a multidisciplinary assessment of the unique strengths and needs of the infant or toddler and the identification of services appropriate to meet such needs. Also required is a family-directed assessment of the resources, priorities, and concerns of the family and the identification of the supports and services necessary to enhance the family's capacity to meet the developmental needs of their infant or toddler.

Part B of IDEA also addresses parents in the preamble of the preschool and school age provisions of the statute by stating that IDEA Part B includes the protection of child and parent rights through the special education process and the assurance that teachers and parents have the necessary tools to improve educational results for children. Though not as explicit as Part C, the law does allow services that target parents under the related service of parent counseling and training. Likewise, parents may participate in the eligibility assessment for their child by providing information about their child in the context of assessment tools and strategies used to gather relevant functional, developmental, and educational information to determine whether the child has a delay or disability and to develop the content of a child's Individualized Education Plan (IEP).

Screening and Identification for Further Assessment

Both Part C and Part B (619) require a Child Find system that includes public awareness of the special needs of infants, toddlers, and preschoolers who may qualify for services under IDEA and the training of primary referral sources (e.g., medical and community program personnel) in screening and referral procedures. Specifically, IDEA requires that states ensure that all children with delays or disabilities are identified, located, and evaluated, and referral sources must be kept informed about early intervention supports, service models, and data on effectiveness.

There are multiple models for developmental and medical screening programs available (Gilliam, Meisels, & Mayes, 2005; McConnell & Rahn, 2016; McLean, Wolery, & Bailey, 2003; Yockelson, Linder, & Asman, 2015). One method used in many states is a developmental screening questionnaire completed by a parent or healthcare provider (Bricker, Macy, Squires, & Marks, 2013). A questionnaire serves several functions, ranging from identifying children who may not be meeting developmental milestones (and therefore need additional evaluation) to providing child development information and education to parents.

Assessment

An infant, toddler, or preschooler who is identified as needing more documentation to qualify for IDEA services undergoes a multidisciplinary assessment to generate a profile of their unique strengths and needs. In Part C the assessment is to be used for eligibility purposes and to identify services appropriate to meet an infant's or toddler's needs. The law states that the assessment must be a timely, comprehensive, and multidisciplinary evaluation of the development of each infant or toddler. To qualify for early intervention services, most children will require an assessment involving various disciplines. This assessment can serve a diagnostic function and create a valuable portrayal of the child's needs from medical, educational, and social systems perspectives. Part B (619) requires that assessments for children over 3 do not discriminate on race or have a cultural basis, are administered in the child's primary language, are used for purposes for which the assessments or measures are valid and reliable, and are administered by trained and knowledgeable personnel. As with screening, assessment tools should be standardized and result in an accurate representation of a child's skills (Gilliam et al., 2005; McConnell & Rahn, 2016; McLean et al., 2003).

After a child is determined to be eligible for Part C or Part B (619) services, further assessment may be carried out in conjunction with intervention (IFSP or IEP) planning. Assessment protocols are intended to focus on a child's application of their social and cognitive competencies in the context of home, community, and classroom-based activities and routines. It is important that these assessments are linked to intervention (Bagnato, McLean, Macy, & Neisworth, 2011), include the family (Macy, Thorndike-Christ, & Lin, 2010), and focus on the child's ability to participate in and use skills related to their adaptive functioning (communicating, walking, self-care, etc.) (Campbell & Sawyer, 2007; Fleming, Sawyer, & Campbell, 2011). Additionally, assessments for eligibility, program planning, and evaluation should share the same conceptual perspective and be linked for a seamless process.

Curriculum

Curricula for infants, toddlers, and preschoolers under IDEA are described as part of the IFSP or IEP process. As proposed by Dunst (1981), a curriculum consists of a series of carefully planned and designed activities, events, and experiences intentionally organized and implemented to reach specified objectives and goals and align with a particular philosophical and theoretical position. Both IFSPs and IEPs document a child's developmental and learning status, outline the day-to-day provision of services and supports designed to promote their development, identify those who will work with the family to deliver the services and interventions, and specify the evaluation procedures to monitor the effectiveness of the program. The IFSP, in particular, requires the inclusion of measurable outcomes expected to be achieved for the infant or toddler and the family, the assignment of a service coordinator to aid the family, and a formal transition process to preschool services when the eligible child turns 3 years of age.

The curricular content used in early childhood intervention derives primarily from developmental theory and the developmental trajectories common to most children. Most curricula in use in Part C and Part B (619) emphasize the unique patterns of individual children: their age, their strengths, their needs, their family preferences, and their outcomes and goals as developed by the intervention team, including the family. For children with cognitive delays in particular, a focus has been on the enhancement and facilitation of a child's competencies needed to participate in everyday activities and routines (Campbell & Sawyer, 2007; Dunst et al., 2000, 2001; McWilliam, 2010a, 2016; Woods, Kashinath, & Goldstein, 2004). This focus emphasizes accommodations, modifications, and adaptations needed by young children to learn within the context of routines and activities in the home, community, and classroom (Bruder, 2010). Examples of approaches, curricula, or combined strategies include embedded instruction, routine-based intervention, milieu teaching, naturalistic teaching, and activity-based instruction (see Snyder, Hemmeter, McLean, Sandall, & McLaughlin, 2013; Snyder, Rakap, Hemmeter, & McLaughlin, 2015). Of note, many of these interventions have their roots in curriculum development using incidental teaching (Hart & Risley, 1975) and teaching matrixes for children with cognitive delays (Williams & Gotts, 1977). These interventions were designed to be functional and efficient and to lead to generalized learning.

Many of the instructional methods that guide the orchestration of such development-enhancing learning opportunities across routines and activities continue to be based on applied behavioral analysis techniques. For almost 50 years, this instructional paradigm has been utilized in early childhood intervention (see Wolery, 2000) and has evolved from the isolated delivery of interventions to include a variety of expanded and naturalistic antecedents and logical consequences (e.g., environmental arrangements, group settings). Expanding and building new skills based on a child's demonstrated abilities or assets seem particularly effective (Raab, Dunst, & Hamby, 2016, 2017).

A more recent approach to the identification of instructional targets for young children with delays or disabilities is response to intervention or multi-tiered systems of instruction (Buysse & Peisner-Feinberg, 2013; Carta, McElhattan, & Guerrero, 2016). The features of this framework include ongoing assessment to provide information about how a child is responding to a general curriculum that is provided to all children (i.e., in inclusive settings). Interventions are then provided in progressive levels of intensity depending on the child's progress in the curriculum and instructional targets.

Services

Part C is designed to provide a coordinated array of services, all designed in a manner intended to center on families. These services include special instruction, coordinated family training, counseling, home visits, speech-language pathology and audiology, sign language and cued language, occupational therapy, physical therapy, psychological services, medical services only for diagnostic or evaluation purposes, health services necessary to enable the infant or toddler to benefit from the other early intervention services, social work services, vision services, assistive technology devices and assistive technology services, and transportation and related costs that are necessary to enable an infant or toddler and the infant's or toddler's family to receive other services, and service coordination. In contrast, Part B (619) provides special education and related services with instruction provided in the classroom and the home as well as in hospitals and institutions if needed. Services are also provided in other settings such as community early childhood or child care programs. A wide range of related services similar to Part C is also provided in these contexts.

Inclusion

IDEA also requires that services be delivered in environments with typical children. Preschool-age children receiving Part B (619) services must receive services in the least restrictive educational environment (LRE) to the maximum extent possible. LRE further mandates that special classes, separate schooling, or other removal of children with disabilities from the regular educational environment could occur only if the severity of their disability prohibited education in regular classes, when using supplementary aids and services. This principle of inclusion has not been easy to accomplish in practice, although IDEA data suggest that as many as two-thirds of eligible children participate in regular preschool settings for some amount of time (US Department of Education, 2017). As most of these children receive Part B (619) services in preschools, the challenge has been to combine well-integrated service delivery within typically occurring classroom routines with the general population of children. Inclusive practices are often constrained by schools where policy is to provide related services by multiple personnel from different disciplines, many of whom provide their services in one-to-one sessions outside of the classroom. While a team approach is still regarded as the preferred method to provide Part B (619) services, time constraints and high caseloads for related service personnel impact the time available to design and implement integrated service delivery for individual children and classrooms (Guralnick & Bruder, 2016).

Early intervention services under Part C of IDEA are to be delivered in natural environments in accordance with the IFSP. Natural environments include the home or places in which same age children who do not have disabilities participate (e.g., child care, community programs). In 2015, nearly 90 percent of infants and toddlers served under Part C received early intervention services primarily in the home (US Department of Education, 2017). Less frequently used were community-based settings as the primary early intervention environment for those served under Part C (Bruder, 2001; Bruder & Dunst, 2011; Guralnick & Bruder, 2016). It has been reported that home visits are delivered once a week on average, and data collected on the content and processes of early intervention home visits suggests that the majority of time is spent by the service provider teaching the infant or toddler, with less time collaborating and working with caregivers (Campbell & Sawyer, 2007; Kemp & Turnbull, 2014; Peterson, Luze, Eshbaugh, Jeon, & Ross Kantz, 2007).

A primary provider service model is common in these circumstances (Vail, Lieberman-Betz, & McCorkle, 2018). In this approach, one home visitor delivers services to families using a coaching method (Shelden & Rush, 2010). This service delivery model is not new and has its roots in the transdisciplinary model of teaming in early intervention which was designed to minimize the number of adults who visited a family and child while maximizing the efficiency of intervention (United Cerebral Palsy National Collaborative Infant Project, 1976). A central feature of the transdisciplinary model is the availability of a full complement of team members representing different disciplines and services and who meet and consult with the home visitor (usually representing the discipline and service most relevant to the needs and priorities of the child and family) to provide input on the delivery and integration of interventions (Bruder & Bologna, 1993). It is clearly essential that service providers understand and support their role in connection with the other service providers and to the family (King et al., 2009).

Guidance and reviews of successful practices for inclusive early childhood service delivery have been published over the years (see Barton & Smith, 2015; Bruder, 1993; Guralnick, 1978, 2001b; Odom, Buysse, & Soukakou, 2011; Sandall, Schwartz, & Gauvreau, 2016; Winton, 2016). Most provide examples of adaptations, supports, and modifications to facilitate a child's inclusion and learning within a general early childhood classroom in the context of activities and routines incorporating adapted materials and instructional practices (Campbell, Milbourne, & Kennedy, 2012). Universal design for learning (UDL) is also a framework being applied to modify and adapt classroom activities for young children with delays and disabilities (Butera, Horn, & Palmer, 2016). UDL has most often been used with older children, though the concepts of providing multiple means of representation of materials and learning activities, multiple means of engagement for children to be involved in learning or teaching routines, and multiple forms of expression for children with varying communication modes and abilities can enhance the development of all young children attending an inclusive classroom. Lastly, assistive technology devices and services may be especially valuable for children with substantial cognitive delays (see Campbell, Milbourne, Dugan, & Wilcox, 2006). These range from low-tech materials such as special seating or utensils to enhance a child's participation in everyday routines and activities to the use of high-tech communication devices with voice synthesizers to enable a child to communicate in the home, community, and classroom environments.

Summary

Taken together it is evident that, in the United States, the importance and benefits of a system of early intervention has been recognized through the implementation of IDEA. The main components of this system have been outlined above, all intended to enhance the development of children with cognitive and other delays and to support families. As is the case for any complex system, it must continue to develop by incorporating new information and adapting and refining its methods, conceptual framework, and structural features to achieve further progress. Recent studies advancing our knowledge base in critical areas focusing on children with cognitive delays are discussed next. In the final section of this chapter, some general suggestions for future directions are presented.

Current Research Directions

With early intervention systems firmly in place in the United States and elsewhere, smaller scale or focused studies involving children with cognitive delays have been conducted with the expectation that advances that result can be incorporated into the existing system of early intervention practices. For example, some of the more recent early intervention research studies focusing on children with cognitive delays have continued to organize intervention activities within a structured, behavioral framework. These techniques, primarily based on applied behavior analysis interventions that have demonstrated their effectiveness in increasing the cognitive development of children with autism spectrum disorder (Eldevik et al., 2010), have been drawn upon to provide comprehensive programs for children with cognitive delays. Preliminary findings suggest that increases in cognitive development occur for a heterogeneous group of children with delays receiving behavioral intervention while attending inclusive preschool programs (e.g., Eldevik, Jahr, Eikeseth, Hastings, & Hughes, 2010). These techniques have also been successfully applied in more specific developmental areas such as motor behaviors, verbal imitation, and requesting strategies for children with delays (Bauer & Jones, 2014, 2015). Clearly, as demonstrated in these and previous studies, structure to promote specific child skills at various points in time can be of considerable benefit. Further work to determine how these skills are integrated and utilized over time in the service of children's goals will provide valuable information for subsequent intervention approaches especially if organized within a broader developmental context.

Parent-Child Interactions

Indeed, given the numerous challenges posed by children with cognitive delays to a family's pattern of interactions throughout the early childhood period discussed earlier, it may be best for early intervention programs to adopt a long-term developmental perspective. This can be accomplished by recognizing at the earliest possible stages the components and significance of a family's pattern of interactions as the primary experiential pathways of influence on a child's development (Guralnick, 2011, 2019a). To be sure, numerous intervention strategies, including focused and structured approaches, can be of value in this regard, many of which can be embedded within a more comprehensive framework that addresses developmental pathways associated with children's social and cognitive competence. Critical to this more developmentally oriented comprehensive approach are strategies that promote relationship formation between parents and children. This often occurs in the context of a discourse framework, an instructional partnership, or socioemotional connectedness discussed earlier, thereby providing the longer-term developmental context essential for establishing high-quality parent-child transactions. Efforts to support these types of relationships can be readily incorporated into well-established family routines (see McWilliam, 2010b).

The building blocks of parent-child relationships noted earlier in this chapter consist of sensitive responsiveness, affective warmth, and engagement. Sensitive responsiveness in particular, in all its various forms, has continued to demonstrate its value with respect to promoting the social and cognitive competence of children with delays (Trivette, 2003). Sensitive responsiveness in the context of a discourse framework has been a special interest to investigators emphasizing, among other strategies, contingent responding to child initiatives, ensuring balanced exchanges, minimizing directives, focusing on the child's attention and interests, and narrating activities (Karaaslan, Diken, & Mahoney, 2013; Kim & Mahoney, 2005; Mahoney, Perales, Wiggers, & Herman, 2006). Through demonstrations, coaching, feedback, reflection, and practice in various contexts and family routines, parents participating in these investigations were able to become proficient in organizing and applying strategies that promote parent-child relationships. Although further evidence with respect to child-specific outcomes is needed, from a developmental and evidence-based perspective, promoting relationships in this manner can be seen as an essential element of contemporary early intervention programs.

Highly focused applications that incorporated sensitive responsiveness strategies in early intervention programs can also be found in studies designed to promote the language and social communication abilities of prelinguistic children with cognitive delays. A detailed review of findings for this extensive group of studies can be found elsewhere (Guralnick, 2019a). However, a common objective of these studies was to promote children's intentional communication and to expand their expressive language. The ultimate goal was intended to further a discourse relationship between parents and children. Interestingly, evidence suggests that even clinician-implemented interventions can produce the most benefits for children specifically from that subgroup of parents who demonstrate a higher initial level of responsiveness to their child at home (Yoder & Warren, 2001). Moreover, maternal responsiveness at home may also increase due to increased intentional communications by children participating in clinician-implemented interventions (Yoder & Warren, 1999). Subsequent work involving alternative and augmentative communication strategies for prelinguistic children has also been carried out, engaging both parents and clinicians to varying degrees in the intervention process. Results have been promising in this very complex area suggesting the value of evidence-based refinements to early intervention practices for prelinguistic children (Romski et al., 2010; Wright, Kaiser, Reikowsky, & Roberts, 2013). However, the existence of inconsistent findings or small effects for a range of parent and clinician strategies must be recognized as well, with an ongoing concern with respect to effects fading over time following the end of the intervention. To be most effective, early intervention systems must be designed to provide a sufficient degree of continuity to ensure optimum outcomes. Perhaps cost-effective techniques utilizing distance learning approaches (video teleconferencing) that are showing promise with regard to supporting a discourse framework will be of value as they are further refined (McDuffie et al., 2016).

From a larger perspective, this pattern further suggests the importance of adopting a systems approach to early intervention. This is especially the case when considering how family-orchestrated child experiences, such as clinician intervention and parent sensitive responsiveness, interact to produce a cumulative effect. Indeed, evidence for heterogeneous groups of preschool children with varying language abilities has indicated that strategies used as part of an enhanced milieu intervention that included both parents and clinicians produced greater benefits than a clinician only group (Kaiser & Roberts, 2013). Benefits included increases in parents' use of sensitive responsive strategies in a naturalistic manner and children's expressive vocabulary. Clearly, early intervention is most effectively accomplished by following a coordinated, comprehensive approach to strengthen children's social and cognitive competence.

It is also important to recognize that progress has been achieved in these and other investigations with respect to identifying subgroups of children and families most likely to be responsive to the types of interventions described above. Moreover, by adjusting to child-specific characteristics, increasingly informed by etiologic-specific studies, the early intervention team may be in a position to more effectively problem-solve over an extensive time period to establish a much needed discourse framework for children with limited communication skills. Ongoing work utilizing adult learning techniques, such as incorporating the sequence of teach-model-coach-review, may be of particular value to the early intervention team in this context (Wright & Kaiser, 2017).

Inclusive Preschools

It is clearly recognized that inclusion is a value well-grounded in philosophical, legal, legislative, as well as international human rights principles. Yet the implementation of inclusive practices in group settings such as preschool programs brings with it the obligation to ensure that children's developmental progress reflected in the many aspects of their social and cognitive competence will, at minimum, be equivalent to progress that would occur within highly resourced yet specialized programs (Guralnick, 2001b). Numerous smaller-scale studies, often evaluated within a resource-rich context implemented by well-trained staff, have indicated that through thoughtful program accommodations to children, this is indeed the case (Buysse, 2011; Guralnick, 2001c). Clearly, these earlier studies provided our field with a level of confidence that inclusive practices, especially in preschool settings, can be both feasible and effective for a wide range of children with delays and disabilities.

As the movement toward universal preschool education continues to gain momentum and the promise that more communities will actually promote full inclusion programs in the future, a key question concerns the progress of children with cognitive delays occurring in inclusive preschool environments organized within large-scale public systems. This is especially critical as preschool programs today are educationally oriented with a substantial number of goals designed to prepare children to be ready to achieve academically. Two studies focusing on high-quality public school programs have addressed this issue (Phillips & Meloy, 2012; Weiland, 2016). Employing regression discontinuity designs that take advantage of cutoff dates for children's enrollment in public preschool programs, evidence from this work revealed that greater progress over the course of 1 year was achieved by children with developmental delays on most academically oriented measures in comparison to children who participated in other programs or community activities. Measures of early literacy, receptive language, and early numeracy were central to these studies. Despite some inconsistency in terms of program effectiveness or rates of change between children who participated in the preschool program and comparison children across outcomes, these studies nevertheless provided strong evidence of the ability of high-quality large-scale public inclusive educational programs to meaningfully and effectively promote the pre-academic skills of children with delays.

Of interest, in the Weiland (2016) study in the Boston public preschool program, the rate of progress of children with special needs, including the subsample of children with developmental delays, even exceeded those of typically developing children on some measures. Certainly curriculum factors, teachers well trained to meet the educational needs of a developmentally diverse child population, and the organizational skills required to create a universal publicly funded pre-kindergarten program are among the factors that contributed to these positive outcomes. Also likely contributing were the daily interactions of children with delays with their typically developing peers. Experiencing more complex language, observing advanced social and problem-solving skills, and receiving informative feedback by more advanced peers can have a substantial developmental impact (Justice et al., 2014). Future research will help identify critical program elements and confirm the ability of these larger-scale publicly funded inclusive programs to meet the needs of children with substantial cognitive delays. Implementation science will likely play a prominent role as well in moving comprehensive early intervention programs to scale and incorporating mechanisms capable of refining and enhancing programs further to accommodate new findings (Halle, Metz, & Martinez-Beck, 2013).

Peer Relationships

Early work also demonstrated that social interactions between young children with delays and their peers occurred at a far higher level in inclusive settings in comparison to specialized settings (Buysse & Bailey, 1993; Guralnick, Connor, Hammond, Gottman, & Kinnish, 1996). However, related work revealed that more in-depth peer relationships such as those characterized as friendships seemed unaffected (Guralnick, Gottman, & Hammond, 1996). This suggested that, despite the social interaction benefits associated with inclusive settings, a closer look into the development and characteristics of the peer relationships of children with delays was in order. Of special interest was an examination of the fundamental features of children's peer-related social competence that underlie children's peer relationships. When research in this area was carried out, numerous problems became apparent (Guralnick, 1999, 2010). In general, compared to appropriately matched groups, preschool age children with cognitive delays displayed peer-related social competence abilities that were not commensurate with their level of cognitive development, likely adversely affecting friendships as well as other important aspects of their peer relationships. Critical aspects of peer-related social competence including the social tasks of peer group entry, maintaining play under rapidly changing circumstances, and resolving conflicts were clearly affected. Problems were also evident with respect to both the appropriateness and effectiveness of social strategies when engaging in social tasks with peers.

To address this issue, a 2-year comprehensive intervention based on a developmental framework was carried out to improve the peer-related social competence of children with delays (Guralnick, Connor, Neville, & Hammond, 2006). Both teachers and parents were involved in the intervention which was individualized to the characteristics of children with delays discussed earlier in this chapter. For example, strategies were devised to address problems related to executive function, social cognition, and emotion regulation in the context of social tasks. Results based on measures derived from observations of interactions in inclusive playgroups revealed that, compared to children randomized to usual community services, important features of the peer interactions of children in the intervention group benefitted, especially for those children with IQs below 70. Minimizing negative exchanges with peers as a consequence of the intervention was perhaps most notable. Yet other measures that reflected more in-depth changes in peer-related social competence, such as social strategies likely to foster friendships and promote core aspects of social competence, were unaffected.

Since the quality of interpersonal relationships becomes more closely linked to an individual's overall well-being over time, it is clear that future work is essential in order to alter this peer-related social competence trajectory. Fortunately, we now have a much better understanding of the underlying developmental processes likely to influence young children's social competence with their peers that can serve as a guide to intervention approaches. The effectiveness and appropriateness of children's relationships with their peers certainly depend upon their developmental resources (e.g., cognition, language) and organizational processes (e.g., executive function, social cognition) as is the case for all competencies displayed as children carry out their interpersonal goals. Designing innovative interventions for children with cognitive delays that can influence these child characteristics in the context of social tasks encountered during peer-peer interactions is essential whether they occur in home, school, or other settings. Of importance, peer relationships are best conceptualized as being embedded within the larger construct of social competence. As such, social competence, including competence displayed in peer contexts by children with delays, is associated with the way in which family members and children interact with one another and model the more balanced and responsive social interactions common to peer relationships (Guralnick, Connor, Neville, & Hammond, 2008; Guralnick, Neville, Hammond, & Connor, 2007). Accordingly, this highlights once again the importance of adopting a comprehensive developmental approach when considering interventions involving complex behavior patterns, including those related to peer interactions.

Future Directions

The consensus principles described earlier provide important guidance for the ongoing development and refinement of early intervention systems. Developmental science provides a well-established framework governing family-centered practices and contributes to our understanding of the mechanisms influencing a child's development. Intervention science consistent with developmental science continues to inform practice, seeking to ensure that only evidence-based practices are selected when IFSPs and IEPs are developed and implemented. Recent refinements, based on intervention science in the early intervention field discussed in this chapter focusing on children with cognitive delays, emphasized strategies to enhance parent-child interactions, studies of the effectiveness of community-based inclusive preschools, and outcomes of comprehensive curricula to promote children's peer-related social competence.

Close examination of current early intervention systems also reveals that numerous opportunities exist to substantially improve virtually all system components. Limits on the comprehensiveness of services are perhaps most evident. As discussed, we now have a firm understanding of the mechanisms that influence child development, including the various components of the quality of parent-child interactions, family-orchestrated child experiences, and a child's health and safety. Yet, many of these components are not incorporated and integrated within current systems or are carried out with such limited intensity to suggest that only minimal effects can be expected. Early intervention problem-solving that incorporates children's characteristics and a family's resources is not as well developed as our knowledge base. In addition to concerns about the comprehensiveness of the system are concerns about its continuity. The evolution of Part B (619) and Part C, with its differing administrative structures and emphases, does not easily allow for continuity of services that maintain a developmental perspective. Unquestionably, a more expansive transition plan would be of value. An emphasis on promoting the well-being of families and enhancing all aspects of a family's resources is especially critical for families of children with cognitive delays (Crnic, Neece, McIntyre, Blacher, & Baker, 2017).

Our dramatically increasing knowledge of the developmental trajectories and corresponding risk and protective factors for children with cognitive delays with confirmed genetic etiologies is certain to generate new intervention strategies responsive to these profiles (Dykens, Hodapp, & Finucane, 2000; Fidler, Daunhauer, Will, Gerlach-McDonald, & Schworer, 2016). The era of personalized interventions will allow early intervention teams to adapt strategies to known developmental mechanisms of influence as reflected in children's developmental profiles in order to maximize the impact of those intervention strategies. A major challenge for early intervention inclusive community-based systems is their ability to utilize this child-specific developmental information as well as second-generation research findings and incorporate this knowledge into practice. Close associations with the early intervention research community and a knowledgeable workforce are critical. Fortunately, an implementation science is also emerging with components that bring a conceptual framework and intervention science into better alignment as programs become established or add new approaches to their service system (Fixsen, Blase, Metz, & Van Dyke, 2013; Guralnick, 2019b; Metz, Halle, Bartley, & Blasberg, 2013).

Perhaps the most crucial element in this regard, and one critical for successful implementation of all conceptually sound and empirically supported interventions, is to ensure that the early intervention workforce operates within the well-established principles that guide early intervention described earlier. Unfortunately, recent examinations of the status of the early childhood intervention workforce have identified a number of issues of concern with respect to the quality and effectiveness of Part C and Part B (619) practices, services, and programs (Bruder, 2010, 2016; Bruder, Mogro-Wilson, Stayton, & Dietrich, 2009; Vail et al., 2018; Woods & Snyder, 2009; Zaslow, 2009). These issues include shortages of personnel; inequities in wages and compensation for personnel across programs; shortages of preservice programs of study, coursework, and practicum opportunities; limited funding for continuing education; the absence of integrated and comprehensive personnel development systems that meet national personnel standards and adult learning guidelines; and limited experimental evidence about the effects of preservice and continuing education on child and family learning. Clearly, outcomes for early intervention systems will be constrained unless this crucial issue is addressed.

These and other issues may ultimately be best addressed within the context of large-scale, comprehensive systems of early childhood development, one inclusive of all children. Although we are a long way from such inclusive, community-based early childhood systems, guidelines and specific recommendations suggest the feasibility and benefits of this framework from both administrative and conceptual perspectives (Bruder, 2010). Should such a system emerge, the successful implementation of agreed-upon early intervention principles and corresponding services and supports for young children with cognitive and other delays becomes more likely, especially in view of the increasing compatibility of systems with a developmental framework relevant to all children (Guralnick, 2019a).

Parenting Support

Trevor G. Mazzucchelli, Lienke Wilker,
and Matthew R. Sanders

Of all the potentially modifiable environmental risk and protective factors that can meaningfully influence children's development, none is more important than the quality of parenting children receive. The influence of parenting on children's development is pervasive, affecting aspects as diverse as the child's cognition, language, emotion regulation, social skills, peer relationships, and physical and mental health (Sanders & Mazzucchelli, 2018b). This chapter explores the challenges faced by families raising a child with an intellectual disability to provide the context and a rationale for the provision of parenting support to parents and carers of children with an intellectual disability. A brief history of parent support in the disability field is provided before a range of contemporary evidence-based parenting support programs are introduced. There is considerable evidence supporting the efficacy and effectiveness of parenting interventions based on social learning theory principles; however, these interventions reach too few families. We present an argument for a population-based approach to parenting support for families with a child who has a disability. We present a model for what such an approach might look like, evidence to show such an approach is both feasible and effective, and describe challenges and future directions for the field.

Challenges Faced by Families Raising a Child with an Intellectual Disability

Parents report both benefits and burdens from raising a child with an intellectual disability. For instance, parents can report personal benefits such as becoming a better person—more compassionate, less selfish, more tolerant—as well as a sense of satisfaction and accomplishment at having done one's best (Hastings & Taunt, 2002). On the other hand, parents also report additional burdens. Raising a child can be a demanding and emotional task for any parent; however, parents raising a child with an intellectual disability are often faced with a range of additional unique and

emotionally demanding challenges (Mazzucchelli & Studman, 2018).

Children with an intellectual disability typically require care and support beyond that provided to typically developing children. By definition, children with intellectual disability present with high support needs in adaptive behavior and functional life activities (Harries, Guscia, Nettelbeck, & Kirby, 2009; Schalock et al., 2010). These children are at greater risk of having other comorbid disabilities such as physical and sensory disabilities and chronic health issues such as seizure disorders which can further complicate parenting (Kapell et al., 1998; Orelove, Sobsey, & Silberman, 2004). Additionally, children with an intellectual disability are three to four times more likely than their typically developing counterparts to develop significant emotional and behavioral problems, including severe and sometimes life-threatening behavior problems such as aggression and self-injurious behavior (Einfeld, Ellis, & Emerson, 2011; Lang et al., 2013).

Severe behavior problems can have serious consequences for the child, their parents, and other family members. They can threaten the physical health of children (Borthwick-Duffy, 1994; Nissen & Haveman, 1997), negatively impact the child's learning at school and peer relationships (Taanila, Ebeling, Heikura, & Jarvelin, 2003), restrict children's access to recreational and educational programs (Parmenter, Einfeld, Tonge, & Dempster, 1998), lead to exclusion from community settings (Borthwick-Duffy & Eyman, 1990; Borthwick-Duffy, Eyman, & White, 1987), and reduce occupational opportunities in the post-school period (Anderson, Lakin, Hill, & Chen, 1992). Behavior problems are also one of the main predictors of parental distress (McIntyre, Blacher, & Baker, 2006; Plant & Sanders, 2007), use of respite services (Chan & Sigafoos, 2001; Sloper, Knussen, Turner, & Cunningham, 1991), and parents relinquishing the care of their child (Nankervis, Rosewarne, & Vassos, 2011).

Even in the absence of severe behavior problems, daily hassles related to providing care can adversely affect a family's ability to cope (Crnic & Greenberg, 1990; Plant & Sanders, 2007). Parents of children with intellectual disability are at greater risk compared to parents of typically developing children of reporting high levels of stress, anxiety, and depression (Herring et al., 2006; Singer, 2006) as well as poorer psychological well-being (Barlow, Cullen-Powell, & Cheshire, 2006; Eisenhower, Baker, & Blacher, 2005). Parents often experience grief when they learn that their child has a disability, and the process of adapting to disability can be prolonged in nature (Eakes, Burke, & Hainsworth, 1998; Rentinck, Ketelaar, Jongmans, & Gorter, 2007). Parents often report difficulty finding respite and specialized childcare for their child (McConkey, Kelly, & Craig, 2011) and experience financial stress due to their reduced capacity to maintain full-time employment due to childcare responsibilities as well as the cost of therapy and medical expenses (e.g., Lin et al., 2013; Parish, Seltzer, Greenberg, & Floyd, 2004). Research also suggests that parents of children with intellectual disability are at increased risk for relationship distress (Kersh, Hedvat, Hauser-Cram, & Warfield, 2006; Risdal & Singer, 2004) and divorce (Hartley et al., 2010).

While individual biological and psychological factors may place children with an intellectual disability at increased risk for developing behavioral and emotional problems, there is strong evidence to suggest that these factors interact with social and environmental factors to precipitate and perpetuate problem behavior (Oliver, Demetriades, & Hall, 2002; Tonge & Einfeld, 2003). In particular, coercive parenting practices, emotional adjustment difficulties of carers, and relationship conflict between caregivers have been implicated in the development and maintenance of the emotional and behavioral problems of children with developmental disabilities (Chadwick, Kusel, & Cuddy, 2008; Koskentausta et al., 2007). Studies indicate that children with developmental disabilities are more likely to be exposed to such risk factors than their nondisabled peers (Green & Baker, 2011; Stalker & McArthur, 2012). Further, a bidirectional relationship has been found between parenting stress and child behavior problems: high parenting stress contributing to a worsening in child behavior problems over time and child behavior problems exacerbating parental stress (Neece, Green, & Baker, 2012; Woodman et al., 2015).

In summary, parents of children with intellectual disability are often faced with challenges greater than those faced by parents of typically developing children but have fewer supports and resources available to address those challenges. These parents are at greater risk of experiencing high levels of stress, and a reciprocal relationship can occur between parenting stress and child behavior problems.

Rationale for Parenting Interventions

Because of the unique needs of children with intellectual disability, their increased risk of developing behavioral and emotional problems, and the severe negative impact of such problems, there is widespread recognition of the importance of prevention and early intervention (McIntyre et al., 2006; Sanders & Mazzucchelli, 2018b). In tandem with this is the recognition that parents of these children have an increased need for support and specifically request information on how to interact with their children to promote their children's development and manage problem behavior (Bailey Jr. et al., 1999; Hamilton, Mazzucchelli, & Sanders, 2015).

Parents have a powerful influence on children's development through the day-to-day, moment-to-moment interactions that take place between themselves and their children (Dunst et al., 2001; Sanders & Mazzucchelli, 2018b). Through their interactions, parents can teach, prompt, and encourage their child's behavior to promote their acquisition of adaptive skills. They can also arrange the situational context and respond to their child's behavior in ways that decrease stressful parent-child interactions and the development of behavior problems (e.g., Buschbacher, Fox, & Clarke, 2004; Clarke, Dunlap, & Vaughn, 1999). Assisting parents to acquire these parenting skills is also likely to enhance parents' self-efficacy, an important element of self-regulation. Parental self-efficacy refers to a parent's belief about their capacity to successfully undertake their parenting responsibilities. When a parent has high levels of self-efficacy, they are more likely to persist with a task and achieve their parenting goals. They are also more likely to report less stress and higher levels of well-being (Sanders & Mazzucchelli, 2013).

Parenting practices, parental adjustment, and family relationships are obvious foci for supporting parents and families. Parenting support has the potential to enhance these important functions thereby addressing a range of factors that may positively impact children's development and family adjustment.

History of Parenting Support in Disability

Early Social History Surrounding Parenting Support

The emergence of parent training has been closely associated with societal change. Until the twentieth century, children with intellectual disabilities were separated from their families and were forced to live in asylums (Braddock & Parish, 2002). This institutionalization was enforced by government mental healthcare acts. Punitive methods of behavioral management were used by custodians, and no serious efforts were made to advance the development of these children (Nehring & Lindsey, 2016). Harsh attitudes found within institutions were reflective of prevailing societal attitudes. Disparaging views of intellectual disability peaked in the 1940s as competition for resources increased during the Second World War. Government-sanctioned massacres were completed in European countries, and an estimated 250,000 adults and children deemed to be "useless eaters" were killed, which included those with intellectual disabilities (Cocks, 1998).

Following the atrocities of the Second World War, global attitudes shifted to having increased tolerance toward others. Progress was made in providing support for people with intellectual disabilities (Braddock & Parish, 2002). In the 1940s and 1950s, there was rapid growth of charitable organizations consisting primarily of parents and family members of children with disabilities (Cocks, 1998). These groups advocated against the removal and maltreatment of their children as well as for better standards of service. This was known as the parent movement, and these associations created alternative residential and educational opportunities for children with intellectual disabilities (Davis, 2016).

The promotion of the civil rights movement in the 1950s and 1960s highlighted the difficulties experienced by minority groups, which contributed to the betterment of social practices concerning people with disabilities, prompting the disability rights movement (Braddock & Parish, 2002). Another considerable influence was concept of normalization proffered in the 1960s by Bengt Nirje, which was widely disseminated by Wolf Wolfensberger in the 1970s (Wolfensberger, Nirje, Olshansky, Perske, & Roos, 1972). The idea of normalization proposed that individuals with a disability should have access to opportunities akin to that of persons without a disability. The notion of normalization in combination with the other movements prompted global systemic change through enabling legislative reforms (Davis, 2016). These advancements in disability rights led to the complete deinstitutionalization of children with an intellectual disability (Nehring & Lindsey, 2016). Alongside this came a great need for interventions for building parental skills (Kazdin 2008).

Theoretical Principles Underlying Parenting Support

A direct influence on the formation of parenting support was the research on operant conditioning (Kazdin, 2008). Skinner suggested that the frequency that a behavior is emitted can be influenced by ensuing environmental consequences. After investigating behavioral modification with animals, Skinner described operant processes based on the type of stimulus change operation that immediately follows a behavior and the effect that operation has on the future frequency of that behavior. These processes are broadly categorized as either reinforcement or punishment (Skinner, 1938). Reinforcement occurs when a stimulus change (e.g., praise and touch) immediately follows a behavior (e.g., following an instruction) and increases the future frequency of that behavior in similar conditions. Punishment occurs when a stimulus change (e.g., a reprimand) follows a behavior (e.g., hitting) and decreases the future frequency of that behavior. Reinforcement is critical for increasing desirable behavior and promoting skill development (Kazdin, 2013; Mazzucchelli, 2018; Skinner, 1953). However, reinforcement alone may not be sufficient for managing severe behavior problems. In these cases, mild, effective, disciplinary consequences may be warranted to produce change (Morawska & Sanders, 2011).

A significant theoretical extension of operant conditioning was Albert Bandura's social learning theory. Bandura (1977) argued behavioral theories did not fully explain the development of behavior and posited that learning also occurs through observation. This theory was incorporated into parent training programs through techniques encouraging parents to model desired behaviors, so that children might learn to enact those behaviors through observation (McIntyre & Neece, 2016; Sanders & Mazzucchelli, 2018a). Later strategies derived from behavior modification principles gave increased attention to the antecedents of behavior, for example, how instructions are delivered as well as the settings in which they are given. The three fundamental constituents of forming behavioral responses are the antecedent stimulus (A), the behavior (B), and the consequence (C), also known as the ABCs of behavior (Kazdin, 2013; Skinner, 1953). The impact of consequences is influenced by motivating operations (Michael, 1982). Motivating operations refer to antecedent events or changes in the environment that alter the effects of consequences on behavior. For example, having recently engaged in exercise, a drink may be strongly reinforcing (Simó-Pinatella et al., 2012).

Initial Research on Parenting Support

Beginning in the 1960s, research on parent training strategies was a response to the lack of effective interventions for children who presented with behavior problems. Psychodynamic approaches had been commonly used but did not result in reliable and generalized reductions in problematic behavior (Eyberg, 1988). A number of psychologists began conducting single group designs and descriptive case studies researching new models of parent training, which promoted parents as agents of change, equipping them with knowledge of behavioral principles. For instance, Jensen and Womack (1967) taught operant conditioning techniques to a mother with a 6-year-old child with autism spectrum disorder. This intervention resulted in substantial decreases in the number of tantrums and disruptive behaviors emitted by the child. Findings from such studies indicated that using operant principles was effective in reducing problematic behaviors. These insights contributed to the founding of the first structured behavioral parent training interventions (Shaffer, Kotchick, Dorsey, & Forehand, 2001).

Parent training programs targeted deficits in parenting skills which were maintaining challenging behaviors. Improvements in parenting practices aimed to strengthen prosocial behaviors of their children, such as following instructions, and to weaken antisocial behaviors such as tantrums (Forehand, Kotchick, Shaffer, & McKee, 2010). An influential model of parenting support was developed by Constance Hanf at the University of Oregon in the 1960s and early 1970s. Hanf's work occurred contemporaneously to that of Gerald Patterson and his colleagues (also in Oregon) whose research program led to what is now known as Parent Management Training - Oregon Model (PMTO). In comparison to PMTO, Hanf's model placed greater importance on the parent-child relationship and was designed as an early intervention for use with younger children (aged 3–8 years). Hanf's work was initially undertaken with children with a developmental disability and their families, and the resulting model formed the basis of many contemporary parenting support programs (Reitman & McMahon, 2013).

In the 1970s and 1980s, the primary objective of parent training research was to investigate the generalization of treatment effects and long-term outcomes (Forehand et al., 2010). Sanders and Plant (1989) investigated the generalization of treatment of effects of parent training with children who had developmental disabilities. Their findings indicated that parents were able to successfully implement behavioral management strategies across environments other than the training setting when provided instruction in antecedent/preemptive parenting techniques. It is now recognized that the effects of parent training often generalize across settings, over time, to other siblings who are not the focus of treatment and to other behaviors which were not targeted (Shaffer et al., 2001).

Contemporary Parenting Support Programs

This section will provide a description of contemporary, empirically supported, parenting support programs for families with children who have a disability.

The Portage Project

The Portage Project is an early intervention program which aims to provide parents with education on behavioral principles via home visits to support the development of children with an intellectual disability. The program was originally designed for children with disabilities from birth to 6 years of age as well as their family (Shearer & Shearer, 1976). The New Portage Guide, which is the current version of the program, begins with a skill assessment of parents' ability to manage difficult behaviors and the child's level of functioning. Parents are then trained to teach their children new skills, which are progressively completed based on the milestones achieved by children up to the age of six. Each week has a different goal, and specific instructions are provided to parents in terms of how to teach their child the new skill and how to record the progress of the child. Home visits by health professionals are intermittently incorporated to assist parents in appropriately delivering the behavioral strategies (Baker, Marquis, & Feinfield, 2016).

The Portage program has been widely disseminated and applied seemingly effectively across diverse populations and cultures, as it is used in over 60 different countries with successful modification of behaviors of children with a disability being reported (Baker et al., 2016). An evaluation of anecdotal and empirical results from studies assessing the effectiveness of the Portage Project program found positive results being reported by the professionals and parents involved in delivering the intervention (Brue & Oakland, 2001). However, it must be noted that there are only a small number of quantitative studies with high methodological rigor which assess for the Portage Project's effectiveness, meaning that further research is needed (Brue & Oakland, 2001).

Parent-Child Interaction Therapy

Parent-child interaction therapy (PCIT) is a behavioral approach which was developed to address challenging behaviors of children aged 2–7 years (Eyberg, 1988). The objective of the treatment is to establish a warm relationship between a parent and a child as well as to change problematic parent-child interactional sequences through the medium of play. Disruptive behaviors are decreased, and prosocial behaviors are increased through the improvements made in the quality of the relationship and by resolving coercive interactional styles that serve to maintain these behaviors (Eyberg, 1988). The therapist provides psychoeducation, role-plays warm interactions, and coaches the parent by giving immediate and specific feedback on the parent-child interaction occurring during play with the child (McNeil & Hembree-Kigin, 2010). Parents are encouraged to avoid using any commands, instructions, and criticisms, which would most likely threaten the warm relationship. Parents are taught skills to deliver verbal directions calmly and clearly and to apply appropriate consequences to target behaviors in ways which the child can understand (Eyberg, 1988).

Bagner and Eyberg (2007) conducted the first randomized controlled trial which specifically examined the efficacy of PCIT with 30 families of children aged 3–6 years with an intellectual disability. The parenting intervention significantly reduced child disruptive behavior and parental stress compared to those in the waitlist condition. Furthermore, it was reported that children in the intervention condition were more compliant post-intervention and that improvements were also observed in parent-child relationships (Bagner & Eyberg, 2007).

A recent case study documented the use of PCIT combined with visual supports with a 5-year-old girl who had an intellectual disability and comorbid epilepsy and autism spectrum disorder (Armstrong, DeLoatche, Preece, & Agazzi, 2014). Improvements in behavioral functioning were reported across home, school, and community settings providing further evidence that the treatment effects of PCIT can generalize across settings. Although there is a significant body of research on PCIT with typically developing children, few studies with high methodological rigor have specifically examined PCIT for use with children with developmental disabilities, and further investigation is required (Armstrong et al., 2014).

The Incredible Years Program

The Incredible Years program is an early intervention parent training program which aims to reduce problematic behaviors of children. The Incredible Years parenting program consists of a suite of programs developed for different age groups, including babies, toddlers, pre-primary schoolers, and primary school aged. The program is delivered in a group format with parents in 12–20 weekly sessions. Trained group facilitators use techniques such as role-play, didactic instruction, video modeling, and discussion. These techniques are used to cover topics such as rewards, strengthening the parent-child relationship, reducing punitive punishments, play, boundary setting, and managing disruptive behaviors. Problematic behaviors of children are reduced through changing negative, coercive, parenting styles to more positive, noncoercive, parenting styles. Adjustments are made to the Incredible Years program when being delivered to parents of children with disabilities, such as including discussions on the unique blessings and challenges faced by families that have children with developmental delays (McIntyre & Neece, 2016).

Adapted versions of Incredible Years have been consistently found to yield significant reductions in disruptive behaviors emitted by children with an intellectual or developmental disability (Kleve et al., 2011; McIntyre, 2008a, 2008b; Phaneuf & McIntyre, 2011). This is consistent with the effectiveness of Incredible Years when used with parents of typically developing children (Menting, de Castro, & Matthys, 2013).

Signposts for Building Better Behavior

Signposts is a multilevel parent training intervention which has been developed specifically for parents or caregivers of youth, aged 3 to 16 years of age, with a developmental delay or intellectual disability (Hudson et al., 2003). The primary aims of the program are to assist parents to implement strategies to manage difficult child behavior, to promote prosocial behavior, and to teach these children new coping skills (Hudson et al., 2003). The program is prevention orientated, with a stated goal being to prevent the escalation of disruptive behavior before the severity rises to a clinical level and requires expensive, specialized interventions (Hudson, Cameron, & Matthews, 2008).

The standard program delivery of Signposts comprises six fortnightly sessions with a 4-week break between session five and six (McIntyre & Neece, 2016). Signposts can be delivered in a group format, individual face-to-face, or in a self-directed fashion with telephone support (Hudson et al., 2008). Each session has a duration of 2 h and 30 min and is delivered by a trained health professional (McIntyre & Neece, 2016). Parents are trained in using strategies such as recording behaviors, modifying interactional patterns, planning to avoid cueing disruptive behaviors, and other behavioral approaches to reduce problem behaviors. The strategies are based on common scenarios which occur within family settings of children with disabilities (McIntyre & Neece, 2016). A small number of studies have found support for the effectiveness of Signposts. In the foundational evaluation, the parents of 115 families who participated in the program reported lower levels of stress, increased efficacy at managing disruptive behavior, and increases in desired behaviors in their children (Hudson et al., 2003). Findings have also indicated that the effectiveness of the intervention is enhanced through fathers' involvement in the program (May et al., 2013). Furthermore, factors such as age, gender, and associated disability have not been found to moderate the treatment outcomes for children with intellectual disabilities or their families (Hudson, Reece, Cameron, & Matthews, 2009).

A Population Approach

Research findings from numerous studies have demonstrated that parenting interventions based on social learning theory, functional analysis, and cognitive behavioral principles result in increased parental competence and confidence in raising their child with a developmental disability, reductions in child emotional and behavioral problems, and significant reductions in parent stress (Hudson et al., 2009; Ruane & Carr, 2018; Tellegen & Sanders, 2013). Unfortunately, despite the strength of the evidence, still too few parents who might benefit from evidence-based parenting support (EBPS) actually participate. Traditional clinical models of service delivery typically reach few families, and the small proportion (13%) of parents that do access parenting programs do not access EBPS (Einfeld et al., 2018a; Sanders et al., 1999). Despite the fact that parenting groups are widely advocated in the parent training field, parents of children with a disability believe that a range of delivery modalities are likely to be useful (e.g., group, individual, seminar, web-based, over the telephone), and parents differ in opinion as to which modalities are likely to be most useful (Mazzucchelli & Moran, 2017). These findings confirm that contemporary parents are looking for alternative, flexible ways of accessing parenting advice (Sanders et al., 1999). The consequence of low program availability, limited program options, and nonoptimal participation rates is inadequate program reach.

Limited program reach means that most families who could benefit from parenting programs do not access them. When relatively few families derive the benefits of EBPS, the potential of these programs to reduce the prevalence of problematic outcomes for children in the entire population is markedly weakened. Effective dissemination of EBPS is critical for programs to have any significant community impact. Of the parent training programs that have been disseminated to date, many have been delivered late in the developmental trajectory as interventions for children already showing signs of challenging behavior rather than as prevention programs (Mazzucchelli & Sanders, 2011).

A population approach to parenting support involves making EBPS available to all who choose to access such support. This usually requires the program to be offered across multiple sites and by many different practitioners (e.g., in disability, education, and health sectors and nongovernment organizations). It also requires that the parenting program can be delivered in different intensities and through different modalities. The benefits of a population approach rather than an approach which targets families who are identified as experiencing difficulties are many. If programs are offered to every family, then participating is normalized, and any stigma that might occur is eliminated. When programs can be accessed through multiple agencies and in a variety of modalities and intensities, then barriers to attendance are reduced, and parents can choose to access as much or as little support as they require at a time (Mazzucchelli & Sanders, 2011).

We suggest that a population approach that addresses the broader ecological context of parenting is required to ensure that more parents can access parenting programs and to achieve a population-level reduction in the prevalence of social, emotional, and behavioral problems in children with developmental disability (Mazzucchelli & Sanders, 2011).

The Stepping Stones Triple P System

Stepping Stones Triple P (SSTP; Mazzucchelli & Studman, 2018; Sanders, Mazzucchelli, & Studman, 2004) is one of the few examples of a population-based approach to parenting for families with a child who has a developmental disability. Parallel to the core Triple P—Positive Parenting Program (see Sanders & Prinz, 2018), SSTP was developed as a comprehensive system of parenting and family support to improve the quality of parenting advice available to parents of children with a disability. The system aims to promote children's development and prevent severe social and emotional problems and child maltreatment, by enhancing the knowledge skills and confidence of parents. It incorporates five levels of intervention on a tiered continuum of increasing strength for parents of children from birth to age 12. The multilevel suite of programs is designed to create a "family friendly" environment that supports parents in the task of raising their children (see Table 40.1). It specifically targets the social contexts that influence parents on a day-to-day basis. These contexts include primary healthcare services, childcare and school systems, disability support organizations, and mental health services. The multilevel strategy is designed to maximize efficiency, to avoid waste and overservicing, and to ensure that the program has wide reach in the community (see Fig. 40.1). It also allows for choice in the intensity and delivery modality to match programs to families' needs and preferences.

Table 40.1 The Stepping Stones Triple P system of parenting and family support

Level of intervention	Target population	Intervention methods	Facilitators
Level 1 Communications strategy • *Universal Triple P* • *Stay Positive*	All parents interested in information about parenting and promoting their child's development	Coordinated communications strategy raising awareness of parent issues and encouraging participation in parenting programs. May involve electronic and print media (e.g., brochures, posters, websites, television, talk-back radio, newspaper and magazine editorials)	Typically coordinated by communications, health, or welfare staff members
Level 2 Health promotion strategy/brief selective intervention • *Selected Stepping Stones Triple P*	Parents of children with a disability who are interested in parenting education or with specific concerns about their child's development or behavior	Health promotion information or specific advice for a discrete developmental issue or minor child behavior problem. May involve a group seminar format or brief (up to 20 min) telephone or face-to-face clinician contact	Practitioners who provide parent support during routine well-child healthcare (e.g., health, education, allied health, and childcare staff) or disability early intervention services (e.g., therapy or psychology staff)
Level 3 Narrow-focus parent training • Primary Care Stepping Stones Triple P • Stepping Stones Triple P Discussion Groups	Parents of children with disability who have specific concerns, as above, who require consultations or active skills training	Brief program (about 80 min over 4 sessions, or 2 h discussion groups) combining advice, rehearsal, and self-evaluation to teach parents to manage a discrete child problem behavior. May involve telephone or face-to-face clinician contact or group sessions	Same as for Level 2
Level 4 Broad-focus parent training • Standard Stepping Stones Triple P • Group Stepping Stones Triple P • Self-Directed Stepping Stones Triple P	Parents of children with a disability who want intensive training in positive parenting skills. Typically, parents of children who want to promote their children's development or with behavior problems such as aggressive or oppositional behavior	Broad-focus program (about 9–16 h over 9–10 sessions) focusing on parent-child interaction and the application of parenting skills to a broad range of target behaviors seen in a disability context. Includes generalization enhancement strategies. May be self-directed or involve telephone or face-to-face clinician contact or group sessions	Intensive parenting interventions (e.g., disability, mental health, and welfare staff and other allied health and education professionals who regularly consult with parents about child behavior)
Level 5 Intensive family intervention modules • Enhanced Triple P	Parents of children with behavior problems and concurrent family dysfunction (e.g., parental depression or stress) or conflict between partners	Intensive individually tailored program with modules (sessions last 60–90 min) including practice sessions to enhance parenting skills, mood management and stress coping skills, and partner support skills	Intensive family intervention work (e.g., disability, mental health, and welfare staff)
• Pathways Triple P	Parents at risk of maltreating their children. Program targets anger management problems and other factors associated with abuse	Intensive individually tailored or group program with modules (60–120 min sessions) depending on delivery model including attribution retraining and anger management	Same as above
• Group Lifestyle Triple P	Parents of overweight or obese children. Targets healthy eating and increasing activity levels, as well as general child behavior	Intensive 14-session group program (including telephone consultations) focusing on nutrition, healthy lifestyle, and general parenting strategies. Includes generalization enhancement strategies	As above, plus dieticians /nutritionists with experience in delivering parenting interventions
• Family Transitions Triple P	Parents going through separation or divorce	Intensive 12-session group program (including telephone consultations) focusing on coping skills, conflict management, general parenting strategies, and developing a healthy co-parenting relationship	Intensive family intervention work (e.g., disability, mental health, and welfare staff)

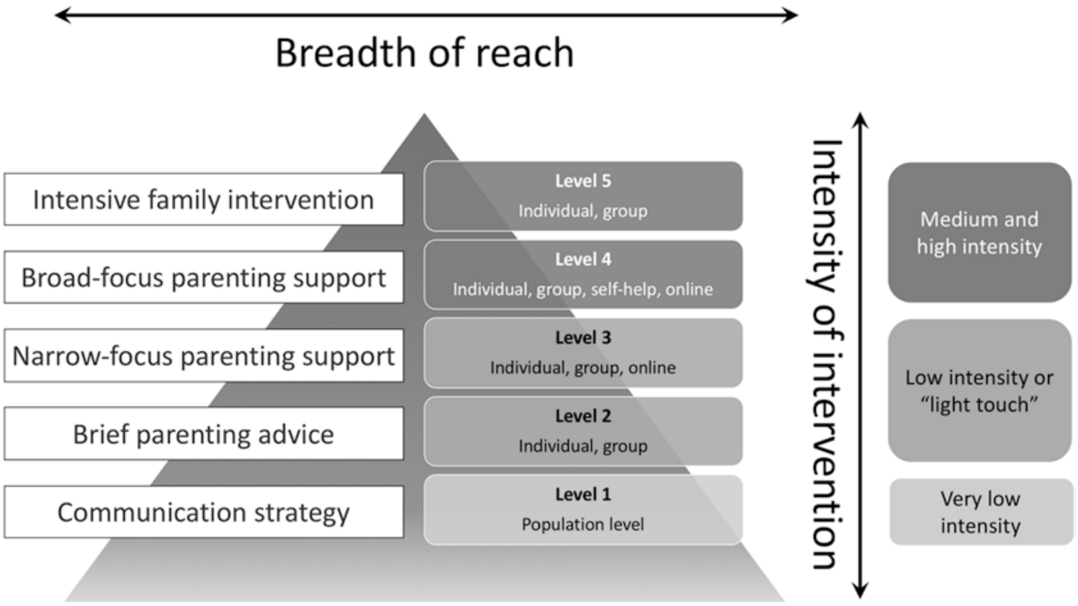

Fig. 40.1 The Triple P model of graded reach and intensity of parenting and family support services

The seven core positive parenting principles that form the basis of the program were selected to address specific risk and protective factors known to predict positive developmental and mental health outcomes in children with a disability (see Table 40.2). Table 40.3 shows how the principles are operationalized into a range of specific parenting skills; see Mazzucchelli and Sanders (2012) and Mazzucchelli and Studman (2018) for a more complete overview and description of the different interventions that make up the system.

The Stepping Stones Triple P system has been featured in two meta-analyses that have drawn from 16 RCTs and 3 uncontrolled trials that have evaluated individual interventions that make up the SSTP system (Ruane & Carr, 2018; Tellegen & Sanders, 2013). Both meta-analyses concluded that the interventions are effective in improving outcomes for children and parents. Statistically and clinically significant effects for all delivery format and program variants have been found for children's emotional and behavioral outcomes; parenting practices; parenting satisfaction and efficacy; parental adjustment; the parental couple relationship; and observed child and parent behavior (Ruane & Carr, 2018; Tellegen & Sanders, 2013). The positive outcomes demonstrated for each of the Stepping Stones Triple P levels provide support for a multilevel, multidisciplinary system of parenting programs, including prevention and treatment options, to increase timely access to cost-effective services promoting child, parent, and family well-being.

A population-level trial of the SSTP system involving the simultaneous delivery of all levels of the SSTP system has recently been undertaken across three states of Australia (Sofronoff, Gray, Einfeld, & Tonge, 2018). Preliminary results from this trial indicate that this approach increases access to parenting support for parents of children with a disability with 38% of the target population participating in a program. Furthermore, it results in significant improvements in a range of indices of family functioning including reductions in parental stress; reductions in negative parenting styles such as parental inconsistency, coercive parenting, and lack of positive encouragement; and decreases in child behavioral and emotional problems (Einfeld et al., 2018a; Gray et al., 2017; Sofronoff et al., 2018). In addition, the population trial was found to be cost-effective; when the cost of establishing and implementing SSTP was calculated and compared with the value of cost savings, the SSTP system

Table 40.2 Principles of positive parenting children with a disability

Principle	Description
A safe and engaging environment	Children of all ages need a safe, supervised, and therefore protective environment that provides opportunities for them to explore, experiment, and play. This principle is essential to promote healthy development and to prevent accidents and injuries in the home
A positive learning environment	This involves educating parents in their role as their child's first teacher and specifically teaching parents to respond positively and constructively to child-initiated interactions (e.g., requests for help, information, advice, and attention) through incidental teaching and other techniques to assist children to learn how to solve problems for themselves
Assertive and consistent discipline	Stepping Stones Triple P teaches parents specific child management and behavior change strategies that are alternatives to coercive and ineffective discipline practices (e.g., shouting, threatening, or using physical punishment). The aim is to develop predictable and consistent responses and avoid factors that may maintain problem behavior (e.g., accidental rewards)
Adapting to having a child with a disability	This involves parents coming to terms with their child's disability, finding a balance between the demands and stresses of parenting and the resources they have to cope, and staying optimistic about the future. Parents may need to acknowledge any sense of grief or sense of loss they feel. They may also find it helpful to decrease demands and stressors, increase their coping resources, and find personal meaning and a sense of control
Realistic expectations	This involves exploring with parents their expectations, assumptions, and beliefs about the causes of children's behavior and choosing goals that are developmentally appropriate for the child and realistic for the parents. Parents who are at risk of abusing their children are more likely to have unrealistic expectations of children's capabilities
Being part of the community	Every individual with a disability has a right to a full and rewarding life that includes employment or meaningful activities throughout the day, living independently in the community, a meaningful social life with friends and family members, and recreation, hobbies, and leisure time. Creating this life begins in childhood by families regularly using facilities and participating in activities in the community
Taking care of oneself as a parent	Parenting is affected by a range of factors that impact on a parent's self-esteem and sense of well-being. All levels of Stepping Stones Triple P specifically address this issue by encouraging parents to view parenting as part of a larger context of personal self-care, resourcefulness, and well-being and by teaching parents practical parenting skills

was found to save each family AUD$574 per year. This was primarily because of increased capacity of parents to return to work (Einfeld et al., 2018a). These results suggest that a population-level approach holds great promise for increasing the reach of EBPPs and having a positive impact on the well-being of all children with a disability and their families. In the next sections, we will outline some of the issues and challenges in implementing such an approach.

Issues and Challenges in Providing Parenting Support

Increasing Reach and Uptake

Despite parenting programs having been around for decades, only a minority of parents of children with disabilities participate in them, even though they have three to four times the level of behavioral and emotional problems of typically developing children. Part of the rationale behind developing a multilevel system of parenting support has been to ensure that parents are able to participate in programs more suited to their preferences, interest, and needs. Strategies from population health need to be employed to social market programs to create "pull" or consumer demand (e.g., Wilkinson, 2018). This will help reduce stigma and to challenge a view that parenting programs are for parents who are struggling.

Engaging Fathers

The vast majority of parents who participate in parenting intervention studies are mothers (Panter-Brick et al., 2014). The under-presentation of fathers in both research and clinical practice

Table 40.3 Core parenting skills introduced in Stepping Stones Triple P

Safe and engaging environment	Positive learning environment	Assertive discipline	Adapting to having a child with a disability	Realistic expectations	Being part of the community	Parental self-care
• Spending brief quality time • Communicating with children • Showing affection • Providing engaging activities	• Giving nonverbal attention • Giving descriptive praise • Giving other rewards • Setting a good example • Using physical guidance • Using incidental teaching • Using ask-say-do • Teaching backward • Using behavior charts	• Using diversion to another activity • Establishing ground rules • Using directed discussion • Using planned ignoring • Giving clear, calm instructions • Teaching children to communicate what they want • Using logical consequences • Using blocking • Using brief interruption • Using quiet time • Using time-out	• Improving personal communication habits • Giving and receiving constructive feedback • Having casual conversations • Supporting each other when problem behavior occurs • Problem-solving • Improving relationship happiness • Getting personal and professional support • Having a break and using respite services • Maintaining optimism	• Monitoring children's behavior • Setting developmentally appropriate goals • Setting practice tasks • Self-evaluating strengths and weaknesses • Setting personal goals for change	• Planning and advanced preparation • Discussing ground rules for specific situations • Selecting engaging activities • Providing incentives • Providing consequences • Holding follow-up discussions	• Catching unhelpful thoughts • Using relaxation and stress management • Developing personal coping statements • Challenging unhelpful thoughts • Developing coping plans for high-risk situations

can be addressed by ensuring program outreach emphasizes the importance of father participation, by training practitioners to identify the preferences, priorities, and needs of fathers and to tailor program delivery so that the needs of mothers and fathers are addressed. There is emerging evidence that programs that tailor delivering to the needs and interests of fathers can be very successful. For example, Frank, Keown, and Sanders (2015) used focus groups and surveys of fathers to identify parenting topics and issues that were concerning to fathers. They then incorporated these findings into program delivery through example selection, emphasis on the importance of the father's relationship with children and their paternal role, and individually tailored homework for fathers and mothers, not just couple homework. Following program completion, intervention group fathers and mothers reported significantly fewer child behavior problems, dysfunctional parenting practices, and interparental conflict about child-rearing than waitlist parents. Intervention group mothers also reported increased parenting confidence and rated their partners as showing significantly fewer dysfunctional parenting practices. Intervention effects were maintained at 6-month follow-up. Both mothers and fathers reported high levels of satisfaction with the program.

Addressing Behavioral Phenotypes

Children with disabilities are not a homogeneous group, and there are a wide range of behavioral phenotypes or syndromes (e.g., fragile X). These children may have unique features (e.g., touch aversion) that require parenting advice to be adapted to take into account the type of condition the child has. The MHYPEDD research team (Einfeld et al., 2018b) developed a range of parent and practitioner tip sheets to assist practitioner adapt principles of positive parenting to the child's unique presentation. Interestingly although these resources were valued by both parents and practitioners, they were rarely used in the rollout of the program.

Practitioner Attitudes and Beliefs

Practitioners across a range of disciplines have a special role in providing timely parenting support in the context of disability, but some practitioners have beliefs about parenting support that may act as a barrier to this. For instance, practitioners may think that parenting support is somehow incompatible with a "family-centered" practice orientation that emphasizes an equal and supportive parent-practitioner relationship. Practitioners might hold the belief that providing instruction/coaching to parents regarding their interactions with children cannot be collaborative (Mahoney et al., 1999). Practitioners may also believe that providing such training may cause parents additional stress, implicitly blame parents, overemphasize parents' role as teachers undermining the parent-child relationship, and be culturally insensitive. These beliefs are not consistent with feedback from parental surveys or the results from trials of EBPS. Good parenting training is not incompatible with family-centered practice; indeed, a supportive and collaborative relationship is a prerequisite to successful parent training (Mazzucchelli & Sanders, 2010).

Staff Turnover

The disability sector has a generally high rate of staff turnover (Hatton et al., 2001). This means that organizations have to continuously invest in training new staff in the delivery of parenting interventions. Low cost on the job training is rarely sufficient for staff to learn how to deliver a parenting intervention and to deliver it with fidelity. Training or purveyor organizations offering training need to develop cost-effective alternatives to intensive 3- to 5-day training programs which may not be offered when an organization needs new staff to be trained. While web-based training that can be accessed 24/7 seems an obvious alternative, there are major challenges in designing online training programs that provide coaching and feedback to practitioners based on their actual performance in a consultation or a simulated one. Until online training courses using artificial intelligence have been shown to be just as effective as in person training, organizations are likely to have to team up with other like organizations to arrange group-based training for new staff. They can manage the supervision process internally using models of supervision such as peer-assisted supervision and support (PASS, McPherson & Schroeter, 2018).

Public Policy

The quality of parenting services available to families of a child with a disability is influenced by the favorability of the broader policy environment and funding priorities of government. For example, in an Australian context although funding is available to support parents' access to individual parenting programs through the National Disability Insurance Agency, group-based programs delivered by organizations are not. This anomaly needs to be addressed as a matter of public policy so parents are able to access programs in a format they are seeking.

Another policy matter that has caused controversy in the disability sector is the use of restrictive practices such as time-out. In some jurisdictions the use of time-out is frowned upon and actually banned in some institutional settings (e.g., childcare, residential care). Misuse of time-out as a punitive measure in a negative environment is very different from parental use of time-out in a highly reinforcing home environment. Also, reports in major news outlets (Time Magazine) claiming time-out damages children's brains have been sensationalized and led to calls to abandon an extremely useful intervention for certain behavior problems (Siegel & Bryson, 2014).

These political considerations point to the ongoing importance of policy advocacy on the basis of evidence to ensure that parents can access programs that work.

Future Directions

The field of EBPS for parents of children with a disability continues to evolve as more studies demonstrate that both children and parents benefit from these interventions. In line with the parenting field generally, there is now a much more diverse range of delivery modalities that have been tested including the use of online parenting programs combined with social media, self-help programs, and low-intensity primary care interventions (Hinton, Sheffield, Sanders, & Sofronoff, 2017; Tellegen & Sanders, 2014).

Although there have been relative few cost-effective studies, a recent independent economic analysis of the Stepping Stone Triple P system showed that it was extremely cost-effective, saving participating families approximately $574 per year primarily because of less missed days of work per year (Einfeld et al., 2018a). Other economic analyses of parenting interventions based on social learning principles with typically developing children have consistently shown them to be cost-effective (Sampaio, Feldman, Richards-Jones, & Mihalopoulos, 2018).

Parenting intervention has primarily focused on challenging behavior in younger children; however, parents continue to influence the well-being of children in every subsequent phase of development. Recently, Stepping Stones Triple P has been extended to support parents of adolescents (Building Bridges Triple P). Pilot evaluation data shows promising positive impact on adolescent behavior problems, parenting practices, and parental confidence and emotional adjustment; however, future randomized trials are needed to establish a sufficient evidence base to justify dissemination (Mazzucchelli, Jenkins, & Sofronoff, 2018).

Grandparents play an important role in the lives of many children with a disability and where they have frequent childcare responsibilities, it makes sense to involve the grandparent in parenting programs. Several recent randomized trials involving both noncustodial and custodial grandparents showed when grandparents were offered Group Triple P (either the standard program or an adapted version specifically for grandparents), there were positive effects on grandparent well-being and parent-grandparent communication, and improvements in grandchildren's behavior (Smith et al., 2018; Kirby & Sanders, 2014). Similar studies are needed with grandparents of children with a disability.

Conclusion

Evidence-based parenting support has evolved from intensive home-based individual and group programs many of which were originally developed for typically developing children with conduct problems to a comprehensive population-based, trans-diagnostic, multilevel system of parenting support (Sanders & Mazzucchelli, 2018c). As with other parents, it is highly likely that offering parenting support to parents of children with a developmental disability as a "one size fits all" will be unlikely to meet the diverse needs of parents. The field should avoid an "inoculation" approach which provides programs in early childhood but ignores the parenting challenges at other stages of the life cycle (elementary school age, adolescent, young adulthood, and beyond). There is little work to date addressing the needs of parents of adult children with a disability. Substantially more research is needed to examine the effects of current program variants with more culturally diverse families. Research is also needed to find ways to engage socioeconomically disadvantaged parents and support them to successfully complete programs. Where parenting programs tailored to the needs of parents with special needs are made available as part of a population-based parenting support strategy for all parents, completing a parenting program will become free of stigma, routine, expected, not exceptional, and a normative rite of passage for all parents.

Take-Home Messages

- Parenting programs based on social learning theory, functional analysis, and cognitive behavioral principles result in increased parental competence and confidence in raising their child with a developmental disability, reductions in child emotional and behavioral problems, and significant reductions in parent stress.
- Evidence-based parenting support should be accessible to all parents of children with a disability.
- A population-level approach holds great promise for increasing the reach of evidence-based parenting programs and having a positive impact on the well-being of all children with a disability and their families.
- Parenting support should be accessible for parents at each phase of the child's life span.

Disclosure Statement The Parenting and Family Support Centre is partly funded by royalties stemming from published resources of the Triple P—Positive Parenting Program—which is developed and owned by The University of Queensland (UQ). Royalties from the program are also distributed to the Faculty of Health and Behavioural Sciences at UQ and contributory authors of Triple P programs. Triple P International (TPI) Pty Ltd. is a private company licensed by UniQuest, Pty Ltd., a commercialization company of UQ, to publish and disseminate Triple P worldwide. Self-Help Skills

Johnny L. Matson and Esther Hong

Overview

A major area of research, historically, in the field of intellectual disabilities (ID; formerly "mental retardation" for those doing literature searches on the topic) has been self-help skills. These issues are particularly salient for children and persons with severe or profound cognitive deficits. However, this area of skill training also has implications for older persons with ID as well as for those individuals whose cognitive deficits are not as impairing.

Other factors are also at play regarding the focus on self-help skills. Obviously, these skills promote independence. Additionally, the move toward normalization, deinstitutionalization, and independent living has played major roles in the development of the area. These trends are exemplified by studies such as the one by O'Neill, Brown, Gordon, and Schonhorn (1985), which studied 27 adults with severe or profound IDs, who had been transitioned from institutional care to a post-institutional placement program in New York City. These new residences were apartments with two or three occupants and group homes with eight residents. The authors noted increased activity and increased communication skills. Additionally, the participants demonstrated improvements in self-care skills, such as eating, table manners, selecting clothing, dressing and undressing, showering, toileting, grooming, preparing meals, and house cleaning skills. The authors speculated that factors, such as more learning opportunities in community living arrangements, may have contributed to these improved outcomes; however, clear reasons for these gains were not directly tested.

Another theme is presented by Fox, Holtz, and Moist (2009). In their study, four adults with autism spectrum disorder (ASD) and severe or profound ID were treated for serious long-term behavior problems. They described their intervention as a community-based accommodation program. The stated focus was to design a highly predictable environment based on individual preference. The authors reported that one participant preferred to work in a rocking chair with cushions, at a table away from others. A second participant preferred to be seated so he could observe people walking down the hall near his work area. Reinforcer surveys were also used to further personalize training, and these data were used in combination with a contingency management program to enhance prosocial behaviors and to aid in the reduction of challenging behaviors.

These examples demonstrate important trends in promoting living in the community, being independent, having programs that are customized

to the individual, and having the right to make choices. Millar (2008) underscored this point in her paper regarding issues that emerge when an individual reaches the age of majority and are impacted by Individuals with Disabilities Education Improvement Act (IDEIA; Rehabilitation Act Amendments of 1992 and 1998, US Congress). Based on each individual's needs and strengths, supports need to be developed to assist the person in reaching their maximum potential. These goals have in large part been achieved via the development of treatments that largely fit into a teaching, structured program, which are complemented by specific applied behavior analysis (ABA) treatment methods.

Assessment

A number of tests, such as the Vineland Social Maturity Scale, have been developed and are widely used in clinical practice. These tests are covered extensively elsewhere in this volume. As a result, the focus here is on a few methods that are used less often but are also valuable. Additionally, these measures are very specific to assisting in the development of treatments for self-help skills. Matson, Dempsey, and Fodstad (2009), for example, studied the Adaptive Behavior Task Analysis Checklist (ABTAC). As with the Murdock Center task analyses, this instrument provides information that can assist in targeting and breaking down skills into discrete tasks. These tasks can be prompted, modeled, and/or reinforced to develop self-help and independence skills. There were 234 adults with ID only and adults with both ID and ASD who participated. Items involved dressing and undressing, grooming, housekeeping, and meal preparation. The greatest skill deficits were evident for persons with ID and ASD. Further, as ASD symptoms became more severe, so did deficits in independent living skills.

Another assessment measure, this one specific to feeding problems, has also been described (Screening Tool of Feeding Problems [STEP]; Matson & Kuhn, 2001). They evaluated 57 people between 10 and 87 years of age, with ID levels of mild to profound. The STEP has 23 items, all of which address essential feeding problems such as the ability to chew, food stealing, eating small amounts of food, and selecting food by texture. The general conclusion was that the measure had good psychometric properties.

These are two studies that present measures to help identify behaviors for intervention and aid in measuring treatment progress. As noted, popular measures of adaptive behavior are covered elsewhere in this book. The reader may also wish to consult Kraijer (2000), who provides a nice review of adaptive behavior measures for persons with ID and ASD.

Overview of Treatment Methods

A variety of strategies have been used to teach independent living skills. Schoen and Sivil (1989) described the teaching of self-help skills to children with disabilities. A variety of methods were employed including chaining, prompting (both verbal and physical, which were gradually faded out), observational learning or modeling, and reinforcement. This group of methods has proven to be typical for many programs with the ID population and has routinely been effective.

Ferretti, Cavalier, Murphy, and Murphy (1993) provided another excellent example of frequently used treatment methods. They rightly pointed out that the transition to less restrictive living settings for persons with ID is important. These authors reviewed self-management strategies and broke them into three categories. Categories were characterized as self-instruction and verbal-mediated chains of behaviors (e.g., goal setting, strategy selection, self-monitoring, self-evaluation, and providing one's own consequences for behaviors). The third category involved self-management skills. Under the self-instruction skills category, trainees learned how to define the problem and learned the correct sequence in which to perform skills that aid in a resolution of the problem. Other skills focused on evaluating one's performance as well as dealing with mistakes and the frustration that can result following the mistakes. Finally, methods of providing consequences, whether correct or incorrect, were taught.

The second category was self-management of a chain of behaviors. Among the skills taught included self-monitoring, self-management, and learning to record target behaviors. Self-administering reinforcement and punishment were also employed in an effort to help the trainee focus on the components of a task that needed to be performed and whether these were being carried out correctly. When necessary, therapists provided prompts and feedback to aid in the learning process. The final category that Ferretti et al. (1993) described was multicomponent self-management studies. They noted that multiple procedures were used at once with these treatments. Among the methods employed were self-evaluation, self-monitoring, self-reinforcement, self-recording, tokens, performance goals, and visual cues.

Akhmetzyanova (2014) pointed out that structured, step-by-step instruction is important for teaching self-help skills to persons with ID. She also pointed out that individuals with severe and profound ID require special one-to-one training in their efforts to achieve independence. We would add that shorter but more frequent training sessions should be employed, with smaller behavioral steps or goals, more physical prompts, and the use of more tangible reinforcements.

Millar (2008), in discussing goals in treatment, underscored the need for self-determination. Certainly, this is a critical goal, and the development of self-help skills provides a vital tool in achieving this goal. These goals and skills within the self-help literature are therefore often referred to as independent living skills. Matson, Smalls, Hampff, Smiroldo, and Anderson (1998) described the use of staff training, feedback, edible reinforcers, modeling, and physical guidance to train these skills among 22 adults with severe and profound ID. Even with these most difficult-to-train adults, marked improvements were noted.

Browder, Hines, McCarthy, and Fees (1984) provided another good example of daily living skills training, which they suggest helped adults with moderate ID to integrate into the community. They used small group training with frequent prompting, using high-rate behaviors to reinforce low-rate behaviors, and time delay to teach sight words in a booklet (i.e., on food preparation, laundry, and telephone skills) to great effect. Falkenstine, Collins, Schuster, and Kleinert (2009) made a very good point with respect to instruction, particularly as applied to special education teachers. They stressed that teachers are constantly looking for strategies that can be employed in small group formats. Obviously, given the teacher-student ratio for children with ID makes these methods essential. They stressed the use of instructions, feedback, and observation of discrete targeted tasks. Falkenstine et al. (2009) stressed that small group instruction, when properly implemented, can be very effective. It was also stressed that the Individualized Education Plan (IEP) is extremely important and should serve as a major source for establishing treatment goals.

Another effective system for teaching and prompting adaptive behaviors has been described for adults with ID living in a group home (Anderson, Sherman, Sheldon, & McAdam, 1997). This study included two women (i.e., a 22-year-old with moderate ID, a 37-year-old with severe ID) and one man (i.e., 21-year-old with severe ID). The big focus was on activity schedules that employed photographs and line drawings. Tasks were performed independently when possible and with staff assistance when necessary. The types of tasks that were prompted included toothbrushing, handwashing, eating, housekeeping, vacuuming, preparing meals, watching TV, playing cards, and reading magazines. No formalized training of staff or residents occurred, yet positive effects were achieved.

Another study using activity schedules is described by Koyama and Wang (2011). They conducted a review and found 23 studies that used this approach for persons with ID. It was concluded that activity schedules could be very effective for teaching self-management and overall independence. Finally, Banda and Grimmett (2008) also promoted the use of activity schedules, in their case for persons with ASD. Their study was also a review which included 13 studies.

Again, as with the Koyama and Wang (2011) review, these authors reported good results. Of particular note was the increase in appropriate social interactions, on-task behavior, and transitions to new activities or settings. In the latter case, a marked decrease in tantrums and other challenging behaviors was noted.

Mancil (2009) stressed the value of milieu therapy. The author defined these treatments as some combination of modeling, manding, time delay, and/or incidental teaching. Time delay, manding, and modeling were the most commonly used methods. To enhance overall quality of life, there was also a focus on involvement of typically developing peers in social situations.

In sum, a range of different treatment procedures have been effectively employed with persons who have ID, which is estimated to occur in as many as 70% of persons with ASD. A combination of structure, schedules, and components of ABA appears to be the primary procedures used. Some of the skill areas that are most prominently featured in the self-help and enhance independence are further discussed.

Mealtime Behavior

Mealtime issues are a major concern for persons with ID. Among the common issues this group experiences are stunted growth, oral-motor deficits, and marked impairments in feeding one's self (Thommessen, Heiberg, Kase, Larsen, & Riis, 1991). A central theme in the self-help literature has been teaching persons with ID to eat independently or at least semi-independently. Typical of these efforts was a program by Song and Gandhi (1974), which taught four children with profound ID to eat with a spoon. They broke the tasks down into steps and used shaping, reinforcement, and, later, the fading of prompts to achieve this goal.

O'Brien, Bugle, and Azrin (1972) also taught a 6-year-old child with profound ID to eat with a spoon rather than with her hands. Manual guidance from the teacher was used for a six-step sequence of skills. These skills were trained in the following order: (1) hold the spoon in the right hand; (2) dip the spoon into the bowl and lift one inch above the bowl; (3) move the spoon to within 2 inches of her mouth; (4) the teacher places her hand on the child's chin and gently opens the child's mouth; (5) the spoon is guided into her mouth; and (6) the spoon is tilted upward, depositing the food into the girl's mouth, and then the spoon is removed. Independence was achieved, but when the treatment stopped, the child began using her hands to eat again; thus, treatment was reinstated and proven to be effective again.

Stimbert, Minor, and McCoy (1977) have also described a feeding program, which was implemented with six "low functioning" children with ID. The participants were served six meals a day, with a maximum time for eating of 15 minutes. Marked improvement in the use of a spoon to eat was noted for all the children treated. Physical guidance, using the least amount of contact possible, was paired with overcorrection when children made a mistake.

Another study using ABA to improve eating skills for persons with severe and profound ID was reported by Munk and Repp (1994). These authors noted that above 80% of persons with this level of cognitive impairment experience problems in eating. In their paper, five participants between 8 and 21 years of age sampled a variety of foods with different textures. Based on their findings, eating problems were grouped into one of four categories: (1) total refusal, (2) type of food, (3) texture of food, and (4) type and texture of food.

Teaching self-feeding skills to 14 boys aged 9–17 years who evinced profound ID was reported by Berkowitz, Sherry, and Davis (1971). Training was conducted on a one-on-one basis and was provided for all 21 meals served each week. A seven-step treatment model was followed. In step one, the trainer held the child's hand while the child grasped a spoon and scooped food from the plate, and the trainer guided the spoon to the child's mouth and then back to the plate. In step two, the child independently guided the spoon for the final 2–3 inches. In step three, the child independently guided the spoon for 6 inches. Step four involved independent eating from the plate. Step five involved independent spoon use, beginning with scooping food from the plate. Step six required the child to bring the spoon to the plate, scoop food, and lift the spoon and food from the plate, after the trainer had released the child's hand. In the seventh and final step, the child completed the entire sequence independently. Depending on the skill level of each child, training varied from 2 to 60 days before independent feeding occurred. The authors concluded that the study underscored that independent eating can be trained to persons with profound ID.

Children with multiple disabilities, including ID and emotional disorders, have also been treated. Sisson and Dixon (1986) worked with six boys who ranged in age from 4 to 9 years old, who had mild to profound ID. Comorbid disorders included attention-deficit hyperactivity disorder (ADHD), ASD, psychosis, or conduct disorder. Intervention targets included chewing with one's mouth closed, using a utensil appropriately, and using a napkin. Intervention procedures consisted of verbal praise and time-out for incorrectly carrying out target behaviors (e.g., pushing plate to the center of the table and refraining from verbal communication for 10 seconds). After the time-out, verbal instructions were provided, and praise for correct execution of target behaviors was given. The authors reported marked improvement of target behavior but modest generalization and maintenance.

Rehfeldt, Dahman, Young, Cherry, and Davis (2003) approached a related but different set of skills, meal preparation. They treated adults with severe or moderate ID. Training included observing a video of a person with ID making a peanut butter and jelly sandwich, during which a trainer praised the participant for each successful step in the sandwich-making process. This approach was sufficient in allowing the three trainees to develop this food preparation skill. Developing skills such as the ones mentioned above is critically important in developing a more independent lifestyle.

The importance of certain aspects of dining is further underscored by Angell, Bailey, and Larson (2008). Their study is of interest in that it focuses on social behaviors of five high school students (15–19 years old) with moderate ID. Behaviors taught included taking turns and asking partner-focused questions. Eye contact and tone of voice were also taught using role-playing and social reinforcement. Graduate students were paired with participants for lunch, twice a week. During lunch, the graduate student initiated scripted communication scenarios. This training model resulted in improved social interactions for the high school students during lunchtime.

A final example study on mealtime behavior reviewed here was conducted by Cannella-Malone et al. (2006). Their treatment included showing videos to five men and one woman, all of whom fell in the mild to moderate domains of ID. The tasks focused on putting away groceries and setting the table. Putting away groceries involved unloading a paper bag that contained 10 items: two apples in a plastic bag, a bag of frozen peas, two oranges in a plastic bag, a box of cereal, a bottle of salad dressing, a can of juice, a box of snacks, and a can of beans. The Murdock Center has an extensive number of skills that have been task analyzed and broken into steps. To promote uniformity, these tasks were adopted from the Murdock materials. Ten steps for unpacking groceries were used, including taking items from the paper bag to placing items in the refrigerator, putting cans in the cupboard, and putting boxes on top of the refrigerator. Setting the table also had 10 steps and included items such as putting down the placement, putting the forks to the left of the large plate, and sitting down at the place and eating a small meal. Prompts, modeling, social reinforcement, and practice of the steps proved to be an effective intervention package.

Video modeling has been a popular choice with respect to treatment options for teaching daily living skills. This method of training is typically paired with the use of task-analyzed steps, prompts, and social reinforcement (Shipley-Benamou, Lutzker, & Taubman, 2002). Note that one paper reviewed previously in this chapter involved teaching conversational skills in the lunchroom. On a somewhat different take on communication skills, Mechling, Pridgen, and

Cronin (2005) used computer-based video training. The focus of their intervention was on answering questions while making a purchase in a fast-food restaurant. They treated two males and one female between the ages of 17 and 20 years, all of whom had moderate ID. All training initially occurred in a secluded room in their high school library. Generalization of skills taught occurred at Wendy's, Hardee's, and McDonald's. These chains were selected due to the frequency of use by the participants. In addition to watching videos, a trainer sat next to the client and provided performance feedback and reinforcement. Items that the participants learned to name were types of sandwiches, drinks, and size of the French fry order. This successful training also included paying the bill.

As noted in the study just discussed, purchasing was one of the tasks trained to the three adults with moderate ID. Depending on the type of purchase made, the complexity of the tasks varied. Haring, Kennedy, Adams, and Pitts-Conway (1987) described one such study. As can be seen from the date of publication, this is a topic that has attracted the attention of researchers for some time. Participants included two males and one female who had ASD and severe ID. The authors stated that according to the Vineland Adaptive Behavior Scales (VABS; Sparrow, Balla, & Cicchetti, 1984), two participants were functioning at the 5-year-old level, while the third participant was assessed at the four-year-old level. Two participants were trained to purchase food in their high school cafeteria, while the third was trained in a convenience store, close to the school. Treatment included verbal praise, the use of tasks analyzed skills, and prompts (both physical and verbal). Typical steps trained in the task analysis were to enter store, get in line, take out money, receive change, and exit store. This approach to training was proven to be effective.

Self-Dressing

Teaching dressing skills to individuals with ID has a long history. In fact, with the advent of behavior modification (now referred to as ABA), self-care skills, particularly independent dressing, has been right at the forefront. One of the early examples of this approach was reported by Azrin, Schaeffer, and Wesolowski (1976). In this groundbreaking study, seven adults with severe ID participated; none of the participants could speak or independently dress or undress themselves. Preferred reinforcers, such as going for a walk, napping, or being with a favorite employee, was provided at the end of the dressing/undressing sequence. During the training itself, reinforcers of shorter duration (e.g., snack items, praise) were used. During training, the participants were seated. Five types of garments, including underpants, shoes, socks, pants, and shirt, were employed. Items were slip-on, so no laces, buttons, belts, or snaps were used. Items were put on and taken off in a natural sequence during a three-hour training session. Prompts, both verbal and physical, were used. All seven participants were able to independently dress and undress after 20 hours of training.

Sisson, Kilwein, and Van Hasselt (1988) also tackled this problem, but in their case, the participants were children. The authors treated two boys, aged 5 and 9. Both children were blind and experienced moderate to severe ID. Assessment and treatment occurred in their bedroom. Tube socks (no heel), pullover shirts, and pants with an elastic waistband were used. A task analysis was used in the training of the three items: 8 steps for putting on socks, 14 steps for putting on pants, and 17 steps for putting on a shirt. Verbal prompts and graduated guidance over a minimum of 10 training trials were used. Training continued over the course of 25 and 95 sessions, until all three skills could be completed at 100%. Independent dressing skills have also been trained by Hughes, Schuster, and Nelson (1993). They taught two students to dress using a shirt, pants, socks, and a jacket.

A treatment package using video modeling and prompts was described by Norman, Collins, and Schuster (2001). The participants included three elementary school students, and the skills taught were cleaning sunglasses, putting on a wrist watch, and zipping a jacket. Trainers evaluated the number of steps in the dressing tasks that were completed correctly before and after observing the video training. The authors reported good results using the methods described.

As noted in this study and the independent dressing studies noted above, breaking tasks down into smaller components is a common practice in self-help interventions. However, other effective methods to teach dressing are available. Young, West, Howard, and Whitney (1986) trained the entire tasks at once instead of breaking it down into components. This model also involved having the participant, two disabled preschool children, receive graduated guidance. This latter approach involved using the minimal amount of physical guidance needed to complete the task. This approach was also accompanied by verbal instructions and praise.

A final dressing study reviewed was published by Day and Horner (1986). Six males with profound ID, between 8 and 23 years of age, were taught how to put on a shirt. Five of the six participants were nonverbal, while the sixth participant had a limited number of simple word responses. Training included prompts (i.e., physical, verbal, and gestural) and praise for correct performance. Errors in the process resulted in interrupting the trial, repositioning the shirt to correct the error, and then providing additional assistance. All participants successfully learned how to put on their shirt, and this skill was generalized to other shirts.

Safety Skills

With the international move to integrated community living for persons with ID, new, more complex safety skills are needed and must be taught. Pedestrian skills would be one example of this trend. Batu, Ergenekon, Erbas, and Akmanoglu (2004) provided one training example in an area in Turkey. They tested five individuals (7–15 years old) with severe ID. Prior to treatment, none of these participants had the skills needed to independently cross the street. Three behaviors were taught: crossing streets using an overcrossing (5 steps), crossing the street using pedestrian lights (4 steps), and crossing the street where there was no traffic patrol or facilitations (9 steps). A simulated model of the crossing was devised in the school gym, which is where the initial training occurred. This simulated approach enhanced safety and eliminated weather issues. Instruction continued until mastery criteria were achieved on all steps of each task using a most-to-least prompt approach. These prompts were both verbal and physical. Verbal praise was reserved until the entire sequence of steps had been performed correctly. Successful generalization of these skills to real traffic situations was achieved.

A range of skills have been studied and reported on in the literature for some time. Martin, Rusch, and Heal (1982) provided a wide-ranging review of topics that have been addressed. They discussed studies on travel, money management, meal preparation, clothing and personal care, telephone use, housekeeping, leisure, social and conversational skills, and self-medication. The use of ABA is almost universal in these studies. Also, the objective is largely to not only promote independence but to enhance community integration.

Personal safety is another important life skill that has been addressed in the literature (Kim, 2010). In this study, the focus was on teaching self-protection skills to persons with ID. In this review, one of the primary focuses was on defending against sexual abuse. In that context, children were taught about body ownership. Additionally, a focus on decision-making, independent thinking, and the recognition about when to obey others versus recognizing inappropriate requests was trained. Social skills training in the context of sexual behaviors has also been addressed, along with the development of educational plans focused on reproduction, parenting, contraception, and sexually transmitted diseases.

Another nice review of the self-help (i.e., safety skills) literature was published by Mechling (2008). She covered 30 years and 36 investigations on the topic. In this review, six topics were targeted: pedestrian/street crossing safety, home accident prevention, applications of first aid and reporting illness, repelling advances of strangers, fire safety, and emergency phone use. She found that behavioral strategies that incorporated the simulation of the skill were common. Additionally, generalization and maintenance strategies were also frequently incorporated in these studies. The author underscored the ability of people with ID to learn a series of complex independent living skills.

Video skills may be the most common form of simulation when teaching self-help skills (Mechling & O'Brien, 2010). This study taught two females and one male high school student (between 19 and 20 years of age) to use public buses. The training video was from the trainee's perspective and showed the participant walking to the bus stop, boarding the bus, sitting down, riding the bus, looking for landmarks from the window, pushing the stop bus signal, and exiting the bus. PowerPoint slides of bus use skills were also included in the successful training program.

Mechling, Gast, and Gustafson (2009) have used a similar treatment model to teach how to extinguish cooking-related fires. They worked with three persons with moderate ID, two females and one male between 9 and 21 years of age. The authors trained three skills, which included scooping and releasing flour, placing a lid on a pot or pan, and using a fire extinguisher. This program, as with the other programs described in this chapter, proved to be effective. Mechling and Seid (2011) also illustrated the use of a handheld personal digital assistant. Using this self-prompting device, the participants were taught pedestrian travel skills across multiple destinations.

While the focus of most self-help studies has been directed toward the trainee, some focus on training parents has also occurred. Feldman and Case (2009) stressed that children can be at risk for impairments in self-help skills when parents display poor career skills. These authors tested self-instructional manuals and audiovisual training. Using low-tech, inexpensive teaching aids, 9 of the 10 parents (who did not have ID) showed marked improvements that were maintained for over half a year.

Parental opinions about safety skills training have been less frequently studied, but are important nonetheless (Agran & Krupp, 2010). In their survey, it was found that most parents (93%) felt that safety training was of critical importance. They also suggested that these skills should be taught at school and at home. Keeping in mind that the children being referenced were in elementary school, parents considered that the following training goals were of most to least: home safety, crime prevention, drug prevention, work safety, and HIV/AIDS prevention.

Horner, Williams, and Steveley (1987) described the use of a telephone, another important skill, with moderate to severely ID high schoolers. With the advent of smartphones, the need to develop some skills in this area becomes an even more important self-help/personal safety skill. In the aforementioned study, four people aged 17–21 years participated. A major focus of the paper was to teach the trainees to use different phones in a variety of settings. This goal is now largely obsolete due to the mobility of most phones now in use.

Hygiene

A final topic included in this overview of treatments for self-help skills is hygiene skills. One topic that has received considerable attention involves menstrual care. Epps, Stern, and Horner (1990) described one of the earliest studies on the topic. The authors noted the high importance of this topic in that there is a high rate of clinic referrals for hysterectomies due to menstrual hygiene issues. In this study, four females participated, three who were 15 years old and one who was 37 years old. For all trainees, menstrual care was not independent, and no previous training on these skills had occurred. The menstrual cycle was described to be "regular," and the mothers or supervisors of participants endorsed the importance of developing these skills. The target behavior was straightforward and involved changing soiled undergarments at designated check times. Verbal prompts, corrections, and praise were also included in this successful program.

Ersoy, Tekin-Iftar, and Kircaali-Iftar (2009) noted that menstrual care is among the most important hygiene skills for adolescents and adult women with ID. They treated three females between 12 and 14 years of age, with mild or moderate ID. In addition to changing soiled clothing, they also targeted other sanitary skills, such as handwashing and drying. Verbal directions, reinforcement, and prompts were successful in the training of an 18-step task analysis.

A bigger study on the same topic was reported by Hamilton, Allen, Stephens, and Daval (1969). The 35 individuals treated had an average IQ of 26 (ranging from 10 to 45) and an average age of 21.5 years. Again, the successful training model involved components of ABA. The topic of personal care has also been addressed by Carnaby and Cambridge (2002). They noted that intimate care issues need to be addressed with respect to specific skill training. Additionally, guidelines for practice and management are needed. The nature of these skills underscores the importance of privacy and choice.

Grooming skills have also been successfully trained. In one study, Salovita and Tuulkari (2000) taught grooming skills to a man with moderate ID. Treatment included picture cues using a task analysis. A least-intrusive prompt and social reinforcement paradigm that focused on toothbrushing, shaving, showering, and washing the body and face were found to be effective. Another grooming skill, learning to shower independently, was targeted with 72 adults (mean age of 32 years). These participants ranged in level of functioning, from moderate to severe ID. The target skill was broken into 27 steps (Matson, DiLorenzo, & Esveldt-Dawson, 1981). The task analysis included acquiring a washcloth, turning on the water, adjusting the temperature, getting wet, washing one's hair, lathering a washcloth, 12 steps on the washing of various body parts, rinsing off the soap, wringing out the washcloth, disposing the washcloth correctly, 5 steps on drying the body, and finally applying deodorant. The trainer, while fully clothed, modeled the task analysis. While the participant was showering, the trainer provided verbal instructions and verbal prompts. This treatment protocol was found to be highly successful.

Summary and Conclusions

Self-help skills have been a training target among persons with the full range of ID (i.e., mild to profound) for decades. Participants of the intervention have included individuals across the life span. Only successful outcomes were reported, which tends to be the nature of journal articles. Likely, this is a bit of a rosy picture, with many people responding to some extent or not at all. However, a number of factors are probably good predictors of success, including level of motivation, the degree of cognitive deficits, and the complexity of the task being trained.

Common elements appear to be evident in most of the wide range of skills that have been taught. These training components routinely involve modeling, verbal and physical prompts, performance feedback, as well as social and other forms of reinforcement. The peak period for training studies were during the 1980s–1990s. The general overall efficacy of this research may account for slowing of the publication pace in recent years. For the most part, the procedures described are now considered tried and true.

Characteristics of Individuals with Intellectual Disability

Individuals with intellectual disability (ID) have various needs in independent living [American Psychiatric Association (APA, 2013)]. They are characterized by impairments in intellectual functioning and adaptive behaviors (APA, 2013). These impairments have impacts on one's functioning, performance, and participation in school, community, and work.

Information from a study using the National Longitudinal Transition Study-2 (NLTS-2) data provides a glimpse into the nationwide school experiences and characteristics of the US secondary (7th–12th grade) students with ID in communication, daily living and functioning, social skills, and academic experiences. Lipscomb et al. (2017) reported that a high percentage of students with ID (72%) live in low-income households and a high percentage of students with ID (75%) cannot perform activities of daily living well. As compared to students with other disabilities, students with ID are more likely to have poor health and chronic conditions and difficulties in communication and understanding. They are also less prepared for independent living and postsecondary employment. Their parents are less likely to expect them to live independently at age 30.

Individuals with ID have delays in social and communication skills (de Bildt et al., 2005). They may be able to initiate social interaction with peers but have problems in sustaining social interactions (Bortoli & Brown, 2008). The students with ID educated in inclusive classrooms have also been found to spend more time alone and have fewer reciprocal friendships compared to their typically developing peers (Kemp & Carter, 2002). There is a positive relationship between ID severity and delays in social and communication areas; the higher the ID severity, the more delays in social and communication skills (de Bildt et al., 2005).

Individuals with ID experience difficulties in academic performance in school settings. Their average academic achievement is lower than that of students with emotional-behavior disorders and students with learning disabilities (Sabornie, Cullinan, Osborne, & Brock, 2005). As compared to students with other disabilities, students with ID are more likely to have problems with course work, need support from teachers, and receive assessment modifications and less likely to be prepared for postsecondary education (Lipscomb et al., 2017).

Individuals with Disabilities Education Act and Students with Intellectual Disability

The Individuals with Disabilities Education Act (IDEA, 2004) regulates special education services provided to students with disabilities including students with ID. ID is one of the disability categories identified in IDEA for which a student may qualify for and receive special education services. The US Department of Education develops regulations to support implementation of IDEA. These regulations define ID as:

> … significantly sub average general intellectual functioning, existing concurrently with deficits in adaptive behavior and manifested during the developmental period, that adversely affects a child's educational performance. [34 CFR Section 300.8 (c) (6)]

Students with ID may also receive special education services under IDEA from the disability category of multiple disabilities. While ID is not inherently part of the multiple disabilities category, many individuals served under this category may have ID. The regulations define multiple disabilities as:

> ... concomitant impairments (such as mental retardation-blindness or mental retardation-orthopedic impairment), the combination of which causes such severe educational needs that they cannot be accommodated in special education programs solely for one of the impairments. Multiple disabilities does not include deaf-blindness. [34 CFR Section 300.8 (c) (7)]

There are numerous requirements detailed in IDEA that impact special education services of students with ID including (1) the Individualized Education Program (IEP), (2) education in the least restrictive environment (LRE), and (3) access to the general curriculum. Each student with a disability should receive an IEP, and an IEP must be developed and reviewed annually. When developing an IEP, the student's educational team must consider the concerns of the parents or guardians, the results of recent evaluations, the strengths of the student, and the academic and functional needs of the student. There are several required components for an IEP, including (1) a description of the student's present levels of academic and functional performance; (2) annual academic and functional goals; (3) methods of progress monitoring of annual goals; (4) special education, related, and supplementary aids and services; (5) explanation of services provided outside of the general education classroom or in settings separate from same-age peers; (6) accommodations provided during state- and district-wide assessments or if the student will take an alternate assessment; (7) the start date, frequency, duration, and location of services; and (8) a transition plan for students who are age 16 or older (IDEA, 2004). The information detailed in the IEP provides a framework for the student's educational programming on an annual basis. Information regarding the impact of the student's disability on participation and progress in the general education curriculum and age-appropriate activities must be included in the present levels of performance. The annual goals are often the academic and functional goals deemed most important for the student to meet their educational or functional needs and to make progress in the general education curriculum.

IDEA (2004) requires that individuals with disabilities be provided services in the LRE, which refers to maximum participation and receipt of services in the general education classroom with same-age peers. Supports and services may be provided to students with disabilities to increase opportunities for inclusion and access to the general education classroom. In the event that special education services will be provided to students outside of the general education classroom, an individual student's IEP must indicate the reasons that services cannot satisfactorily be provided in general education settings. IDEA (2004) has noted that special education should be viewed as a service and not a place in which students with disabilities receive their education.

The requirements that students be educated in the LRE and that the general education classroom be considered the first placement option have led to increased numbers of students with disabilities receiving some or all of their education and services in the general education classroom. The proportion of students with disabilities educated in various education environments is reported on an annual basis. In the 2017 Annual Report to Congress (US Department of Education, 2017), which reports the data from 2015, 16.5% of students with ID spent 80% or more of their school day in the regular classroom, 26.3% spent 40–79% of their day in the regular classroom, and 49.7% of students with ID spent 40% or less of their school day in the regular classroom. Furthermore, 7.4% of students with ID were educated in other placements such as separate schools, residential facilities, home or hospital settings, correctional facilities, or private schools. According to the report, 13.3% of individuals with multiple disabilities are included in the regular classroom for 80% or more of the day, 16.5% spent 40–79% of the day in the regular classroom, 46.2% spent 40% or less of the day in the regular classroom, and 25% were educated in other settings. While data indicates that more students with disabilities are being educated in general education classrooms, individuals with ID and multiple disabilities spend less time in general education classroom than students with other disabilities. However, the Annual Report to Congress regarding educational setting does not provide a high level of detail regarding placement decisions and individual characteristics of students. It is important to consider that students with ID are a diverse group, and information regarding educational setting is not reported for students with ID with varying support needs. Research does indicate that secondary students with ID who are considered to have “low” cognitive functioning are less likely to be educated in regular schools with same-age peers than students with ID who are considered to have “moderate” or “high” cognitive functioning (Yu, Newman, & Wagner, 2009). In a study examining placements of students who took alternate assessments based on alternate achievement standards, those who had lower communication skills, used augmentative or alternative communication, and had lower academic skills in reading and math were less likely to be educated in inclusive classroom settings (Kleinert et al., 2015). It should be noted that the students who took alternate assessments were those who had the most significant cognitive disabilities. Yu et al. (2009) further found that the rate of the secondary students with ID who took at least one special education course was higher than that of the secondary students with ID who took at least one general education course.

IDEA (2004) further requires that individuals with disabilities be provided opportunities to access the general education curriculum. Annual goals must be written to support progress and involvement in the general education curriculum. Furthermore, special education, related, and supplementary aids and services must be described and provided to support access to the general education curriculum that is provided to all students. The Every Student Succeeds Act (ESSA, 2015), which replaced No Child Left Behind, also requires that students with disabilities have access to the general education curriculum and participate in the same statewide accountability measures as their peers. The ESSA also puts a 1% limit on the number of students who may take an alternate assessment based on alternate achievement standards, which is limited to students with significant cognitive disabilities. This limit results in the majority of the students with disabilities taking the same assessments, with or without accommodations, as their same-age peers. Nonetheless, this new policy ensures that students with disabilities continue to have opportunities to access the general education curriculum and their educators have high expectations for these students’ progress and performance in the curriculum.

Research on access to the general education curriculum and education service in the general education classroom provides important findings on the educational experiences of students with ID. In a review of research studies, Freeman and Alkin (2000) found that students with ID who were more fully integrated or spent more substantial amount of time in general education classrooms had better academic and social outcomes than students with ID who spent less time in general education settings. Wehmeyer, Latting, Lapp-Rincker, and Agran (2003) found that students with ID in inclusive settings were more likely to work on the activities connected to academic standards than those in special education settings. Last, Soukup, Whmeyer, Bashinski, and Bovaird (2007) found that students with ID who were included in general education classrooms had more access to the general education curriculum than those who were not.

Curriculum Development for Individuals with ID

A curriculum consists of sequential planned learning activities. It can be conceived in a narrow way as subjects taught or in a broad way as whole learning experiences (Oliva, 2005). A curriculum used in an intervention program for individuals with ID may be considered as the sum of the sequential learning experiences of learners (Johnson, 1968; Shepherd, 1992). Having a well-designed curriculum is the first step to provide effective learning experiences for individuals with ID.

Steps for Developing a Curriculum

There are five steps that may be used for designing a curriculum. The first step is to understand the needs of individuals with ID. The second step is to design intervention goals based on the observed needs. The third step is to select the assessments that will be used to determine whether a teaching activity or an intervention has met its goals. The fourth step is to design lesson/instructional plans for each teaching activity/intervention session. The last step is to select the instructional strategies that will assist a teacher/therapist to effectively deliver a lesson/intervention session.

Step 1. Understand Clients' Needs

Individuals with ID have intellectual and adaptive functioning deficits in conceptual, social, and practical domains (APA, 2013). However, because of family and cultural background and other personal factors (e.g., gender, age, health, abnormalities in gene(s)), intellectual and adaptive functioning abilities may be different in each learner with ID. Thus, it is important to understand a learner's needs and skills before designing a customized curriculum or adopting an existing curriculum.

Various methods (e.g., interview, observation, and assessment) can be used to understand the needs of a target learner with ID.

Interview. Interviewing parents allows teachers/therapists to understand a learner's needs from parents' points of view. When working with parents from culturally diverse backgrounds, culturally sensitive approaches should be applied. For example, an interpreter who is fluent in both of the language used by parents and the language used by the interviewer should be arranged during parent interviews. If such a service is not available, a translated version of the questionnaire(s) to be used during the interview should be made available to the parents, and parents should be encouraged to read and ask questions before the interview. An interviewer should have basic understanding of interviewee's cultural background so he/she knows to avoid culturally inappropriate topics/questions and demonstrate culturally appropriate courtesy. A sample of the list of the questions that may be used during a parent interview is listed below:

(a) *Parents characteristics*. The questions in this section are used to gather information about the characteristics of parents. The questions can include parents' age, educational background, household income, and career.
(b) *Child characteristics*. The questions in this section are used to gather information about the learner's characteristics. The questions can include learner's age, gender, grade level, the most current IQ score as measured by a standardized test, the most current adaptive skills levels as measured by a standardized test, any other diagnosis besides ID, health conditions, interests, strengths, weaknesses, and job preferences if appropriate.
(c) *Needs*. The questions in this section are used to understand a learner's needs based on parents' perspectives. The questions can be divided into two categories: (a) for learners who are in school and (b) for learners who have left school.

For learners who are in school. Sample questions can include: What difficulties does your child have in school? What difficulties does your child have at home? What difficulties does your child have in community? What goals do you have for your child at school? What goals do you have for your child after high school? What do you want this intervention to help your child?

For learners who have left school. Sample questions can include: What difficulties does your child have at work or day rehabilitation center? What difficulties does your child have at home? What difficulties does your child have in community? What goals do you have for your child in the next 5 years? What do you want this intervention to help your child?

Observation. Observation in naturalistic environments can reveal a learner's abilities in real-life situations. Given that behavior expectations can be varied across settings and a learner may function differently in different settings, observation should be conducted across various settings (e.g., school, home, community). A sample of the questions to guide observation may include:

(a) How does the learner function when performing an activity as compared to his/her peers without disabilities? For example, does the learner require a longer time to complete the activity? Does the learner need extra support? Does the learner finish the activity? Does the learner behave appropriately during the activity?
(b) How does the learner feel about the activity? For example, does he/she seem to enjoy the activity? Does he/she use facial expression/body gestures/language to indicate he/she wants to do the activity again? Does he/she seem to not like the activity or feel nervous about it? Does he/she use facial expression/body gestures/language to reject the activity?

Standardized assessments. Standardized assessments can be conducted to reveal a learner's current functioning level as compared to same-age peers without disabilities and his/her relative strengths and weaknesses as compared to his/her own abilities. Several assessment tools are available for examining adaptive behaviors of individuals with ID. Two of the most commonly used assessment tools are:

(a) Adaptive Behavior Assessment System, Third Edition (ABAS-3) (Harrison & Oakland, 2015). This assessment can be used on individuals aged 0–89 years. The administration time for this assessment is 15–20 min.
(b) Vineland Adaptive Behavior Scales, Third Edition (Vineland-3) (Sparrow, Saulnier, & Cicchetti, 2016). This assessment can be used on individuals aged 0–90 years. The administration time is about 20 min for the interview form and 10 min for the parent/caregiver and teacher forms.

Step 2. Set Up Goals

After knowing a learner's needs, the next step is to determine the desired outcomes that an intervention aims to achieve. Depending on the nature of the intervention, various types of goals may be addressed through an intervention. The intervention goals can be generally grouped into two basic categories: remedy weakness and cultivate strength.

*Remedy weakness***.** It is very common that the focus of an intervention for individuals with ID is on their deficits. In fact, why a student with a disability can receive special education and other related services is because his/her disability affects his/her education performance (Public Law 108–446, 2004). Thus, the interventions conducted in school and the IEPs for students with ID are mainly designed to address their deficits. Addressing the deficits of individuals with ID represents an effort to reduce the gap between the abilities of these individuals and their same-age peers without disabilities. However, remedy deficits, this purpose, often bring low expectation on individuals with ID, and low expectation can result in someone not to learn something challenging enough to promote his/her learning motivation, constantly learning the skills he/she has already acquired, or learning not age-appropriate skills.

Deficits are one's *not good* abilities. No one likes people always talking about his/her *not good* abilities. However, individuals with ID may experience their deficits being mentioned over and over when receiving the intervention focusing on remedy deficits. If an intervention does not concern how an individual with ID may feel, his/her self-esteem and self-confidence may potentially be harmed.

Cultivate strength. Cultivate strength takes a positive approach to address the needs of an individual with ID. Instead of focusing on deficits, this approach concerns the strengths of an individual with ID and aims to bring the strengths to the next level and transform the strengths to the skills that an individual with ID can use to improve their quality of life. Because of the label, ID, strengths of individuals with ID are often overlooked. However, each individual with ID has his/her own strengths. Their strengths can be discovered by conducting strength-based assessment (Cosden, Koegel, Koegel, Greenwell, & Klein, 2006). Questions such as *What are the learner's interests? When does the learner enjoy interacting with another person?* can be used to explore learners' interests (Cosden et al., 2006). Focusing on strengths can have several benefits on individuals with ID (e.g., improving learning motivation, self-confidence, self-esteem, and quality of life). However, the number of the interventions focusing on cultivating strengths is much smaller than that focusing on remedying deficits. More interventions that can transform the strengths of individuals with ID to the skills that they feel proud of themselves should be encouraged.

An intervention can aim to address a single goal or multiple goals depending on the length of the intervention and available resources. An intervention goal can be conceptualized as a specific skill or cluster of skills that a learner will acquire during intervention (Sailor & Guess, 1983). For each intervention goal, there should be short-term objectives that are measurable intermedia steps between a client's current level of performance and an intervention goal (Fiscus & Mandell, 1983). Both goals and objectives should be stated in a clear, precise, and measurable way. The *Case Study of Mark* illustrates intervention goals and objectives.

Case Study: Martin

Martin is a 10-year-old boy with ASD who also has moderate ID. He loves drawing and is very good at drawing. He can follow directions and complete assigned tasks with minimal prompting. However, he has significant delays in language skills, social interaction skills, academic skills, and independent living skills.

	Intervention goals	Short-term objectives
Language	Martin will answer *Wh* questions Martin will request desired items verbally	When presenting with *Who* questions, Martin will verbally answer the questions correctly four out of five trials without prompts When presenting with a desired item, Martin will say, *Can I have xx (the name of the item)?* four out of five trials without prompts
Social interaction	Martin will initiate social interactions with peers Martin will respond to social interactions initiated by peers	When seeing peers are playing cars, Martin will say, *Can I play with you?* four out of five trials without prompts When peers ask him to play with them, Martin will join them four out of five trials without prompts
Academics	Martin will solve addition problems with sums up to 50 Martin will write a paragraph including at least three sentences about an interested topic	When presenting with addition problems with sums up to 20, Martin will solve the questions correctly four out of five trials without prompts When presenting with pictures, Martin will write two sentences without errors on four out of five trials without prompts
Independent living	Martin will place cell phone calls Martin will wear a coat when it is cold outside	Given his mom's cell phone number, Martin will successfully place the phone call on four out of five trials without prompts When presenting with weather information, Martin will wear a coat when going outside on four out of five trials without prompts

Step 3. Determine Assessments

In order to understand whether an intervention has achieved its goals, methods to evaluate a learner's learning outcome should be determined. A comprehensive evaluation plan should be determined before starting an intervention. Various evaluation tools can be used, and they can be grouped into two categories: formal standardized tests and informal procedures.

*Formal standardized tests***.** These tests can be either norm-referenced or criterion-referenced (Hickson, Blackman, & Reis, 1995). Norm-referenced tests allow interventionists to compare a learner's performance to that of same-age peers. Criterion-referenced tests allow interventionists to measure a learner's performance against predetermined criteria. These tests often are commercially published tests (e.g., intelligence tests, academic achievement tests, language tests, adaptive behavior tests) which can be purchased through publishers.

*Informal procedures***.** These assessment procedures include observation, work sample analysis, task analysis, checklists, rating scales, interviews, and questionnaires (Hickson et al., 1995). These assessments are often made by interventionists to determine whether learners have acquired target skills that they have been specifically taught.

The effectiveness of an intervention can be determined through carefully following its evaluation plan. The evaluation plan should consist of assessment material(s) and an evaluation design. Depending on the number of participants in an intervention, the evaluation design can be a single-subject design or a pretest-posttest group experimental design.

*Single-subject design***.** This design allows the teacher to determine the intervention effects on a single participant or a small group of participants. There are three commonly used single-subject designs including the reversal or withdraw (ABA) design, multiple baseline design, and changing criterion design (Rusch, Rose, & Greenwood, 1988).

*The reversal or withdraw (ABA) design***.** This design consists of three phases: baseline 1 (A), intervention condition (B), and baseline 2 (A). During baseline 1, the target behavior(s) is/are observed without any presentation of intervention. During intervention, the participant(s)' target behavior(s) is/are observed while receiving intervention. After some stable and substantial changes of the target behavior(s) are observed, the treatment condition will be withdrawn. The baseline condition will then be reintroduced, for example, if one wishes to determine whether using participants' interested items would increase their attending behaviors using an ABA design. If the numbers of participants' attending behaviors during the intervention condition are higher than those during the baseline 1 and baseline 2 conditions, it can be concluded that the intervention was effective.

*The multiple baseline design***.** This design can be used across subjects, behaviors, or settings (Hickson et al., 1995). Baseline data are collected on the same behavior across two or more participants, two or more behaviors on the same participant, or on the same behavior across two or more settings for the same participant (Christensen, Burke Johnson, & Turner, 2011). After baseline data are collected, the intervention will be introduced. If the number of target behavior(s) recorded during the intervention condition is noticeably higher than that during each baseline condition, it can be concluded that the intervention was effective.

*The changing criterion design***.** This design begins with the collection of baseline data. During the first intervention phase, a criterion level is determined. If a participant has successfully reached the criterion level across several trials, a higher criterion level will be introduced during the next intervention phase. If a participant's target behavior improved as the criterion level was increased, this overall pattern of results is the evidence of the positive results of the intervention on the participant (Christensen et al., 2011).

*Pretest-posttest group experimental design***.** There are two types of this design. One allows a comparison of the mean performance of the same participants before the intervention and after the intervention (i.e., one-group pretest-posttest design). Another one allows the comparison of two groups (intervention vs. nonintervention) before and after the intervention (i.e., pretest-posttest control-group design).

One-group pretest-posttest design. Before starting the intervention, all participants receive pretests. After pretests, all participants begin to receive the intervention. Upon completion of the intervention, all participants receive posttests which are the same as the pretests. The differences between the pretest and posttest performances of the participants can be determined by using statistical analyses. If participants' posttest scores are significantly higher than their pretest scores, it may be concluded that the intervention has positive influences on the participants.

Pretest-posttest control-group design. Participants are randomly assigned to either of the intervention group or the nonintervention (control) group. Both groups will then receive pretests. After pretests, only the intervention group will receive the intervention. After the intervention has completed, both groups will then receive posttests. Statistical analyses are used to determine if the intervention effects exceed what would be expected by chance (Hickson et al., 1995).

Step 4. Design Lesson/Instructional Plans

Each intervention session should have a lesson/instructional plan to guide an interventionist to deliver instructional activities to address the needs of a learner(s). This plan specifies the time, duration, teaching materials, and learning content for a to-be-delivered activity(ies). It helps interventionists stay organized and ensure intervention time is used efficiently and effective instruction is delivered to help learners acquire target skills (Selmi, Gallagher, & Mora-Flores, 2015). A lesson plan does not always need to be written in great details, but it has to be completed before starting an intervention session. A lesson/instructional plan should at least include the sequence of learning activities, instructional time for each learning activity, and the learning materials to be used.

Three lesson plan samples targeting different skills at different grade levels are presented below.

Lesson Plan 1: Teaching Functional Math Skills

Title: Count objects to 20	Grade level: K	Time: 45 min
Standard: CCSS.MATH.CONTENT.K.CC.B.5Count to answer "how many?" questions about as many as 20 things arranged in a line, a rectangular array, or a circle, or as many as 10 things in a scattered configuration; given a number from 1 to 20, count out that many objects.	**Objective:** When given a number, students will count the given number from 1 to 20.	
Context: This is an inclusive kindergarten classroom where students with ID are educated with their typically developing peers in the same classroom. There is a general education kindergarten teacher and a paraprofessional in the classroom full time. During math instruction, a special education teacher joins the classroom to co-teach. At the beginning of math instruction, the teacher introduces the skill to the class as a whole group. After the topic has been introduced, students participate in centers that are designed to align to and practice the skill. Teachers support students during the centers. Snack time also occurs during math centers because of the many opportunities to practice math during snack. Whenever possible, the teacher designs an activity at the snack table that corresponds to the math skill. There are four centers, including snack. The teacher divides students into heterogeneous groups of four. Students rotate through centers, spending 8 min at each center.		
Materials: • SMART Board at level that students can reach. The SMART Board is set up as an upside down "T" grid with 20 math manipulative images at the bottom and number dice on left side. • Set of up to 20 manipulatives for each student in a bowl. • Tray for each student. • 5 × 4 grid for some students. • Beanbags. • Hula-hoop. • Multisided dice with numbers. Dice are available in various sizes and with different difficulty. Some dice have smaller sets of numbers (1–6), while other dice have larger numbers (1–20). • Game board. • Math manipulatives. • Number cards. • Grapes for snack. • Trays, plates, and 5 × 4 grid for some students.		

(continued)

Lesson implementation:

1. Each student is seated on the classroom rug in front of the SMART Board. There are seating options for students (e.g., carpet squares, textured cushions, chairs, etc.). Each student has a tray and bowl with up to 20 math manipulatives. For some students, the bowl is attached to the tray. Some students also have a 5 × 4 grid attached to their tray. The teacher introduces the lesson by showing students a game on the SMART Board. The teacher touches the dice on the SMART Board to roll the dice. The teacher and class then count out the number of items shown on the dice. The teacher moves the correct number of manipulatives from the bottom to the right side of the grid. Students count the number of items on to their tray. Students with the grid attached to their tray place the manipulatives in the grid as they count. Teachers help students as needed. After the class has counted, the teacher moves the SMART Board manipulatives back to the bottom of the grid. The teacher repeats this process several times, calling on students to help her at the SMART Board. After 4–5 repetitions, the teacher introduces and models each center to the students.
2. Center 1: Students in this center continue to play the SMART Board game.
3. Center 2: This center takes place on the rug. It is placed far enough away from the SMART Board, so as not to distract students in either center. In this center, students take turns rolling a dice. A variety of dice are available, and a teacher helps students select an appropriate dice. Students then toss the corresponding number of beanbags into a nearby hula-hoop. Students may stand as close to the hula-hoop as needed. A teacher spends time on the rug supporting students at Center 1 and Center 2 as needed.
4. Center 3: Students in this center play a game. The game board has four racetracks with square spaces. Students may select any math manipulative they would like to use. Students take turns drawing a number card. Students then place the correct number of their chosen manipulatives on the square spaces. A teacher is seated at this center to support students and uses modeling and prompting as needed.
5. Center 4: Snack. Students count out 20 grapes at snack. Some students have a 5 × 4 grid available to support counting. A teacher is seated at this center to support students, and uses modeling and prompting as needed. The teacher also facilitates discussion with students during snack.

Assessment:

Teachers keep data sheets at each center. Teachers record the number(s) rolled/drawn and accuracy of counting objects. Teachers also record any prompting that was needed.

Lesson Plan 2: Teaching Functional Language Skills

Title: I love reading	Grade level: 4th	Time: 45 min
Standard: CCSS.ELA-LITERACY.RL.4.3Describe in depth a character, setting, or event in a story or drama, drawing on specific details in the text (e.g., a character's thoughts, words, or actions). CCSS.ELA-LITERACY.SL.4.1 Engage effectively in a range of collaborative discussions (one-on-one, in groups, and teacher-led) with diverse partners on *grade 4 topics and texts*, building on others' ideas and expressing their own clearly.	**Objective:** Student(s) will answer *Who* and *What* questions about characters in a story.	

Context:

This lesson takes place in an inclusive fourth grade classroom. There is one general education teacher and one special education teacher in the classroom. There are four students with disabilities. One of the students has ID. Students in the class read a short story and work in groups to identify and describe the main characters. The learning groups are heterogeneous, and teachers circulate the room to support students.

Materials:

- Short story at fourth grade reading level
- Adapted version of story with visuals added and text reduced
- Audio version of story
- Graphic organizer for students to identify characters and their traits
- Visuals cut out from adapted version of story
- *Wh* question prompt cards

Lesson implementation:

1. Students read the story independently. Some students may also use an audio version of the story. The student with ID uses the adapted version of the story.
2. Students are given time to begin completing their graphic organizer about the story's main characters. A teacher works with the student with ID to complete his graphic organizer. The student has visuals available from the adapted story to complete the graphic organizer. The teacher asks the student *Who* and *What* questions while completing the graphic organizer.
3. Students engage in a group discussion about the characters in the story. Students share with the group their thoughts about the characters by describing their completed graphic organizer. Students ask each other *Wh* questions during the group time. Students may use the *WH* prompt cards.

Assessment:

The teacher collects the graphic organizers. The teacher records the student responses to *Wh* questions, including any prompting needed to answer questions.

Lesson Plan 3: Teaching Community Living Skills

Title: Making lunch with friends	Grade level: 8th	Time: 40 min
Standard: NA	**Objective:** Students will follow multistep directions to make sandwiches for lunch.	

Context:

This lesson takes place during an inclusive lunch group with four students, two with ID and two with typical development. The purpose of this group is to focus on skills of daily living, social skills, community engagement, and academic skills. This group meets for lunch twice a week, as well as participating in other school activities such as working at the school store, tending to the school garden, and participating in other school initiatives. The primary role of students with typical development in the group is to be a peer and friend. These students with typical development have learned strategies for prompting, modeling, reinforcing, and engaging in interactions with students with ID.

Materials:

- Task analysis with images for making a sandwich
- Video model of making a sandwich
- Food items for lunch: lettuce, tomato, bread, cheese, turkey, ham, mayonnaise, mustard
- Drinks for lunch
- Plates
- Napkins
- Cups

Lesson implementation:

1. Prior to the lunch group, the teacher meets with students with ID to watch the video model and cover the steps of the task analysis. The video model and task analysis were designed to align with each other. As students watch the video, the teacher discusses each step of the task analysis. The teacher asks questions as appropriate to probe for comprehension.
2. Students meet in one of the school's cooking labs for lunch.
3. Students split in to two groups; each group has one student with ID and one student with typical development.
4. Students work at one of the cooking tables to make their sandwiches. Students follow the task analysis to gather the materials and make their sandwich. Students check off each step of the task analysis as it is completed. A teacher is present to support students as needed. However, students are prepared to support each other as well.
5. Once each student has made their sandwich, the group sits down to eat lunch together. While eating, the students engage in planned topics of conversation.
6. When students have finished eating, they clean up together and play a game of their choice.

Assessment:

The teacher monitors students while making the sandwich. She keeps a checklist to mark each step the student completed, as well as if the step was completed independently or with prompts.

Step 5. Select Instructional Strategies

After goals are determined, the teaching strategies that will be used during intervention should then be decided. Teaching strategies are the instructional tools that interventionists use to assist learners to acquire target behaviors. They include instructional methods and behavior management techniques (Hickson et al., 1995). Appropriate teaching strategies should be selected based on the philosophical orientations of the intervention program, target behaviors, and students' ability levels.

Instructional methods. There are various evidence-based instructional methods for teaching individuals with ID, and they can be grouped into four categories, including skill acquisition, motivation improvement, skill maintenance, and skill generalization.

Skill acquisition. Various approaches can be used to teach individuals with ID to acquire new skills.

Modeling. This is a teaching strategy that an adult or a peer demonstrates a target behavior to a learner (Wong et al., 2013). For example, the target behavior is saying *water*. An adult demonstrates saying *water* to a learner. Another form of modeling is *video modeling* which offers a visual model of the target behavior via videos (Wong et al., 2013).

Prompts. Prompts, such as verbal, gestural, or physical assistance, are given to a learner to assist him/her to learn a target skill (Wong et al., 2013). For example, a learner is learning to say *car*. An adult presents a toy car and provides a verbal instruction (say car) to verbally prompt the learner to acquire the skill of saying car. An example of the gestural prompt is to point to a toy car and wait for a learner to say car. If an adult wants to use physical assistance to prompt a learner to say car, he/she will hold a learner's hand and put it on a toy car. Adults can provide prompts to learners in several ways: (a) the least-to-most prompting system, (b) the most-to-least prompting system, (c) simultaneous prompting, and (d) flexible prompt fading.

(a) The least-to-most prompting system is that adults systematically increase guidance to assist learners to acquire the target skill(s).

For example, adults first use verbal prompts, then verbal prompts + gestural prompts, and lastly verbal prompts + gestural prompts + physical prompts to guide a learner to learn a target skill (Horner & Keilitz, 1975; Murzynski & Bourret, 2007).

(b) The most-to-least prompting system is that adults start from providing the most assistive prompt and the prompting system ends with no prompt. For example, adults use physical prompt first, then gestural prompt, verbal prompt, and lastly provide no prompt (Leaf et al., 2016).

(c) Simultaneous prompting is a procedure that adults provide a prompt that results in a learner making a correct response 100% of the time immediately following instructions. This makes a learner no chance to error and always receive reinforcement (Leaf, Sheldon, & Sherman, 2010). For example, adults want to teach learners to learn a concept (e.g., long). Adults will say "Which one is long?" and then immediately point to the correct picture and say "This is long." Adults will then wait for 2 s to get a learner's response. If the learner answers correctly, he/she will be rewarded right away. If the learner does not answer correctly, adults will repeat the procedures: "Which one is long?" "This is long" (Celik & Vuran, 2014).

(d) Flexible prompt fading is that adults make moment to moment assessments in deciding which type of prompt to be provided and when to assist a learner to learn a target skill, as opposed to adhering to a predetermined system (Leaf et al., 2016). For example, adults want to teach a learner some object labels. Adults will predetermine how likely the learner will say the names correctly. If adults determine that the learner is likely to say the names correctly, adults will not provide any prompt to the learner. However, if the learner will likely to respond correctly with a more assistive prompt, adults will provide this type of prompt to the learner (Leaf et al., 2016).

Reinforcement. A learner's desired item or activity is given to him/her once he/she has produced the target behavior. For example, a learner says *water* to request drinking water. An adult heard the learner saying water. He/she then allows the learner to drink water. Reinforcement should be provided to a learner immediately after he/she has displayed a target skill. After a learner has successfully shown a target skill several times, adults should begin to fade the reinforcement delivery gradually. The goal of fading reinforcement is to train a learner to display a target behavior independently without relying on any prompt.

Time delay. This is a strategy that adults allow time between the presentation of an instruction request and the presentation of a prompt (Snell & Gast, 1988). There are two types of time delay: (a) constant time delay and (b) progressive time delay.

(a) Constant time delay is a procedure that adults allow a fixed delay between a task request and prompt (Ault, Wolery, Gast, Doyle, & Eizenstat, 1988). For example, adults want to teach a learner to write his/her name. Adults demonstrate how to write the learner's name and then ask the learner to write his/her name. Adults will wait 5 s for the learner's response. If the leaner successfully writes his/her name, adults will provide a reinforcement. If the learner does not successfully write his/her name, adult will use a prompt to assist the learner to demonstrate the target behavior. Adults will wait for 5 s for the learner's response every time they have made a task request.

(b) Progressive time delay is a procedure that adults gradually increase the amount of the time between the presentation of a task request and the presentation of a prompt (Wolery, Gast, Kirk, & Schuster, 1988). Using the example described above that adults want to teach a learner to write his/her name, adults will wait for 5 s for a learner's response for the first trial. They will then increase the waiting time to 10 s for the second trial, 15 s for the third trial, 20 s for the fourth trial, and go on if more trials are required.

Task analysis. It is a strategy that an instructor breaks down a target behavior into several small continuous steps and teaches these steps to students (Anderson, Taras, & Cannon, 1996). Adults can teach the behavior from the first step to the last one or backward (from the last step to the first one) using modeling and prompting procedures (Anderson et al., 1996). For example, the procedures of making photocopies can be broken down to these steps: (a) turn on the photocopy machine, (b) place paper on copier, (c) select quantity, (d) hit the copy button, and (e) collect the copies. If an adult aims to teach a learner how to make photocopies, he/she can model each of the steps from step (a) to step (e) and then ask the learner to practice each step. While the learner is practicing each step, adults can take notes on the prompt level required by the learner. For example, if a learner can complete step (a) independently, the individual instruction for the learner can skip step (a). If a learner only has difficulty in placing paper on the copier, the individual instruction for this learner may only focus on this behavior.

Performance feedback. This is a strategy that adults provide supportive and corrective responses to a learner's performance during instruction (Gilson, Carter, & Biggs, 2017). For example, using this strategy to teach a learner to learn math, adults will provide performance feedback immediately following the learner's response. If a learner solves a math problem correctly, adults will let the learner know whether his/her answer is correct and provide a reinforcement to the learner. However, if a learner does not solve a math problem correctly, adults will use supportive comments (e.g., "I see you get this part right, but the other part should be done in this way") to give feedback.

Device-assisted instruction. This strategy uses computer or other technological devices (e.g., tablet, mobile phone, digital watch) to facilitate a learner's learning (Gilson et al., 2017). For example, adults can teach learners with ID who have not developed verbal skills to use an aided augmentative and alternative communication (AAC) device (e.g., communication board, computer-based technology with voice output) to communicate.

Mnemonics. This strategy uses words that provide acoustic reconstructions of unfamiliar information (Gilson et al., 2017). For example, to help learners remember the continents, Africa, Antarctica, Australia, Europe, Asia, North America, and South America, adults can take the first letter out of these continent words and arrange them into a new word, AAAEANS. Adults will use a silly sentence: Three ants eat apples North and South to help students remember it (Frank & Smith-Rex, 2015).

Peer-mediated instruction. This type of instruction utilizes peers of learners with ID to promote their target skills. For example, adults can train typically developing peers of learners with ID to use time delay to help these learners' improve their grade-aligned science skills (Jimenez, Browder, Spooner, & Dibiase, 2012).

Incidental teaching. This is a naturalistic instruction that adults arrange the environment and materials to increase a learner's initiated communication and respond to the learner's communication with modeling, prompts, and reinforcement (Hart & Risley, 1982). For example, adults want to teach a learner to request markers. Adults can put markers in a clear container where it is located at a bookshelf where the learner can see but cannot reach. When the learner uses facial expression and/or gestures to request adults to deliver the markers to him/her, adults model "I want markers." and instruct the learner to say the sentence. Adults will wait for the learner's response. If the learner correctly says the sentence, adults will deliver the makers to the learner. However, if the leaner does not say the sentence correctly, adults will use prompts to facilitate the learner to say the correct sentence.

Motivation improvement. Motivation is one of the pivotal areas that can have positive influence in the learning of children with autism spectrum disorder and ID (Koegel, Koegel, Harrower, & Carter, 1999). Motivation can be defined as "observable characteristics of a child's responding" (Koegel et al., 1999, p. 178). Improvement in motivation can be described as increased responsiveness to social and environmental stimuli (Koegel, Carter, & Koegel, 1998). If a learner has high level of motivation in learning, it will be easier for interventionists to provide instruction, and it will also be easier for the learner to learn new skills. Thus, it is important to apply strategies to improve learners' learning motivation. Several strategies can be used to improve learner's learning motivation. They include child choice, interspersal of acquisition and maintenance tasks, natural reinforcement, and reinforcing attempts.

Child choice. Allow learners to choose preferred items or activities, and the items or activities chosen by them are then used in or as the learning activities (Koegel et al., 1999). This simple strategy can effectively improve learners' learning motivation. For example, an adult asks a child if he/she would like to use a pen or marker to do writing. If the child wants to use a marker, he/she is allowed to use it for writing (Koegel, Singh, & Koegel, 2010).

Interspersal of acquisition and maintenance tasks. Students often are not interested in completing the tasks that they feel difficult. Learning new tasks often make students feel challenging and want to escape. However, in order to achieve intervention goals, students are required to complete challenging tasks. Blending difficult tasks with easy tasks can increase students' learning motivation. Numerous previously learned tasks are interspersed with the target skill that the learner has not already learned (Koegel & Koegel, 2012). For example, a learner can add two numbers less than 10 to yield a sum smaller than 10 but is learning the tasks adding two numbers less than 10 to yield a sum greater than 10. The easy questions can be interspersed with the difficult ones to increase students' learning motivation.

Natural reinforcement. Another strategy to improve motivation is to use natural reinforcers. A natural reinforcer is the item/activity that is directly and functionally related to the target task (Koegel & Koegel, 2012). Once a learner displays a target behavior, he/she should receive the item or activity that is directly related to the target behavior. For example, a cup of water is given to a learner once he/she said *water*.

Reinforcing attempts. Before a learner can successfully display a target behavior, he/she may need to practice the behavior many times. Depending on the learner's learning speed, his/her learning process may be long. If interventionists only provide reinforcement to learners when they successfully produce target behaviors, they may lose motivation to learn new skills. Thus, reinforcing learning attempts while a learner is trying to acquire a new skill is important. Reinforcing attempts means that a learner's goal-oriented attempts are reinforced (Koegel & Koegel, 2012). For example, a learner is learning to name balloon and wants to play with a balloon, but he/she has difficulty sounding the whole word. He/she looked at the adult and said, *ba*. The adult reinforced his/her attempt by giving him/her a balloon.

Skill maintenance. Maintenance refers to learners continue to display learned behaviors after an intervention has completed. Several strategies may be used to improve skill maintenance (Westling & Fox, 2009).

Continue practice. After learners have acquired a target skill, he/she should be taught to continue to practice the skill.

Multiple opportunities to practice. Learners should be given opportunities to practice one skill at different times, instead of all at once.

Intermittent reinforcement. Once a learner has learned a target skill, reinforcement should not be given to the learner immediately but every couple trials or minutes.

Self-monitoring. This instruction teaches learners to self-monitor their own behaviors (Strain, Kohler, Storey, & Danko, 1994). For example, a learner often forgets to complete his/her homework. Adults can work with the learner to create a homework checklist and teach him/her to write down the list of homework and cross out the ones he/she has completed. The learner can earn a desired item as a reward after he/she has successfully completed all the homework.

Skill generalization. Generalizing a learned skill to a novel situation or environment may be difficult for individuals with ID (Oreilly & Chadseyrusch, 1992). They may not know how to apply a learn skill to a non-training setting or non-training interaction partner. Specific strategies should be applied to promote skill generalization in learners with ID. Several strategies could be used to improve skill generalization (Stokes & Osnes, 1986).

1. The target skills should be useful to the learner's daily life.
2. The target skills should result in receiving natural reinforcers.
3. Use a wide variety of stimulus exemplars.
4. Use a wide variety of response exemplars.
5. Provide training in various training conditions and settings.

Behavior management techniques. Individuals with ID and/or autism who are nonverbal or have limited spoken language use challenging behaviors (e.g., tantrum, aggression) as a form of expressive communication (Chiang, 2008). Learners with a more severe degree of ID are more likely to display challenging behaviors than learners with a milder degree of ID (McClintock, Hall, & Oliver, 2003). Children's problem behaviors may bring challenges for interventionists to deliver interventions to them and decrease children's learning time. Thus, it is critical to apply appropriate strategies to manage learners' behaviors.

Functional analysis of problem behaviors. The first step to design a program to manage learners' problem behaviors is to conduct a thorough functional analysis of the problem behaviors (Hickson et al., 1995). This analysis is to identify the antecedent conditions that trigger the problem behavior, define the challenge (i.e., a description of the problem behavior), and identify the consequent conditions that maintain the problem behavior (Horner, Albin, Todd, Newton, & Sprague, 2011). Once these information is obtained, intervention alternatives may be introduced to learners. For example, if a learner is likely to bite his teacher to escape from the task demands. Changing the nature of the task demands to be more interesting to the learners may decrease his biting behavior. Also, teaching the learner to say *No* or point to a picture with *No* sign when he wants to reject an uninterested task may replace the biting behavior.

Extinction with positive reinforcement of other behaviors. Extinction means that interventionists intentionally withhold reinforcement following a learner's behavior or ignore a learner's behavior (Snell & Brown, 2011). Extinction is most effective when positive reinforcing other behaviors is also used (Kerr & Nelson, 1989). For example, if a learner uses screaming to get adults' attention, in order to decrease the challenging behavior, adults will not look at the learner when he screams but will look at him to praise him when he does something good.

Issues to be Considered When Developing a Curriculum

Educators must consider several important factors when developing and implementing curriculum for learners with ID in their classrooms. IDEA requires that educators develop annual goals and provide appropriate aids and services that support progress of students in the general education curriculum. This means that educators must consider methods to promote and improve access to grade-level standards and curriculum for their students. In order to do so, Ryndak, Moore, Orlando, and Delano (2008) suggest that educators must consider general education contexts (e.g., general education classrooms, peers, teachers, etc.), general education content (e.g., content standards and processes), high expectations, and participation in state- and district-wide accountability measures. Educators should adopt the strategies that can support students with ID to participate in the general education curriculum as well as help them to show progress in functional skills (Hunt, McDonnell, & Crockett, 2012).

Researchers have developed frameworks and models for promoting access to the general education curriculum for students with ID. Hunt et al. (2012) recommend using an ecological curricular framework to support student access to the general education curriculum and standard-based academics. As part of process of developing curricula as part of an ecological framework, educators consider goals that are high priority, focus on quality of life outcomes, and are relevant and meaningful to individuals, which may include academic content knowledge and skills. Hunt et al. (2012) describe a process for applying the ecological framework, which requires educators to consistently consider the needs of students with ID and their personal quality of life outcomes while promoting access to the general education curriculum. Hunt et al. (2012) suggest identifying the “critical function” of grade-level content standards in order to develop individualized performance outcomes for students with ID. Once outcomes are developed that connect the content standard to the student’s personal quality of life goals, educators must teach the skills using activities that are meaningful and relevant to the student. Trela and Jimenez (2013) also suggest the use of an ecological framework to support access to the general education curriculum for students with ID. They suggest using curricular modifications that are “personally relevant” by making connections between the student’s school community and the content being taught.

Educators may also consider promoting self-determination in order to facilitate access to the general education curriculum. The Self-Determined Learning Model of Instruction prompts students through a problem-solving process that supports self-directed learning (Wehmeyer, Palmer, Agran, Mithaug, & Martin, 2000). During instruction, students answer a series of questions that are designed to support the student to set goals and make plans to achieve their goals. Furthermore, students utilize self-directed learning strategies such as self-monitoring and self-reinforcement. The Self-Determined Learning Model of Instruction has been used successfully with students to increase outcomes such as improving public speaking and question asking, as well as academic outcomes such as scientific inquiry, understanding maps, and learning about organ systems (Agran, Cavin, Wehmeyer, & Palmer, 2006; Agran, Wehmeyer, Cavin, & Palmer, 2010). Based on the positive results of this model, educators may consider promoting self-determined behaviors and self-directed learning to promote access to the general education curriculum for students with ID.

Universal Design for Learning (UDL) should also be utilized by educators when developing curriculum and supporting access to the general education curriculum for students with ID. UDL is a framework that promotes access to the curriculum and learning environments for a variety of learners by providing flexibility and options (Meyer, Rose, & Gordon, 2014). There are three principles of UDL that are used to guide educators when developing curriculum, designing learning environments, and selecting materials and instructional methods. These principles (1) provide multiple means of representation, (2) provide multiple means of engagement, and (3) provide multiple means of action and expression (Meyer et al., 2014). Guidelines have been further provided in each of the three principles to provide suggestions for educators to consider the needs of their learners and provide flexibility when designing curriculum and instruction. Educators provide a number of options for how content is presented and delivered in their classrooms in order to meet the principles of multiple means of representation. In order to provide multiple means of engagement, educators should consider student interests, provide choices, and create relevant activities. Finally, educators provide options for students to demonstrate their knowledge in order to provide multiple means of action and expression. When educators use the UDL principles and guidelines, they create learning environments that support all of their students to access instruction and reduce barriers to learning.

Educators should also consider the need for accommodations and modifications for their students with ID when developing curriculum and supporting access to the general education curriculum. Wehmeyer, Lattin, Lapp-Rincker, and Agran (2003) describe strategies for adapting and augmenting the curriculum to support access. Curriculum adaptations are strategies that modify presentation and engagement with the curriculum. Several strategies of curriculum adaptations have been described including (1) strategies that support organization such as graphic and advance organizers, chunking, and outlines; (2) strategies that promote understanding such as comparisons, examples, and diagrams; (3) strategies that augment content presentation such as videos and stories; (4) strategies that improve demonstration such as role-play; and (5) strategies that promote recall such as keywords and visual images (Lee et al., 2006; Wehmeyer et al., 2003). Curriculum augmentation strategies are learning strategies that promote success and independence. Some augmentation strategies overlap with adaptation strategies such as the use of graphic organizers and keywords to support students with retrieval of information (Wehmeyer et al., 2003). Other curriculum augmentation strategies include self-directed learning strategies such as goal-setting and problem-solving (Lee et al., 2006).

Existing Curricula

Practitioners can develop the curriculum specially designed to address a particular intervention program philosophy and to meet the needs of the learners with ID in their program or adopt an existing available curriculum specially designed for teaching learners with ID. Several searches using a combination of ID related terms [e.g., cognitive disability(ies), developmental disability(ies), intellectual disability(ies), mental retardation, Down Syndrome] and curriculum or teaching as keywords were conducted in WorldCat, PsycINFO, and Web of Science. These searches were limited to publications in the past 20 years and English language. A total of 13 curricula for teaching learners with ID was found. The list of these curricula is presented below:

- Accessible Literacy Learning (ALL) Curriculum (Light & McNaughton, 2009)
- This curriculum is used to improve literacy skills in learners with autism, cerebral palsy, Down syndrome, and other disabilities. It includes sections on assessing skills, teaching component skills, teaching simple sentence and story reading, building comprehension, troubleshooting, writing skills, and six skill binders (e.g., sound blending, phoneme segmentation, letter-sound correspondence, single word decoding, sight word recognition, and shared reading).
- Health U: A Nutrition Curriculum for Teenagers with Intellectual and Developmental Disabilities (Bandini, Curtin, Fleming, Maslin, & Scampini, 2012)
- This curriculum is used to provide age-appropriate nutrition education for adolescents and young adults with mild to moderate intellectual disabilities. It includes ten lessons covering topics such as added sugar in food and drinks, added fats, making healthy choices, and healthy portions. Each lesion introduces new concepts and contains hands-on learning activities, movement/physical activities, and a taste test to encourage students expand their food repertoires.
- Conversation Skills on the Job and in the Community: A Curriculum for Adolescents and Adults with Developmental Disabilities (Banks, 2005)
- This curriculum teaches learners with developmental disabilities conversation skills on the job and in the community. It contains 50 plus self-managed lessons, such as learn the names of your coworkers, be the first to ask a question, and be the first to give a compliment.
- Conversation Skills II: Extending Conversations (Banks, 2008)
- This curriculum teaches learners with developmental disabilities to remember names, develop friendships at work and in the community, and extend conversations.
- Activities for Students with Special Needs: A Social Skills Curriculum (grades 3–5)(Bray, Morton, & Novotny, 2008)
- This curriculum is for students diagnosed with Autism, ADHD, intellectual disabilities, learning disabilities, behavioral difficulties, and emotional difficulties. It contains 11 units that are designed to help school-age children with special needs to learn and practice appropriate social skills.
- Feed All My Sheep: A Guide and Curriculum for Adults with Developmental Disabilities (Clark, 2000)
- This curriculum teaches adults and older youth with disabilities about the church and provides advice about how to set up church classes for these adults and how to integrate them into the church community.
- Creating a Meaningful Day: An Innovative Curriculum for Adults with Significant Intellectual Disabilities (Cofield-Van Dyke, 2008)

- This curriculum includes lesson plans for socializing, athletics, nature awareness, drama, visual arts, creative movement, sensory events, and storytelling. Each lesson plan has objectives, a material list, and areas of documentation.
- Improving Social Behaviors in the Classroom: An Easy Curriculum for Teachers of Young Children with Autism, Developmental Disabilities, and Typical Children (Freeman, 2011)
- This structured and structured curriculum contains day-by-day lessons for 25 weeks to be incorporated into the regular school day. It contains four categories: possessive understanding/acknowledgement of others, basic initiation skills, turn taking and simple social play, and cooperation.
- Effective Strategy-Based Curriculum for Abuse Prevention and Empowerment (ESCAPE) for Individuals with Developmental Disabilities
- (Hickson, Khemka, Golden, & Chatzistyli, 2015; Khemka & Hickson, 2002; Khemka & Hickson, 2008)
- This curriculum teaches individuals with intellectual and developmental disabilities to make effective, self-protective decisions in a wide range of sexual, physical, and verbal abuse situations.
- Attainment's Health Advocacy Program: An Activity-Based Curriculum for Adults with Developmental Disabilities (Holburn, Cea, & Gordon, 2008)
- This curriculum consists of 20 1-hour lessons covering topics, such as healthy eating, exercise, relationships, sexuality, stress, and medical issues like high blood pressure, diabetes, and depression.
- Teaching Math to People with Down Syndrome and Other Hands-On Learners (Horstmeier, 2008, 2016)
- This book provides strategies and activities/lesson plans relevant to daily living and covers topics, such as pre-number concepts, counting, recognition and writing of numbers, time and measurement, addition, subtraction, multiplication and division, fractions, money, and calculator use.
- Women be Healthy: A Curriculum for Women with Mental Retardation (Lunsky, Straiko, & Armstrong, 2003; Lunsky, Straiko, & Armstrong, 2002)
- This curriculum was designed for women with mental retardation and other developmental disabilities who had difficulty with gynecological and breast examinations or who had never had an exam. Its primary emphasis is on early detection of breast and cervical cancer. It contains three components: health education, anxiety reduction, and assertiveness and empowerment training.
- Health Matters: The Exercise and Nutrition Health Education Curriculum for People with Developmental Disabilities (Marks, Sisirak, & Heller, 2010)
- This curriculum is used to help adults with developmental disabilities to build healthy lifestyles. It contains 59 1-hour sessions that help people make the best choices about health, exercise, and nutrition.

Conclusion

Learners with ID need effective instruction to cultivate their strength and to help them develop skills for independent living. Developing or adopting a curriculum that can address intervention goals is the foundation of an effective intervention. This chapter presents information regarding how to develop a curriculum to meet the needs of individuals with ID, demonstrates sample lesson plans, and compiles a list of existing curricula published within the last 20 years. Practitioners may find the information presented in this chapter useful for their clinical work.

43 Emerging Technology for Students with Intellectual Disability

Luis J. Mena, Vanessa G. Felix, Rodolfo Ostos, and Gladys E. Maestre

Introduction

Development of technological innovations is an engine of integration with the capacity to mitigate the obstacles that continue to hinder full insertion of individuals with intellectual disabilities in all areas of our social context (Brown & Duguid, 2017). The use of new technologies has emerged as a transformative tool to mediate and enhance the inclusion of people with disabilities, becoming an effective alternative to break the physical and cognitive barriers that limit the learning and communication of this sector of the population (Carver, Ganus, Ivey, Plummer, & Eubank, 2016; Leopold, Lourie, Petras, & Elias, 2015; Lancioni & Singh, 2014). Thus, in the last decade, the use of new supports and digital applications in the school environment has significantly increased, acting as effective mediators in the teaching and learning process (Altınay-Gazi & Altınay-Aksal, 2017; Díaz, 2017; Kirkwood & Price, 2014; Teo & Zhou, 2017).

Emerging technology-aided learning interventions can be used creatively to improve the development of abilities of people with academic skill deficiencies in math, reading, and/or writing. Under an interactionist conception that shifts its focus from the individual characteristics of students to a curricular support model, these types of interventions are expanding (Crossley & Mcnamara, 2016; Felix, Mena, Ostos, & Maestre, 2017; Kim, Park, & Coleman, 2017; Weng, Maeda, & Bouck, 2014). Through the interaction of software, peripherals, and an adequate methodology, the facilitator of learning – professor, companion, and family member – helps everyone in the classroom to develop their potential. This interaction is carried out in the zone of proximal development and converts what many call the problem of diversity – from the perspective of the deficit-based model – into an opportunity to broaden and enrich the educational context. The goal is to provide a suitable response to the didactic needs of students with intellectual disabilities and help them to be included in the physical and digital environments with creativity and full equality of opportunities (Cortiella & Horowitz, 2014; Felix et al., 2017; Shalev, Asmus, Carter, & Moss, 2016).

Although the role of technology as a mediator of learning is widely accepted, new forms of

social exclusion have emerged from different fronts and for various reasons. The absence of specific policies on digital inclusion, the difficulties in accessing technological infrastructures, insufficient training in and for the use of emerging technologies, the lack of references and supports, or the scarce application and promotion of design standards and guidelines for all people are some of the causes of what is rightly called *digital exclusion* (Chadwick & Wesson, 2016; Ditchman, Kosyluk, Lee, & Jones, 2016; Newman, Browne-Yung, Raghavendra, Wood, & Grace, 2017).

To guarantee access to technological resources to all people, including those who suffer some type of disability, it is not enough to develop emerging assistive technologies adjusted for each type of disability. It is also necessary that the design of technological resources considers standards and recommendations that facilitate the adoption of new technologies (Ayres, Mechling, & Sansosti, 2013; Carey, Friedman, & Bryen, 2005; Standen, Brown, & Cromby, 2001). Consequently, the design of technological aids or adaptations should be oriented to the development of simpler materials and high accessibility in their contents. Therefore, the desirable characteristics include using clear language, not overloading the user interface with information, using graphic icons or enough description to help in navigation, and using alternative supports of comprehension through auditory resources, graphics, and/or text, among others (Dekelver et al., 2015; Davies et al., 2015; Stock, Davies, Wehmeyer, & Palmer, 2008).

The aspiration toward greater accessibility has led to the idea of a *design for all* or *universal design* (Alnahdi, 2014; Hall, Cohen, Vue, & Ganley, 2015; Hartman, 2015). *Universal design* implies that learning is flexible and supportive for all learners, including those with intellectual disabilities, so that instructional goals, assessments, methods, and materials are usable and accessible by all (Hall, Meyer, & Rose, 2012; Rose, 2000). This framework aims to take into account in the design phase the accessibility requirements derived from the different types and degrees of people's functional capacity. Hence, failure to meet this objective in design processes could lead to discrimination, exclusion, and problems of social participation for groups with learning disabilities.

This chapter provides an overview of some technological developments that claim to assist students with disabilities, ensuring that users can access them regardless of their cognitive characteristics and also can use them efficiently to meet minimum criteria of usability and accessibility. Devices such as microswitch-based program technology to enhance adaptive behaviors, computer-assisted learning to improve cognitive and academic performances, and potential future developments, such as educational robotics, will be reviewed and discussed.

Microswitch-Based Program Technology

Persons with severe to profound intellectual and developmental disabilities may exhibit challenging behaviors and few adaptive responses that seriously hamper their acceptance and social desirability in daily context (Cannella, O'Reilly, & Lancioni, 2006; Lancioni et al., 2009; Spittle & Orton, 2014). Therefore, when individuals with serious limitations in adaptive response also exhibit problematic behaviors, technological interventions should try to increase constructive responding and reduce negative behaviors (Lancioni et al., 2005, 2008, 2009).

To overcome both issues, emerging assistive technology includes the implementation of microswitch cluster approaches (Lancioni et al., 2009). Basically, microswitches are electronic tools or devices designed to assist persons with severe and multiple developmental disabilities to independently access the preferred stimuli through the exhibition of small or minimal motor responses (Holburn, Nguyen, & Vietze, 2004; Lancioni, Sigafoos, O'Reilly, & Singh, 2012; Mechling, 2006; Saunders et al., 2003). The latest microswitch cluster interventions simultaneously monitor adaptive responding and atypical behaviors and deliver preferred stimuli automatically on positive responses performed without the presence of aberrant behaviors (Lancioni et al., 2006, 2009;

Stasolla, Damiani, & Caffo, 2014). Additionally, positive stimulation delivered for a constructive response would be interrupted when challenging behavior is demonstrated.

For example, Lancioni et al. (2013) assessed the use of microswitch clusters strategy to promote adaptive responding and decrease inappropriate posture consisting of the head and trunk leaning forward in two participants: a 10-year-old boy with a congenital encephalopathy diagnosis and reportedly profound intellectual disability and a 64-year-old woman presenting a neurodegenerative condition with decline in all aspects of life. Optic, tilt, and vibration microswitches were used to record their adaptive responses, while optic and tilt microswitches monitored their posture. Initially, the participants accessed brief periods of preferred stimulation for each cleaning response regardless of whether their posture was correct or not. Subsequently, the adaptive responses led to positive stimulation only if the inappropriate posture was absent. Moreover, in the case of appearing inadequate posture, the stimulation was interrupted. Results showed that both participants had large increases in adaptive responding and a drastic reduction in inappropriate posture during the first and second intervention phases and improved their problematic posture at the 2-week post-intervention check.

Microswitch technology can be implemented as educational intervention in school settings to improve the academic skills of students with multiple disabilities (Lancioni et al., 2004, 2006, 2008, 2010; Lancioni, Singh, Oliva, Scalini, & Groeneweg, 2003; Stasolla et al., 2015; Wacker, Wiggins, Fowler, & Berg, 1988). Individuals with extensive intellectual and communication disabilities can experience a reduced level of participation and/or active role within school environment, affecting their academic progress and, consequently, deteriorating their quality of life (Lancioni et al., 2006; Schalock et al., 2002). Therefore, a suitable/effective microswitch intervention strategy may foster their motivation and self-determination by learning and acquiring adaptive responses, thereby reducing passivity and preventing isolation (Lancioni et al., 2006; Stasolla et al., 2015).

Stasolla et al. (2015) evaluated six participants (mean age 10.7 years) with intellectual and extensive motor disabilities on a combined computer and microswitch-based program aimed at promoting academic activities in a school setting. The study provided educational activities and positive stimulation as primary reinforcements. By activating pressure and keyboard emulator microswitches (Fig. 43.1), participants were able to request and choose geography, literature,

Fig. 43.1 Keyboard emulator and pressure microswitches from Stasolla et al. (2015)

mathematics, and literacy activities through a computer interface. Each academic option was linked to specific stimuli, and the student could choose which response to perform and which stimuli to pursue. A final response was necessary in order to confirm a definitive choice. Results indicated that all students significantly improved their academic skills, positive participation, and indices of happiness during intervention phases compared to baselines. At the 3-month post-intervention check, a maintenance/generalization phase indicated that all participants consolidated the performances at their homes involving their parents. Finally, effectiveness was corroborated by a social validation assessment including support teachers as raters, who considered that the combined intervention was more favorable than those singularly learned.

One the other hand, Lancioni et al. (2010) assessed the effectiveness and acceptability of a microswitch-based program technology to support the literacy performance of a 12-year-old girl with extensive neuromotor disabilities to write words. Educational intervention included using a touch/pressure panel and voice-detecting microswitches connected to a computer with a scanning keyboard emulator. Panel activation enabled her to light up the keyboard and select/write letters and the vocalization to perform the scanning of the letters until reaching the one needed. Results indicated that the use of the microswitch strategy allowed the participant to successfully manage both scanning and letter selection/writing in an independent manner. It was a less tiring performance with respect to the traditional solution of expanded keyboard connected to a computer screen. Furthermore, effectiveness of the microswitch intervention was corroborated by a social validation assessment involving university psychology students as raters who manifested a significant personal support for the use of microswitch technology instead of the pre-existing solutions.

Earlier studies were consistently positive and support the use of microswitch technology in educational programs for individuals with severe to profound intellectual and developmental disabilities to provide constructive engagement, self-determination, and independence (Algozzine, Browder, Karvonen, Test, & Wood, 2001; Lachapelle et al., 2005; McDougall, Evans, & Baldwin, 2010; Stasolla et al., 2014). Thus, microswitch-based interventions may be of relevant and even of crucial importance to facilitate the acquisition of an active role and to develop some forms of constructive/functional response in an independent manner to increase academic performance, to improve general mood, and to enhance social image, desirability, and acceptability by others (Lancioni & Singh, 2014; Lancioni et al., 2012; Petry, Maes, & Vlaskamp, 2005). Within school settings, microswitch intervention strategies can be offered to students with learning difficulties to support a wide range of academic activities, pursuing the dual objective of improving integration and inclusion and reducing stereotypic and/or challenging behavior, with beneficial effects for the entire classroom (Lancioni & Singh, 2014). More extensive forms of microswitch sessions involving home context could promote positive interactions between teachers and parents and consolidate generalization and maintenance of academic achievements of students (Lancioni et al., 2006; McLay et al., 2015; Stasolla et al., 2015).

Although microswitch-based approaches represent a constructive and effective way to help people with intellectual and developmental disabilities to improve their academic performance, their implementation in educational settings is insufficient (Stasolla et al., 2015). Therefore, a research effort must be aimed to understand the barriers and facilitators of implementation of microswitch technology within learning environments. Design of new microswitch programs should deal with the following issues: (1) envisaging the interaction with other emerging technologies as mobile computing, pattern recognition, and virtual reality, among others, (2) performing a post-intervention phase involving home context to maintain learned abilities and generalize academic skills, and (3) enlarging social validation assessment with teachers and parents as raters to endorse the intervention program with greater validity and reliability (Lancioni et al., 2006; Stasolla et al., 2014).

Computer-Assisted Learning

Individuals with intellectual disability have different capacities and skills for understanding and learning (Daunhauer, Fidler, & Will, 2014). Thus, their learning potential depends on their educational environment and on the encouragement and support received in learning situations. Accordingly, they need more reinforcement and stimulation to function independently within school settings (Carlson, 2009). Therefore, it is necessary to design additional strategies for students with intellectual disabilities to improve their independence and self-determination, enabling them to carry out successfully education tasks, facilitating academic progress with beneficial effects on school staff and peers (Barnard-Brak, Thompson, Wei, & Richman, 2014).

Specific skills or abilities are learned through exposure to various situations, experiences, and learning opportunities. Some suggest that for individuals with intellectual disabilities to learn new skills, activities need to be broken down into smaller steps, and more repetition and structure are required for retention (Hulme & Mackenzie, 2014). Every person with cognitive disabilities demonstrates individual abilities, strengths, and weaknesses and has their own learning profile. These personal patterns of learning can be used to develop teaching strategies and therapies that are particularly effective for each individual (Felix et al., 2017). Given this set of educational characteristics, the use of computer-assisted interventions emerges as a suitable method for teaching students with intellectual disability (Clarfield & Stoner, 2005; Fletcher-Watson, 2014; Kulik, 2003; Tanimoto, Thompson, Berninger, Nagy, & Abbott, 2015).

Computer technologies have been found to be beneficial in the instruction of persons with intellectual disabilities for several reasons. People with learning difficulties often show attention problems because they have difficulty screening out unnecessary sensory information. Viewing of instructions through electronic media may maximize attention by eliminating or reducing information that might distract from the main task, allowing individuals to work at their own pace (Sansosti, Doolan, Remaklus, Krupko, & Sansosti, 2015; Williams, Wright, Callaghan, & Coughlan, 2002). Computer-assisted teaching can counteract difficulties in motivation and fatigue that often occur in individuals with learning disabilities. Creative and playful activities using computers can increase their confidence and motivation (Bosseler & Massaro, 2003; Goldsmith & LeBlanc, 2004; Ortega & Gómez, 2006). The use of computers promotes individualized teaching, allowing adaption of the work to the skill level of each student. Additionally, a computer system can offer an extensive choice of rewards and stimuli, which can be personalized to the student's needs and interests (Constantin, Johnson, Smith, Lengyel, & Brosnan, 2017).

Computer-assisted instruction enables repetition, errorless learning, self-correction, and immediate feedback about response accuracy. Academic software can be designed to provide support at each step, allowing students to learn a sequence of steps to achieve success. A computer can be a patient and repetitive teacher, providing students with multiple opportunities for learning and assessment, creating an environment that appeals to individuals with intellectual disabilities as less threatening, and ultimately decreasing anxiety and expectation of failure (Felix et al., 2017; Sansosti, Powell-Smith, & Cowan, 2010). Computers offer students the possibility of increasing their autonomy and personal independence, to be able to learn alone, and they need less help from others. They can accomplish tasks with less effort, greater speed, and higher quality, reducing work avoidance, frustration, and inappropriate behavior (Meyers, 1988). The computer can also store achievement data for each student, providing an objective record of their progress. Finally, computers can act as an interface between the individual with cognitive disability and other people, ameliorating social communication and interaction deficits and reducing social anxiety (Constantin et al., 2017).

Research evidence has identified that individuals with learning disabilities not only demonstrate significant skill acquisition when taught via computers but also have a preference for instruction delivered through such devices over standard print materials (Ortega & Gómez, 2006; Shaw & Lewis, 2005; Walcott, Marett, & Hessel, 2014). Nevertheless, some research has suggested that there may be differential effects for the effectiveness of the computer-assisted learning based upon the academic skill targeted and the age of the population (Kulik, 2003; Murphy et al., 2002). Moreover, several studies evaluated the benefits of computer-assisted learning approaches for students within special education without comparing participants' outcomes with those of a control group (Butcher & Jameson, 2016). Additionally, many studies showed that students with learning difficulties spent more time on task and completed more problems during the computerized intervention but demonstrated similar levels of academic performance using paper-and-pencil methods (Lewandowski, Wood, & Miller, 2016). This could be explained by the studies that show the main difference between teaching approaches was simply the presentation of academic instructions (computer vs. printed text), rather than offering, for example, a game format based on multimedia instructional design utilizing touch-screen technology (Felix et al., 2017).

To effectively assess the positive impact of computer learning intervention in students with intellectual disabilities, it is necessary to examine academic benefits from well-designed studies based on group experimental research within natural classroom settings (Butcher & Jameson, 2016; Dunst & Hamby, 2012; Gersten et al., 2005; Sansosti et al., 2015). It is also important to evaluate academic achievement and educational outcomes in specific scholar domains. Selection of digital approaches based on emerging computer technologies seems to be justified in supporting students' learning and cognitive processes and outcomes within special education settings (Fernández-López et al. 2013; Liu, Wu, & Chen, 2013; Shah, 2011).

In this context, Felix et al. (2017) conducted a pilot study on an experimental and control group to assess the effectiveness of a computer-assisted learning tool for children with Down syndrome. Complementary learning strategies included mobile computing, multimedia instructional design principles (Mayer, 2005; Sorden, 2005), and automated handwriting and speech recognition using an artificial neural network (Graves, Mohamed, & Hinton, 2013; Jiao, Liu, Yuan, & Bai, 2012) aimed at improving literacy skills of participants, through speech and drawing activities within a playful environment. Software design was assisted by special education therapists, and graphical use interface included animated characters with features of people with Down syndrome (Fig. 43.2). The treatment group

Fig. 43.2 Graphical user interface of computer learning approach from Felix et al. (2017)

was taught using a digital approach on tablet computers, and the control group received individual instruction on the same material but for paper-and-pencil tasks. The differences between adjusted posttest scores for both groups were statistically significant in favor of the intervention group on single-word reading ($p = 0.048$) and handwriting form ($p = 0.046$) measures, with large effect sizes ($d > 0.80$).

Felix et al. (2017) concluded that effectiveness of the computer instructional approach was possibly attributable to its ability to present very tightly controlled stimuli in an entertaining game-like format, providing enough repetitions for learning and helping to avoid frustration and stress; integration of speech and touchscreen input to perform personalized task sequences that address attention deficit and working memory limitations; adjustable neural network recognition thresholds that helped to make adaptations in progress to facilitate teaching according to learning profile of each student; and the presentation of animated objects that aided overcome deficits in abstract thinking.

Instead, Bakker, Heuvel-Panhuizen, and Robitzsch (2016) examined the effects of a teacher-delivered intervention with online mathematics mini-games on special education students' multiplicative reasoning ability. A pretest/posttest control group design was employed with three experimental and two control schools of special primary education. The only difference between the two groups was that in the experimental group part of the academic program for multiplicative reasoning was replaced by the online digital intervention. Computer mini-games were adapted versions from the mathematics games website RekenWeb (Jonker, Wijers, & Van Galen, 2009). In accordance with the needs of special education students, adaptations were easy to learn, contained simple graphics and minimal sound effects, and provided rewards, and the mathematics content was integrated into the main activity of the games. A scoring mechanism that increased scores as students finished the game successfully was also added. Furthermore, many of the games allowed for different difficulty levels. Results indicated that students in the experimental condition had higher learning outcomes than control students on declarative knowledge of multiplication facts ($d = 0.39$, $p = 0.047$).

Bakker et al. (2016) concluded that positive effects of computer intervention may be because mathematical knowledge was more easily transferred from the mini-games since these included less distracting features and required only a little reading. Additionally, it appears important for special education students that games provide continuous rewards and that they allow for different difficulty levels – for example, by providing choices in the types of problems to be solved or making available supportive features. Therefore, games delivered an engaging environment in which students were motivated to practice basic multiplicative number facts. Finally, they argued that findings were in agreement with Kroesbergen and Van Luit's (2003) conclusion that for students with intellectual disabilities, basic skill interventions are more effective than interventions targeting more complex mathematics tasks.

Despite the potential of computer emerging technologies for helping students with intellectual disabilities to improve their academic performance and motivation, consistent evidence to support their implementation in the classroom and evaluating their efficacy is lacking (Fletcher-Watson, 2014; Lewandowski et al., 2016). A possible explanation is that computer innovations are evolving much faster than the research needed to demonstrate their effectiveness as a learning strategy in special education. In this sense, the rapid pace of technology has delayed the separation of the leading features of new technologies that are most significant in supporting students with learning disabilities to improve their academic achievement. Consequently, it is possible that many of the new technological developments actually help non-disability students more than students with intellectual disabilities, creating a digital divide with respect to their educational outcomes (Lussier-Desrochers et al., 2017; Lewandowski et al., 2016).

Beyond the positive claims suggesting that computer-assisted learning effectively supports academic skill acquisition of students with intellectual disabilities, the field of new technologies for special education has yet to accumulate evidence-based practices (Gersten & Edyburn, 2007). Because several studies found that very few computer-aided instruction approaches met the standards of quality required for evidence-based interventions (Anderson, Anderson, & Cherup, 2009; Edyburn, 2013; Fitzgerald, Koury, & Mitchem, 2008; Weng et al., 2014), it is difficult to determine which features of computer technology resulted in specific academic gains for students in special education. Therefore, it is important to build a robust research base demonstrating generalizable efficacy of emerging computer-based learning interventions for students with intellectual disability, meeting quality criteria needed to derive evidence-based learning strategy, developing collaborative approaches between special education staff and software developers, and examining the positive impact of digital technology use for both non-disability students and students with learning disabilities within school settings.

Educational Robotics

Emerging technology advances and research developments in the area of robotics have allowed robots to become an integral component of our society. In the case of applications for education, students with disability have received particular attention due to evidence from several studies and more reasonable new robotic platforms (Conti, Di Nuovo, Buono, & Di Nuovo, 2017; Hedgecock, Standen, Beer, Brown, & Stewart, 2014; Pennington, Welch, & Scott, 2014).

In general, educational robotics is the set of pedagogical activities that support and strengthen specific areas of knowledge and develop competencies in the student through the conception, creation, assembly, and implementation of robotic prototypes and specialized programs for pedagogical purposes (Kazakoff, Sullivan, & Bers, 2013). Within special education, it has shown the potential to be implemented as a learning strategy to reinforce social, emotional, and academic skills in students with concentration problems and learning disabilities (Den Brok & Sterkenburg, 2015).

Students with intellectual disabilities require a high degree of repetition and face-to-face time with an instructor, as well as consistent, timely, and precise feedback (Cacioppo & Petty, 1979; Cook, Meng, Gu, & Howery, 2002; Park & Kwon, 2016; Reardon, Zhang, Wright, & Parker, 2015). Robots can tirelessly provide consistent and continuous academic interactions with students and avoid mistakes, which are an advantage over human teachers who may experience fatigue and common teaching errors (Park & Kwon, 2016; Reardon et al., 2015).

Learning and retention for academic subjects such as mathematics or science can be improved when students actively participate in direct purposeful practices, as opposed to watching demonstrations, because these emphasize the integration of several hands-on activities while communicating educational concepts (Adams, Alvarez, & Rios-Rincon, 2017; Petress, 2008). Students with intellectual and developmental disabilities may miss the hands-on component of learning due to their limitations in handling with precision objects used in hands-on lessons. Therefore, developing robots used for augmentative manipulation in education activities can contribute to the hands-on learning of students with multiple disabilities, acting as a practical learning partner to interact with the same objects as their peers in the classroom, and increase the active component of learning experience in the real world (Adams et al., 2017; Chang, Lee, Wang, & Chen, 2010; Cook, Bentz, Harbottle, Lynch, & Miller, 2005).

However, the most significant advantage of learning strategy from robots is the tendency of positive acceptance and motivation for students with intellectual disability (Den Brok & Sterkenburg, 2015; Park & Kwon, 2016; Standen et al., 2014). People with learning disabilities can have difficulties with understanding and showing interest in the outside world. Robots seem to operate as a key tool able to draw the attention of students with learning difficulties. They appear to encourage a process of interaction, by increasing joint attention, communication, and autonomous

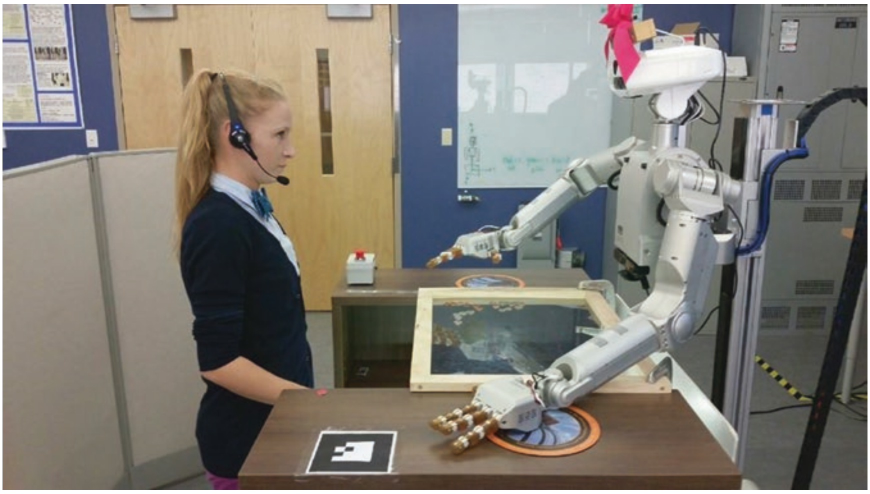

Fig. 43.3 Interaction setting for intelligent robot instruction from Reardon et al. (2015)

social behavior, moreover of supporting the work of teachers and parents (Costa, Soares, Santos, Pereira, & Moreira, 2016; Den Brok & Sterkenburg, 2015; Fridin, 2014; Lehmann, Iacono, Dautenhahn, Marti, & Robins, 2014). In addition, research evidence indicates that robots can stimulate the social development of children with multiple disabilities because affective touching, imitation, and expressing emotions toward the robot were encouraged (Kozima, Nakagawa, & Yasuda, 2007; Pioggia et al., 2008; Robins, Dautenhahn, Te Boekhorst, & Billard, 2005).

Cho and Shin (2011) demonstrated that cognitive-disabled children tend to accept social robots more enthusiastically than other kinds of toys, agents, or even humans. Studies found that using robots as a tool to perform explorative learning activities is more motivating than microswitch interventions or computer learning programs (Cook et al., 2005; Fridin, 2014; Kim et al., 2013). Therefore, this tendency toward positive acceptance of robots by learners could be helpful when dealing with different learning needs.

As an example, Reardon et al. (2015) proposed the creation of an autonomous, intelligent robot instructor to teach social and life skills based on mathematical competencies to students with intellectual disabilities. The primary robotic hardware was a mobile humanoid robot equipped with a couple of elastic arms with hands, a sensor head with 2 degree of freedom movement, high-definition cameras, Bluetooth microphone, and stereo speakers (Fig. 43.3). Two computer systems provided real-time functionality of the motion, vision, and audio components. The selected instructional task was the ability to calculate the correct quantities and denominations of currency that should be exchanged after a cash transaction. Participants in this study were three college-age students attending a postsecondary education program for young adults with intellectual and developmental disabilities.

During baseline, each participant performed at least three trials related to counting amounts of change back to researchers for purchases of items under US$1. No feedback, prompting, or assistance was provided. Under the baseline condition, none of the students were able to correctly perform the skills related to making change independently. The general outline of experimental trial began with the robot delivering the task instruction and then asking the student to show the correct change for 1 dollar from a randomly selected price less than US$ 1. Robotics approach observed the performance of the requested task through a real-time object tracking system and provided feedback by means of speech and gestures by using response prompting methodology as part of a cognitive process (Wolery, Ault, & Doyle, 1992).

The robotics system interpreted the answer of the student and provided precise instruction, reevaluating and presenting an updated prompt, if necessary. In the case of a correct response, the robot delivered a positive and differential reinforcement tailored to the level of intrusiveness of the prompt that was required. After reinforcement, the student was asked if he or she would like to continue with another lesson. By repetitions of this process, the goal was for the student to require less and less prompting, to the point of performing the task independently.

Experimental results showed that all students were able to achieve accurate performance to identify the correct amount of change for a given price and to provide the correct amount of change using the least amount of coins possible. An acceptability study was conducted to examine the opinions of students under the robot's tutelage. Post-instruction survey results indicated that participants felt a beneficial interaction and showed greater willingness to work with robots again. Authors concluded that intelligent autonomous robot instructors have the potential to teach a non-trivial life skill to students with intellectual disabilities with the purpose of empowering them to lead more independent lives.

Positive acceptance and motivation toward robotics learning approaches by students could provide an affective component to learners and encourage their participation in educational settings, increasing their overall well-being. Nevertheless, despite its full potential to allow more scalable didactic supports to improve student engagement, implementation of robotics academic intervention in real special education environments is still scarce (Adams et al., 2017; Den Brok & Sterkenburg, 2015). Current evidence consists of mostly case studies in relatively artificial conditions (Adams et al., 2017), where students used the robotic approaches for a short period at school but with a research team present. One possible explanation is that although students with learning difficulties have shown a positive perception and a significantly higher willingness to use robots within educational contexts, it seems that there is still some skepticism among the specialized teachers in the treatment of intellectual disabilities, who perceive the robot as an expensive and limited learning tool (Adams & Cook, 2017; Conti et al., 2017; Encarnação et al., 2017).

In a recent study that examined the views of disability service organization employees toward social robotics, many expressed concerns about safety, normality for disabled people, and artificial interactions (Wolbring & Yumakulov, 2014). Furthermore, findings of Encarnação et al. (2017) indicated that special education teachers had more reservations about the difficulties related to the use of robotics technology in the educational context when compared to regular education teachers. Even in some cases where teachers agreed that a robot system was useful and had a positive impact on students with intellectual disabilities, they also felt that the amount of time it took to do things with the robot was not always practical in the classroom due to time constraints and the energy level of the participants to complete the activities (Adams & Cook, 2017; Encarnação et al., 2017). In addition, the cost of an autonomous, intelligent robot instructor with a range of functions large enough to engage students with learning difficulties is considered prohibitive for most special education schools (Hedgecock et al., 2014; Pennington et al., 2014).

More research involving teachers into designing, developing, and implementing of robotics intervention in special education settings is needed. Only with their active participation, the synergistic integration of the pedagogical and academic protocols will be up to the standards and expectations of educational staff. On the other hand, the professional experience of educators could also help to identify practical issues, to adapt robotic solution to the needs and skills of learners, and to provide effective outcome measures for assessing the use of robotics learning approaches for students with intellectual disability.

Conclusions and Future Directions

In this chapter we have reviewed some of the most recent emerging technological developments that support learning for students with intellectual disabilities. In general, available research has shown that technological innovations used by students with learning difficulties have the potential for many positive academic outcomes. However, further control group instead of single-case studies are needed to assess the benefits and challenges of using emerging technological interventions for educational development and academic achievement in special education settings.

From an empirical point of view, it is clear that emerging technologies have made teaching for students with learning disabilities more flexible and adaptive. Nevertheless, it is also necessary to demonstrate which technology supports which kind of learning strategy or specific academic outcome better. Each technology can facilitate academic learning in different ways depending on its own features. Therefore, we desperately need robust research initiatives that focus on user experience design and validation of studies because current evidence in these research aims for most emerging technologies embedded in special education settings is scarce and weak.

Therefore, in agreement with Butcher & Jameson (2016) it is necessary to build a pedagogical framework that guides design and validation into emerging technology interventions for supporting academic performance and learning outcomes for students with intellectual disabilities. The lack of this framework makes it difficult to assess the effectiveness and validity of academic gains reported in individual interventions or small-group studies to determine the true impact of emerging technologies on special education sessions. This framework should be focused on identifying best practices in user-centered interface and experimental design. Thus, this pedagogical framework could provide a solid understanding of which technology or features of technology are the more effective to promote a specific academic achievement for students with learning disabilities. Moreover, this will help to optimize the use of technology for educational support and to accelerate the accumulation of valid knowledge for effective intervention (Butcher & Jameson 2016).

However, emerging technological developments cannot be considered as a panacea for teaching students with intellectual disabilities because the actual benefits of technology-assisted learning depend greatly on the quality and adequacy of the academic intervention. Therefore, to reach educational goals promoting motivational and independent learning, emerging technological approaches must be developed through the collaboration of an interdisciplinary team comprised of special education teachers, researchers, developers, therapists, and parents, as well as intervention programs must be expanded in different settings involving school and home and maintenance and generalization of academic achievement in post-intervention phases be systematically designed.

Finally, it is essential to emphasize that the development and implementation of emerging technologies within special education environments are mainly aimed at providing teachers with improved support and feedback for students with intellectual disabilities in order to facilitate successful social integration. In this sense, future research should also address how to assess the acquired academic competences by emerging technology intervention within meaningful environments which can potentially result in increased access of these traditionally marginalized persons to an expanded social context.

Anxiety and Phobias in Individuals with Intellectual Disabilities

Lauren J. Moskowitz, Megan Braconnier,
and Melissa Jeffay

Background

History of Anxiety in ID

Prior to the last 40 years, it was generally assumed that mental health problems such as anxiety disorders could not exist in individuals with intellectual disabilities (ID) (Matson, Belva, Hattier, & Matson, 2012; Reardon, Gray, & Melvin, 2015). Anxiety is a construct that involves (a) subjective mental state inferred from verbal reports of *emotions* (e.g., subjective fear and panic experienced) and *cognitions* (e.g., beliefs, thoughts, images, such as worrying, "I'm going to get hurt"), (b) *behaviors* indicating fear or anxiety (e.g., physically escaping or avoiding the feared stimulus or situation, such as running out of the room, whining, crying, or pacing), and (c) *physiological arousal* (e.g., heart racing, palms sweating, muscles tightening) (Barlow, 2000). The difficulty diagnosing anxiety disorders in individuals with ID may be due in large part to the communication deficits often present in this population, since diagnosis of an anxiety disorder typically requires verbal report of cognitions and affect. In addition to difficulties with communication and introspection, anxiety may also be unrecognized or overlooked in this population because of the atypical manifestation of anxiety disorders in individuals with ID (Helverschou & Martinsen, 2011); the misattribution of symptoms of anxiety to the intellectual disability (i.e., "diagnostic overshadowing," Reiss, Levitan, & Szyszko, 1982) or to problem behavior (i.e., "behavioral overshadowing"); and the reluctance of behavior analysts to use the construct of anxiety to describe or explain behavior in those with ID, given that—unlike behaviors—the cognitive/affective and physiological components of anxiety cannot be directly observed (Groden, Cautela, Prince & Berryman, 1994).

Prevalence of Anxiety in ID

In spite of these difficulties identifying anxiety in ID, it is increasingly recognized that individuals with ID do experience fear and anxiety, at increased rates in comparison to the general population. The prevalence of anxiety disorders ranges from 3% to 22% in youth with ID (see Reardon et al., 2015 for a review) and 2–17% in adults with ID (e.g., Deb, Thomas, & Bright, 2001; Reid, Smiley, & Cooper, 2011), depending on the methods used to diagnose anxiety and on the sample (e.g., whether including individuals with severe or profound ID). The rate of phobias is significantly higher in adults with ID compared

to the general population (Deb et al., 2001). Even higher rates of anxiety are reported in some genetic syndromes associated with ID, most notably fragile X syndrome (FXS), with 70–83% of individuals meeting criteria for at least one anxiety disorder, the most common being specific phobia and social phobia (Bailey, Raspa, Olmstead, & Holiday, 2008; Cordeiro, Ballinger, Hagerman, & Hessl, 2011), and Williams syndrome (WS), with a rate of anxiety disorders at approximately 48%, the most common being specific phobia and generalized anxiety disorder (GAD) (Royston, Howlin, Waite, & Oliver, 2017). Anxiety was also found to be three times as common in individuals with ID and comorbid autism spectrum disorder (ASD) (Gillott & Standen, 2007).

Several researchers have found that children without ID (IQ ≥ 70) were rated by parents as displaying more symptoms of anxiety than those with ID (IQ < 70) (Sukhodolsky et al., 2008; Witwer & Lecavalier, 2010) and that anxiety disorders are more common in those with mild ID than moderate to profound ID (Cooper, Smiley, Morrison, Williamson, & Allan, 2007; Dekker, Koot, van der Ende, & Verhulst, 2002). This may be because individuals with higher intellectual functioning are likely to have a greater understanding of their condition than those with lower intellectual functioning, which presumably leads to increased anxiety. Alternatively, these findings may be due to the aforementioned difficulty of identifying anxiety in individuals with more severe ID. Thus, it may be that parents, teachers, staff, or other informants may not recognize the person's fear/anxiety and may even attribute the person's aggression, self-injury, or tantrums to disobedience, oppositionality, or anger/irritability rather than to fear or anxiety.

Definition of the Anxiety Disorders

DSM-5 Anxiety Disorders

The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*; APA, 2013) defines anxiety as "the apprehensive anticipation of future danger or misfortune accompanied by a feeling of worry, distress, and/or somatic symptoms of tension." Although some researchers (e.g., Brown, Aman, & Lecavalier, 2004) have argued that *DSM* criteria are applicable to individuals with mild or moderate ID, other researchers have questioned the applicability of the existing diagnostic system to individuals with ASD, DD, and ID (e.g., Leyfer, Woodruff-Borden, Klein-Tasman, Fricke, and Mervis, 2008). For example, results of a study by Leyfer et al. (2008) suggested the need either to modify the definition of GAD or create a new category of anxiety to capture the "anticipatory" anxiety exhibited by a large proportion of children with WS. To begin to address the limitations in applying *DSM-5* criteria to those with ID, the *Diagnostic Manual for Diagnosing Mental Disorders in Persons with ID* (*DM-ID-2*) was created to adapt *DSM-5* diagnostic criteria for individuals with ID. In the *DM-ID-2*, Cooray et al. (2016) make the point that – to receive a diagnosis of most *DSM* anxiety disorders – the person must have some ability to recognize and describe his emotions and/or thoughts (more so for anxiety and worry than for fear), which may be difficult or impossible for many people with ID. However, with visual prompts, some individuals with mild to moderate ID may be able to describe worries and rate time spent worrying and related distress (Cooray et al., 2016). Further, fear can often be observed through behavioral and/or physiological indicators for individuals who are unable to self-report, as described for the following *DSM* disorders. Caretakers are often able to recognize subtle facial expressions and other behaviors associated with anxiety in individuals with ID (e.g., Helverschou & Martinsen, 2011). As such, some researchers have attempted to identify behavioral descriptors of DSM anxiety symptoms (e.g., Charlot et al., 2007).

The *DSM-5* defines 11 types of anxiety disorders, which we will now describe. All of the disorders with the exception of selective mutism involve fear ("the emotional response to real or perceived danger"), anxiety ("anticipation of future threat"), and/or worry ("apprehensive expectation"). To receive a diagnosis for any of the anxiety disorders, the person's fear or anxiety must be severe enough to cause significant distress or impairment, interfering with his/her social, occupational, or other areas of functioning. To meet criteria for most of the anxiety disorders, the fear/anxiety must be out of proportion to the actual danger posed by the situation, be persistent (≥ 6 months), and not be better explained by another mental disorder.

Separation Anxiety Disorder (SAD). SAD is defined by developmentally inappropriate and excessive fear or anxiety regarding separation from an attachment figure, as evidenced by at least three of eight symptoms (APA, 2013). The *DM-ID-2* does not recommend any modifications for diagnosing SAD in individuals with ID, given that fear can be observed rather than subjectively described for three of the symptoms (e.g., distress when anticipating or experiencing separation from home or attachment figures, reluctance/refusal to go away from home or go to sleep without attachment figure). However, assessing whether nightmares and complaints of physical symptoms pertain specifically to separation and assessing the more cognitive symptoms of SAD (e.g., worry about harm befalling attachment figures) may still be challenging in individuals with ID. For example, in Moskowitz et al. (2013), although a child with ASD and ID exhibited recurrent excessive distress when he anticipated or experienced separation from his parents, it was difficult for his parents to know whether he was worried about losing them or harm befalling them or that an event would lead to separation, as he was unable to articulate such worries.

Selective Mutism (SM). SM is defined as failure to speak in social situations in which the person is expected to speak (e.g., school) for at least 1 month, despite speaking to a select few people in other situations (APA, 2013). The failure to speak is not due to a lack of knowledge of the spoken language required in the social situation. The *DM-ID-2* does not recommend any modifications for diagnosing SM in individuals with ID, given that failure to speak can be directly observed (no subjective inferences required).

Specific Phobia (SP) and Social Phobia (SoP). Individuals with SP display marked fear, anxiety, or avoidance about a circumscribed object or situation (e.g., heights, animals) that is almost always immediately provoked by the phobic situation, is persistent, and is out of proportion to the actual risk posed (APA, 2013). Individuals with SoP, or social anxiety disorder, are fearful or anxious about social situations in which they might be scrutinized by others, including social interactions (e.g., meeting unfamiliar people), being observed, and performing in front of others (e.g., giving a speech) (APA, 2013). This involves fear of being negatively evaluated by others (i.e., being embarrassed, humiliated, and rejected or offending others). These social situations are avoided or endured with intense fear/anxiety. For children who cannot verbalize fear or anxiety, the *DSM-5* allows fear or anxiety to be expressed by "crying, tantrums, freezing, or clinging" for both SP and SoP (APA, 2013). Although the *DSM-5* does not specify any such modification for individuals with ID, Cooray et al. (2016) recommend using this modifier for adults with ID who are functioning at a similar developmental level so that fear can be observed rather than subjectively described. Although with the *DSM-5* it may still be difficult for individuals with ID to recognize or articulate fear of embarrassment or humiliation or rejection, one positive development is that the criterion for both SP and SoP was revised from "the person recognizes that the fear is excessive or unreasonable" in the *DSM-IV* to "the fear or anxiety is out of proportion to the actual threat" in the *DSM-5*, which may make it easier for individuals with ID to meet this criterion without having to express "recognition."

Panic Disorder (PD). PD involves recurrent unexpected panic attacks, which are abrupt surges of intense fear or discomfort that reach a peak within minutes accompanied by physical symptoms (e.g., pounding heart, sweating, trembling, shortness of breath, chest pain, nausea, dizziness, chills) and/or cognitive symptoms (derealization or depersonalization, fear of losing control or "going crazy," fear of dying). To meet criteria for PD, at least one attack must be followed by ≥1 month of persistent worry about having more panic attacks and/or a maladaptive change in behavior to try to avoid having panic attacks. Given that an individual with even mild ID might have difficulty with that temporal sequencing, the *DM-ID-2* recommends identifying 1 month of time using a time frame or anchor events or description of time frame from informant report (Cooray et al., 2016). Individuals with ID may not be able to articulate the more abstract cognitive symptoms of being detached from oneself, feelings of unreality, fear or losing control, and/or fear of dying, making it more difficult for them to reach the criterion threshold for PD. The *DM-ID-2* recommends modifying the *DSM-5* criteria for those with moderate to profound ID so that a panic attack can be either observed or reported and recommends reducing the criteria from ≥4 to ≥3 symptoms for those with severe to profound ID. The *DM-ID-2* also suggests relying on direct behavioral observations for those with severe to profound ID, such as identifying racing heartbeats by taking pulse, shortness of breath by observing overbreathing or hyperventilation, or chills or heat sensations by observing flushing (Cooray et al., 2016).

Agoraphobia. Agoraphobia involves marked fear or anxiety regarding two or more of five situations: using public transportation, being in open spaces, being in enclosed places, standing in line or being in a crowd, and being outside of the home alone (APA, 2013). To meet the *DSM-5* criteria for agoraphobia, the individual must be able to express that he fears/avoids these situations because of thoughts that escape might be difficult or help might not be available if he/she develops panic-like or other incapacitating symptoms (APA, 2013) – thoughts that may be difficult for individuals with more severe ID to express. Thus, the *DM-ID-2* recommends modifying the criteria for agoraphobia for those with severe or profound ID so that fear can be observed rather than subjectively described. In addition, *DSM-5* requires that the agoraphobic situations are actively avoided, require the presence of a companion, or are endured with intense fear or anxiety. The *DM-ID-2* cautions that avoidance of agoraphobic situations may not be prominent in individuals with moderate to profound ID if they are not given the opportunity to make choices such as where they go, what they do, and what they avoid (Cooray et al., 2016). Further, the *DM-ID-2* recommends establishing that individuals with ID require the presence of a companion due to fear/anxiety rather than due to low adaptive functioning.

Generalized Anxiety Disorder (GAD). GAD is characterized by excessive, persistent, and uncontrollable anxiety and worry about a variety of areas (e.g., work, school performance) (APA, 2013). Given that it may be difficult for people with severe or profound ID to verbalize thoughts of anxiety and/or worry, the *DM-ID-2* recommends modifying the criteria for GAD so that fear or anxiety can be observed rather than subjectively described (as with SoP, PD, and agoraphobia) and eliminating the criterion that the person finds it difficult to control the worry (Cooray et al., 2016). In addition, to meet *DSM-5* criteria for GAD, one must frequently experience three out of six physical symptoms including restlessness, being easily fatigued, irritability, sleep disturbance, muscle tension, and difficulty concentrating or mind going blank. Individuals with ID may be unable to articulate these symptoms, particularly the last two. As such, the *DM-ID-2* recommends including a modifier for individuals with severe to profound ID that only one of these six physical symptoms is required, a modification that the *DSM-5* includes for children.

Obsessive-Compulsive Disorder (OCD). Although OCD is now included in its own section in the *DSM*-5 due to its distinction from the aforementioned anxiety disorders (it was subsumed under anxiety disorders in *DSM-IV*), we will mention OCD in this chapter because obsessions and compulsions are frequently observed in those with ID (Matson & Dempsey, 2009). OCD is an anxiety disorder characterized by the presence of obsessions (recurrent and persistent thoughts, urges, or images that are intrusive and unwanted) and/or compulsions (repetitive behaviors or mental acts aimed at preventing/reducing anxiety or distress) that are time-consuming or cause clinically significant distress or impairment in important areas of functioning (APA, 2013). While anxiety or distress occurs in most individuals with OCD, this is no longer required for a diagnosis in *DSM-5*, which facilitates making the diagnosis of OCD in individuals with ID. Although the *DM-ID-2* does not recommend specific adaptations to the *DSM-5* criteria, they note that obsessions may not be experienced as intrusive/unwanted for some individuals with ID and that they may not attempt to ignore or suppress or neutralize their obsessions (Cooray et al., 2016). They further note that repetitive behaviors or mental acts may be difficult to elicit due to cognitive deficits and limited expressive language skills and suggest considering ordering, telling, asking, or repetitive physical acts as compulsions. Importantly, they caution that it might not be possible to ascertain the function of the compulsion (i.e., to prevent or reduce distress) in some individuals with ID, which is traditionally the main way that compulsions have been discriminated from stereotypic/repetitive behavior in ASD and/or ID.

Other Specified Anxiety Disorder (OSAD). Many individuals with ID may be diagnosed with OSAD (formerly *anxiety disorder not otherwise specified* in *DSM-IV*) because their fears and anxieties do not clearly fit into any *DSM-5* category. Although some of the *DSM-5* anxiety disorders may be applicable to those with ID, traditional *DSM*-consistent symptoms are more often present in individuals with intact intellectual and language ability (Kerns et al., 2014). Many anxiety-like behaviors occur in people with ID and other DDs – particularly those with ASD – that may not meet the criteria for any *DSM-5* disorder except OSAD (Kerns et al., 2014). For example, Kerns et al. (2014) found that almost half of youth with ASD (IQ, 67–158) displayed “atypical anxiety” – impairing symptoms of anxiety that were not consistent with any *DSM* disorders, the most common type (22%) being worry around routine, novelty, and restricted interests (e.g., changes in daily schedule, losing access to a special interest, rule-breaking). Other atypical anxieties included unusual specific fears (12%, e.g., fear of radio jingle), social fearfulness without the awareness of social judgment required to meet SoP (8.5%), and compulsive behavior in the absence of a clear desire to prevent distress or feared outcome as in OCD (8.5%) (Kerns et al., 2014). These atypical symptoms may reflect a more diffuse form of anxiety that is not addressed by the *DSM* but which still may be impairing (Kerns et al., 2014). As such, Kerns et al. (2016) proposed a four-step framework for differential diagnosis of anxiety disorders in ASD (many of whom have ID). For example, an individual with ASD and/or ID who presents with anxiety about transitions and routine changes might not experience the range of worries or feared consequences (“what if?”) that are characteristic of GAD yet nonetheless experiences anticipatory anxiety that is (1) excessive for his developmental level, (2) causes significant impairment to functioning, (3) is distinguishable from sensory difficulties, and (4) is above and beyond what can be explained by ASD or ID alone, which would warrant a *DSM-5* diagnosis of OSAD (excessive worry about change) (Kerns et al., 2016).

Finally, within the anxiety disorder category, the *DSM-5* also includes diagnoses for *substance-/medication-induced anxiety disorder* (which involves anxiety due to substance intoxication/withdrawal or to a medication treatment), *anxiety disorder due to another medical condition* (anxiety symptoms are attributed to the physiological consequences of another medical condition such as hyperthyroidism), and *unspecified anxiety disorder*.

In sum, although the *DSM-5* has rearranged the anxiety disorders into separate groups of classical anxiety disorders that now include SM and SAD, the *DSM-5* criteria still largely depend on adequate cognitive function and communication, which makes anxiety disorders difficult to diagnose in individuals with more severe ID (Cooray et al., 2016). While the *DM-ID-2* might be useful for adults with mild to moderate ID in that its use helped to avoid the OSAD category, resulting in more specific diagnosis, Cooray et al. (2016) suggest the use of behavioral equivalents for diagnosing anxiety in adults with severe or profound ID and point out that there are no studies looking at utility of *DSM* criteria for anxiety disorders in children with ID.

Although using behavioral equivalents may be helpful in identifying fear or anxiety in individuals with ID, it is important to note that it still may be difficult to differentiate anxiety from avoidance or challenging behavior in individuals with ID.

For example, Khreim and Mikkelsen (1997) observed that fear in adults with ID may manifest itself as "agitation, screaming, crying, withdrawal, freezing, or regressive clingy behavior." Although these behaviors or other behaviors might indicate fear or anxiety in an individual with ID at certain times in certain contexts, that same individual might also cry, scream, withdraw, cling, become tense, or behave irritably because he is tired, in pain, angry, sad, overstimulated, or otherwise distressed or because he dislikes an object, person, or situation (or simply prefers another situation). As such, Hagopian and Jennett (2014) differentiated between "simple avoidance" in which the individual avoids non-preferred stimuli or situations (such as a chore or academic task) and "anxious avoidance" in which the individual exhibits avoidant behavior accompanied by traditional symptoms of anxiety, including facial expressions of fear, increased physiological arousal, and, if possible, self-reported anxiety. Along these lines, Moskowitz et al. (2013) developed a multimethod assessment strategy to operationally define the construct of "anxiety" in children with ASD and ID. They assessed (1) the *behavioral* component of anxiety by collecting data on idiosyncratic behaviors that were reported to indicate anxiety for each child, (2) the *physiological* component of anxiety by collecting data on heart rate and respiratory sinus arrhythmia, and (3) the *cognitive/affective* or "subjective" component of anxiety by assessing the context in which the behaviors and physiological arousal occurred, given that labeling one's state of affective arousal as "anxiety" or any other emotion is highly influenced by the situational context in which the arousal occurs (Bandura, 1988). When multiple sources are taken together, converging data may support that the behavior is indicative of anxiety.

Intervention for Fear and Anxiety in ID

Goals for Intervention

From a diagnostic standpoint, sometimes it may be difficult to discriminate whether an individual with ID is running away from a blender while crying and covering his ears because he is anxious/afraid of the blender or because he is hypersensitive to auditory stimuli (e.g., Koegel et al., 2004). However, from a pragmatic behavioral standpoint, one could argue that it may not matter. That is, regardless of whether running away from the blender is due to a specific phobia of blenders or hyperacusis, our intervention goals would likely be the same: to encourage the individual to approach rather than avoid the given stimulus (e.g., the blender), to engage in the formerly avoided activity, or at the very least to calmly tolerate that stimulus or situation without aggression, self-injury, tantrums, or other problem behaviors.

Review of Evidence-Based Treatments

Although about a quarter of intervention studies that treat individuals with ID or cognitive delay mentioned specific *DSM* anxiety disorders (e.g., SoP, SM, GAD; Suveg et al., 2006), most studies that treat fear or anxiety in individuals with ID do not apply *DSM* criteria or other formal diagnostic criteria to establish the presence of anxiety disorders in these individuals. Rather, most intervention studies treating fear or anxiety in individuals with ID rely on overt avoidance behavior (i.e., avoidance of a phobic stimulus), verbalizations or vocalizations of fear, and other behavioral indicators of fear or anxiety (e.g., crying, screaming, running away, shaking, wide eyes), from which the presence of anxiety may be inferred. Therefore, we will review the literature on treating anxiety and/or "phobic avoidance" more broadly in individuals with ID, rather than restricting our focus to the treatment of specific *DSM* anxiety disorders.

Additionally, similar to other reviews (e.g., Rosen, Connell, & Kerns, 2016), we reviewed intervention studies that target individuals with impaired intellectual, adaptive, and/or developmental abilities even when standardized IQ testing was unavailable. This is because, in some studies, participants were untestable on standardized IQ tests or because, in some older behavior analytic studies, standardized measures of IQ or adaptive functioning were likely not seen as vital to describe participants' functioning. Regardless, with the new *DSM-5*, there is an increased emphasis on adaptive functioning over IQ, given that it is adaptive functioning that determines the level of supports required. With these considerations in mind, we will now review the evidence on interventions that address anxiety or phobic avoidance in individuals with ID.

In Vivo Exposure. The power of stimuli to evoke fear reactions can be reduced by exposing individuals to their feared stimuli or situations, known as in vivo exposure, which is typically the most critical component of treatment for any anxiety disorder. Most researchers would agree that engaging in exposure is necessary for positive treatment outcome when treating anxiety (Kendall et al., 2005). Indeed, 76% of the intervention studies that targeted fear or anxiety in individuals with ID used in vivo exposure (see Tables 44.1 and 44.2). This exposure is typically done in a gradual fashion, also known as "graduated exposure" or "in vivo desensitization" or "contact desensitization," in which brave behavior (i.e., approach/acceptance response) is positively reinforced, while fearful/avoidant responses are extinguished, as the individual is gradually exposed to increasing proximity, intensity, or amounts of the feared stimulus or situation. These exposures are typically conducted in a hierarchical fashion from situations that are rated as less anxiety-provoking to those rated as more anxiety-provoking. For example, in Moskowitz et al. (2017), Jon was exposed to people singing happy birthday, progressing from a cake with the candles unlit to a cake with the candles lit, and gradually increasing proximity to the cake.

Contingent Reinforcement. This refers to providing the individual with some type of positive reinforcement, such as social reinforcement (e.g., praise) and/or tangible reinforcement (e.g., toy, tokens to be exchanged for desired item), contingent upon approaching the feared stimulus or engaging in a feared activity/task, or contingent on remaining in a feared situation without resisting or engaging in problem behavior. Most of the intervention studies (68%) that target fear or anxiety in individuals with ID involved some type of reinforcement for approach or completing an exposure. For example, in Love, Matson, and West (1990), the therapist praised the child and dispensed positive reinforcement (e.g., verbal praise, sticker, stuffed dog toys, Gummi Bears) to the child for his successful partial approach toward the feared stimulus. Of note, contingent positive reinforcement includes both differential reinforcement of alternative behavior (DRA), in which approach behavior or compliance is reinforced (e.g., sitting still during blood draw; Hagopian et al., 2001), and differential reinforcement of other behavior (DRO), in which the absence of escape/avoidance behavior is reinforced.

Hierarchy/Shaping/Stimulus Fading. A hierarchy refers to breaking down the task of approaching or engaging with the feared stimulus or situation into small steps, with gradual increases in response requirements or successive approximations toward the final goal/step. Steps can be broken down sequentially into a task analysis (as in the steps in the hierarchy of a dental examination; e.g., sit in dental chair, and lean back in dental chair, Luscre & Center, 1996), or steps can include time exposed to the stimulus, amount of the stimulus, size of the stimulus (e.g., increasingly larger dogs; Erfanian & Miltenberger, 1990), intensity of the stimulus (e.g., increasing volume of audio recordings of thunder), or distance to the stimulus (e.g., decreasing distance between the needle and the tip of the child's finger, i.e., stimulus fading; Shabani & Fisher, 2006). Over half of the intervention studies (56%) that target fear or anxiety in individuals with ID involved hierarchy/shaping/stimulus fading. To illustrate, in Koegel et al. (2004), Steps 1–2 of the hierarchy for one child with a fear of vacuums involved placing a turned-off vacuum in the child's environment to expose him to seeing the feared stimulus, Steps 3–12 exposed him to an out-of-sight vacuum that became increasingly louder as it was moved closer to the child, and Steps 13–14 exposed the child to both seeing and hearing the vacuum. In most studies, progression to the next step of the hierarchy is typically contingent on a certain number of successfully

Table 44.1 Treatment studies summary

Study	*N*	Participant characteristics (age, diagnoses, functioning)	Anxiety disorder or feared stimuli or presenting problem	Dependent variables/ outcome measures	Study design	Intervention	Results/primary findings
Bouvet and Coulet (2016)	30	Adults with mild to moderate ID (15 in relaxation group, 15 in waitlist control group)	General anxiety management	Anxiety (state-trait anxiety inventory [STAI-Y]), self-esteem, emotional regulation	Randomized controlled trial	Relaxation therapy	Significantly reduced anxiety and improved self-esteem and cognitive reappraisal in relaxation group vs. control group
Burgio, Willis, and Burgio (1986)	1	21yo male with severe ID	Stair avoidance	Percentage of staff requests complied with for stair ascent and descent on staircases of varying lengths	Multiple baseline design across settings; within settings, a withdrawal of intervention (ABAB) was also used	Prompting, contingent reinforcement (praise and edibles), and physical guidance	Treatment was effective in increasing stair use in both settings (5 and 11 stairs)
Chok et al. (2010)	1	15yo male with ASD, moderate ID	Specific phobia, animal type (dogs)	Distance from dog, presence of behavioral escape/avoidance, heart rate	Case study (AB design)	Reinforced practice (graduated exposure, positive reinforcement), hierarchy, prompting	Approached and pet 4 dogs without elevated heart rate; maintained at 6-month follow-up
Conyers et al. (2004)	6	3 male and 3 female adult subjects (ages 33–54) with profound or severe ID	Fear of dental procedures Crying, yelling, hitting, biting, grabbing, or refusing to enter dentist's office	Participants' compliance with an 18-step task analysis associated with a dental examination	Multiple baseline design across participants; 3 received desensitization, and 3 received video modeling; crossover to other treatment for participants that did not complete task analysis with first treatment	In vivo desensitization (including verbal and physical prompts) and video modeling	Desensitization increased compliance with dental procedures for all 5 participants; video modeling increased compliance for 1 of 3 participants

Davis, Kurtz, Gardner, and Carman (2007)	1	7yo male with developmental delays (IQ or adaptive behavior not reported) and severe behavior problems	Phobia of water and heights	Behavioral avoidance, specific phobia symptoms (anxiety disorders interview schedule-IV-parent [ADIS-IV-P]), subjective fear (fear survey schedule for children-revised [FSSC-R]), negative vocalizations	Multiple baseline design across water and height phobias	CBT (in vivo exposure, participant modeling, cognitive challenges to catastrophic beliefs, reinforcement); one-session treatment for each phobia	Reduced or eliminated behavioral avoidance, specific phobia symptoms, and subjective fear; reduced negative vocalizations in height exposure
Dixon and Gunary (1986)	9	Adults with ID (ages 32–62)	Phobia of dogs	Ability to cope with dogs	Pre-post design	Gradual desensitization (exposure to 4 different dogs), video and modeling procedures	Majority showed an increased ability to cope with dogs, maintained after 9 months for those who practiced
Efranian and Miltenberger (1990)	2	39yo male with moderate ID 18yo male with profound ID	Phobia of dogs	Avoidance and approach behavior	Multiple baseline design across participants	Contact desensitization	Elimination of avoidance behavior in both adults; behavior generalized to outdoor setting and maintained at 2-month follow-up
Florez and Bethay (2017)	1	28yo female with mild ID, GAD, and intermittent explosive disorder	Challenging behaviors, emotional dysregulation, and GAD	Frequency of challenging behavior	Case study	Adapted DBT (individual therapy and social skills training)	Decrease in challenging behaviors; maintained average of <1 challenging behavior per month during year after treatment
Hagopian, Crockett, and Keeney (2001)	1	19yo male with moderate ID, intermittent explosive disorder, and cerebral palsy	Blood-injury-injection phobia (BIIP)	Refusals (verbal and physical), inappropriate behavior (aggression and disruption), compliance	Changing criterion design	Fading (graduated exposure), modeling, noncontingent and differential reinforcement, presession anxiolytic medication, and topical analgesic cream	During final two sessions, participant sat unrestrained in chair and complied with having blood drawn

Table 44.1 (continued)

Study	*N*	Participant characteristics (age, diagnoses, functioning)	Anxiety disorder or feared stimuli or presenting problem	Dependent variables/ outcome measures	Study design	Intervention	Results/primary findings
Hall et al. (2013)	7	Adults with learning disabilities	Anxiety and emotion regulation	Anxiety, depression, mindfulness, caretaker component	Qualitative and repeated measures design	Group DBT skills training	Treatment successfully reduced anxiety and depression and increased the use of mindfulness skills
Idusohan-Moizer, Sawicka, Dendle, and Albany (2015)	15	Adults with borderline, mild, or moderate ID and anxiety and/or depression (ages 21–44)	Anxiety, depression, and self-compassion	Anxiety and depression (hospital anxiety and depression scale), self-compassion and compassion for others (the compassion scale)	Pre-post design	Mindfulness-based cognitive therapy (MBCT)	Improvement in anxiety, depression, self-compassions, and compassion for others, maintained at 6-week follow-up
Koegel, Openden, and Koegel (2004)	3	3yo female with ASD (VABS = 1y7m) 2yo male with ASD (VABS = 2y1m) 2yo with ASD (VABS = 1y5m)	Fear of auditory stimuli (vacuum cleaner, blender, hand mixer, toilet flushing, and animal sounds)	(a) Number of hierarchical steps completed with the child's anxiety level rated as comfortable per week, (b) mean level of anxiety per session	Changing criterion design for each child, clinical replication for all 3 children, and multiple baseline across stimuli design for 1 child	Systematic desensitization implemented by teachers or parents with clinician assistance or directly by clinician	Number of steps completed in hierarchy increased Anxiety level decreased from intolerable to comfortable level
Lindsay (1999)	15	Adults with mild/ moderate ID	General anxiety management	Simplified versions of standardized self-report anxiety instruments Intensity and duration of maladaptive cognitions	Quantitative case series	CBT was simplified and adapted but included essential elements of Beck et al.'s (1979) cognitive therapy (e.g., challenging negative automatic thoughts, reviewing evidence for/ against dysfunctional beliefs, role-playing more positive ways of thinking)	Large and significant decreases in scores on standard measures and maladaptive cognitions; maintained at 6-month follow-up
Lindsay and Baty (1986)	3	3 adults with ID	General anxiety management	Anxiety levels	Case studies	Behavioral relaxation training	Treatment successful in reducing anxiety levels

Lindsay and Baty (1989)	20	Adults with moderate and severe ID (ages 25–69; IQ < 55)	General anxiety management	Anxiety score (composed of 10 behavioral ratings) and pulse rate	Randomly allocated to 2 groups: Abbreviated progressive relaxation (APR) or behavioral relaxation training (BRT)	Abbreviated progressive relaxation (APR) or behavioral relaxation training (BR)	While both relaxation procedures produced improvement, BRT was quick, consistent, and significantly better than APR; no differences in pulse rate
Lindsay, Baty, Michie and Richardson (1989)	50	Adults with moderate to severe ID (ages 25–69; IQ 30–55)	General anxiety management	Anxiety score (composed of 10 behavioral ratings) and pulse rate	Randomly allocated to 5 groups: Individual behavioral relaxation training (BRT), individual abbreviated progressive relaxation training (APR), group BRT, group APR, or control	Abbreviated progressive relaxation (APR, focusing on internal states of muscular tension and release) or behavioral relaxation training (BRT; copy relaxed behaviors)	Though both BRT and APR improved more than control group, BRT resulted in lower levels of rated anxiety than APR; no significant differences in pulse rate
Lindsay, Michie, Baty, and McKenzie (1988)	2	Women with ID	Phobia of dogs	Overall ratings of fear, number of positive approaches to a dog, number of negative reactions to a dog, number of requests to remove a dog, and self-assessments of anxiety	Unknown	Anxiety management training, exposure, and modeling	Both women responded to treatment
Love, Matson, and West (1990)	2	4.5yo male with ASD (VABS = 1y10m) 6yo male with ASD (VABS = 1y8m)	Avoided going outside alone, avoided running shower water	(a) Number of approach steps completed, (b) verbalizations and vocalizations of fear, (c) appearance of fear	Multiple baseline design across participants	In vivo desensitization, modeling of approach steps, prompting approach response, positive reinforcement contingent upon approach	Increase in approach, decrease in fear verbalizations, and decrease in ratings of appearance of fear
Luscre and Center (1996)	3	9yo, 9yo, and 6yo males with ASD and severe ID	Fear of dental procedures	Completion of the steps in a dental exam (in vivo and in an analog dental office)	Multiple baseline design across participants	Desensitization with guided mastery, video peer modeling, and reinforcement	Successful completion of the steps in a dental exam and clinically significant increase in steps completed in vivo

(continued)

Table 44.1 (continued)

Study	*N*	Participant characteristics (age, diagnoses, functioning)	Anxiety disorder or feared stimuli or presenting problem	Dependent variables/ outcome measures	Study design	Intervention	Results/primary findings
Maguire, Lange, Scherling, and Grow (1996)	4	4 adult males (ages 28–40) with mild to severe ID	Dental procedure resistance	Aggression and noncompliance Target behaviors: Sit calmly in dental chair, be vocally quiet, keep hands in lap, keep mouth open, tolerate procedure	Multiple baseline design across participants	Increasing predictability (i.e., tell-show-do), monetary and social reinforcement, brief and frequent dental visits, increased client control	Significant increases in cooperativeness with dental procedures, maintained over several months with 1 booster session per month
Matson (1982)	3	3 adult males with mild ID	Obsessive-compulsive behaviors	Clothes and body checking for extended periods of time	Multiple baseline design across behaviors, settings, and targets	Differential reinforcement of incompatible behavior, overcorrection as response suppression	Perceived improvement in appropriateness of target behaviors and rapid reduction in target behaviors and self-ratings of anxiety
Matson (1981a)	3	8yo, 8yo, and 10yo females with moderate ID	Fear of talking to or being near unfamiliar adults	Approaching and talking to unfamiliar adults and child ratings of overall fear	Multiple baseline design across participants	Participant modeling by mother with gradual fading of physical/verbal prompts, contingent reinforcement (tangible and praise)	Treatment was effective at reducing fear, and gains were maintained at 6-month follow-up
Matson (1981b)	24	24 adults with mild to moderate ID (ages 25–45)	Fear of participating in community-based activities	Fear level of going into a grocery store	Pre-post design	Participant modeling, behavioral rehearsal, shaping, in vivo exposure, graduated hierarchy	Participant modeling was significantly more effective at reducing fear than no treatment
Moskowitz et al. (2017)	3	6yo, 8yo, and 9yo males in the low range of intellectual and/or adaptive functioning with ASD, anxiety, and behavior problems	Fear of happy birthday, fear of separation from parents, fear of left/right turns in car	Anxious behaviors, problem behaviors, heart rate, respiratory sinus arrhythmia (RSA), ratings of appearance of anxiety	Multiple baseline design across participants	Graduated exposure, psychoeducation, cognitive restructuring, choices, counterconditioning, incorporating perseverative interests, prompting, positive reinforcement, extinction	Decreases in anxiety and problem behaviors and increases in RSA in anxiety-provoking situations

Neil, Vause, Jaksic, and Feldman (2017)	1	11yo male with ASD and IQ in borderline range	Ripping and sniffing paper, counting his fingers in a specific order	Obsessive-compulsive behaviors (OCBs) (repetitive behavior scale-revised [RBS-R], children's Yale-Brown obsessive-compulsive scale [CY-BOCS], child obsessive-compulsive impact scale-revised [COIS-RP])	Multiple baseline design across behaviors	Functional behavior-based CBT: CBT (e.g., psychoeducation, skills training, exposure and response prevention) plus FBA and FB intervention	Clinically significant decreases in OCBs, increase in psychosocial functioning, and high consumer satisfaction
Rapp, Vollmer, and Hovanetz (2005)	1	14yo female with ASD and severe ID	Swimming pool avoidance	Elopement, flopping, face hitting, choking, screaming, depth of water at which most time was spent	Within-subject design including multiple reversals	Blocking for flopping and elopement; reinforcement for movement toward pool; exposure to varying water depths	Eliminated pool avoidance and other disruptive behaviors
Riccardi, Luiselli, and Camare (2006)	1	8yo male with ASD and language and cognitive delays	Specific phobia of animatronic objects	Approach and time spent at a specified distance from the feared stimulus	Changing criterion design	Contact desensitization (reinforcing approach responses), shaping	Able to encounter previously avoided stimuli
Runyan, Stevens, and Reeves (1985)	3	1 adult male and 2 adult females (ages 33–41) with profound to severe ID	Escalator avoidance	Avoidance behavior toward escalators	Multiple baseline design across participants	Contact desensitization and contingent social approval	Reduced avoidance behavior toward escalators
Schmidt, Luiselli, Rue, and Whalley (2013)	1	16yo male with ASD and severe ID	Setting and activity avoidance of gymnasium, music room, and gross-motor exercise room	Approach distance or duration in setting before displaying problem behaviors Participation in activities within each setting	Multiple baseline design across settings and changing criterion design	Graduated exposure and positive reinforcement	Able to enter settings without resistance and participate in activities within each setting
Shabani and Fisher (2006)	1	18yo male with ASD, ID, and type 2 diabetes	Phobia of needles	Percentage of successful blood draw trials	ABAB reversal design	Stimulus fading and differential reinforcement	Successful in obtaining daily blood samples

Table 44.1 (continued)

Study	*N*	Participant characteristics (age, diagnoses, functioning)	Anxiety disorder or feared stimuli or presenting problem	Dependent variables/ outcome measures	Study design	Intervention	Results/primary findings
Suveg, Comer, Furr, and Kendall (2006)	1	8yo female with cognitive delays (IQ = 78; borderline)	Social phobia (SoP), selective mutism (SM), generalized anxiety disorder (GAD)	Anxiety symptoms (anxiety disorders interview schedule for children [ADIS-C/P-IV], state-trait anxiety scale for children [STAIC-P], child behavior checklist for children [CBCL], teacher rating form [TRF], coping questionnaire [CQ])	Pre-post design	CBT (e.g., imaginal and in vivo exposure, modeling, role-play, reinforcement, relaxation)	Significantly reduced anxiety symptoms; participant no longer met criteria for GAD or SM
Waranch, Iwata, Wohl, and Nidiffer (1981)	1	21yo male with Down's syndrome and mild ID	Phobia of mannequins	Approach responses	Multiple baseline design across mannequins	Shaping (mannequin gradually pulled closer), verbal prompts to touch mannequin, reinforcement	100% approach responses to different sized mannequins; effects generalized and maintained at 6-month follow-up
Wolff and Symons (2013)	1	41yo male with ASD, ID, and a history of medical noncompliance	Phobia of needles	Compliance with needle-to-skin contact	Changing criterion design	Exposure, differential reinforcement, and safety signal	Compliance with needles was achieved and maintained at follow-up; differential reinforcement and safety signal added value
Wright (2013)	1	19yo male with ASD, ID, and social anxiety	Social anxiety	Idiosyncratic measure of anxiety Global anxiety symptoms (brief symptom inventory [BSI])	A-B design	CBT (psychoeducation, relaxation, cognitive restructuring)	Anxiety severity significantly reduced, reaching and maintaining zero; BSI showed reduction posttreatment

Note. Studies highlighted in blue were included in calculations of empirically supported treatments (EST) according to Chambless and Hollon (1998) criteria because they were either a randomized control trial (RCT) or a single-case experiment with at least three participants; case studies, pre-post designs, or single-case experiments with fewer than three participants were not included in EST calculations

[a] Denotes use of video modeling

completed trials of the previous step. Of note, although this treatment component overlaps with the previous component of gradual exposure, this component refers to creating the steps in the fear/avoidance hierarchy, whereas gradual exposure refers to progressively moving the individual through each step in that hierarchy.

Prompting. Prompting is the presentation of any antecedent stimulus – a physical, verbal, or sensory stimulus – to initiate a response. Hagopian and Jennett (2008) suggested including prompting as a way to help the individual to comply with the steps of the exposure hierarchy, which may be especially important when the individual is displaying highly intense anxiety behaviors or not approximating the approach response. Half of the intervention studies (50%) that target fear or anxiety in individuals with ID involved assisting the individual to approach or engage with the feared stimulus using verbal prompts (e.g., mother verbally prompting her child to speak to a stranger; Matson, 1981a, 1981b) or physical prompts (e.g., physically guiding an adolescent to enter a feared setting at school; Schmidt et al., 2013). To illustrate, Runyan et al. (1985) used a least-to-most prompting sequence to help three adults with ID complete the steps of the hierarchy to ride an escalator. The prompting sequence involved the trainer modeling the desired behavior (e.g., approaching to within 1.5 m of escalator), verbally prompting the adult to complete the behavior, physically prompting him/her if necessary (i.e., light physical contact, such as holding hand or touching elbow), and, finally, manually guiding the adult through the behavior if necessary (i.e., physically moving his/her body through the desired behavior, which was stopped if the adult said "no" or moved away). One note of caution is that prompting should be used to *teach* approach responses rather than *force* them, as this can lead to negative emotions and problem behavior (Hagopian, Lilly, & Davis, 2017).

Modeling. With modeling, a therapist, parent, or peer demonstrates engaging in the anxiety-provoking situation or engaging with the feared stimulus appropriately while the participant observes. This can include the model demonstrating a step in the hierarchy and/or receiving reinforcement for brave behavior. Half of the studies (50%) that treat fear or anxiety in individuals with ID involve modeling. For example, in treating fear of grocery shopping in Matson (1981a, 1981b), participants were shown how to perform shopping behaviors, with the therapist first walking through the steps of the task. While some studies employ in vivo or live modeling (as in Matson, 1981a, 1981b), other studies use video modeling. For example, in Luscre and Center's (1996) study treating dental fear in children with autism and ID, four typically developing children acted as the peer models in a video of a dental exam conducted in the dentist's office. As another example of video modeling, in Moskowitz et al. (2017), a child with ASD and ID who was afraid of "happy birthday" viewed several internet videos of his favorite Sesame Street characters singing happy birthday and blowing out candles on a birthday cake.

Noncontingent Reinforcement/Counterconditioning. This intervention involves providing the person with noncontingent access to preferred or "anti-anxiety" stimuli before or during exposure to the feared stimulus/situation in order to inhibit or compete with a fear response. Only 26% of the intervention studies that target fear or anxiety in individuals with ID used this approach. In illustration, upon presentation of the birthday cake accompanied by the "happy birthday" song (feared stimuli), Jon was immediately given his most highly preferred item, a Sesame Street pop-up toy, without him having to perform any action to receive the toy (Moskowitz et al., 2017). This antecedent-based strategy of pairing anxiety-producing stimuli with positive stimuli *before* or during the exposure stands in contrast to the consequence-based strategy of positive reinforcement contingent upon the person displaying a certain behavior or completing a certain task (e.g., reinforcing Jon only after he attempts to blow out the candle). Related to noncontingent reinforcement, some studies provided individuals with noncontingent access to stimuli to help the individual relax or provide a distraction, such as allowing individuals to hold a coin purse or small bottle to keep their hands still during dental examinations (Maguire et al., 1996). Although it is not clear whether stimuli such as purses or bottles were reinforcing and could therefore be classified as noncontingent reinforcement, we will include these studies that provided noncontingent access to distracting stimuli in this category of noncontingent reinforcement.

This strategy of noncontingent reinforcement can also be conceptualized as counterconditioning, in which the conditioned stimulus (CS) is repeatedly paired with an unconditioned stimulus (US) having a valence opposite from the original US that was used for acquisition. Thus, counterconditioning involves presenting an item or activity that produces a relaxed, positive state that is incompatible with anxiety, such as pairing exposure to mannequins (Waranch et al., 1981) and dogs (Erfanian and Miltenberger 1990) with playing checkers or cards. Similarly, Luscre and Center (1996) used anti-anxiety stimuli (e.g., hand-held mirror, Play-Doh, the song "Achy Breaky Heart") to help counter a fear response to dental examinations; these anti-anxiety stimuli were paired with presentation of dental procedures and were individualized for each child. Although counterconditioning has not proven more effective than standard exposure (repeated presentation of the CS in the absence of the US) in the treatment of fear/anxiety, it should be noted that, in Moskowitz et al. (2017), the participants' anxious behaviors did not decrease throughout the repeated exposures of the baseline sessions. Thus, we decided to pair the anxiety-provoking situation (the CS) with a highly preferred and otherwise inaccessible positive reinforcer (e.g., pairing birthday cake/song with Sesame Street toy), rather than just exposing the participants to the anxiety-provoking situation without any accompanying positive stimuli.

Incorporating the Individual's Perseverative Interests. Given the level of anxiety that the targeted contexts appeared to provoke in three children with ASD and ID, Moskowitz et al. (2017) paired the anxiety-provoking situation with stimuli/activities that were not only reinforcing but taking it one step further by incorporating perseverative items or activities that were *the most* highly salient/preferred in an attempt to override or counteract the aversiveness of the anxiety-provoking contexts. "Perseverative interest" (also called "circumscribed interest" or "special interest" or "obsessive interest") refers to an object, activity, or topic with which the individual is intensely preoccupied. Studies have shown that using obsessions as reinforcers are more effective at reducing problem behaviors than other reinforcers such as edible reinforcers (Charlop-Christy & Haymes, 1996; Charlop, Kurtz, & Casey, 1990). It is possible that this could be because of the anxiety-reducing properties of a person's idiosyncratic perseverative, stimulatory, or obsessive reinforcers, in contrast to other tangible or social reinforcers, although – once again – there is a lack of research in relation to anxiety. To illustrate, in Moskowitz et al. (2017), Sam's parents used his primary perseverative interest (Dr. Seuss) as the reinforcer to pair with riding in the car (counterconditioning). Although Sam's favorite book, *The Sneetches* by Dr. Seuss, was an item he owned before intervention and could access at home, audio recordings of this book and other Dr. Seuss books were created at the start of intervention; Sam was only allowed to listen to these recordings during car rides. Of note, although incorporation of children's "special interests" is a part of treatment protocols for youth with ASD (e.g., Reaven et al., 2012), with the exception of Moskowitz et al. (2017) and Neil et al. (2017), these treatments have only included youth with "high-functioning" ASD (without ID).

Increasing Predictability **(e.g., safety signal, visual schedule, social story, priming).** Research has demonstrated that problem behavior is lower in predictable than in unpredictable conditions for individuals with ID (e.g., Flannery & Horner, 1994). Although Flannery and Horner (1994) did not conceptualize the reduction in problem behavior as being due to a reduction in "anxiety" per se, startle studies suggest that the ability to predict aversive events attenuates anxious responses (Grillon, 2008). However, only 12% of studies that targeted fear or anxiety in individuals with ID used some strategy designed to increase predictability.

One way to increase predictability is to provide an advanced warning to signal upcoming transitions or changes in routine or aversive events, which can provide the individual with time to prepare for the upcoming aversive situation or can signal how much time is left until an aversive activity will be over. These advanced warnings can be verbal and/or visual, including countdowns (e.g., "You have 10 seconds left until the blood test is finished… 10, 9, 8, 7, 6, 5, 4, 3, 2, 1, it's finished"), picture prompts (Mace, Shapiro & Mace, 1998), visual schedules (Dettmer, Simpson, Myles, & Ganz, 2000), and visual representations of time such as a time timer (displaying section of red indicating the given amount of time, with the red disappearing as the time runs out) (Dettmer et al., 2000). Although almost all of these studies that used advanced warnings did not mention fear or anxiety and only mentioned "aversive" events such as transitions, transition-/change-related anxiety is increasingly recognized as anxiety in individuals with ASD (e.g., Kerns et al., 2014, 2016), many of whom have co-occurring ID. To illustrate the use of advanced warnings to treat a traditional anxiety disorder, after three unsuccessful trials of attempting to treat a needle phobia with stimulus fading plus DRA, Wolff and Symons (2013) added a "safety signal" (i.e., a timer) to convey that the trial was of a finite duration and show when the trial would end. The addition of the safety signal corresponded with a change in the participant's behavior (increased compliance, reduced agitation) (Wolff & Symons, 2013). Further, even after the safety signal was later removed, the participant continued to keep his arm on the table for the duration of the needle exposure, suggesting he may have learned that all trials, with or without the safety signal, were of a limited duration.

In addition to advanced warnings such as timers and visual schedules, Social Stories (Gray & Garand, 1993) are individualized narratives that visually depict the sequence of events involved in a routine or situation and describe appropriate behavior relevant to the situation, which may decrease unpredictability and provide a model for non-anxious or coping behavior. For example, for a boy with ASD and ID who exhibited separation anxiety, Ben's Social Story normalized anxiety, explained that anxiety has a function or purpose, explained the concept of habituation (e.g., "I will see that my anxiety goes down after a while, even when Mommy and Daddy are not home"), and provided Ben with replacement behaviors that he could do instead of crying, screaming, and trying to run after them (i.e., coping self-talk such as "This is just my anxiety talking," relaxation techniques such as deep breathing, and fun activities such as playing or watching a movie) (Moskowitz et al., 2017). Although Social Stories have been shown to decrease levels of problem behavior in individuals with ASD and ID (Kokina & Kern, 2010), with the exception of Moskowitz et al. (2017), no other Social Stories studies have targeted or mentioned fear or anxiety specifically. A recent meta-analysis of Social Stories for students with ASD revealed that Social Stories are more effective when addressing inappropriate behaviors than when teaching social skills and when participants had lower cognitive ability rather than high or average intelligence (Kokina & Kern, 2010), which suggests that Social Stories could be helpful in treating anxiety or anxiety-related behaviors in individuals with ID (particularly anxiety that is related to unpredictability), although more research is necessary to support this.

Finally, another way to increase predictability by manipulating antecedent events is through priming, in which an individual previews future events so that they become more predictable. The use of video also allows for priming with children who are nonverbal or limited in their ability to comprehend verbal descriptions. Similar to advanced warnings, visual schedules, and Social Stories, the research on priming (Wilde, Koegel, & Koegel, 1992) and video priming (Schreibman, Whalen, & Stahmer, 2000) has shown that it decreases problem behavior associated with transitions or an upcoming unpredictable situation, but no studies except for Moskowitz et al. (2017) have mentioned treating fear or anxiety using priming.

In illustration, Sam, who had a fear of left/right turns, first watched videos of cars making turns on YouTube before exposure to turns while riding in the car (Moskowitz et al., 2017).

Extinction/Blocking. Escape extinction refers to not allowing the person to escape the anxiety-provoking situation or stop performing the given step in the hierarchy in response to problem behaviors or anxious/avoidance behaviors (so that these behaviors no longer produce reinforcement in the form of escape). This generally involves physically guiding the individual to engage in a step in the hierarchy (preventing him from escaping) or, in some cases, even blocking the individual from escaping. Only 12% of the intervention studies that target fear or anxiety in individuals with ID involved extinction or blocking. For example, in Rapp, Vollmer, and Hovanetz (2005), two therapists blocked or prevented Amy's attempts to elope from the swimming pool or flop to the ground by prompting her to sit in a rolling chair. In other cases, extinction does not involve response blocking but simply involves continuing with the anxiety-provoking situation regardless of the child's problem behavior or anxious behavior. To illustrate, in Moskowitz et al. (2017), when Sam was riding in the car with his parents during baseline, his parents often altered their driving route in response to his anxious behavior (e.g., crying "no left!" or "drive straight!") to avoid his feared stimulus of left/right turns, thus negatively reinforcing his anxious behavior. Thus, one component of intervention involved extinction, in which Sam's anxious behavior was no longer reinforced by escape through terminating the task (driving back home) or altering the driving route to accommodate Sam's anxiety (i.e., driving straight instead of turning right/left).

Providing Choices/Control. Allowing individuals to choose activities and reinforcers has been shown to increase task engagement while minimizing escape-motivated problem behaviors (Shogren, Faggella-Luby, Jik Bae, and Wehmeyer, 2004). Only 6% of the intervention studies that target fear or anxiety in individuals with ID involved providing individuals with ID with increased control or choices. To illustrate increased control, Maguire et al. (1996) asked clients with ID when they were ready to start at the beginning of each dental session and after each break. Similarly, to illustrate providing choices, in Moskowitz et al. (2017), Sam was given the opportunity to choose several preferred items (e.g., balls, books) to pack in a "car bag" that he could bring with him while riding in the car. In addition, whenever possible, Sam's parents attempted to provide him with a choice of the location to which they would drive. Although the existing research on providing choices/control to individuals with ID only mentions escape-motivated problem behaviors and (with the exception of Moskowitz et al. (2017)) does not mention fear or anxiety, researchers in the field of anxiety disorders have suggested that a sense of unpredictability and uncontrollability is at the heart of anxiety and that the development of coping responses that impart a sense of control can buffer anxiety (Barlow, 2000). Given that problem behavior can possibly be a way of exerting control over one's life (Wehmeyer, 1999), providing opportunities for choice-making may provide individuals with ID – especially those who are anxious – with an increased sense of control over their environments (Dattilo & Rusch, 1985), possibly reducing problem behavior that functions to escape/avoid anxiety, although this hypothesis remains to be tested.

Cognitive Behavioral Therapy (CBT). CBT typically includes not only graduated exposure to feared situations and stimuli (see above) but also psychoeducation (providing corrective information about fear and anxiety), cognitive restructuring (identifying maladaptive thoughts and teaching coping-focused thinking), somatic management (targeting autonomic arousal and physiological responses; e.g., relaxation), and relapse prevention (Albano & Kendall, 2002). CBT is widely considered to be the most effective evidence-based treatment for both neurotypical children and adults with anxiety disorders and has also demonstrated efficacy in reducing anxiety in youth with "high-functioning" ASD who do not have ID (Kerns, Renno, Storch, Kendall, & Wood, 2017). However, there is limited research on CBT to treat anxiety in individuals with ID. Only 21% of the studies that treat fear or anxiety in individuals with ID involved CBT. For the studies that used CBT to treat anxiety in children with borderline IQ or developmental delays, modifications included increased structure and emphasis on visuals, presenting concepts more concretely (e.g., robot versus ragdoll for relaxation), more practice opportunities to use concepts and skills, increased parental involvement, incorporation of the child's special interests, and, in some cases, a reduced focus on thoughts (Neil et al., 2017; Suveg et al., 2006). Although a systematic review of CBT for anxiety or depression in adults with ID (Unwin et al., 2016) did not identify any controlled trials for anxiety-focused CBT, they found equivocal evidence for the effectiveness of CBT in reducing anxiety in the three anxiety-focused CBT studies they located (Lindsay, 1999; Douglass et al., 2007; Marwood & Hewitt, 2012), with the latter two studies including participants with learning disabilities rather than ID. Of note, few studies in the review used standardized, objective criteria relating to a diagnosis or specific level of symptomatology. Further, the studies reviewed included only those with mild-moderate ID or learning disabilities and had inclusion criteria relating to verbal ability, which makes sense in light of the cognitive and verbal demands of cognitive restructuring.

Cognitive Restructuring. Cognitive restructuring (a component of CBT) involves identifying anxious thoughts or "self-talk"; challenging or disputing the accuracy, likelihood, or usefulness of those anxious thoughts; and replacing anxious self-talk with more accurate, probable, or productive thoughts that facilitate coping with anxiety-provoking situations rather than avoiding them (i.e., teaching coping self-talk). For example, in a case study of CBT for a man with ASD, ID, and social phobia, the man's negative automatic thoughts were identified, and the evidence for and against his thoughts was used to challenge his assumptions and develop more realistic alternative thoughts (Wright, 2013). When individuals have a cognitive deficit or are impaired in their ability to understand and/or express language, the cognitive components of CBT (i.e., cognitive restructuring, psychoeducation) are often downplayed, de-emphasized, simplified, modified, adapted to the individual's level, or most typically excluded altogether so that the intervention is more "behavioral" (e.g., exposure, reinforcement) rather than "cognitive behavioral." To illustrate, Moskowitz et al. (2017) used Social Stories as a way to provide psychoeducation (e.g., normalizing anxiety, explaining habituation) and a simplified form of cognitive restructuring in a visual modality that could be more easily comprehended. Although Moskowitz et al. (2017) did not address identifying or disputing anxious thoughts, which would have been too cognitively and verbally challenging, for Ben, cognitive restructuring took the form of prompting coping self-talk through the use of a Social Story. Coping self-talk is often used before exposures to help reduce anticipatory anxiety and/or during exposures to encourage brave/calm behavior rather than avoidance/anxious behavior. For example, Neil et al. (2017) taught a boy with ASD and ID to use coping statements (e.g., "I can do it, I'm not going to let OCD beat me!") to help himself refrain from ritualizing by ripping and sniffing. Similarly, in Moskowitz et al. (2017), Ben's Social Story provided him with coping statements that he could tell himself when he was feeling anxious, such as "I am going to fight my anxiety and I will win!" that appeared to help calm him when his parents left. However, it is unclear what role – if any – the cognitive elements played in the reduction of anxiety in these multicomponent treatments and whether the same results would have been achieved with the behavioral components (e.g., counterconditioning) alone. Thus, more research is needed on the use of the cognitive components of CBT (cognitive restructuring and psychoeducation) with individuals with ID.

Relaxation Training. Relaxation typically involves deep breathing and/or progressive muscle relaxation (PMR; Jacobson, 1938). Only 24% of the intervention studies that target fear or anxiety in individuals with ID involved relaxation. Although relaxation is often part of a wider CBT program for individuals with ID, Bouvet and Coulet (2016) examined the effect of relaxation on its own; they conducted an RCT comparing adults with mild to moderate ID who received PMR to those in a waitlist control group and found that relaxation significantly reduced state anxiety. Although some research (Luiselli, 1980) suggested that relaxation did not appear to be more effective than non-relaxation activities for individuals with ID, this could be because the individual was required to concentrate on internal states of muscle tension and relaxation, which may be conceptually challenging for individuals with ID. Lindsay, Baty, Michie, and Richardson (1989) found that individuals with moderate and severe ID who were randomly allocated to behavioral relaxation training (which focused on modeling/prompting of relaxed positions rather than subjective states of tension and relaxation) showed lower levels of rated anxiety than those who were allocated to abbreviated progressive muscle relaxation, suggesting the importance of focusing on observable behaviors to a greater degree than internal states in this population.

Acceptance-Based Interventions. The "third wave" CBT or acceptance-based interventions such as acceptance and commitment therapy (ACT), dialectical behavior therapy (DBT), and mindfulness-based cognitive therapy (MBCT) retain elements of traditional CBT (i.e., emphasizing the connection between thoughts, feelings, and behavior) but focus less on challenging thoughts and more on radical acceptance of those thoughts and oneself. Only 8% of studies that target fear or anxiety in individuals with ID used acceptance-based interventions.

MBCT combines elements of cognitive therapy with breathing meditations and yoga exercises to help increase the individual's awareness of the present moment and bodily sensations without attempting to get rid of those sensations. MBCT relies less on verbal exchange than traditional CBT, which could make it a good fit for individuals with ID. Idusohan-Moizer et al. (2015) consecutively ran two MBCT groups for adults with ID, incorporating metaphors and analogies from ACT (Hayes et al., 1999), modified exercises on developing self-compassion (Neff, 2003) and meditation on the Soles of Feet (Singh et al., 2003), and found participants reported significant decreases in anxiety post-group compared to pre-group. However, the findings suggested that MBCT appears to only be suitable for those with borderline and mild ID who are able to read and write and may not be suitable for those with moderate or severe ID (Idusohan-Moizer et al., 2015).

DBT incorporates skills training (mindfulness, interpersonal effectiveness, emotion regulation, distress tolerance), contingency management, exposure, and cognitive restructuring (Linehan, 2014). Results of a systematic review by McNair, Woodrow, and Hare (2017) suggested that DBT and DBT skills groups can be adapted for individuals with ID, although more high-quality studies are needed to demonstrate efficacy and only one of the studies they reviewed assessed anxiety specifically (Hall et al. (2013), who found a decrease in anxiety following DBT, though that was in individuals with learning disabilities rather than ID). Florez and Bethay (2017) also described a case study of adapted DBT (e.g., briefer sessions of skills training, more concrete images, simpler language, all skills taught through multiple experiential exercises) for a woman with mild ID and GAD; although they reported a decrease in the frequency of challenging behavior, they did not assess or report on anxiety or fear.

Summary and Future Directions

Chambless and Hollon (1998) classified a treatment as *possibly efficacious* if it has been shown to be beneficial to at least three participants in a single-case experimental study or one RCT, whereas they required at least two RCTs or at least three replications in carefully controlled single-case experiments by two or more independent research groups before classifying a treatment as *efficacious*. Other reviews (Lydon, Healy, Callaghan, Mulhern, and Holloway, 2015; Rosen et al., 2016) have used the Chambless criteria to determine the efficacy of interventions to treat anxiety in individuals with ASD and/or ID.

Using the Chambless and Hollon criteria to classify the studies reviewed in Tables 44.1 and 44.2 (excluding the case studies and pre-post designs), in vivo exposure, contingent reinforcement, hierarchy/shaping/stimulus fading, prompting, modeling, noncontingent reinforcement, increasing predictability, and relaxation can be classified as *efficacious* interventions for treating anxiety in ID; extinction/blocking, providing choices, incorporating perseverative interests, and CBT as *possibly efficacious* interventions; and acceptance-based interventions (MBCT, DBT) as interventions that *do not have enough evidence* to determine their efficacy. These classifications must be viewed with caution, given that evaluating the quality or methodological rigor of these studies (e.g., reliable and valid outcome assessment measures; see Chambless & Hollon, 1998) was beyond the scope of this chapter. Not evaluating the methodological quality of each study means that the number of interventions classified as efficacious and possibly efficacious treatments might be an overestimate (e.g., noncontingent reinforcement might have ≤3 replications in single-case experiments by ≥2 independent research groups, but these single-case studies might not necessarily meet all of the quality indicators outlined by Chambless & Hollon, 1998). Interested readers can refer to the paper by Jennett and Hagopian (2008) that reviews the quality of interventions used to treat phobic avoidance in individuals with ID as well as the paper by Rosen et al. (2016) that reviews the quality of interventions used for those with ASD and ID (not including those with ID who do not have ASD).

Overall, consistent with Jennett and Hagopian (2008) and Rosen et al. (2016), behavioral interventions as a whole can be considered efficacious for the treatment of phobic avoidance, fear, and anxiety (though not necessarily as a treatment for *DSM-5* anxiety disorders) in individuals with ID, with **exposure and reinforcement being the most commonly used and well-established interventions**. However, it is important to note that almost all of the studies we reviewed included multicomponent interventions, which makes it challenging to determine the unique contribution of exposure or reinforcement or any of the individual intervention components and clarify which components are necessary or sufficient for change. Thus, future research should aim to identify the active elements of multicomponent intervention packages. That said, most of the interventions reviewed in this chapter have been demonstrated in previous research to be effective in reducing fear or anxiety in neurotypical individuals with anxiety disorders who do not have ID. Further, the use of multicomponent rather than single-component interventions is currently considered to be the best practice for individuals with ID and developmental disabilities (e.g., Carr et al. 1999).

Another important point to consider is that one quarter of the reviewed studies provided noncontingent access to preferred or anti-anxiety stimuli, which would be considered distraction in the CBT literature. Foa and Kozak (1986) posited that distraction interferes with the activation of fear by disrupting the match between aspects of the stimulus setting and the fear structure. Nevertheless, anecdotally, our clinical observations suggested that pairing the anxiety-provoking stimuli with equally potent or even more powerful perseverative stimuli served to counteract the fearful/anxious responses for children with ID in a way that exposure to the feared stimulus alone (without pairing it with antianxiety stimuli) may not have been able to accomplish or at least may not have been able to accomplish as quickly (Moskowitz et al., 2017). Future research must be conducted to examine this hypothesis in individuals with ID, perhaps comparing an “exposure paired with anti-anxiety stimuli” (i.e., counterconditioning) to an “exposure-alone” condition. Although using anti-anxiety stimuli would be considered distraction by some researchers and would be contraindicated for individuals with anxiety disorders who have intact intellectual functioning, this may not be as true for individuals with ID, who may not habituate as quickly or lack the cognitive capacity to understand that their feared outcomes did not come true and that their anxiety may eventually habituate if they remain in the feared situation for long enough without them having to do anything at all to escape or avoid or terminate it.

Finally, as some researchers have noted (Chok et al., 2010; Lydon et al., 2015; Moskowitz et al., 2017), most intervention studies have focused only on the behavioral component of fear/anxiety (overt, observable behaviors) and have neglected the other two components – cognitive and physiological – most likely due to the difficulty measuring cognitions and (to a lesser extent) physiological arousal in those with ID. Moskowitz et al. (2017) found that the more sessions the children with ASD and ID participated in (regardless of whether baseline or intervention), the lower their heart rate (HR) dropped in the presence of the feared stimulus. However, respiratory sinus arrhythmia (RSA) was significantly higher (reflecting increased ability to self-soothe) in intervention than in baseline. This suggests that although it may be possible to reduce HR (and potentially anxiety) in individuals with ASD and ID solely through repeated exposures to feared stimuli, it is possible that the other intervention components (e.g., positive reinforcement, pairing the anxiety-provoking situation with anti-anxiety stimuli, increasing predictability) may have promoted coping, reflected in improvements in RSA as well as substantial behavioral improvements. This hypothesis remains to be explored and highlights the need for more studies that examine physiological arousal when treating anxiety in those with ID. Further, no studies formally assessed changes in the cognitive component of anxiety as a result of intervention for those with ID, suggesting the need to determine better ways to assess thoughts and feelings in this population.

As a result of only measuring overt fear/avoidance behaviors, it is easier to identify specific phobia in those with ID than the other anxiety disorders. As such, almost all of the studies we reviewed in this chapter treated SP or non-*DSM* "phobic avoidance" in individuals with ID, with only 6% of studies treating GAD or SoP, 3% of studies treating SM and OCD, and 0% of studies treating SAD or PD in those with ID. It is therefore much less clear how to assess or treat anxiety disorders that involve thoughts of anxiety (anticipation of future threat) and/or worry (apprehensive expectation) in individuals with ID, an important direction for future research.

Finally, although one might assume that the function of all anxious or fearful behavior in individuals with ID is to escape or avoid anxiety-provoking stimuli/situations, other possible functions must be examined (obtaining reassurance or comfort [i.e., attention], access to soothing or comforting tangible object/activity) and conceptualized as anxiety – when appropriate – rather than only as escape-maintained or attention-maintained problem behavior. Only a few studies have discussed functions other than escape in relation to anxiety, such as access to attention (Moskowitz et al., 2017; Neil et al., 2017). There is a need for more research into individualized interventions tailored to individuals with ID based on the function of their anxious behavior, the specific antecedents that evoke the anxious behavior, and the setting events that increase the likelihood of the anxious behavior (e.g., unpredictability, uncontrollability).

Concluding Comment

Affective states such as fear and anxiety and comorbid anxiety disorders were rarely discussed or acknowledged in individuals with ID until relatively recently, in part because of the difficulty assessing anxiety in this population. In the studies we reviewed, descriptions of the presenting problems varied across treatment studies (e.g., "specific phobia" versus "dental fear" versus "swimming pool avoidance," though all may be phobias) as did the names of treatments used (e.g., "exposure" versus "systematic desensitization" versus "contact desensitization," all seeming to describe the same or similar interventions), with little use of standardized diagnostic measures, outcome measures, or treatment protocols, all of which are important directions for future research. Nevertheless, taken together, the results of our review suggest that behavioral interventions – particularly exposure and reinforcement – can substantially reduce anxious and/or avoidant behaviors and increase approach responses in individuals with ID. Future research must examine whether and how to modify cognitive strategies to adapt to the needs of individuals with ID as well as how to affect components of anxiety other than behaviors (i.e., cognitions, emotions, physiological arousal) in this population.

Depression

Gemma L. Unwin, Shoumitro Deb, and John Rose

Definition of Depression, Incidence and Prevalence

Depression refers to a range of mental health problems characterised by low mood, absence of positive affect, loss of interest and enjoyment, and a range of concomitant behavioural, physical, emotional and cognitive symptoms, and results in significant behavioural and functional disability. The course of depression can be recurrent or chronic but in some cases complete remission is possible. In people with ID, depression tends to be more severe and enduring than in the general population (Collishaw, Maughan, & Pickles, 2004), perhaps due to increased vulnerability or poorer management. Depression commonly co-occurs with anxiety in people with ID and intervention studies with combined samples are common.

The DSM-V (APA, 2013) has separated out depressive disorders from bipolar and related disorders and includes a new diagnostic category of 'disruptive mood dysregulation disorder' alongside major depressive disorder, persistent depressive disorder (dysthymia), premenstrual dysphoric disorder, substance/medication-induced depressive disorder, and depressive disorder due to another medical condition. Disruptive mood dysregulation disorder may become the focus of future research in ID. It was developed to address the over-diagnosis of bipolar disorder in children, however, both children and adults with ID could meet the diagnostic criteria, but to date, no studies have examined its clinical utility in ID (Charlot et al., 2017). The new version of the International Classification of Diseases, currently in development (ICD-11 Draft/Beta version; World Health Organization, 2017) has single episode and recurrent depressive disorder, dysthymic disorder, and mixed depressive and anxiety disorder as diagnostic categories. The DM-ID-2 provides an adapted framework for diagnosis of mental health problems in people with ID (Fletcher, Barnhill, & Cooper, 2017). It makes limited adaptations to the standard diagnostic criteria for depression but provides detailed behavioural descriptions of symptoms which can be used with informants to improve the reliability of their report and therefore diagnosis (Chap. 12; Charlot et al., 2017). Whilst diagnostic categories may be helpful for epidemiological, research, and clinical purposes, their clinical validity in understanding complex

mental health problems has been questioned (Stenfert Kroese, Dewhurst, & Holmes, 2001). In the UK, the British Psychological Society promotes the use of formulation to move away from a disease model of mental illness to understand conditions as a response to psychosocial factors such as trauma, loss or inequality (Jahoda, Stenfert Kroese, & Pert, 2017).

Clinical Presentation and Diagnosis

Box 45.1 gives an overview of the features of clinical depression.

Box 45.1: Clinical Features of Depressive Disorder

General Features

- Severe, persistent low mood that is pervasive across all situations and unresponsive to circumstances, even those that would normally lift a person's mood.
- Can be precipitated by a life event.
- A marked loss of interest in all activities ('anhedonia').
- Feelings of excessive tiredness.
- Loss of energy and initiative.

Biological Features

- Sleep disturbance (usually insomnia in the form of early morning awakening, however, in atypical cases excessive sleep can be a feature, early insomnia and interrupted sleep may also be present).
- Changes in appetite (usually decrease but increase in some atypical cases).
- Significant weight loss not due to dieting or any other physical illness (increase in weight in atypical cases).
- Psychomotor retardation or agitation.
- Decreased libido.
- Diurnal variation in mood (mood being worse in the morning).

Cognitive Features

- Loss of self-esteem or confidence.
- Lack of purpose in life (life is not worth living, there is no future).
- Feelings of guilt or self-reproach.
- Suicidal thoughts or behaviour.
- Difficulty with concentration.
- Marked slow thought processes.
- Ruminative thoughts (pre-occupation with depressive thoughts).
- Speech is slow and lacks content.

Appearance

- Depressed look (may be crying).
- Restless and agitated.
- Poor eye contact.
- Evidence of self-neglect (or sometimes self-harm).
- Stooped posture.
- Slow and sometimes awkward movements.

Psychotic Features (in Severe Cases)

- Auditory hallucinations (often derogatory and in second person) or delusions (nihilistic).

Those with milder ID may present with depressive symptoms similar to those of the general population and be able to recognise and articulate their emotional state. Standard diagnostic criteria such as DSM-V (APA, 2013) or ICD-10 (World Health Organisation, 1992) may therefore be applied in some cases. However, those with moderate or severe ID are less able to express their internal states so clinicians will be more reliant on observable features and informant-report. Diagnosis is more commonly based on agitation, aggression, self-injury, appearance of sadness, and changes in sleep or appetite, however, these are not reliable behavioural equivalents of depression, as discussed in more detail later. Thus, diagnosis is more complicated than for the general population, and may in part, be reliant on the observational and reporting skills of informants such as paid carers and family members as well as the assessment skills of the clinician.

Rose et al. (2013) found that 34% of a sample of people with ID who were referred for an anger management group had high levels of depression as measured by the Glasgow Depression Inventory (Cuthill, Espie, & Cooper, 2003). They also asked the people with ID themselves and the staff who supported them to complete a range of other measures that were then used to predict self-reported anger in the people with ID. The staff relied on a number of indicators which reflected the outwardly expressed challenging behaviours of individuals to explain expressed anger. The scores people with ID achieved on measures relating to their own emotional state, including their depression scores, best reflected their own assessment of expressed anger. This finding suggests, perhaps not surprisingly, that staff were using mainly external cues to understand the emotional state of people with ID. When the people with ID themselves report their own internal state, information provided by them is often unknown, not used or may be disregarded by staff in relation to the person with ID's emotional condition. Previous research has suggested that staff measures do not correlate well with the self-report of individuals with ID in this area (Bramston & Fogarty, 2000) however, there are some behavioural correlates of depression including: sad mood, crying, and anhedonia (Hurley, 2008).

As staff are likely to facilitate a referral to health services to support people with ID their relative lack of ability to identify depression may partially explain why people with ID are more likely to be identified as having difficulties with externalising symptoms such as challenging behaviour and anger rather than depression. For example, Hurley (2008) found that depressed mood was rarely cited as the primary complaint for people with ID and diagnosed depression, rather it was behavioural disturbances which prompted referral. Similarly, Mileviciute and Hartley (2015) found that informants reported fewer depressive symptoms than people with ID reported themselves. This suggests that a much more detailed assessment process is required that includes an assessment from the individuals' personal perspective, where possible, to get a true insight into the levels of depression in this population. Furthermore, awareness raising in carers about mental health problems beyond behavioural features may be required. The Diagnostic Manual-Intellectual Disability (DM-ID-2, Chap. 12, Charlot et al., 2017) therefore provides examples of how people with ID may demonstrate each depressive symptom in an attempt to reduce diagnostic errors related to reliance on informant reports.

In the field of ID 'diagnostic overshadowing' has been implicated whereby excessive focus is given to the ID rather than underlying mental health problems, resulting in under diagnosis (Reiss & Szyszanko, 1993). This may be further compounded by 'behavioural overshadowing' in which presenting behavioural problems may be indicative of underlying mental health problems, such as depression, but serve to mask the condition with treating clinicians (especially non-specialists) giving excessive attention to the behaviour rather than seeking to identify underlying mood disorder (Hemmings, Deb, Chaplin, Hardy, & Mukherjee, 2013). Whilst behavioural problems may be a common and atypical manifestation of depression in people with ID, they should not be considered as behavioural equivalents as they are non-specific – they occur at high rates in all mental health problems in people with ID. Aggression could be considered as a "final common pathway for distress" for people with ID who have limited other opportunities to demonstrate this (Charlot et al., 2017).

Prevalence

Depression is a common disorder among the general population and even more common among people with ID, however, prevalence is currently unknown due to the aforementioned problems with diagnosis along with methodological issues in existing prevalence studies such as differences in sampling and diagnostic procedures. Emotional problems, such as depression, are the most common psychiatric diagnoses for people with ID

(Azam, Sinai, & Hassiotis, 2009; Reid, Smiley, & Cooper, 2011; Richards et al., 2001; Smiley, 2005; Tsiouris, Kim, Brown, & Cohen, 2011). One of the few population-based studies reports a prevalence rate of 4.1% for unipolar depression, (based on clinical diagnosis) among 1025 service-users with ID aged 16 year or over in the Glasgow Health Board area in Scotland (Cooper, Smiley, Morrison, Williamson, & Allan, 2007). When using DSM-IV (American Psychiatric Association, 1994) criteria, 3.6% were diagnosed with affective disorder and the rate increased to 5.7% when using DC-LD (Royal College of Psychiatrists, 2001) adapted criteria. It could be anticipated that reported prevalence will increase with the addition of the new diagnostic category 'disruptive mood dysregulation disorder' and associated adapted criteria in the DM-ID-2 (Charlot et al., 2017). More recently, a large-scale survey reported that 14% of 4069 community-based adults with ID receiving specialist services in New York had a documented DSM-IV or DSM-IV-TR diagnosis of depression (Tsiouris et al., 2011).

Risk Factors for Depression

Risk factors for depression in the non-ID, general population include: (a) negative affectivity as a temperamental factor, including borderline personality disorder; (b) environmental factors including childhood adverse experiences; (c) genetic and physiological factors (for example, two to four fold increase of depression among first degree relatives of those who have suffered from major depressive disorder); (d) other biological factors such as presence of chronic medical and other disabling conditions and substance use (American Psychiatric Association, 2013). As with the general population, a range of biological, psychological and social factors are also implicated in the development of depression in people with ID (Irvine & Beail, 2016; see Fig. 45.1). A biopsychosocial model may account for the increased prevalence of depression in people with ID who may have more physical predispositions, higher rates of physical illness, exposure to psychological stressors, limited capacity for adaptive coping, and poorer social environments. Psychosocial factors for people with ID play a significant role as they face inequities such as social disadvantage, poor self-esteem, stigmatisation and poor social support.

Research has sought to identify risk factors for depression among people with ID, most commonly a range of demographic variables, life events and psychiatric diagnoses/mental health conditions. The following presents a brief overview of the research findings pertaining to the most commonly studied risk factors. Some research results have been inconsistent and determining a definitive risk profile remains elusive, not least because of the aforementioned challenges in diagnosing depression.

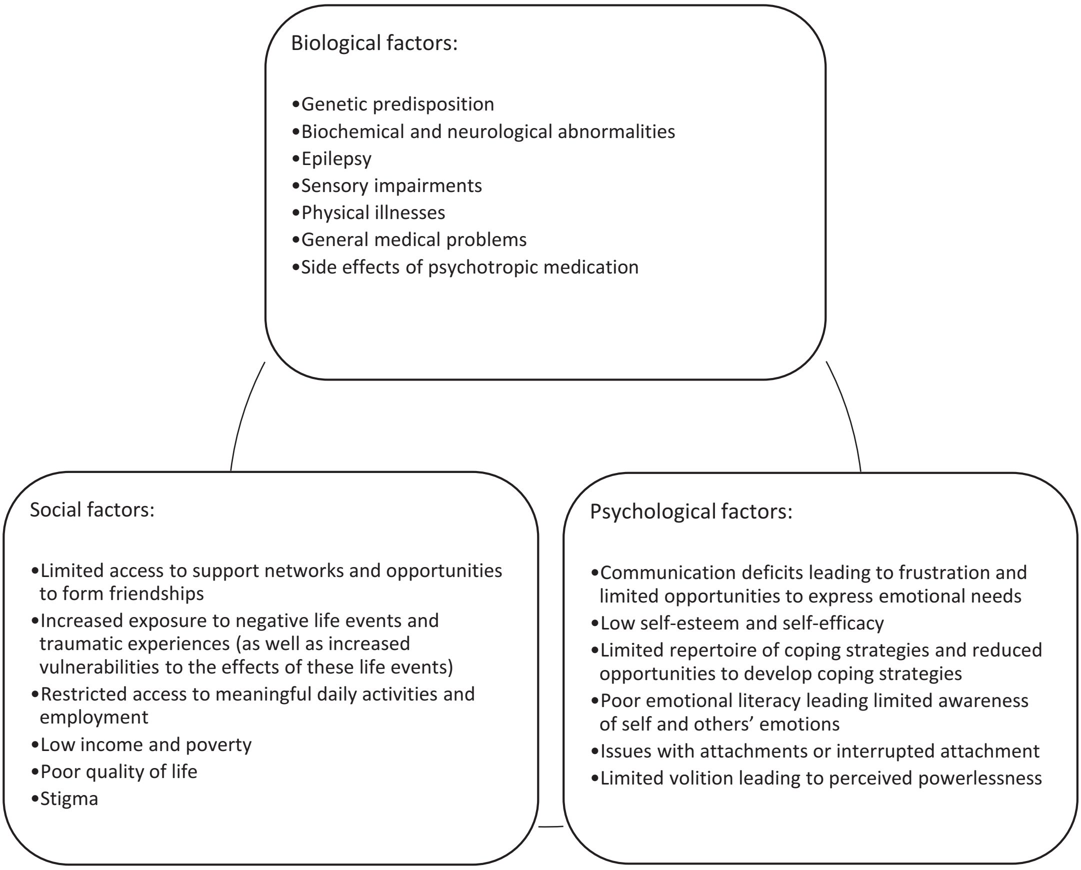
Gender: Diagnosis of depression is more common in females with ID (Bhaumik, Tyrer, McGrother, & Ganghadaran, 2008).

Age: Depression is more common in older people (over 65 years) with ID (Cooper, 1997) with a positive correlation between depressive symptoms and age (Hermans & Evenhuis, 2013).

Severity of ID: No association between depression and severity of ID has been reported (Cooper et al., 2007).

Genetic syndromes: There are certain genetic syndromes that cause ID in which there is an increased rate of depression (Levitas et al., 2016). These include Tuberous sclerosis, 22 q11 deletion syndrome, Neurofibromatosis, Prader-Willi syndrome, untreated Phenylketonuria, Myotonic dystrophy type 1 and Rubenstein Taybi syndrome (Charlot et al., 2016; Deb, Unwin, Rojahn, & Cooper, 2018),. A review did not find any evidence of increased prevalence of depression among people with Down syndrome (Walker, Dosen, Buitelaar, & Janzing, 2011).

Neurological abnormalities: Low levels of neurotransmitters, particularly serotonin in the brain has been implicated in depression among the non-ID general population and the underlying brain damage in people with ID may make them more vulnerable to these neurochemical changes but the empirical evidence to support this hypothesis is not currently available (Hassiotis, Stueber, Thomas, & Charlot, 2014).



Biological factors:

- Genetic predisposition
- Biochemical and neurological abnormalities
- Epilepsy
- Sensory impairments
- Physical illnesses
- General medical problems
- Side effects of psychotropic medication

Social factors:

- Limited access to support networks and opportunities to form friendships
- Increased exposure to negative life events and traumatic experiences (as well as increased vulnerabilities to the effects of these life events)
- Restricted access to meaningful daily activities and employment
- Low income and poverty
- Poor quality of life
- Stigma

Psychological factors:

- Communication deficits leading to frustration and limited opportunities to express emotional needs
- Low self-esteem and self-efficacy
- Limited repertoire of coping strategies and reduced opportunities to develop coping strategies
- Poor emotional literacy leading limited awareness of self and others' emotions
- Issues with attachments or interrupted attachment
- Limited volition leading to perceived powerlessness

Fig. 45.1 Risk factors for depression in people with ID

Epilepsy: The relationship between epilepsy and mental illness in adults with ID is complex (see review by Deb, 2007b) but minor psychiatric symptoms of depression and anxiety seem to be more commonly associated with epilepsy.

Autism spectrum conditions: Similar rates of depression for those with and without autism have been reported (Melville et al., 2008). However, other research has reported that the onset or increase in behaviours such as hoarding, repetitive touching or tapping may be presenting features of depression (Kannabiran & McCarthy, 2009).

Dementia: Onset of dementia is associated with signs of depression such as low mood and disturbed sleep (Strydom et al., 2010).

Medical conditions: A number of chronic medical conditions such as hypothyroidism (common in people with Down syndrome), dental problems, acid reflux, drug induced Parkinsonism, sensory problems (vision and hearing), all of which are common in people with ID, are likely to be associated with a higher rate of depression (Kwok & Cheung, 2007).

Life Events: Exposure to adverse life events such as bereavement or moving home increase the risk of depression (Hulbert-Williams & Hastings, 2008). Furthermore, total number of negative life events has been shown to be associated with depression in both children (Hatton & Emerson, 2004) and adults (Cooper et al., 2007; Esbensen & Benson, 2006) with ID.

Social factors: Other social factors including poor diet, lack of physical exercise, and lack of appropriate social, occupational and vocational opportunities make people with ID vulnerable to developing depressive symptoms (Hassiotis et al., 2014) whereas positive social support seems to mitigate against depressive symptoms (McGillivray & McCabe, 2007).

Psychological factors: Low self-esteem, loneliness and negative automatic thoughts have been shown to be associated with depressive symptoms in adults with mild to moderate ID (Lunsky, 2004).

Medication for Depression

The management of depression includes comprehensive assessment and diagnosis followed by treatment by competent practitioners in either a psychological or pharmacological approach, or a combination of these. Psychological therapies have become first line interventions for the treatment of depression in the general population and UK-based guidelines on the treatment of depression in people with ID (NICE, 2016). However, antidepressants are commonly prescribed to people with ID, often in the absence of a diagnosis of depression, and in the absence of robust evidence of their effectiveness as people with ID are often excluded from medication trials. Doan, Lennox, Taylor-Gomez, and Ware (2013) found that 20% of community-based adults with ID residing in Brisbane, Australia were taking antidepressant medication with 30% of those prescribed psychotropic medication not having a psychiatric diagnosis. Newer generation antidepressants (selective serotonin reuptake inhibitors; SSRIs) are prescribed more often than old generation antidepressants. A study of medication use among a clinical sample of 100 adults with ID and aggressive behaviour found that 10% were prescribed citalopram, 6% fluoxetine and 7% paroxetine (Deb, Unwin, & Deb, 2015). Previously, Holden and Gittlesen (Holden & Gitlesen, 2004) found that 8.5% of 300 adults with ID who were in receipt of ID services were prescribed SSRIs and 2.4% other antidepressants. Of those taking SSRIs, only 40% had a diagnosis of depression and none of those taking other antidepressants had a diagnosis of depression.

Prescribing guidelines for people with ID recommend starting low and going slow (NICE, , 2016; Deb, 2016; Bhaumik, Branford, Barrett, et al., 2015; Sullivan et al., 2018; Rush & Frances, 2000). It is recommended to use the lowest effective dose, taking account of side effects and difficulties the person may have in reporting them, whilst avoiding sub-therapeutic doses which may not be sufficient to treat the mental health problem. There is limited evidence of the effectiveness of antidepressants among people with ID, as highlighted below, and therefore guidelines are based upon evidence derived from the general population as it is asserted that they have a similar effectiveness and side effect profile (Bhaumik et al). SSRIs are recommended as first line medication-based treatment for depression in people with ID (NICE; Bhaumik et al). This group of medications work by increasing the levels of serotonin in the brain. The reason SSRIs are the first choice antidepressant is because there is good evidence that they are as effective as other classes of antidepressants and they have a better risk-benefit balance with regards to their adverse effects as compared with the other classes of antidepressant medications. They are also less dangerous in overdose as compared with older generation of antidepressants (Cleare et al., 2015).

Tricyclic antidepressants (TCAs) are an older class of antidepressant medication compared with SSRIs. They work by increasing serotonin and noradrenaline levels in the brain. Monoamine oxidase inhibitors (MAOIs) are again an older class of antidepressants compared with SSRIs. They work by increasing the levels of serotonin and noradrenaline in the brain. However the action of MAOIs is not limited to the brain. They also act in the liver and gut. When a person taking a MAOI eats food containing tyramine (a substance that can affect blood vessels), due to the action of the MAOI in the gut, the tyramine is not broken down. This leads to high levels of tyramine in the body which can enter the blood stream and cause a 'hypertensive crisis'. This is a dangerous adverse effect of MAOIs and therefore tyramine-containing foods need to be avoided. Due to the serious adverse effects of MAOIs, they are rarely used in people with ID. There are several other antidepressants that do not fall into the categories of SSRIs, TCAs or MAOIs. These include mirtazepine, venlafaxine, agomelatine and duloxetine.

These antidepressants are often used before trying TCAs or MAOIs (NICE, 2009). In certain patients depression can be very difficult to treat. It may be necessary to 'augment' the antidepressant therapy by adding another medication. This should only be done in consultation with prescribing guidelines. An antidepressant can be augmented with lithium, an antipsychotic (e.g. aripiprazole, olanzapine, quetiapine or risperidone) or another antidepressant such as mirtazepine.

A systematic review located no controlled studies of medication for depression among adults with mild to moderate ID (Koslowski et al., 2016). Another systematic review of interventions for adults with mild ID (a broad definition used to include studies where 50% + had mild ID) and mental ill-health found only two studies of two different antidepressants (Osugo & Cooper, 2016). Bhaumik, Collacott, Gandhi, Duggirala, and Wildgust (1995) conducted a retrospective case notes review to evaluate the effects of antidepressants among 71 adults with ID (60% with mild ID) with an ICD-9 diagnosis of depression. They used retrospective ratings of clinical global improvement (CGI) based on descriptions in clinic notes. Mean CGIs were 2.09 for those prescribed SSRIs and 1.96 for those prescribed tricyclic antidepressants indicating that both groups were 'much improved' over the course of the 3 year review period. However, 6.4% discontinued SSRIs and 9.5% discontinued tricyclics due to lack of efficacy and 9.6% and 26% discontinued due to adverse effects respectively. The same group carried out another case notes review to examine the effectiveness of fluoxetine and paroxetine among 56 adults with ID with similar results to those of the SSRI group in the earlier study (Bhaumik & Wildgust, 1996). Of those discontinuing paroxetine, 41.6% experienced withdrawal symptoms whereas none of those discontinuing fluoxetine reported withdrawal symptoms. The results of these studies need to be interpreted with caution as the CGI is subjective and retrospective, being based on evidence provided in case notes, there were no control groups, and administration of the medications were not standardised.

An additional long-term, open label study of citalopram in 20 inpatients with ID and symptoms aligning to affective, motivational, motor, and vital domains of depression followed participants up for six to 12 months (Verhoeven, Veendrik-Meekes, Jacobs, van den Berg, & Tuinier, 2001). A moderate to marked improvement on the CGI was reported for 12 participants. No response was observed for the other eight participants. One participant without history of epilepsy developed seizures and another developed a delirious state; no other side effects were reported. Again, this study does not have a control group and subjective outcome measures were used. Furthermore, reporting of results is incomplete – there are no data on biweekly monitoring of frequency and intensity of target symptoms.

Owing to the lack of studies of antidepressants for depression, it may be useful to examine the literature on antidepressants for other indications, such as behavioural problems, especially given the aforementioned challenges with making diagnoses and with reference to information on tolerability. Sohanpal et al. (2007) conducted a systematic review of studies evaluating antidepressants for behavioural problems such as aggression, self-injurious behaviour and property destruction. They found one cross over, randomised controlled trial (RCT), seven prospective uncontrolled studies and two retrospective studies. The RCT evaluated the tricyclic antidepressant clomipramine and the rest investigated SSRIs. The studies tended to use small sample sizes, non-validated outcome measures, were of short duration with limited follow-up periods, and used antidepressants as add on therapy. The authors summarise that response to SSRIs was varied – some studies showed favourable results, others showed negative effects and some reported mixed outcomes with improvement in self-injurious behaviour or aggression in less than 50% of participants across the studies. More favourable results were found in those with underlying anxiety or obsessive compulsive disorder.

Authors have expressed concern over adverse effects related to antidepressant use and the results of the limited studies support this. One adverse effect of antidepressants, of particular concern for people with ID owing to the increased prevalence of epilepsy (Berney & Deb, 2012; Deb, 2007a), is the potential to increase seizure frequency or reduce the threshold at which seizures occur in people with epilepsy. Another is the potential to increase anxiety or agitation, which may already be elevated among people with ID who also have difficulties expressing their discomfort verbally, however, this usually settles after a few weeks of treatment. Other adverse effects of SSRIs include gastrointestinal adverse effects (e.g. nausea, vomiting, indigestion, abdominal pain, diarrhoea, constipation, reduced appetite and weight loss), possible increased thoughts or self-harm and suicidal thoughts and acts when initiating treatment, sexual dysfunction, difficulty sleeping, urinary retention (being unable to pass urine), sweating, tremor, rash, low sodium levels in the blood (hyponatraemia), and serotonin syndrome (a rare but serious adverse effect). Adverse effects of TCAs include effects on the heart (such as abnormal heart rhythm), low blood pressure on standing which could increase risk of falling, 'antimuscarinic' adverse effects (e.g. dry mouth, blurred vision, constipation, and urinary retention), anxiety, dizziness, agitation, confusion, sleep problems, 'pins and needles', hallucinations, delusions and mania, breast enlargement, changes in appetite and weight, changes in blood sugar (glucose) levels, nausea and vomiting, and taste disturbance. Withdrawal of antidepressants can also result in unwanted effects such as headache, anxiety, dizziness, sleep disturbance, sweating and flu like symptoms. For this reason, it is recommended that medication should be withdrawn slowly and gradually and the introduction of medication should be rationalised in the first place. Any cognitive and functional impairments, as a result of starting or withdrawing medication is an additional concern for people who already have such impairments.

Meins (1996, cited in Verhoeven et al., 2001) observed that, owing to atypical symptomatology, mis-diagnosis and under-diagnosis, depression in people with ID may be treated with antipsychotics rather than antidepressants. A further retrospective case notes review comparing various antipsychotics with no antipsychotics was identified in the review by Osugo and Cooper (2016; Shedlack et al., 2005) in which 37% of 72 participants had major depression (with or without psychosis). For those with major depression, Global Assessment of Function (GAF) ratings increased by 9 points in the no antipsychotic group but showed little change in the atypical antipsychotic group. The opposite was reported for those with major depression with psychosis. However, the same methodological weaknesses persist in this study (use of subjective outcome measures, unstandardised medication procedures including different doses and concomitant medication, limited information on blinding provided, etc.) and no information is provided on side effects. There is therefore no evidence to support the use of other classes of medication in the treatment of depression in ID and this practice is not recommended.

In the UK, a national project has been initiated to stop the overuse of medication of people with ID (Stopping over medication of people with a learning disability, autism or both; STOMP). It is in reaction to the high levels of inappropriate psychotropic medication prescription to these vulnerable groups.

Psychological Interventions for Depression

It was previously asserted that, owing to cognitive deficits, people with ID could not engage in psychological therapy. This assumption has been challenged and there are now a greater range of psychological therapies available to people with ID. Cognitive behavioural therapy (CBT) remains the most commonly studied (e.g. see Beail, 2016) and is recommended for the treatment of depressive disorders (American Psychiatric Association, APA, 2010; National Institute for Health and Clinical Excellence, NICE, 2009). However, the application of CBT for depression among people with ID is not considered in these guidelines which focus on the general population. In the UK, CBT adapted for people with ID is recommended for the treatment of depression or subthreshold depressive symptoms in people with milder ID (NICE, 2016). The evidence base for CBT's effectiveness with this population is discussed in more detail later in this chapter.

The evidence of effectiveness for other forms of psychological therapy, such as psychotherapy and 'new wave' therapies remains more limited, however, trials are increasingly being planned and funded. In line with this, modified psychological interventions are being developed, appropriate for different communication styles, necessity for prompting, simplification, and breaking down of tasks etc. In developing the UK-based guideline for the treatment of mental health problems among people with ID, NICE recommend that psychological interventions are adapted and trialed to ensure they are accessible to people with ID (NICE, 2016). Whilst adapted therapeutic protocols may be suitable for people with mild ID, it is not clear whether such protocolised interventions are suited to people with more severe intellectual impairments (Campbell, Robertson, & Jahoda, 2014) and people with severe ID, or without capacity to consent, are still often excluded from trials due to ethical issues. Making large modifications to interventions to make them more suitable for people with ID limits the applicability of the evidence base derived from the general population (Leyin, 2011) and may compromise fidelity to the approach. Therefore, trials with people with ID which also consider fidelity are required to make more evidence-based psychological interventions available. More research with people with more severe ID is warranted to investigate whether psychological interventions can be sufficiently adapted. For example, whilst certain aspects of CBT may not be accessible for some people with ID, some of the behavioural aspects such as activity scheduling are relevant to all. Practice-based evidence may be especially helpful here to resolve some of the ethical issues in involving people who lack capacity in clinical trials. The following presents an overview of the evidence for the effectiveness of the most common forms of psychological interventions for depression.

Behavioural Activation

Behavioural activation has been shown to be effective in treating depression in the general population (Ekers, Richards, McMillan, Bland, & Gilbody, 2011; Richards, Ekers, McMillan, et al., 2016). In behavioural activation, the focus is on behaviour change, rather than affecting behavioural change through modifying thinking patterns (as with cognitive therapy). In this way, it may be more accessible for people with cognitive impairments as it is less cognitively demanding and an RCT has shown promising results among people with ID (Jahoda et al., 2017). The authors compared an adapted, manualised behavioural activation intervention with guided self-help (mainly psychoeducational) among 161 adults with mild-moderate ID and clinical depression. In behavioural activation, clients are facilitated in increasing their levels of activity and helped to address barriers (e.g. emotional or organisational) in engaging in activities. In guided self-help, clients are provided with self-help materials and some contact with therapists to help them to use those materials outside of clinic settings. The authors report for both groups significant reductions in depression scores and improvements in mental health and wellbeing measures at the end of treatment (four months after randomisations) that were maintained at 12-month follow-up with moderate to large effect sizes. Neither intervention was superior to the other and no serious adverse effects were reported. The authors reflect on the limitation of no treatment as usual arm in the study, but this was not possible as the trial funders insisted on an active treatment comparison arm.

This trial represents a significant advancement in the field as it is the largest trial of individual psychological therapy among people with ID. Its high quality design makes an important contribution to the evidence base and reinforces the idea that large-scale trials of psychological interventions among people with ID are possible. The interventions were provided by community nurses and allied health professionals working with people with ID who received 1–2 days training in the intervention indicating that psychological interventions can be successfully delivered by professional groups other than psychologists who are already working with people with ID and who receive some training. Furthermore, aspects of this type of intervention may be appropriate for those with more severe ID, something which future research could seek to investigate.

Cognitive Behavioural Therapy (CBT)

CBT is a collaborative talking therapy in which the client and therapist work together to identify relationships between thoughts, feelings and behaviours and attempt to moderate patterns in these systems to produce changes. A systematic review and meta-analysis by Koslowski et al. (2016) located four controlled studies that had evaluated CBT for depressive symptoms among people with mild and moderate ID, three of which used samples of adults with depressive symptoms only (Hassiotis et al., 2013; McCabe, McGillivray, & Newton, 2006; McGillivray, McCabe, & Kershaw, 2008) and the fourth was concerned with anger management (Willner et al., 2013). The meta-analysis of these four studies showed a moderate, but non-significant effect size of CBT on depressive symptoms, but with high levels of heterogeneity between studies. Similarly, an earlier meta-analysis by Vereenooghe and Langdon (2013) included the same three studies of CBT for depression and found a moderate to large, but non-significant effect size. They also comment on the high levels of between-study variance as each study employed different study designs.

Owing to the limited and varying evidence, Unwin, Tsimopoulou, Azmi, and Stenfert Kroese (2016) undertook a broad scoping review of CBT for anxiety or depression among adults, which included studies of any design and took a narrative approach to analysis. Unwin et al. located two additional studies which evaluated CBT for depression (Lindsay, 1999; McGillivray & Kershaw, 2015) and three additional studies (one of which resulted in two separate papers) which included mixed clinical presentations (including mood and emotional disorders such as anxiety and anger; Lindsay et al., 2015; Stenfert Kroese et al., 2014; Pert et al., 2013; Ghafoori, Ratanasiripong, & Holladay, 2010) Tables 45.1 and 45.2 present summaries of the eight studies.

The three RCTs including people with ID and depression report varying results with the trial by Hassiotis et al. (2013) reporting no overall treatment effect whereas the other two report significant treatment effects that were maintained at three month follow-up. Unwin et al. (2016) suggest that these discrepancies may be due to methodological differences, especially as Hassiotis et al. used a trans-diagnostic approach which may have diluted the effect of CBT: the authors found a trend towards treatment effect for those with clinical depression, but not for those with anxiety disorder. More recently, an RCT of computerised CBT for adults with mild and moderate ID and anxiety or depression has been published with the opposite results: significant treatment effects were observed on the primary outcome measure of anxiety, but not on depression (Cooney, Jackman, Coyle, & O'Reilly, 2017). The authors suggest that computerised CBT may not be a good match for people with depressive symptoms but also highlight that few participants presented with depression compared to anxiety symptoms resulting in low levels of depression across the sample and therefore loss of statistical power.

Unwin et al. (2016) considered qualitative studies in their review and suggest that results from these studies are more consistent and reflect a positive perception of CBT among clients and carers: 'participants especially valued the space and time to discuss their thoughts and feelings, the validation of their problems, and the formation or development of empathetic relationships with therapists and, in the case of group therapy, other group members' (pg. 69). CBT is a collaborative therapy and other research has shown that clients with ID adopt a collaborative rather than passive role in the therapeutic process, contributing to the analytic process and dialogues (Jahoda et al., 2009). Furthermore, in line with research with the general population, the importance of a supportive therapeutic relationship was emphasised in these studies. Therapists, working with people with ID, also view the therapeutic relationship as fundamental to their work, influential on outcome, and more important than theoretical

Table 45.1 Summary of studies of CBT for depression

First author (year)	Study design	Participants	Mental health condition	Intervention	Measures	Main findings
Lindsay (1999)	Quantitative Case series Pre, post and follow-up assessments	$N = 5$ (referred between 1990–1996) Age: not mentioned ID: not mentioned Country: USA	Depression	Individual adapted Beck's Cognitive Therapy (simplified form) Delivered by therapist	– BDI or ZDS – reported frequency or intensity of problematic cognitions	– BDI or ZDS reduced from around 50% of total score to around 25% (no statistical analyses due to small sample size) – Decrease remained at 6-month follow-up
McCabe (2006)	Quantitative RCT (quasi-independent) Pre, post and follow-up assessments ($n = 18$ for follow-up)	EG $N = 34$ (including 15 from CG) Mean age: 34 16 M/18F CG $N = 15$ Mean age: 40 6 M/9F ID: mild-moderate Country: Australia	Depression (at least minimal, as measured by the BDI-II, clinical and depressive symptoms)	EG Group CBT 5 weekly, 2-hour sessions Delivered by therapist CG Waitlist, received intervention after follow-up for EG complete	– BDI-II – SCS – ATQ-R – Rosenberg Self-esteem Scale (RSES)	– Significant difference between the groups at the three time points on the combined outcome measures ($p < 0.001$). - When the measures were considered separately, BDI-II ($p < 0.001$), SCS ($p < 0.001$), and ATQ-R ($p < 0.001$) reached significance. – No difference in RSES – Significant reduction in BDI-II scores and frequency of negative automatic thoughts, and increase in SCS scores (indicating that the participants viewed themselves more positively) from pre-test to post-test within the EG (p values not given) - Significant improvements remained at 3-month follow-up
McGillivray (2008)	Quantitative RCT (cluster) Pre, post and follow-up assessments ($n = 45$ for follow-up)	EG $N = 20$ Mean age: 38 13 M/7F CG $N = 27$ 7Mean age: 31 19 M/8 F ID: mild (IQ 50–70) Country: Australia	Depression (as measured by the BDI-II; 49% minimally depressed, 17% mildly depressed, 15% moderately depressed, 19% severely depressed	EG Manualised group ($n = 5$–6) CBT 12 weekly, 2-hour sessions Delivered by agency staff ($N = 13$) CG Waiting list, received the intervention after follow-up for EG complete	– BDI-II – ATQ-R – SCS – The Social Readjustment Rating Scale (SRRS; 10 items only)	– Significant group by time (pre-test to post-test) interaction effect on the combined outcome measures ($p < 0.001$). Significant main effect for time ($p < 0.001$), not group - Significant group by time interaction effect for BDI-II ($p = 0.000$), ATQ-R ($p = 0.021$) and SCS ($p = 0.015$) – No difference in SRRS – Significant decrease in BDI-II ($p < 0.01$) and ATQ-R ($p < 0.01$) scores within EG from pre-test to post-test – Positive effects on BDI-II and ATQ-R comparable across groups (once CG also received intervention) over time (pre-test, post-test, and follow-up) – Changes were maintained at 3-month follow-up

ID = level of intellectual disabilities; IPA = Interpretative phenomenological analysis; M = males; F = females; EG = Experimental Group; CG = Control Group; IPA = Interpretative Phenomenological Analysis; CBT = Cognitive Behavioural Therapy; CT = Cognitive Therapy; BT = Behavioural Therapy; TAU = Treatment As Usual; RCT = Randomised Controlled Trial

Scales: GAS-ID = Glasgow Anxiety Scale-for people with an Intellectual Disability; GDS = Glasgow Depression Scale; BAI = Beck Anxiety Inventory; ZUS = Zung Anxiety Scale; QOLS = Quality of Life Scale; HoNOS-LD = Health of the Nation Outcome Scale – Learning Disability Version; BDI = Beck Depression Inventory; ZDS = Zung Depression Scale; SCS = Social Comparison Scale; BSI = Brief Symptom Inventory; ATQ-R = Automatic Thoughts Questionnaire – Revised approaches (Jones, 2014). Therapeutic relationships may be especially important for people with ID due to more limited opportunities to develop positive relationships, however, research has not yet investigated the association between quality of relationship and outcome. In the study by Hassiotis et al. (2013), CBT was delivered by CBT therapists who were not specialists in ID, and Unwin et al. (2016) suggest that this lack of experience of working and engaging with people with ID may have affected the relationship and subsequently the outcome.

The review authors comment on the methodological limitations of the studies including small sample sizes, few control groups, short-term follow-ups, and lack of treatment fidelity assessment (Unwin et al., 2016). Furthermore, issues in the choice of outcome measure persist (such as non-validated measures or those designed for the general population) and Unwin et al. recommend that researchers should move beyond symptom measurement to use more holistic, personally-meaningful measures which reflect the client's aims for therapy. Attempting to detect changes in symptoms as a result of psychological therapy may be compounded by the aims of therapy which often seeks to improve emotional literacy (understanding, identification and expression of emotions) as a first goal of therapy. Thus, self-report of symptoms could improve and therefore result in an increase in scores on symptom measures.

There is emerging evidence to suggest that CBT for depression among people with mild and moderate ID is feasible, well tolerated, and effective at reducing symptoms of depression, including negative automatic thoughts. There is currently no evidence for people with severe ID and CBT may not be suited due to language impairments and high support needs (Sturmey, 2004). Other psychological approaches may be more appropriate such as behavioural activation.

Psychoanalysis, Psychoanalytic and Psychodynamic Psychotherapy

Psychodynamic therapy for people with ID remains one of the least well investigated, but long-established psychological therapies (Flynn, 2012). The development of adapted manuals of psychotherapy for people with ID needed for trials has been slow (Shepherd & Beail, 2017). However, in the general population, there is evidence of efficacy for depression (Shedler, 2010). A systematic review found 13 papers which evaluated the effectiveness of psychoanalytic and psychodynamic psychotherapy for adults with ID; no papers were located for psychoanalysis (Shepherd & Beail, 2017). Two papers included samples with mixed clinical presentations that included depression (Bichard, Sinason, & Usiskin, 1996; Carlsson, 2000). Both of these studies are case series of individual therapy and include 4 and 11 participants with mild-moderate ID but it is not clear how many participants had a diagnosis of depression. Neither study reports on depressive symptoms, but improvements were observed in tests of specific psychoanalytical concepts such as increased integration and decreased primitive defensive functioning.

More recently, Statham & Beail (2018) investigated client views of the accessibility, acceptability and effectiveness of psychodynamic psychotherapy through interviews with 10 participants with mild ID and difficulties including anger, trauma, low mood and interpersonal difficulties. As with similar research on CBT, participants appreciated being listened to but were unhappy about therapy ending and struggled to generalise what they learnt in therapy to other settings and with others. Some participants were surprised by the content of sessions and some felt anxious when travelling to sessions. However, participants were able to identify ways in which therapy had helped.

'New Wave' Psychological Interventions

Mindfulness and Acceptance-Based Therapies

Mindfulness approaches aim to help people focus on the present moment, including what is happening in mind, body and the world around them. It "relies more on reducing experiential avoidance by enabling individuals to become aware of and normalise emotions and bodily sensations" (pg. 95), rather than challenging thoughts, and beliefs, and this process relies less on verbal exchange between therapist and client which may be more suited to people with problems with communication (Idusohan-Moizer, Sawicka, Dendle, & Albany, 2015). Two structured, mindfulness-based intervention packages have been developed: mindfulness-based stress reduction (Kabat-Zinn, 1990) and mindfulness-based cognitive therapy (Segal, Williams, & Teasdale, 2002). There is evidence to suggest that mindfulness is useful for a range of psychological conditions among the general population, especially recurrent depressive episodes (Piet & Hougaard, 2011), but mindfulness has not been widely used with people with ID (Chapman et al., 2013). A review found evidence of improvements in aggression for people with ID, but did not locate any studies specifically on depression (Chapman et al., 2013). Subsequently, in a small study, Idusohan-Moizer and colleagues (2015) adapted mindfulness-based cognitive therapy for people with ID and incorporated aspects of acceptance and compassion-focused therapy. They evaluated this therapy among 15 participants with recurrent episodes of anxiety or depression and borderline to moderate ID. None of the participants had depression in isolation and only four had depression and anxiety; the majority had anxiety. Depressive symptoms and compassion towards the self significantly improved after the intervention and these effects were maintained at 6-week follow-up; however, there was no control group in this study. Other research has focused on mindfulness for other problems in adults with ID with limited, but positive and promising results (see Pert, 2017 for a review).

Solution-Focused Therapy

Solution-focused brief therapy is a short-term, client-directed and goal-focused approach, originally developed by de Shazer and colleagues (De Shazer, 1985). Central is the idea that clients should be supported to reach their goals by developing solutions rather than analysing problems (de Shazer et al., 1986). Researchers have recognised the potential of solution-focused therapy for people with ID due to its focus on empowerment, strengths and competencies (Carrick & Randle-Phillips, 2018; Roeden, Bannink, Maaskant, & Curfs, 2009). Furthermore, through solution-focused coaching or consultation, there is the potential to work with family and care staff on their competencies to achieve their goals in working with/caring for a person with ID (Roeden, Maaskant, Bannink, & Curfs, 2012). A meta-analysis found support for solution-focused brief therapy for depression among the general population (Gingerich & Peterson, 2013). More recently, a systematic review of solution-focused approaches for people with ID found 12 papers, of which 5 included participants referred for treatment of depression (Carrick & Randle-Phillips, 2018: Stoddart, McDonnell, Temple, & Mustata, 2001: 4/16 participants; Roeden, Maaskant, Bannink, & Curfs, 2011: 1/10 participants; Roeden, Maaskant, & Curfs, 2014: 2/38 participants; Lloyd & Dallos, 2006, 2008: 3/7 participants). The authors conclude that there is preliminary evidence for effectiveness, primarily from case studies. None of the reviewed studies used measures of depression and, owing to the small proportion of participants referred for depression in each study, it is hard to extrapolate the results.

Dialectical Behavioural Therapy

Dialectical behaviour therapy (DBT) was developed for people with borderline personality disorder and high-risk suicidal behaviour (Linehan, 1993) and has subsequently been adapted for use with older adults with depression (Lynch, Morse, Mendelson, & Robins, 2003). It consists of weekly, individual sessions, group skills training and access to telephone coaching (Linehan). In the field of ID, interest has grown in terms of its use for people with poor impulse control or difficulty with emotion regulation, however, few studies implement all three aspects of traditional DBT (Crossland, Hewitt, & Walden, 2017) and none have evaluated DBT specifically for depression. A brief outline of group DBT skills training among seven people with ID does report decreases in depression measures, but very little information is provided (Hall, Bork, Craven, & Woodrow, 2013). Another study reports significant decreases in depression scores following DBT among 18 participants with ID and difficulties relating to emotion regulation, managing crises and interpersonal effectiveness (McNair, 2014).

Other Interventions

A variety of other interventions are used to treat depression. Among the general population, exercise interventions have been recognised for their antidepressant effect. Given the health inequalities experienced by people with ID, exercise interventions may be especially helpful in improving both physical and mental health. A small-scale RCT evaluated a 12-week exercise intervention among 27 participants with mild-moderate ID with promising results (Carraro & Gobbi, 2014). The authors report a significant reduction in depressive symptoms in the exercise group compared with the control group (who received painting classes). However, the participants were not diagnosed with depressive disorder and there was no long-term follow-up. Other treatments for depression include bright light therapy, particularly or seasonal affective disorder. Hermans, Soerokromo, and Evenhuis (2017) evaluated bright light therapy among 14 adults with moderate, severe or profound ID and depressive symptoms. They report some positive effects and suggest that bright light therapy was well tolerated by participants with no adverse effects; however, there are practical issues in using this type of therapy which require the participant to remain still for a period of time at the same time each day (preferably upon getting up).

Electroconvulsive therapy (ECT) is rarely used for people with ID but it is still available as a treatment option for severe depression (Osugo & Cooper, 2016) despite concern over adverse effects, the invasive nature of this procedure, and problems gaining fully informed consent (for example, assurance that people with ID can weigh up the risk: benefit profile of the intervention and issues with acquiescence). Osugo and Cooper did not locate any studies involving 20 or more participants (and at least 50% with mild ID) that evaluated ECT in their review. Despite this, ECT is still recommended for severe psychotic depression or serious suicide risk in people with ID, after unsuccessful medication trials (Bhaumik et al., 2015). Another review of ECT for people with ID located 72 case reports, of which almost 58% had an affective disorder (Collins, Halder, & Chaudhry, 2012). The authors conclude that ECT had few adverse effects; however, there are problems with positive reporting bias in case studies. Short-term adverse effects of ECT include headache, aching muscles and risk of the anaesthetic. Longer-term risks include problems with memory (Barnes, 2010) which is especially problematic for people with existing cognitive impairments. Other uncommon treatments include repeated transcranial magnetic stimulation, transcranial direct current stimulation and vagus nerve stimulation but they are not recommended as first line interventions (even in the general population), are invasive procedures, and are not evidence-based in ID.

The herbal remedy ‘St. John’s Wort’ is purported to be useful in low mood, anxiety and premenstrual stress. Despite being available over-the-counter, it can have serious interactions with other medications. This includes interactions with antidepressants, strong painkillers and the oral contraceptive pill. It can also reduce the effectiveness of some anti-epileptic drugs, digoxin and warfarin (Werneke, 2010).

Conclusions

Depression in people with ID is likely to be more common than in the general population but is currently underdiagnosed. It is therefore likely to be inappropriately treated as treatment may focus on behaviours that challenge. This is also reflected in the evidence base which is much more limited than for behaviours that challenge; however, some studies which focus on treatment of behaviour may also include measures of depression and therefore can be used to supplement the evidence. For example, a CBT-based anger management intervention showed positive effects on depressive symptoms (Willner et al., 2013). However, other research on trans-diagnostic CBT have mixed results. Future research should ensure that adequate resources are afforded to assessment and detection of depression to facilitate intervention studies.

There are a range of interventions available for depression in people with ID, however, evidence pertaining to their effectiveness remains limited. Much evidence comes from practice-based research (for example, case studies) which provides important, ecologically valid evidence about effectiveness, but more large-scale trials are required to establish the efficacy of both psychological and biological interventions. Furthermore, systematic, qualitative evaluation of the process of providing interventions is warranted to ascertain acceptability of interventions from the perspectives of those who receive, those who provide and those around the person. These studies can also investigate the components of interventions, especially psychological interventions, in an attempt to determine mechanisms of action. Further research should also compare credible treatment options, including psychological interventions and medication.

Currently, CBT is the most evidence-based intervention option for those with mild or moderate ID, however, interest in other therapeutic modalities is growing and subsequently the evidence base will continue to expand. There is limited evidence to support the use of antidepressants in people with ID, unless evidence is extrapolated from the general population. The evidence for people with ID raises concern over adverse effects, especially given the poorer physical health of people with ID and problems in reporting adverse effects. As with the general population, it is appropriate that minimally invasive treatment options are prioritised.

Almost all the research in the field is with people with mild or moderate ID. There is scant research which involves people with severe ID, most likely owing to the ethical complexities of involving adults who may not have capacity to consent in intervention trials. This is especially problematic in relation to psychological interventions as further adaptation of therapies may be required to make them suited to people with more limited cognitive and verbal abilities. Indeed, people with moderate or severe ID may need a more tailored, one-to-one approach to psychological therapy which is not easy to evaluate in trials which require consistency in intervention. Furthermore, assessing symptoms of depression in intervention studies are susceptible to the same issues as diagnosis of depression in people who are unable to self-report on internal emotional states. As a result, treatment options outside of antidepressants are very limited for those with severe or profound ID. The only study in the present chapter to include people with severe ID evaluated bright light therapy. This is an initial study to assess acceptability rather than effectiveness but it is representative of the diversification of interventions being made available and the strive for equity in healthcare for people with ID. Improving the involvement of people with moderate and severe ID in research remains a challenge to be met by researchers.

Psychosis

Arlene Mannion, Keeley White, Emily Porter,
Julia Louw, Bernadette Kirkpatrick,
Shawn P. Gilroy, and Geraldine Leader

Introduction

Psychosis is a topic of importance in research in individuals with intellectual disabilities (ID). The focus of this chapter is to review the literature on definition, incidence, and prevalence of psychosis in individuals with ID. Importance of studying psychosis in ID, difficulties of studying psychosis in ID, assessment of psychosis in ID, and risk factors of psychosis in ID will be discussed. Treatment of psychosis in ID will be presented, including pharmacological and behavioral treatments, and recommendations for treatment will be given. Following this, future directions for research will be outlined.

Definitions of Psychosis

Psychosis is a set of symptoms related to mental health issues that occurs in a range of psychotic disorders, to include schizophrenia spectrum disorder, bipolar disorder, posttraumatic stress disorder, and major depressive disorder (Doherty & Owen, 2014). Several diagnostic guidelines and assessments exist that can be used to categorize and summarize the dimensional representations of psychosis (Bakken & Høidal, 2014; Cooper & Bailey, 2001; Schützwohl et al., 2016; van Os & Tamminga, 2007). Generally, psychosis is defined as an experience that affects a person's concept of reality, wherein their perception of reality differs considerably from those around them (Krishnan, Kraus, & Keefe, 2011; Sass & Parnas, 2003). During a psychotic occurrence, the person may experience either partial or total loss of contact with reality, and symptoms can range from hallucinations, delusions, disorganized confused thinking and speech, abnormal motor behavior to catatonia (Bakken & Høidal, 2014; Canitano & Pallagrosi, 2017; Spauwen, Krabbendam, Lieb, Wittchen, & Van Os, 2006; Yung, Nelson, Thompson, & Wood, 2010). Positive symptoms of psychosis refer to abnormal, disturbing thoughts, perceptions, and behaviors, such as hallucinations (seeing, hearing, tasting, smelling, and feeling things that are not real) and delusions (fixed false beliefs). Negative symptoms refer to disruption to normal emotions or behavior, for example, apathy and lack of emotional reactivity (Doherty & Owen, 2014). Psychosis differs considerably from person to person however the psychotic experience is very real to that person and it is this lack of awareness of reality that can be very distressing and frightening.

The literature often refers to psychosis as a psychotic episode (Cooper et al., 2007; McCarthy & Barbot, 2016; Tandon et al., 2013). An episode is defined by the duration of time in which the person has developed symptoms that meet the symptomatic criteria of a specific mental health disorder (Tandon et al., 2013). Episodes can differ in accordance with the type of mental health disorder and can include several symptoms, or a quantified severity or frequency of symptoms (Bakken & Høidal, 2014). They are further differentiated into a single (first) episode or recurrence or relapse of multiple episodes (Tandon et al., 2013).

Defining psychosis in a person with an intellectual disability (ID) or Autism Spectrum Disorder (ASD) is a complex process (Cooper et al., 2007). Quite often a psychotic episode can share core characteristics with repetitive patterns of behaviors, cognitive, social, communication and emotional deficits (Bakken & Høidal, 2014; Canitano & Pallagrosi, 2017; Schützwohl et al., 2016), and observable challenging behaviors which are possibly attributed to the person's ID or ASD rather than a psychotic disorder (Cooper et al., 2007; McCarthy & Barbot, 2016). Even though the core symptoms of psychosis can be difficult to differentiate with the characteristics attributed to varying degrees of ID (Carthy et al., 2010), ID is not a psychiatric disorder, despite being part of the psychiatric classification system (Deb, Matthews, Holt, & Bouras, 2001).

A person with moderate, severe, and profound ID or ASD may have restricted ability to communicate or self-report the symptoms of a psychotic episode (Bakken & Høidal, 2014), which may impede an accurate definition of psychosis. These factors have presented a challenge not only in the diagnosis of psychosis but have also contributed to the lack of explicit ID and ASD psychosis definitions presented within the literature. Researchers have recognized that heterogeneity in cognitive abilities and communication skills of those with an ID and ASD has made it difficult to standardize a definition of psychosis for this population (Canitano & Pallagrosi, 2017; Doherty & Owen, 2014).

Incidence and Prevalence of Psychosis

In general, determining how many people have experienced or are experiencing psychosis can be challenging, especially for individuals with intellectual disabilities, and therefore, estimates on incidence and prevalence can vary (Bagalman & Cornell, 2018; Cooper et al., 2007; Kildahl, Bakken, Holm, & Helverschou, 2017). Some of the challenges associated with quantifying the prevalence of psychosis in the population include changing diagnostic criteria over time (especially for schizophrenia and affective disorders), differing diagnostic tools and instruments (across time and geography), and problems in case finding and confirmation (Perälä et al., 2007). For those with ID, the challenges are even greater, and include lack of appropriate assessment tools, difficulties in separating symptoms of comorbid disorders, and barriers for individuals with ID to self-report their symptoms (Cooper et al., 2007; Hassiotis, Barron, & Hall, 2009; Kildahl et al., 2017). Despite these challenges, a range of studies have examined the prevalence and incidence of psychosis. This section will provide an overview of the key findings in this area.

Prevalence

The lifetime prevalence (LTP) of psychotic disorders in the general population is estimated at just above 3% (Perälä et al., 2007). As psychotic disorders can be severe and impairing, this LTP is substantial and indicates that these conditions likely have a notable impact on public health and well-being. The total LTP corresponds to an approximate LTP of 2.29% for non-affective psychotic disorders and 0.62% for affective psychotic disorders (Perälä et al., 2007). It is thought that psychosis is more prevalent in individuals with ID than in the general population (Cooper et al., 2007; Hassiotis et al., 2009; Holden & Gitlesen, 2004b; Smiley, 2005; Welch, Lawrie, Muir, & Johnstone, 2011). For example, in Cooper et al. (2007) in a study of more than 1000 adults with ID, the point prevalence of psychotic disorders in those with ID was found to range between 2.6% (95% CI = 1.8–3.8%) to 4.4% (95% CI = 3.2–5.8%), depending on the diagnostic criteria. Notably, these rates are significantly higher than those of the general population. In the UK general population, the 12-month prevalence was found to only be 0.4%, which is around 10 times less than the reported point prevalence of 2.6–4.4% (Cooper et al., 2007). Further, the prevalence of schizophrenia specifically in the general population is approximately 1%, while the prevalence in individuals with ID is reported around 3% (Hassiotis et al., 2009; Smiley, 2005).

The prevalence of psychotic disorders in individuals with ID likely varies based on the level of ID. It was reported that the point prevalence in adults with mild ID is around 5.8%, while it is around 3.5% in those with moderate to profound ID (Cooper et al., 2007; Hassiotis et al., 2009). This trend was also confirmed in Holden and Gitlesen (2004b), where it was found that psychosis was more prevalent in those with moderate ID than in those with severe or profound ID; while the difference in prevalence between those with severe ID and profound ID was minor.

In the general population, prevalence estimates have been found to vary based on a wide number of factors (McGrath, Sukanta, Chant, & Welham, 2008), and research has shown that psychosis and schizophrenia do not occur equally across all geographic and demographic groups (Kirkbride et al., 2012; Messias, Chen, & Eaton, 2007; Steel et al., 2014). For example, the prevalence of schizophrenia was found to differ across latitude and economic status, with developed countries having a median prevalence estimate of 3.3 per 1000, with less-developed countries having 2.6 per 1000 (McGrath et al., 2008). The prevalence was also associated with migration status (McGrath et al., 2008). However, there is still uncertainty in the exact factors that impact prevalence. For instance, in McGrath et al. (2008) the prevalence of schizophrenia was found not to statistically differ between males and females, between urban and rural environments, or over time; while in Messias et al. (2007), schizophrenia was found to be more prevalent among males, with males having a 30–40% higher lifetime risk of developing schizophrenia than females. Despite this, it is clear that schizophrenia affects males and females differently, with varying ages of onset and incidence.

Gender differences in the prevalence of psychotic disorders, along with the subtype of disorder, have also been indicated in individuals with ID, however results have not been consistent across studies and therefore more research is needed in this area (Axmon, Sandberg, & Ahlström, 2017). Overall, further investigation in this area is warranted, as individuals with ID may differ from the general population with regard to their interaction with societal factors (Axmon et al., 2017).

Incidence

Based on a recent international, multisite study, the crude incidence of psychotic disorders in the general population is estimated at 21.4 per 100,000 person-years (95% CI = 19.4–23.4) (Jongsma et al., 2018). Of all non-organic psychotic disorders, it was estimated that 78.7% of incident cases are non-affective psychotic disorders and 19.9% are affective (Jongsma et al., 2018). The average age at the first contact with a first diagnosed episode of a non-organic psychotic disorder, was 30.5 years. The first contact age is generally earlier in men (28) than in women (34) (Jongsma et al., 2018). Crude incidence rates of the first episode peaked at 61 per 100,000 person-years for men between the ages of 18 and 24, and decreased sharply after this age range. For women, the peak incidence occurred also at 18–24, however decreased more slowly afterwards with another, more minor, peak between ages 50 and 54 (Jongsma et al., 2018). Similar trends in age were also found in other studies (Kirkbride et al., 2012; Messias et al., 2007).

In adults with ID, the 2-year incidence of psychosis is 1.4% (95% CI = 0.6–2.6), and the first-episode incidence is 0.5% (95% CI = 0.1–1.3) (Cooper et al., 2007). The incidence ratio for (first-episode) psychosis in adults with ID is 10 (95% CI = 2.1–29.3) relative to the general population (Cooper et al., 2007; Hassiotis et al., 2009).

However, like prevalence estimates in the general population, the current literature on incidence estimates have shown significantly varying rates across groups (Jongsma et al., 2018; Kirkbride et al., 2012, 2017; McGrath et al., 2008; Messias et al., 2007). Specifically, incidence of psychotic disorders has been demonstrated to vary by sex (Jongsma et al., 2018; Kirkbride et al., 2012; Messias et al., 2007), age (Jongsma et al., 2018; Kirkbride et al., 2012; Messias et al., 2007), migration status and ethnicity (Bourque, vander Ven, & Malla, 2011; Jongsma et al., 2018; Kirkbride et al., 2012; McGrath et al., 2008), and geographical region (Jongsma et al., 2018; Kirkbride et al., 2012, 2017; McGrath et al., 2008; Messias et al., 2007). Geographical region variations include across countries and latitudes, along with local variations from urban to rural regions (McGrath et al., 2008). Socioeconomic factors may also impact incidence (Jongsma et al., 2018; Kirkbride et al., 2012).

Notably, individuals with schizophrenia have a two- to three-fold increased risk of death relative to the general population (McGrath et al., 2008). As approximately 7 individuals out of every 1000 may be affected by this condition (McGrath et al., 2008), and it co-occurs with ID three times more than in the general population (Welch et al., 2011), the burden on health is considerable. Overall, while it is clear that there is a degree of heterogeneity in the incidence of psychotic disorders globally, both in the general population and in those with ID (Axmon et al., 2017; Holden & Gitlesen, 2004b; Steel et al., 2014) further research is needed to examine the impact of the factors that may be responsible for this heterogeneity.

Importance of Studying Psychosis in Intellectual Disabilities

Advances in our understanding of psychosis in intellectual disabilities and comorbidity between behavioral profiles and psychiatric disorders may help to identify diagnostic overshadowing, that is, attributing the symptoms of mental ill-health to a person's intellectual disability behavioral profile (Canitano & Pallagrosi, 2017). Psychotic episodes may create a disorganized, frightening, isolated, and socially withdrawn environment (Bakken & Høidal, 2014), in which the person with ID and ASD may not have the cognitive, social, emotional, and communication capabilities to seek help. Research that focuses on observations of the nonverbal communications and suspected psychotic symptoms of individuals with ID may help to differentiate psychosis from the person's behavioral profile and thus help to improve the diagnostic system (Bakken & Høidal, 2014). In the absence of further research into psychosis and coexisting behaviors associated with ID, there is risk for individuals with ID to receive the incorrect mental health diagnosis (Bakken & Høidal, 2014), and subsequently an inappropriate ineffective treatment (Allen, 2008). Any treatment outcomes must be considered within the context of improved quality of life and daily functioning and must provide relief of physical and perceived emotional pain (Allen, 2008). Implications extend to the provision of mental health care for the person with ID or ASD, who often fall between services, particularly as they transition into adulthood (Selten, Lundberg, Rai, & Magnusson, 2015).

Research into psychosis and ID has important implications for psychiatric research. By developing new procedures to detect and identify psychosis we can advance our knowledge of the pathways from genotype to clinical phenotype, which are essential to inform new classification systems and to develop innovative therapeutic treatments (Doherty & Owen, 2014).

Recent research has suggested that prescription of psychotropic medication prescribed to adults with ID results in an overmedicated population with the prescription of antipsychotics drugs (Axmon, Kristensson, Ahlström, & Midlöv, 2017; McNamara et al., 2017; O'Dwyer et al., 2017; Schützwohl et al., 2016) and in some cases the drugs may be ineffective (McNamara et al., 2017; O'Dwyer et al., 2017) and cause adverse effects (O'Dwyer et al., 2017). Prescription of psychotropic medication needs to be reassessed to evaluate their overuse and effectiveness.

Difficulties of Diagnosis of Psychosis in Intellectual Disabilities

The identification of psychosis in individuals with intellectual disability (ID) presents considerable challenges. Some of these challenges consist of the limited number of appropriate assessment tools, the presence of dual diagnosis of ID and psychiatric disorders, the level and severity of ID and the difficulty in self-report of diagnostic and/or psychotic symptoms (Helverschou, Bakken, & Martinsen, 2011; Underwood, Kumari, & Peters, 2016). One of the cautionary aspects on which clinicians are particularly advised is to be careful and pay special attention to the diagnoses of schizophrenia in the presence of ID (Feinstein, Eliez, Blasey, & Reiss, 2002). The section below describes the complexity and difficulty in diagnosing psychosis in individuals with ID.

Diagnostic Systems and Assessment Tools

Several researchers have reported a higher prevalence of psychosis in adults with ID compared to the general population (Buckles, Luckasson, & Keefe, 2013; Cooper et al., 2007). However, existing diagnostic systems that measure the diagnoses in individuals with ID may not be fully compatible when making a psychiatric diagnosis in them (Watson, 2005). This may be related to the lack of one standardized criterion for psychiatric diagnosis across the whole spectrum of ID (Cohen-Kettenis & Pfäfflin, 2010). Therefore, typical diagnostic systems are not always useful for individuals with intellectual disabilities. Further, the heterogeneity in abilities and communication skills among adults with ID is varied. Some features might not always be apparent, or may be difficult to elicit, making the diagnosis difficult, particularly in those who have severe intellectual disability, and impaired communication (Wing, Gould, & Gillberg, 2011). This explains the reasons why the evidence-based knowledge on the assessment and diagnosis of psychosis problems in individuals with ID is still under-researched (Perry et al., 2018).

It has also been noted that a number of limitations with classification systems such as the *Diagnostic Manual-Intellectual Disability* or *Diagnostic Criteria for Psychiatric Disorders for Use with Adults with Learning Disabilities/Mental Retardation* still exist (Madhavan, 2018). In addition, factors such as gender differences have also been reported as potentially explanatory predictors in understanding psychiatric ill-health in the general population (Axmon, Sandberg, & Ahlström, 2017; Cohen-Kettenis & Pfäfflin, 2010). But given the social differences in how individuals with ID are treated in society with regard to accessibility, attitudes, and perceptions, this association between gender and psychiatric disorders in individuals with ID will not apply similarly as in the general population (Cohen-Kettenis & Pfäfflin, 2010). What is imperative in the development of assessment tools and systems is a detailed description of specific clinical features of psychiatric illness, with special reference to where these may differ from their presentation in the general population without disabilities. Moreover, a stronger emphasis on reports from support staff and caregivers is often required.

Some tools do aim at screening for psychiatric disorders in individuals with ASD and ID such as the Psychopathology in Autism Checklist (PAC; Helverschou, Bakken, & Martinsen, 2009). The PAC is a behavior checklist that is designed for completion by caregivers or family members, and therefore no general knowledge of psychiatric disorder is required. However, it is unclear whether or not such subjective knowledge influences final scores. Another instrument designed to identify psychiatric symptoms in individuals with ID is the Mini Psychiatric Assessment Schedules for Adults with Developmental Disabilities (Mini PAS-ADD; Moss & Hurley, 2014; Prosser et al., 2002). However, the Mini PAS-ADD may not be sensitive enough to detect symptoms in individuals with no or very limited speech.

The Presence of Dual Diagnosis

Similar deficits exist between developmental disabilities (such as ID and ASD) and psychosis. Therefore, psychosis and developmental disabilities have overlap (Matson, Mayville, Lott, Bielecki, & Logan, 2003). Intellectual disability and psychosis occur 300% more often than would be expected by chance (Cooper et al., 2007; Turner, 1989). Some note that the psychosis demonstrated by those with ID may be subtly different (Welch et al., 2011). In adulthood, negative symptomology of psychosis shares some similarities with autism spectrum disorder (Skokauskas & Gallagher, 2010). These populations warrant intervention to address several areas of negative symptoms, which are largely similar to those addressed as adaptive functioning deficits, such as deficits in communication, socialization, daily, adaptive living skills, and deficits in the management of behavior problems.

The manifestation of correlated symptoms of comorbid disorders including psychopathologies other than cognitive impairments has been recognized in individuals with ID (Kozlowski, Matson, Sipes, Hattier, & Bamburg, 2011). It is also evident in the literature that the presence of ID reduces the diagnostic significance of behaviors that normally constitute psychiatric symptoms (Holden & Gitlesen, 2004b). Research often discusses the terms psychosis and ID separately but makes no mention of their possible interrelationship (Allington-Smith, 2006; Clarke, 2006). It is important to review the extent of the correlation between comorbid disorders to address the difficulty in clear and reliable diagnosis of psychotic symptoms.

Similarities in the Etiology of Challenging Behavior and Psychiatric Disorder

Often, challenging behavior is referred to as the severe level of behavior problems among individuals with ID (Emerson et al., 2001). In particular, aggression towards others, extreme temper tantrums, screaming or shouting, and self-injury are examples of behaviors that may be challenging. A number of authors have suggested that such behavior problems may be indicators of psychiatric disorders in individuals with intellectual disability (Emerson et al., 2001; Moss & Hurley, 2014). Family members, support staff, and carers tend to excessively manage these behaviors that may result in social isolation and restricted opportunities for taking part in ordinary social and societal activities. This makes it very difficult to establish a dignified life situation for individuals with disabilities as endorsed by United Nations Convention of the Rights of People with Disabilities (United Nations General Assembly, 2006). Therefore, the emerging consensus may be accurate that individuals with severe to profound ID may be more prone to psychiatric illness, because they are unable to live normal lives (Munir, 2016). In spite of the parallels, the relation between behavior problems and psychiatric disorders is not entirely clear, given the mixed empirical results that indicate that perhaps studies adopted varied methodologies. What we know is that psychiatry refers to the study of the mind and treatment of disorders of the mind, including but not limited to mood, personality, development, and cognition. Psychosis on the other hand, is understood to be a symptom and essentially a flawed ability to perceive reality with the most commonly discussed symptoms being hallucinations and delusions but, this is not all necessarily experienced in a negative way. It is worth considering that in diagnosing psychiatric illness, it is important to differentiate which symptoms can be part of such an illness, and which can be explained by the intellectual disability.

Severity of Challenging Behaviors

In recent years, maladaptive and challenging behaviors are increasingly explained by psychiatric disorders, however, because of little or total lack of speech, the diagnosis relies predominantly on more tangible behaviors (Emerson et al., 2001). However, diagnosing psychiatric disorders in individuals with ID, particularly those with severe and profound ID, is more problematic. Individuals with milder levels of disabilities can use self-report measures and can be diagnosed using standard criteria with little modification, but for those with moderate and severe disability, diagnosis is challenging. The severity of behavior problems relates to signs and symptoms common in psychiatric illness such as social withdrawal, excessive agitation, lack of concentration, stereotyped movement disorders, abnormal sleep, and certain other behaviors (Kelly, 2013). These symptoms have been described as the expression of "diagnostic overshadowing," where the diagnostic symptoms are an underlying result from possible brain damage rather than symptoms of an illness (Mason & Scior, 2004).

The Level and Degree of Intellectual Disability

Studies show controversial evidence as to whether or not psychiatric illness is more common among individuals across the spectrum of mild-to-profound ID (Hove & Havik, 2010). Current research indicates that schizophrenia can be reliably diagnosed in adults with mild ID (Deb, Thomas, & Bright, 2001). For example, researchers made a comparison to the general population and there appears to be a higher rate of schizophrenia among adults who have a mild intellectual disability (Kessler, Chiu, Demler, & Walters, 2005). However, studies report the overall rate of psychiatric illness in adults with ID does not differ significantly from that of individuals without ID in the general population if diagnoses like behavioral disorder, personality disorders, ASD, and Attention-deficit/hyperactivity disorder (AD/HD) are excluded (McGough et al., 2005). But the diagnosis of schizophrenia in those with an IQ less than 45 may be difficult or impossible, because of the inability to do an in-depth verbal interview (Friedlander & Donnelly, 2004). In particular, the difficulty in diagnosing schizophrenia is of concern, specifically in those with a moderate or more severe intellectual disability (Deb, Thomas, & Bright, 2001). The diagnosis is based upon the presence of a number of complex subjective symptoms, delusions and thought broadcasting. The diagnosis of psychosis not otherwise specified (NOS) in individuals in particular is associated with moderate or severe ID (Friedlander & Donnelly, 2004).

While psychiatrists tend to use a cluster of symptoms or behaviors that relate with each other, also referred to as syndromic classification, some clinicians believe that the approach of behavioral classification that is more prevalent in the clinical psychology literature may be more appropriate for use in adults with severe intellectual disability (Drake et al., 2001). As a result, diagnoses of affective disorders are even possible in profound intellectual disability, due to observable behavioral elements of such disorders (Drake et al., 2001).

Difficulties in Self-Report

Generally, individuals with ID have significant limitations in verbal ability with increasing levels of the degree of ID. However, psychiatric assessment in ID often requires knowledge through verbal expression of the individual's previous functioning, and that can be a very complicated and time-consuming process in individuals with severe to profound ID. It involves investigating and identifying qualitative changes in symptoms related to the level of ID and interpreting atypical symptoms. In addition, investigating of conventional symptoms of psychiatric disorder is also crucial (Helverschou et al., 2011). Consequently, a certain level of communicative ability is needed to describe such symptoms.

Clinical reviews do provide valuable information about the identification, diagnosis and outcome of psychotic symptoms in individuals with low verbal abilities (Friedlander & Donnelly, 2004). In the absence of limited validated tools for assessment of psychosis in individuals with ID, it is noted that conventional assessment tools can be useful in such assessments. However, a full compensation for a lack of self-report is not always possible when relying on conventional assessment tools. It is possible though to partly compensate for lack of self-report by using multiple informers, a process sometimes referred to as triangulation (Yin, 2013). In this instance, it involves including family and professional caregivers as informers, instead of the challenging self-report of the person with ID. As such, a systematic assessment can be initiated with in-depth interviews with family members and caregivers, as well as direct observation by clinicians.

Some anxiety symptoms can be difficult to assess in nonverbal individuals, like excessive worry, unreasonable thoughts, and verbal reports of physiological signs (Bailey & Andrews, 2003). Therefore, the identification of psychiatric disorders in this group is reported to be difficult because of inherent communication and cognitive deficits. As such, giving symptoms a higher score in individuals with more severe ID in order to increase total scores is hardly justified, as there is no gold standard (Mungkhetklang, Crewther, Bavin, Goharpey, & Parsons, 2016). One possibility might be to improve the observational skills of caregivers. However, for behavior to be observed, it must have some strength and clarity related to the specific behavioral symptoms.

Many psychiatric symptoms are a subjective phenomena, for instance hearing voices, and not available to observers unless the individual with ID has the necessary verbal ability to report such experiences. As a result, it is not feasible to reliably diagnose in individuals who are nonverbal or those with limited communication skills. Where an individual's level of functioning and disorganized behavior make self-report impossible, no observer is able to report such symptoms. Treating observational data as interchangeable with self-report data would have led to a serious risk of symptoms being overlooked. Research within behavior analysis indicates that verbal behavior plays a key role in the development and maintenance of psychopathology, not only in anxiety and depression (Tone, Garn, & Pine, 2016).

It is clear that to address the challenges in the diagnoses of psychosis in individuals with ID, an accurate diagnosis will likely not be made from a one-time encounter by a professional. Instead, the diagnosis will rather evolve over time, because a key component of psychosis is based on internal experiences and their description. Thus, a comprehensive assessment and a clear description of the diagnostic criteria used are needed.

Risk Factors of Psychosis

Psychotic disorders are heterogeneous, and as such, a wide range of risk factors and protective factors have been investigated (Hassiotis et al., 2009; Heckers, 2009; Radua et al., 2018). As incidence rates vary significantly across geography and demographics, risk factors are also likely to vary across time and space (McGrath et al., 2008). While many potential risk factors for psychosis have been identified, for some factors the evidence is not conclusive to date. What follows is an examination of the potential risk factors for psychosis, and an indication of the level of evidence for each is provided. The risk factors are divided into four broad categories, based on those in Dean and Murray (2005) and in Heckers (2009): (1) baseline risks, (2) early-life risks (in utero and during birth), (3) childhood risks, and (4) risks that develop later in life and those that occur close to the incidence of psychosis. It is important to note that for individuals with ID, the risk factors have not been as thoroughly investigated as for the general population (Axmon et al., 2017; Cooper et al., 2007; Hassiotis et al., 2009; Smiley, 2005), and as such the risk factors are sometimes extrapolated from those of the general population (Hassiotis et al., 2009). Furthermore, many risk factors for psychosis are also risk factors for intellectual disabilities so it can be difficult to separate the impacts of each (Hassiotis et al., 2009).

Baseline Risks

The baseline risk relates to the level of risk that an individual may have due to their family history, genetics, and place and time of birth. For psychotic disorders, the risk topology for the general population is generally viewed as a complex interaction between environmental risk factors and susceptibility genes (Dean & Murray, 2005; Heckers, 2009; Radua et al., 2018; van Os, Rutten, & Poulton, 2008), and this view is maintained for individuals with intellectual disabilities (Hassiotis et al., 2009).

For schizophrenia, in particular, genes are necessary but are not the sole operator in developing the condition (Dean & Murray, 2005). However, genetics do play a substantial role in an individual's probability of developing schizophrenia (Heckers, 2009; Messias et al., 2007). For example, the risk of an individual presenting with a psychotic disorder increases several fold if a first-degree relative also has a history with a psychotic disorder (Heckers, 2009). Several genes are being investigated in terms of their link to psychosis (Hassiotis et al., 2009).

Baseline risk factors aside from genetics include gender, culture, residence type (urban versus rural), ethnicity, and immigration status (Dean & Murray, 2005; Heckers, 2009; Messias et al., 2007). In general, men are at increased risk for developing schizophrenia, with a 30–40% higher risk than women (Messias et al., 2007). More research is needed to identify whether this increased risk holds for individuals with ID, however current research does suggest that there are gender differences in this group as with the general population (Hassiotis et al., 2009).

Early-Life Risks (In Utero and During Birth)

Many risk factors that occur in utero or during birth have been well documented in the general population (Dean & Murray, 2005; Heckers, 2009) and have also been suggested for those with intellectual disabilities (Hassiotis et al., 2009). These risk factors include obstetric complications, such as intrauterine growth restriction (also called fetal growth retardation) or hypoxia, prenatal or postnatal infections, maternal malnutrition, and maternal stress (Dean & Murray, 2005; Heckers, 2009; Messias et al., 2007). These complications can impact the process of normal brain development (Heckers, 2009).

Childhood Risks

A number of risks that can occur during childhood have been identified in the general population, and may also impact individuals with ID. These include the broad categories of traumatic life events (TLEs) or adverse events or experiences, developmental abnormalities, and infections and immune responses.

In Khandaker et al. (2018) it was reported that exposure to infections can lead to an increased risk of developing non-affective psychoses (with a hazard ratio for an infection during the first year of life of 1.19, with a 95% confidence interval of 1.06–1.33). Other studies have linked meningitis to an increased risk (approximately 5×) of developing psychosis and schizophrenia (Messias et al., 2007), and shown that individuals with *Toxoplasmosis gondii* antibodies have a higher prevalence of schizophrenia (Messias et al., 2007). In general, it is thought that infections during early childhood may impact typical neurodevelopment (Khandaker et al., 2018).

Childhood developmental delays or abnormalities have also been associated with an increased risk in developing schizophrenia and psychosis (Hassiotis et al., 2009; Khandaker et al., 2018; Messias et al., 2007). The relation between psychosis and IQ has been investigated thoroughly, and studies suggest a linear association between premorbid IQ and schizophrenia (Khandaker et al., 2018). There may be a common risk that links low IQ and psychosis (for example, abnormal brain development), or the link may be causal (Hassiotis et al., 2009). Future research is needed in this area. As early childhood infections are associated with both risk of lower IQ and developing psychosis, these associations may also be causal (Khandaker et al., 2018).

Typically developing children who experience traumatic life events (TLEs) including abuse, trauma, or adverse experiences have increased risk of developing psychosis (Dean & Murray, 2005; Gibson, Alloy, & Ellman, 2016; Radua et al., 2018). Children who have experienced TLEs are at increased risk of psychotic disorders, and such TLEs have been shown to be one of the most robustly associated (environmental) risk factors for psychosis (Bendall, Alvarez-Jimenez, Nelson, & McGorry, 2013;Gibson et al., 2016 ; Varese et al., 2012). Specifically, the odds of developing a psychotic disorder or psychotic symptoms in individuals with a history of TLEs are between 2.78 and 11.50 (where the value varies based on TLE type and methodology) (Gibson et al., 2016; Varese et al., 2012). Notably, there has been a demonstrated dose–response relationship between TLEs and psychosis (Gibson et al., 2016). Similarly, life events have also been significantly associated with the development of schizophrenia in individuals with ID (Hassiotis et al., 2009; Tsakanikos, Bouras, Costello, & Holt, 2007).

Risks Later in Life

The risks discussed below include risks that occur later in life, and those that occur close to the transition into psychosis and during the symptomatic risk stage. In the general population, studies have shown that there is a robust link between sleep dysfunction and psychosis, but more investigation is needed to establish a causal association (Reeve, Sheaves, & Freeman, 2015). Exposure to drugs, especially marijuana, or drug abuse, are also suggested as risk factors (Dean & Murray, 2005; Hassiotis et al., 2009; Heckers, 2009) for the general population and for individuals with ID. A range of studies across the world have shown higher risk, ranging from 2 times up to 25 times higher for typically developing individuals using cannabis (Messias et al., 2007). However, this risk is difficult to study in individuals with ID since this population has low rates of usage (Cooper et al., 2007).

Smoking has been associated with a risk of psychosis in the general population and in individuals with ID, as has visual impairment (Cooper et al., 2007). However, in individuals with ID, not having comorbid epilepsy was found to correspond with psychosis; while in the general population the opposite appears to be true (Cooper et al., 2007).

The most significant risk factor for the general population, with the strongest level of evidence of association with psychosis, is the existence or emergence of sub-threshold psychotic symptoms (Heckers, 2009; Yung, Phillips, Yuen, & McGorry, 2004). Individuals already experiencing subthreshold symptoms, along with a family history of psychotic disorders, were categorized as being at "ultra-high-risk" (UHR) for developing schizophrenia and other psychotic disorders (Yung et al., 2004). It was found that 34.6% of the individuals at UHR developed obvious psychotic symptoms within 1 year (i.e., the transition rate to disease was 34.6%) and 39.4% developed psychosis eventually.

The identification of such high-risk individuals is of special interest, as this group may benefit in particular from early interventions that aim to prevent the onset of psychosis (Yung et al., 2004). Another recent review found that those individuals with prodromal symptoms were at greater risk for developing a psychotic disorder; however, less than 40% of those actually did (Fusar-Poli et al., 2013). For youths (under age 18) with intellectual disabilities, the early onset of psychotic symptoms led to a later diagnosis of schizophrenia or schizoaffective disorder in more than half of the individuals (Friedlander & Donnelly, 2004) suggesting transition rates for young people with ID may be higher than rates in the general population; but it should be noted that the sample size in this study was small. Overall, however, transition rates for those at high risk have been highly variable in the literature (Conrad et al., 2017) and more investigation of the role of negative symptoms (as opposed to solely positive symptoms) may provide useful clinical information (Fusar-Poli et al., 2013).

Assessment of Psychosis

As discussed above, an accurate diagnosis of psychotic disorders in individuals with ID is difficult partly because of the cognitive and language difficulties, making it difficult for the individual to describe psychotic symptoms

(Helverschou et al., 2011; Myrbakk & von Tetzchner, 2008). However, behavioral phenotypes have been used in identifying psychotic disorders among individuals with ID. For instance, disorganized behavior has been described as potentially being equivalent to disorganized thought or speech in individuals without ID (Bakken, Eilertsen, Smeby, & Martinsen, 2009; Bakken, Friis, Løvoll, Smeby, & Martinsen, 2007; Kildahl et al., 2017).

It has been recommended that clinicians gain knowledge about the person's previous functioning and modes of communication for those with ID referred for concerns of psychosis (Kildahl et al., 2017). This information in addition to behavioral observations will allow the clinical to investigate conventional symptoms of psychiatric disorders (Helverschou et al., 2011). Furthermore, combined knowledge of ID and psychosis/psychiatric disorders are invaluable to the assessment (Kildahl et al., 2017). Although general assessment tools are helpful, they warrant careful interpretation and inclusion of multiple informers (e.g., caregivers, family, or other professionals), as this may help to attain a more accurate diagnosis (Kildahl et al., 2017).

Generally, clinicians utilize a combination of structured diagnostic interview as well as assessments of positive and negative symptoms. For example, a structured diagnostic interview like the Mini-International Neuropsychiatric Interview (MINI; Sheehan et al., 1998) as well as the use of a structured clinical scale for assessment of positive and negative symptoms such as the Positive and Negative Syndrome Scale (PANSS) or Brief Psychiatric Rating Scale, which have been used in a case study (Kildahl et al., 2017).

Tools aimed at screening for and aiding in the diagnosis of psychotic disorders have been developed. These include the Assessment of Dual Diagnosis (ADD; Matson, 1997), the Diagnostic Assessment for the Severely Handicapped-II (DASH-II; Matson, 1995), and Psychopathology Instrument for Mentally Retarded Adults (PIMRA) (Matson, Kazdin, & Senatore, 1984), among others. The ADD is used for assessment of individuals with mild or moderate intellectual disabilities, while the DASH-II is used with individuals with severe or profound intellectual disabilities. The ADD is a parent/caregiver report measure which contains 79 items and measures comorbid psychopathology such as mania, depression, anxiety, post-traumatic stress disorder (PTSD), substance abuse, somatoform disorders, dementia, conduct disorder, pervasive developmental disorder, schizophrenia, personality disorders, eating disorders, and sexual disorders.

The DASH-II is an 84-item parent/caregiver report measure which assesses psychopathologies such as anxiety, depression, mania, pervasive developmental disorder/autism, schizophrenia, stereotypies, self-injury, elimination, eating, sleeping, sexual, organic, and impulse control. The PIMRA is a 56-item parent/caregiver report measure which assesses schizophrenia, affective disorder, psychosexual disorder, adjustment disorder, anxiety disorder, somatoform disorder, and personality disorder and inappropriate adjustment.

The Mini Psychiatric Assessment Schedule for Adults with Developmental Disability - Mini PAS-ADD (Prosser et al., 2002) and the PAS-ADD Checklist (Moss et al., 2002) have been used to assess psychotic disorders in individuals with ID. The PAS-ADD checklist consists of 27 items that can be used to help clinicians recognize mental health problems, including psychotic disorders. The Mini PAS-ADD is more elaborate requiring more extensive training in its administration and allows clinicians to gage the presence of psychosis. The Mini PAS-ADD comprises of 86 psychiatric symptoms and generates subscale scores on depression, anxiety, hypomania, obsessive-compulsive disorder, psychosis, unspecified disorder, and pervasive developmental disorders. Both of these measures have been shown to be reliable and valid measure for assessing psychiatric disorders in adults with ID (Moss et al., 2002; Prosser et al., 2002).

Recommendations for the assessment of psychosis in individuals include the following. First, screening tools should be used in combination with the International Statistical Classification of

Diseases and Related Health Problems (ICD-10; World Health Organization, 2004) and the Diagnostic and Statistical Manual of Mental Disorders (DSM-5; American Psychiatric Association, 2013). Second, a biopsychosocial approach should be taken, therefore a multidisciplinary team, including a psychiatrist, psychologist, and physician is recommended. Third, medical conditions should be assessed. It is important to assess for preexisting conditions that may predispose an individual to psychosis. Medication side effects and drug interactions need to be evaluated. It must be determined if certain symptoms are related to substance use. Assessing for medical conditions may include a complete physical, blood tests and brain scans. Certain medical conditions may display similar symptoms to psychosis including neurological diseases (e.g., Parkinson's disease, Huntington's disease), delirium, brain tumors or cysts, dementia/Alzheimer's disease, HIV and other infections that affect the brain, some types of epilepsy, stroke, hyponatremia, hepatic encephalopathy, uremia, hyperadrenalism, or Wilson's disease. Genetic disorders that may have a predisposition to psychosis should also be considered, including velocardiofacial syndrome, Prader–Willi syndrome, Turner's syndrome, Phenylketonuria, or Klinefelter's syndrome. It is possible that psychosis has a medical cause if hallucinations are olfactory, as this may be seizure related. Where hallucinations are tactile, it may be delirium or substance abuse/withdrawal. If hallucinations occur while going to sleep or while waking up, they may be hypnogogic or hypnopompic hallucinations. Fourth, if there is no medical cause for psychosis (such as seizures), the following should be assessed through interview with significant others: Background and life history, current living circumstances, environment, history of presenting symptoms, and changes in presentation of symptoms over time or in different places or situations. Fifth, the following needs to be ruled out: developmentally appropriate self-talk, imaginary friends, reports that are culturally normative (e.g., seeing relatives who have died) in isolation from other symptoms, and learned behavior that is adaptive to the environment. Sixth, the individual should be observed over time. Accurate diagnosis comes over time and with a multidisciplinary team. A major reason for the identification of a psychiatric disorder, or a thorough psychiatric assessment may increase the probability of prescribing effective treatment, both pharmacological and psychological.

Pharmacological and Psychological Treatment of Psychosis in ID

There exists limited empirical evidence on the treatment of psychotic disorders in adults with ID. As such, treatment approaches are often extrapolated from research in the general population and from clinical experience. Treatment for most individuals with comorbid mild ID and major mental illness is delivered predominantly by the mental health services (Patil, Keown, & Scott, 2013). However, interagency and/or intensive support approaches providing coordinated and integrated services have been associated with improved clinical outcomes in some (Lunsky, Bradley, Durbin, & Koegl, 2008; Lunsky, Gracey, Bradley, Koegl, & Durbin, 2011) but not all cases (Martin et al., 2005).

Much like assessment, treatment takes a biopsychosocial approach, including both pharmacological and psychological treatments, which is tailored to the individual's needs. Prior to initiating treatment, it is important to conduct a risk assessment to ensure the client's safety as well as the safety of others.

Pharmacological Treatment

Pharmacological treatments for psychotic disorders include both first and second generation antipsychotic medications. Particularly, antipsychotic drugs are the most frequently prescribed of the psychotic drugs among ID population (Matson & Mahan, 2010). In terms of psychosis, they are used to treat the positive symptoms such as hallucinations and delusions. See Table 46.1. for a list of first- and second-generation antipsychotic medications.

Table 46.1 List of common first-generation antipsychotics (FGAs) and second-generation antipsychotics (SGAs)

FGAs (Typical)	SGAs (Atypical)
Haldol (Haloperidol)	Clozaril (Clozapine)
Loxitane (Loxapine)	Risperdal (Risperidone)
Mellaril (Thioridazine)	Abilify (Aripiprazole)
Moban (Molindone)	Seroquel (Quetiapine)
Navane (Thiothixene)	Zyprexa (Olanzapine)
Prolixin (Fluphenazine)	
Serentil (Mesoridazine)	Invega (Paliperidone)
Stelazine (Trifluoperazine)	Fanapt (Iloperidone)
Thorazine (Chlorpromazine)	Zeldox (Ziprasidone)
Trilafon (Perphenazine) (Droperidol) (Pimozide) (Prochlorperazine) (Thioridazine)	Saphris (Asenapine)

First-Generation Antipsychotics (FGAs)

First-generation antipsychotics (FGAs) are also known as *typical antipsychotics*, dopamine antagonists, neuroleptics, and classic antipsychotics. These terms have evolved over the years due to historical and conceptual implications. Neuroleptics refers to the ability of a drug to cause "neurolepsis" which includes psychomotor slowing, emotional quieting, and affective indifference. These symptoms were initially a reliable sign of antipsychotic efficacy; however, we now know that these effects are not required for drugs to have therapeutic action and that the presence of these symptoms predicts low treatment adherence. Dopamine antagonists act on different regions such as mesolimbic, mesocortical, nigrostriatal, and tuberoinfundibular pathways.

Typical Antipsychotics is the most commonly used term in practice and is based on the view that SGAs have atypical properties (e.g., low risk of extrapyramidal symptoms [EPS]). Therefore, drugs that do not have atypical properties are referred to as typical antipsychotics. This original concept of atypicality risk (low EPS) changed to a broader definition that included efficacy for negative and cognitive symptoms in schizophrenia (Gründer, Hippius, & Carlsson, 2009). This definition was revised after the CATIE (Clinical Antipsychotic Trials Intervention Effectiveness) trial failed to confirm that SGAs are more effective than FGAs, with the exception of clozapine for treatment-resistant schizophrenia. In order to avoid confusions regarding effectiveness in schizophrenia, the World Psychiatric Association suggested the term first-generation antipsychotics.

FGAs are the primary treatment of schizophrenia and related psychotic disorders. The use of FGAs has declined, mainly due to the increase in prescriptions of second-generation antipsychotics. However, they remain a valuable option in the treatment of psychotic disorder as they are considered less expensive. FGAs are associated with higher risk of neurological side effects such as tardive dyskinesia, extrapyramidal side effects (EPSE), and dystonia. For instance, haloperidol is effective in reducing psychotic symptoms; however, they can produce unpleasant sides effects such as drowsiness and EPSE (particularly dystonia, parkinsonism, and akathisia) which can lead to discontinuation of medication and relapse.

Second-Generation Antipsychotics (SGAs)

Second-generation antipsychotics (SGAs), also known as *atypical antipsychotic*s. There is a lower risk of EPS associated with the use of clozapine (Leucht, Kissling, & Davis, 2009). Atypical antipsychotics were broadened to include efficacy against negative and cognitive symptoms, lack of prolactin elevation, and efficacy in treatment-resistant individuals. SGAs also block D2 receptors (like in FGAs) in addition to their ability to block 5HT2A receptors. Specifically, SGAs are known as dopamine–serotonin antagonists, due to their high affinity for 5HT2A receptors (Sadock & Sadock, 2009). Although SGAs have lower risk of neurological side effects, they have an increased risk of developing metabolic side effects such as hyperglycemia, weight gain, and dyslipidemia.

Clozapine was manufactured by Sandoz in 1959 and was the first of the SGAs to be produced. However, it was later discontinued and withdrawn in several countries following reports of severe blood reactions (i.e., neutropenia) and subsequent death of eight individuals (Crilly, 2007; Hippius, 1999). Clozapine was later reintroduced with a rigid monitoring protocol after several studies showed its efficacy and safety in treatment-resistant schizophrenia. Currently, it is used in the UK as second-line treatment for schizophrenia after a failed trial with two antipsychotic medications for an adequate time period (Farooq et al., 2011). Though, in some countries it is routinely used as first-line treatment (Tang et al., 2008; Wang & Li, 2012).

Antipsychotics as a Treatment of Challenging Behavior and Comorbid Psychopathology in ID Population

There is a high rate of prescription of psychotropic medication, including antipsychotics, among individuals with an ID (Deb, Unwin, & Deb, 2014; Scheifes, Egberts, Stolker, Nijman, & Heerdink, 2016). In fact, there are about 25–30% of all individuals with ID using services that regularly receive antipsychotics (Branford, 1994; Holden & Gitlesen, 2004a). This increases to 48% when you include challenging behaviors (Kiernan, Reeves, & Alborz, 1995). There are two main reasons for the use of antipsychotics among this population. First, antipsychotics are used to treat comorbid psychosis. Second, and perhaps more controversially, antipsychotics are used to manage challenging behaviors.

Studies have consistently reported that the rate of prescription of antipsychotics far exceed the expected prevalence of psychoses in individuals with ID (Perry et al., 2018; Robertson et al., 2000). For instance, of the 74% of the sample who were prescribed antipsychotics, 26% had documented evidence of psychotic features (e.g., bipolar, psychosis) whereas 48% did not (Perry et al., 2018). In a survey of 500 residents with ID, Robertson et al. (2000) reported significantly higher use of all psychotropics, especially typical antipsychotics, in those living in residential campuses (56%), versus those living in village communities (17%) or dispersed housing (27%).

Furthermore, residents having good mobility, with challenging behaviors, living in residential campuses, not having been diagnosed with epilepsy, and not having moved to the current residence from a family home predicted higher use of antipsychotics (Robertson et al., 2000). Similarly, having a diagnosis of autism and dementia or being older was also associated with the use of antipsychotics in individuals with ID (Sheehan et al., 2015). Nevertheless, challenging behaviors are commonly examined as a rationale for the higher use of antipsychotics. For instance, Holden and Gitlesen (2004a) indicate that nearly 50% of individuals with ID have been using psychotropic medications in the treatment of psychiatric disorder and/or challenging behaviors in the last 20 years. As such, although antipsychotic medications are often used to manage psychosis in the general population, it is evident that adults with ID are treated at a rate far exceeding that of recorded mental illness and that individuals with ID and challenging behaviors are significantly more likely to receive antipsychotics (Sheehan et al., 2015).

As such, there is concern that antipsychotics are overused and might often be prescribed for challenging behavior in itself rather than for diagnosed mental illness, despite inconsistent evidence of efficacy (Aman, Buitelaar, Smedt, Wapenaar, & Binder, 2005; Aman, De, Derivan, Lyons, & Findling, 2002; Duggan & Brylewski, 2004; Deb, Sohanpal, Soni, Lenotre, & Unwin, 2007; Duggan & Brylewski, 1999; La Malfa, Bertelli, & Conte, 2001; Scheifes, Stolker, Egberts, Nijman, & Heerdink, 2011). In fact, the most common reason for the prescription of antipsychotic medication to individuals with ID is the management of challenging behaviors (Aman, Sarphare, & Burrow, 1995; Matson & Mahan, 2010; Oliver-Africano, Murphy, & Tyrer, 2009). For example, clozapine has been shown to reduce aggression and self-injurious behavior independent of psychiatric diagnosis (Thalayasingam, Alexander, & Singh, 2004).

In a recent review of electronic case records, approximately 92% of a sample of 60 individuals with ID had been on antipsychotic medication. The vast majority of these individuals were prescribed antipsychotics to reduce challenging behaviors or psychotic symptoms; however, some were using them as a mood stabilizer or to reduce anxiety (Thalitaya, Reynolds, & Ismail, 2017). In a similar study exploring the association between prescription of psychotropic drugs, mental illness, and challenging behaviors in individuals with ID, 49% (of a sample of 33,016 adults with ID) had a record prescription of psychotropic drugs (Sheehan et al., 2015). Most antipsychotics were prescribed to individuals without a record of severe mental illness. In fact, challenging behavior was associated with the prescription of antipsychotics after adjusting for psychiatric diagnoses, suggesting that these drugs are being used to manage challenging behavior (Sheehan et al., 2015).

Commonly prescribed antipsychotics include risperidone, aripiprazole, olanzapine, chlorpromazine, clozapine, depixol, fluenthixol, zuclopenthixol, quetiapine, and benperidol (Thalitaya et al., 2017). Similar antipsychotics are reported in the literature as the most frequently reported psychotropic drugs include thioridazine, haloperidol, and chlorpromazine (Aman et al., 1995; Robertson et al., 2000) as well as risperidone, olanzapine, and quetiapine (Connor & Posever, 1998; Williams, Clarke, Bouras, Martin, & Holt, 2009). There are concerns due to whether the antipsychotics are actually effective in controlling challenging behaviors and there are a host of side effects associated with antipsychotics. Side effects of atypical antipsychotics are commonly identified as a concern with this population (Frighi et al., 2011; Mahan et al., 2010; Matson & Mahan, 2010). Thalitaya et al. (2017) reported common side effects of weight gain, sedation, hypersalivation, EPSE, hyperprolactinemia, hypertension, tremors, and hypercholesterolemia.

As such there are international guidelines for prescribing psychotropics for managing challenging behaviors (Deb et al., 2009) and for diagnosing mental health disorders in individuals with ID (Clarke & Gomez, 1999; Cooper, Melville, & Einfeld, 2003; Fletcher, Loschen, Stavrakaki, & First, 2007). For example, in 2006, the Royal College of Psychiatrists of the UK suggested that if there is no diagnosis of comorbid mental disorders and the challenging behaviors are a result of psychosocial factors, then use of antipsychotics should be used to alleviate short term risks to self and others, while other non-pharmacological programs are implemented to manage behavior. As such, researchers and clinicians assume that there will be a decline in use of antipsychotics (due to their questionable efficacy with challenging behaviors and reported side effects) and increased use of mood stabilizers, antidepressants, antianxiety medications given such international guidelines (Tsiouris et al., 2013). Recently it has been reported that current prescribing practice of antipsychotics in persons with ID in the UK is consistent with evidence-based practice and overall prescribing practice (Paton et al., 2011).

Antipsychotics as a Treatment of Psychosis in ID Population

The diagnosis of psychiatric disorders in individuals with ID is a complex process with difficulties increasing with lower IQ scores and poorer verbal communication (Thalayasingam et al., 2004). This would also mean that psychiatrists would have similar problems in establishing treatment refractoriness. Given the difficulty with diagnosis and treatment of psychosis in individuals with ID, it is not surprising that limited research exists. Many researchers outline the lack of studies on the efficacy of antipsychotics on schizophrenia or other psychotic disorder in individuals with ID (Duggan & Brylewski, 1999; Malfa, Lassi, Bertelli, & Castellani, 2006; Matson, Bielecki, Mayville, & Matson, 2003). There are also concerns regarding the greater risk of developing side effects and the impact of antipsychotics on learning and cognitive abilities of individuals with ID (Aman, 1993; Frighi et al., 2011; Mahan et al., 2010; Matson & Mahan, 2010).

Not only do individuals with ID receive psychotropic medications at high rates, but these drugs tend to be prescribed for many years (Yen, Lin, Loh, Shi, & Hsu, 2009), and with little or no current data collected to determine treatment efficacy (Matson & Neal, 2009). In a sample of 2069 adults with ID, almost half of the survey sample (45%) received antipsychotic medication, 39% of which was atypical antipsychotic, and the remaining 6% typical antipsychotic (Tsiouris et al., 2013). Tsiouris et al. (2013) noted the frequent use of antipsychotics for psychosis (70%) and bipolar disorder (67%).

Although typical antipsychotics such as haloperidol or chlorpromazine are most prescribed in ID, on a long-term basis they turn out to be less effective than new antipsychotics (Malfa et al., 2006). For instance, in the abovementioned sample of 2069 adults with ID, typical antipsychotics such as haloperidol, thioridazine, and chlorpromazine were infrequently prescribed, while atypical antipsychotics like risperidone, olanzapine, quetiapine, and aripiprazole were more commonly used (Tsiouris et al., 2013). This finding is consistent with other commonly used SGAs in the literature (Frighi et al., 2011; Leucht et al., 2009; Malfa et al., 2006). In a sample of 13 adults with mild ID and 8 with moderate ID and comorbid psychiatric disorders (with significant challenging behaviors in 10 cases), olanzapine and risperidone were well tolerated by individuals with ID and psychiatric disorders (with improvements in psychotic features), with only one case where olanzapine was discontinued due to side effects.

In a review of the literature, Connor and Posever (1998) concluded that atypical antipsychotics appeared better tolerated than typical antipsychotics, but there is a need for more research into their clinical efficacy for individuals with ID. Despite the efficacy for some antipsychotics, a Cochrane review did not find sufficiently detailed randomized controlled trials that examined antipsychotic medication versus placebo for individuals with both ID and psychosis, specifically schizophrenia (Duggan & Brylewski, 2004).

While there is limited evidence of antipsychotic medications, Clozapine has been shown to have a good response on treatment-resistant individuals with ID and DSM-IV diagnosis of schizophrenia, schizoaffective disorder, bipolar disorder, delusional disorder or other psychotic disorders (Ayub, Saeed, Munshi, & Naeem, 2015; Chakos, Lieberman, Hoffman, Bradford, & Sheitman, 2004; Farooq et al., 2011; Malfa et al., 2006; Thalayasingam et al., 2004; Singh, Singh, Kar, & Chan 2010). When at least two antipsychotics are not effective in treating the symptoms of psychosis, it is labelled as treatment-resistant psychosis. Individuals with ID who also suffer from psychosis are at a higher risk of developing treatment-resistant psychosis (Ayub et al., 2015). The extent of treatment resistance in individuals with ID is unclear (Ayub et al., 2015). Much of the evidence for treatment-resistance psychosis in ID is based on the fact that low IQ is a predictor of poor prognosis in psychosis and one manifestation of poor prognosis is treatment resistance (Thalayasingam et al., 2004).

A recent Cochrane review conducted by Ayub and colleagues (2015) revealed poorly designed randomized controlled trials (RCTs) that examined the efficacy and side effects of clozapine in individuals with ID and psychoses. Of 1224 titles and abstracts screens, 38 articles were initially included. However, these articles were subsequently excluded as they did not meet the inclusion criteria. Specifically, these studies were not RCTs. This makes sense as individuals with ID are a very heterogeneous population and psychiatric disorders are difficult to diagnose, which makes randomized controlled trials even more difficult to conduct. Nevertheless, small studies have shown that clozapine appears to efficacious and safe for individuals with ID (Antonacci & de Groot, 2000; Thalayasingam et al., 2004). Thalayasingam et al. (2004) found that clozapine may be used to effectively treat either refractory schizophrenia or bipolar affect disorder in individuals with ID. They highlighted that the dose of clozapine was comparable to those without ID and the effectiveness did not appear to diminish over time.

In line with the international guidelines, careful monitoring of side effects is recommended (Thalayasingam et al., 2004). The effect of psychotropic medication can be different in individuals with ID; that is, antipsychotics can have different (desired and undesired) side effects in different individuals. For instance, individuals with ID are reportedly more prone to side effects (Ayub et al., 2015). Common side effects of the use of clozapine include anemia and leukocytosis, drowsiness, hypersalivation, tremors, syncope, disturbed sleep or nightmares, restlessness, hypokinesia or akinesia, agitation, sedation, seizures, rigidity, akathisia, confusion, fatigue, insomnia, and hyperkinesia (Miller, 2000). Clozapine is also associated with weight gain (Leucht et al., 2009).

Psychological Treatment

Treatment models exist for individuals with comorbid major mental illness and ID. One of which is assertive community treatment (ACT), which was originally designed to support individuals with severe and enduring mental illness (Herman, 2014). The main goals of ACT include maximizing medication compliance, minimizing relapse, meeting basic social and occupational needs, enhancing quality of life, improving social and vocational functioning, promoting independent living skills, reducing carer burden, and facilitating community integration (Martin et al., 2005). Research has indicated that benefits are mixed (Balogh, Ouellette-Kuntz, Bourne, Lunsky, & Colantonio, 2008). Raftery et al. (2006) provided an intensive personalized support program for individuals with mild ID and comorbid psychosis over an 18-month period.

With regard to ecological treatments, these approaches are largely psychoeducational, tailored to particular presentations and levels of intensity. These approaches often target psychosis in a typically developing population, as opposed to in individuals with ID or developmental disabilities. There are no manualized approaches, but instead a variety of strategies are implemented together. Due to the idiopathic nature of psychosis, this approach is appropriate.

With regard to behavioral treatments, cognitive behavior therapy for psychosis (CBTp) has been implemented for typically developing individuals with psychosis. The cognitive behavior therapy model (combining cognitive exercises and behavioral strategies) has been extended for use with this population. In many ways, the standard CBT approach has been adjusted for use with psychotic thoughts (e.g., delusions, hallucinations). With regard to negative symptoms, a psychoeducational approach is taken, which focuses on behavioral support and traditional skills training. For positive symptoms, a more traditional CBT approach is taken, which focuses on identifying patterns and thoughts, and opting not to act upon them. The CBT package is not very different to traditional CBT, in that it focuses on both observable behavior and covert behavior. Despite many programs practicing this model, there is not a formalized treatment package available. Much of the research literature is conceptual and practice-based.

Morrison and Barratt (2010) conducted a Delphi study, which highlighted some of the key components of CBTp. It was found that there was not a clear consensus regarding the essential elements of treatment (Morrison & Barratt, 2010). No CBTp package has been found to consistently improve outcomes for individuals with ID and psychosis. Treatment packages that exist for comorbid ID/ASD are not well defined and are unclear in how they differ.

Support of CBTp for psychosis ranges from supportive to little or no support. Over 30 RCTs demonstrated positive outcomes for CBTp on positive and negative symptoms of schizophrenia (Wykes, Steel, Everitt, & Tarrier, 2008). In their review, Jauhar et al. (2014) found a small therapeutic effect for CBTp. In contrast, a meta-analysis of highly controlled CBTp found that CBTp does not reliably, if ever, lead to significant outcomes when compared to controls (Jones, Hacker, Cormac, Meaden, & Irving, 2012; Lynch, Laws, & McKenna, 2010; Newton-Howes & Wood, 2013). Various scales have been developed for use in CBTp, including the Cognitive Therapy for At Risk of Psychosis Adherence Scale (Bell et al., 2008), the Cognitive Therapy for Psychosis Adherence Scale (Rollinson et al., 2008), and the Cognitive Therapy Scale for Psychosis (Haddock et al., 2001). There is some evidence that CBTp can be effective in psychosis (with and without ID), though support is very limited. Future research is needed to determine the effectiveness of CBTp in individuals with ID and psychosis.

Support for acceptance and commitment therapy for psychosis (ACTp) ranges from having some benefit to minimal benefit in the general population. The approach found that there were some improvements displayed, though not much over psychosocial comparative treatment in typically developing individuals (Shawyer et al., 2017). Bach and Hayes (2002) found positive improvements compared to controls on self-report data in typically developing individuals. The ACTp approach is still in formative stages, though nothing to suggest as of yet that it provides anything beyond what CBTp offers. There are little standardized measures used in ACTp. ACTp is highly experimental at this point, without many well-controlled trials. Future research is needed on ACTp in the typically developing population, as well as expanding this research to include individuals with ID and psychosis.

In summary, ecological treatment models for psychosis (with or without developmental disabilities) do not lead to reliable differences in well-controlled trials. Some studies that indicate improvements with regard to self-reported data, though these are not highly controlled studies. Ultimately, these studies suggest these approaches lead to arguably small effects on real-world outcomes (e.g., hospital readmissions, symptom counts). No studies exist that directly compare CBTp to ACTp. As can be seen, the psychological treatment of psychosis in individuals with ID is an area where much more research is needed. Predominantly, treatment is pharmacological and therefore, research on psychological treatments are warranted.

Recommendations for Treatment

Recommendations for the treatment of psychosis in individuals include the following. First, the medication type that the individual is prescribed needs to be considered. There needs to be a focus on balancing the individual's needs with treatment and the side effect profile of the medication. Second, regular physical health checks, including cardiovascular and endocrine review should be conducted; for example, an ECG prior to starting antipsychotics and at regular intervals thereafter is useful to monitor any ECG abnormality (like QT prolongation). Third, medication needs to be monitored. This includes monitoring the benefit and response, as well as the side effects, and the possibility of reducing medication over time and as appropriate. Fourth, clinicians need to familiarize themselves with existing guidelines, such as the National Institute for Clinical Excellence (NICE) guidelines. Fifth, a full diagnostic evaluation with clear description of psychotic symptoms should be conducted. Sixth, there should be a clear statement outlined of the risks and use of antipsychotics, given the side effects. Seventh, informed consent to treatment needs to be given. Eighth, behavioral supports and therapy should be given, where appropriate.

Future Directions for Research

Research in this area is difficult as the literature is limited by inconsistent definitions, use of small or highly selected samples (Sheehan et al., 2015). Therefore, future researchers are encouraged to better define inclusion criteria (e.g., symptoms, adaptive functioning). Moreover, researchers should focus on RCTs (with double-blind vs. placebo or other medications) for clinical evidence to guide the medication for this population, especially given its use for those with challenging behaviors. Although pharmacotherapy is necessary to alleviate the symptoms of psychiatric disorders, it is only part of a coordinated comprehensive treatment plan.

There is limited research into cognitive impairment related to ID and psychotic disorders (McCarthy & Barbot, 2016), and as such further research is required to enable a better understanding of psychosis experienced by a person with ID. Further evidence is required to initiate effective, suitable treatment based on strong empirical evidence (McCarthy & Barbot, 2016).

Additional research is required to provide information about the extent to which existing support systems meet the needs of adults with ID with mental health disorders (Schűtzwohl et al., 2016). Research that contributes relevant information to the literature regarding mental health service provisions for adults with mild, moderate and profound ID is essential to guiding future policies. By creating a greater awareness of psychosis and the related genetic and environmental factors (Doherty & Owen, 2014; McCarthy &

Barbot, 2016) we may help to accumulate evidence that could support high quality clinical practice for those with ID and ASD (Allen, 2008; Canitano & Pallagrosi, 2017). Research evaluating a range of support systems would allow for comparison and consequently an improved understanding of the fundamental factors which contribute to an effective service provision for individuals with an ID or ASD who are diagnosed with psychotic mental health problem (Schűtzwohl et al., 2016). Further research into psychosis and ID could focus on support for health care practitioners, carers, and individuals with ID in reducing antipsychotic medication, if possible (McNamara et al., 2017; O'Dwyer et al., 2017).

Conclusion

This chapter provides an overview of psychosis in individuals with ID. Definitions of psychosis are discussed, as is the incidence and prevalence of psychosis in individuals with ID. The importance of studying psychosis is given, as well as the difficulties in diagnosing psychosis in individuals with ID. The risk factors of psychosis are given including baseline risks, early-life risks (in utero and during birth), childhood risks, and risks that develop later in life. Assessment of psychosis in ID is outlined, including recommendations for assessment. Following this, pharmacological and psychological treatment for psychosis in individuals with ID is discussed, including recommendations for treatment. Finally, future directions for research are suggested. In conclusion, psychosis in individuals with ID is an area where much more research is needed in order to better assess, understand, and treat psychosis.

Evidence-Based Treatments for Comorbid Autism Spectrum Disorders

Karolina Štětinová, Michelle S. Lemay, Megan O. Bird, and Robert D. Rieske

Introduction

Autism spectrum disorder (ASD) is a neurodevelopmental disorder which presents with deficits in social communication and social interaction across settings. It includes restricted and repetitive patterns of behavior, interests, or activities. Symptoms typically become apparent in early childhood development and limit or impair everyday functioning (American Psychiatric Association, 2013). ASD first appeared in the third edition of the Diagnostic and Statistical Manual (DSM-III). Prior to the DSM-III diagnosis of ASD as a neurodevelopmental disorder, it was considered to be a dimensionally defined developmental disorder, both behaviorally and categorically. Understanding the neurological nature of the disorder has allowed for more accurate diagnosis and intervention (Mintz, 2016). Previously, the DSM included Asperger's disorder, which was added in 1994 to the DSM-IV, in addition to autistic disorder (Kite, Gullifer, & Tyson, 2012). However, with the update of the DSM-5, both Asperger's disorder and autistic disorder fall under the diagnosis of ASD, which allowed both previously separate diagnoses to fall into the same spectrum of symptoms, although the altered criteria now often excludes those with higher functioning forms of ASD (McPartland, Reichow, & Volkmar, 2012). Symptoms of ASD usually are first recognizable between 12 and 24 months of age. However, if developmental delays are severe, symptoms can be seen prior to 12 months; and if the symptoms are less severe, such as with high functioning autism, they may not be identified until after 24 months or until adulthood (American Psychiatric Association, 2013). Symptoms can include loss of social or language skills, delayed language development, odd play patterns, unusual communication, unusual sensory interests, and repetitive behaviors (Faras, Al Ateeqi, & Tidmarsh, 2010). The severity of symptoms is directly correlated to the individual's adaptive functioning.

Although scientists have still not been able to determine the exact cause of ASD, the prevalence of those diagnosed has increased significantly in recent years. It is reported that between 1970 and 2010, autism diagnoses have increased from 0.5 to 14.7 per 1000 children (Dave & Fernandez, 2014). There are multiple theories as to this increase, which include an increased awareness of the disorder, expansion of the diagnostic criteria, and an actual increase in ASD. Dave & Fernandez (2014), examined whether or not autism is increasing independently of other mental health disorders or if autism diagnoses are

displacing other disorders (i.e., diagnostic substitution) and found that there is, in fact, an increase in the true prevalence of autism. However, determining the true increase in prevalence in relation to the multitude of other factors involved in the diagnosis and treatment of ASD continues to be difficult.

There are three core areas of development that are affected by ASD: communication, social interaction, and behavior. In a 2010 article Faras, Ateeqi, and Tidmarsh explained that for preschool-age children with ASD, it is common to see communication impairment in the form of delayed or absent speech and a lack of nonverbal communication, such as little to no pointing and struggling to follow one's gaze or point. In school-age children, it is common to see persistent echolalia, or immediate repetition of words, muteness, and unusual/abnormal vocabulary for their age group. Adolescents are likely to struggle with communicating even if they have a wide vocabulary and understand grammar (Faras et al., 2010). According to Faras et al. (2010) they are also likely to talk *at* people instead of *with* people and provide excessive information about topics of their own interest. Their speech can be flat and repetitive and they may have a hard time understanding sarcasm or metaphors.

In regard to social impairment, Faras et al. (2010) stated that preschool-age children often lack response to others' facial expressions, imagination, initiation of activity, ability to share pleasure, and play with peers. School-age children often inappropriately attempt joint play and lack awareness of classroom rules and norms. Adolescents may have a hard time making friends and lack awareness of personal space or not tolerate others intruding on their own space.

The third area includes impairments in behavior, interests, and/or activities. These impairments for preschool-age children can include repetitive hand movements, inability to deal with change and repetitive play. Like preschool-age children, school-age children have a hard time coping with change. They may also struggle with imaginative play and creativity, as well as have an unusual response to sensory stimuli. Adolescents also have a hard time with imagination, unusual responses to sensory stimuli, and prefer a familiar routine. Adolescents with ASD also tend to have specific, narrow interests/hobbies (Faras et al., 2010). While all of these impairments are common, it is important to keep in mind that the effect ASD has on these core areas of development can be different for each person with ASD. Additionally, with proper interventions, the majority of these symptoms can be corrected or improved upon, especially when the intervention begins earlier in life.

Relationship Between ASD and ID

As previously stated, prevalence rates of ASD have steadily increased over the past decade, with 1 in 59 children being diagnosed in 2014 compared to 1 in 125 ten years earlier (Autism and Developmental Disabilities Monitoring Network, 2018). With these increased rates, the mental health and medical fields have been able to devote more research and time to the disorder and have formed a better understanding of what symptoms and comorbid disorders are seen. One of the disorders often seen with ASD is an intellectual disability (ID). In fact, based on a study from 2004, approximately 70% of individuals with ASD have a comorbid diagnosis of intellectual disability (La Malfa, Lassi, Bertelli, Salvini, & Placidi, 2004). Conversely, ASD is the second highest comorbid disorder with ID, with approximately 40% of those with a diagnosis of ID having a co-occurring diagnosis of ASD (Matson & Shoemaker, 2009).

Although this text describes in some detail the criteria and process related to a diagnosis of ID, it is important for the purposes of this chapter to explain in further detail the similarities and differences between ASD and ID and how the symptom presentation may be different depending upon severity of ASD symptoms or upon level of intellectual functioning. One of the most notable symptoms seen within both disorders is a language or communication deficit (Pinborough-Zimmerman et al., 2007). Although this does not mean that all those with either or both diagnoses will have a language/communication problem, people with either of these diagnoses have a strong tendency to fall under the umbrella of communication disorders. Another diagnostic criterium that is seen with both disorders is the developmental component. More specifically, both a diagnosis of ID and ASD require symptoms to be present in the early developmental period and are considered to be lifelong diagnoses (American Psychiatric Association, 2013).

As previously stated, the symptoms observed in an individual are strongly dependent upon the severity of ASD symptoms as well as the deficit in intellectual functioning. Additionally, having a comorbid diagnosis is also strongly dependent upon the severity of these symptoms. For example, the term “high-functioning autism” applies to individuals diagnosed with ASD without having a comorbid ID diagnosis. Conversely, individuals with “low functioning autism” have a comorbid diagnosis of ID. This is due to the fact that one’s cognitive ability directly affects their level of functioning in social situations and otherwise, which is tied to the diagnosis of autism. Due to the fact that we predominantly see mid-to-low functioning autism diagnosed with ID, we will be focusing predominantly on this population within this chapter. In terms of symptoms seen within a low functioning ASD-ID population, there is a trend towards increased rates of tantrums, repetitive, and avoidant behaviors compared to children with higher IQs (Tureck, Matson, Cervantes, & Konst, 2014). Similarly, research suggests that there are more individuals with impaired verbal and nonverbal communication with an ASD-ID population compared to an ASD only population (Deb & Prasad, 1994). A similar result is seen when comparing those with comorbid ASD-ID to those with a diagnosis of ID such that individuals with comorbid symptoms would respond less frequently to social presses than individuals with an ID diagnosis alone (Jackson et al., 2003). Lastly, we also see more severe deficits in adaptive behavior in those with a comorbid diagnosis of ASD-ID compared to either diagnosis alone (Bolte & Poustka, 2002; Fodstad & Matson, 2008; Matson, Mayville, Lott, Bielecki, & Logan, 2003).

The severity of symptoms within this population emphasizes the importance of therapeutic interventions to improve the quality of life and improved level of functioning for these individuals, but it also highlights the fact that typical interventions implemented for either of these diagnostic clusters will have to be modified in order to effectively treat someone with a comorbid ASD-ID diagnosis. There are several treatments that have been developed over the years to improve functioning and decrease negative symptoms (e.g., self-injurious behaviors, tantrums). Many of those treatments have been proven to be efficacious, although some non-efficacious treatments are still used today. The following sections will discuss various treatments including behavioral and cognitive-behavioral interventions, naturalistic intervention, early-intervention programs, social skills training, language training, as well as parent and peer training. These treatments have been shown to be effective in treating ASD populations and will further discuss how they may be modified for an ASD-ID population.

Behavioral and Cognitive-Behavioral Interventions

The largest group of evidence-based treatments suitable for individuals with ASD and ID diagnoses are behavioral and cognitive-behavioral interventions. This group includes but is not limited to the following interventions: antecedent-based intervention (ABI), discrete trial teaching (DTT), functional behavior assessment (FBA), functional communication training (FCT), and cognitive behavioral intervention (CBI).

Common ABA Components

Many of the above mentioned behavioral and cognitive-behavioral interventions are based on the traditional learning principles of applied behavior analysis (ABA), which is grounded in the ideology proposed by operant conditioning. The ABA approach was built on three theoretical frameworks stating that all human behaviors are learned, purposeful, and could be changed through modification of the client's environment (Hanley, 2012). The goal of the ABA approach is to promote learning and positively shape the client's behavior by reinforcing desirable behaviors and punishing the undesirable ones (Hanley, 2012). This goal can be achieved using a variety of behavioral components, which are essential for the ABA approach. Some of the commonly used ABA components include prompting, time delay, extinction, differential reinforcement, modeling, video modeling, visual support, scripting, and exercise.

Prompting and time delay. In the treatment of ASD and ID, many teachers, parents, and professionals will use prompts to help teach the child different things such as names of objects or people or appropriate item labels (e.g., "Show me the card with the bird"). Prompts have several types such as physical (e.g., pointing to a correct response), verbal (e.g., stating the correct response), modeling (e.g., showing the correct behavior), decreasing the number of possible choices, or hand-over-hand prompting (e.g., physically guiding the child to the correct response; Leaf, Leaf, Taubman, McEachin, & Delmolino, 2014). Time delay procedures are often implemented within a prompting framework by first having the discriminative stimulus and prompt presented simultaneously. After a number of trials with no time delay, the prompt is faded, with more time between the discrete stimulus and prompt, allowing for a greater opportunity for learning the discrete stimulus (Walker, 2008).

Extinction. By definition, extinction is a behavioral modification technique used to reduce the frequency of a specific behavior and is often used as a form of treatment for disorders in which a specific behavior is intended to be reduced such as in obsessive-compulsive disorders and for specific phobias (Wolff, Hupp, & Symons, 2013). Within an ASD/ID population, this treatment can help to reduce ritualistic behaviors or harmful behaviors by preventing the child from completing the behavior within the presence of the controlling stimulus such as by blocking a child from biting their arm any time they make an attempt. After a set of time in which the extinction is in place, the behavior will typically decrease.

Differential reinforcement. In order to treat problem behaviors, one method often implemented is differential reinforcement of an alternative behavior (DRA). DRA, often implemented with extinction includes attention given to an alternative behavior that the caregiver wants to see while ignoring the unwanted behavior, putting it on extinction (e.g., providing the child with positive attention and praise when appropriately requesting an item of food but ignoring the child when they are throwing a tantrum because they want the food; MacNaul & Neely, 2018). However, there are instances in which differential reinforcement cannot be implemented with extinction such as with aggression, although several studies continue to support the fact that DRA can be effective in treating unwanted problem behaviors in individuals with ASD (Athens & Vollmer, 2010; Ingvarsson, Kahng, & Hausman, 2008; Slocum & Vollmer, 2015). Additional methods of differential reinforcement include differential reinforcement of other behaviors (DRO) and incompatible behaviors (DRI) and implementation depends on the behavior being treated.

Modeling and video modeling. In vivo, or live, modeling has been implemented for decades in the establishment and modification of many different behaviors for children with ASD and ID alike. Children could learn appropriate behaviors by viewing another person, typically their caregiver, engaging in that same behavior and then they would practice and be reinforced for engaging in the modeled behavior. However, with new technology advancements, it is argued that video modeling is more effective in several ways including the ability to involve same-aged peers within the video modeling routine which may not be something possible within a traditional modeling routine (Wilson, 2013). Modeling cannot only improve behaviors such as toileting and similar self-care activities but can also help the child practice social-communication skills as well.

Visual support. Similar to video modeling, visual supports are tools created to help children with ASD. Visual supports include items with images or tangible objects that are intended to represent language (such as items or tasks) and are used as a method of communication. As an example, families can have a card with a picture of a cup on it representing a drink and when the child presents the card to a caregiver it indicates that they are thirsty. Another example of visual supports is the use of a visual schedule which includes pictures of tasks or activities that the child can see and manipulate to indicate the completion of a task. Visual schedules can address issues related to struggles with transitions between activities and help the child understand language tied to the completion of tasks. The use of visual supports in an ASD/ID population has been shown to reduce symptoms of cognitive and communication delay as well as social disabilities (Hayes et al., 2010).

Scripting. Scripting is often a component involved in social skills training in which the child is given a script or narrative that describes an activity and template for a conversation or may include only the initiation of a conversation. These scripts can be helpful to a child who struggles with social interactions but is also limiting because the child may not learn to generalize to different "scripts" and may become dependent upon the taught script (Bellini & Peters, 2008). However, script fading, in which the child practices fading the use of the script through sequential practices has been shown to be an effective method of helping the child generalize social interaction skills.

Exercise. The treatment of stereotypic behaviors such as hand-flapping or body rocking has successfully been done through the use of exercise. Although the underlying cause behind improvements in stereotypic behaviors with exercise are unclear, it is suggested that the sensation provided with exercises is similar to that of the behavior, or it could be due to implementing a competing behavior such as repeatedly tapping a ball instead of engaging in hand-flapping behaviors (Tse, Pang, & Lee, 2018).

The various approaches and components utilized are dependent upon the specific symptoms the child is presented with, and some have significantly more research than others, but all have been shown to provide some degree of improvement in ASD symptomology. The effectiveness of the traditional ABA approach was, for example, supported by McEachin, Smith, and Lovaas (1993) who found that ABA leads to improvements in cognitive functioning in children diagnosed with ASD. The following treatments utilize many of the components discussed, and although each varies in the implementation and approach, they are based on the basics of behaviorism.

Antecedent-Based Intervention (ABI)

An intervention closest to the traditional ABA approach is the antecedent-based intervention (ABI). The function of ABI is to modify the environment in order to enhance the client's efforts to engage in the desired behaviors. ABI operates on the principle of the three-term behavioral contingency, often called ABC, where A is the Antecedent, B is the Behavior, and C is the Consequence (Hart & Carr, 2016).

Antecedents are environmental stimuli which trigger a specific behavior of the client. Therefore, a behavior and the consequence linked to that behavior (reinforcement or punishment) follow up after an antecedent is presented in the environment. For this reason, the goal of ABI is to eliminate the presence of antecedents triggering an undesirable behavior through a variety of modifications done in the client's environment (Hart & Carr, 2016).

The first step of the modification process involves identification of the environmental stimuli which reinforce the undesirable behaviors. Subsequent removal of these stimuli ought to prevent the client from engagement in the undesirable behaviors. Advantageously, an environment free of antecedents triggering the undesirable behaviors prevents their interference with the learning process, facilitating the client's attention and motivation. Aside from modification of the client's environment, ABI utilizes components commonly found in the ABA approach including scripting, scheduling, and priming.

According to the report published by the National Professional Development Center on ASD (NPDC) which covers literature published between years 1990 and 2011, the effectiveness of ABI has been validated by 32 single-case studies (Wong et al., 2015). Empirical support regarding the effectiveness of ABI has been found for toddlers, preschool and school-aged children, and adolescents with ASD and ID diagnoses (Adcock & Cuvo, 2009; Butler & Luiselli, 2007; Conroy, Asmus, Sellers, & Ladwig, 2005; Dunlap & Plienis, 1991; Ladd, Luiselli, & Baker, 2009; Reinhartsen, Garfinkle, & Wolery, 2002; Schreibman, Whalen, & Stahmer, 2000; Sigafoos, Green, Payne, O'Reilly, & Lancioni, 2009).

ABI can also be effectively implemented in conjunction with other evidence-based treatments. For example, Stichter, Randolph, Kay, and Gage (2009) used ABI in combination with structural analysis (SA) to develop a treatment addressing difficulties in social and adaptive behaviors in three students diagnosed with autism. All three students were found to become more socially engaged with their classmates and teachers.

In summary, the goal of the antecedent-based intervention (ABI) is to modify the client's environment in order to minimize the occurrence of a specific event (antecedents) resulting in unwanted behavior. The ABI approach was found to have a great empirical base addressing various behavioral problems in children and adolescent clients diagnosed with ASD and ID.

Discrete Trial Training (DTT)

While ABI focuses on the antecedents preceding a specific behavioral response, the discrete trial training (DTT) method focuses more on the consequences of the behavior (i.e., reinforcement and punishment). The function of DTT is to provide a client with a gradual and achievable learning experience using scaffolding and repetition. DTT is typically implemented by a teacher or a behavioral specialist, who uses a scripted instructional process to promote client's learning.

When implementing DTT, the teacher should first identify the targeted complex behavior and break it down into small steps. The complex behavior is then taught step by step using discrete trials or teaching attempts (Smith, 2001). In DTT, it is very important to clearly define and script each step before any teaching trial begins. Scripting not only ensures consistency between the discrete trials but also allows for evaluation of the client's progress. As mentioned, consequences play an important part in the DTT intervention. Clients are reinforced for a successful competition of each step, but no reinforcement is provided for incorrect responses. Traditionally, discrete training trials have been divided into the five following steps (Smith, 2001):

1. Antecedent (i.e., teacher's actions).
2. Prompt.
3. Client's response.
4. Consequence for a correct and incorrect response.
5. Inter-trial interval (i.e., spacing between the trials).

According to the NPDC report, the effectiveness of DTT has been supported by 13 studies (for more detail, see Wong et al., 2015). Those studies included individuals diagnosed with ASD ages 3–11 years and were found to lead to improvements in social, academic, and language skills (Goldsmith, LeBlanc, & Sautter, 2007; Jahr, 2001; Jones, Feeley, & Takacs, 2007; Lang et al., 2011; McHugh, Bobarnac, & Reed, 2011; Summers et al., 2011; Wynn & Smith, 2003). The DTT teaching technique is a popular form of intervention due to its simple structure, consistency, and applicability to a variety of problematic behaviors.

Functional Behavior Assessment (FBA)

Functional behavioral assessment (FBA) and ABI share a similar task—determining the origins of a specific, often problematic, behavioral response. However, while ABI is a comprehensive intervention whose goal is to address the problematic behaviors, FBA is a standardized method used solely for the identification process. FBA, therefore, should not be perceived as a stand-alone treatment, but rather as a technique designed to assist in the development of individualized treatment plans. For optimal results, FBA should always be paired with an additional treatment addressing the problematic behaviors.

According to Walker, Lyon, Loman, and Sennott (2018) functions of behavior could be grouped into the following categories:

1. Escape—avoiding undesirable activity.
2. Attention.
3. Reinforcement—obtaining access to a reinforcer.
4. Sensory stimulation.

To ensure convergence of evidence during the identification process, FBA is often implemented by a functional assessment team composed of clinicians, speech therapists, teachers, school administrators, and the caregivers (Fettig, 2013). The FBA process follows six standardized steps starting with a description of the problematic behavior. Once the problematic behavior is clearly defined, the team collects the baseline data and formulates a hypothesis regarding the antecedents and reinforcers which maintain the problematic behavior. The hypothesis is then tested and data about the client's behavior are collected. If the FBA hypothesis is accurate, the team develops an intervention and continues monitoring its effectiveness (Fettig, 2013).

FBA was found to be effective when developing interventions for academic, adaptive, and communication skills, as well as when determining origins of aggression and self-injurious behaviors (Fettig, 2013; Minshawi, Hurwitz, Morriss, & Mcdougle, 2015). Even though FBA is a behavioral strategy rather than a complex intervention, its effectiveness has been widely documented, meeting the evidence-based practice criteria (Wong et al., 2015).

Functional Communication Training (FCT)

Many individuals diagnosed with ASD and ID face daily challenges when communicating their needs and thoughts (Heath, Ganz, Parker, Burke, & Ninci, 2015). functional communication training (FCT) was developed by Carr and Durand (1985) as an intervention designed to address these exact problems. The goal of FCT is to determine the origins of the communication difficulties and provide the client with appropriate substitute skills. For example, if a child client shows physical aggression towards a younger sibling every time the sibling starts playing with the client's trains, the goal of FCT would be to identify the antecedents leading to the physical aggression and teaching the client appropriate substitute behaviors (verbally or nonverbally asking for the trains or seeking out assistance from the caregiver).

Similar to FBA, FCT is typically implemented by a team composed of mental health professionals, speech therapists, teachers, and the caregivers. FCT also uses FBA methods when identifying the functions of problematic interpersonal behaviors. Once the function of the problematic behavior is determined, a functionally equivalent substitute (or replacement) behavior has to be selected by the team (Walker et al., 2018). The substitute behavior is then taught using differential reinforcement, prompting, and shaping.

Several literature reviews have been conducted in order to evaluate effectiveness of FCT for a variety of populations including individuals diagnosed with ASD and ID (Heath et al., 2015; Kurtz, Boelter, Jarmolowicz, Chin, & Hagopian, 2011; Tiger, Hanley, & Bruzek, 2008; Walker et al., 2018). The NPDC report by Wong et al. (2015) identified studies which included participants diagnosed with ASD between ages 3 and 18 years. Overall, FCT interventions have been found to be very effective when addressing maladaptive interpersonal communication skills in individuals with ASD and ID diagnoses.

Cognitive Behavioral Intervention (CBI)

A combination of cognitive and behavioral approaches resulted in the development of a popular intervention for addressing comorbid anxiety for individuals diagnosed with ASD. Cognitive behavioral intervention (CBI) is grounded in the beliefs that some level of cognition underlies all human behaviors and that human behaviors are purposeful. Modification of the cognition might, therefore, result in observable behavioral changes.

In practice, CBI relies on teaching strategies which assist the client with understanding their own thoughts and emotions. For example, when a client experiences physical symptom of anxiety, CBI is designed to help the client to examine its source. Comorbidity of anxiety disorders in individuals with ASD and ID is very common; according to Steensel, Bögels, and Perrin (2011), about 40% of children diagnosed with ASD have at least one diagnosis of anxiety disorder. Aside from anxiety, CBI was found to effectively address communication, social, and adaptive difficulties (Wong et al., 2015). In fact, the NPDC report identified one single-case design study (Singh et al., 2011) and three group design studies (Drahota, Wood, Sze, & Van Dyke, 2011; Sofronoff, Attwood, & Hinton, 2005; Sofronoff, Attwood, Hinton, & Levin, 2007) whose results suggested that CBI is an effective intervention for individuals between 6 and 18 years of age.

CBI is often implemented by a trained professional who assumes the role of a teacher helping the client to acquire insight and develop strategies addressing maladaptive thoughts and behaviors (Brock, 2013). CBI could be divided into two types of components, cognitive and behavioral. The cognitive components include strategies promoting the client's engagement in problem-solving and self-regulation. Implementation of the cognitive components could be summarized in the following steps (Brock, 2013):

1. Assisting the client to recognize and define the problem.
2. Modeling steps of problem-solving to the client.
3. Generating alternative strategies and substitute behaviors.
4. Evaluating possible consequences of the alternative strategies.
5. Selecting the most suitable strategy.
6. Evaluating the effectiveness of the selected strategy.

The behavioral components include reinforcement and contingency. Implementation of behavioral components could be summarized in following steps (Brock, 2013):

1. Scripting an intervention outline.
2. Identification of reinforcers.
3. Writing up a behavioral contract including a description of the desirable behaviors.
4. Explaining the contract to the client.
5. Rewarding the client for appropriate behavior.
6. Monitoring the client's outcomes.

Implementation of CBI should involve an interactive relationship between the teacher and the client, and the client should assume an active role in the learning process. CBI can also be implemented in conjunction with other interventions (e.g., social narratives) (Brock, 2013). In the implementation of CBI, it is important to take into account the verbal and cognitive abilities of the individual being treated and making adaptations when needed. In many cases of comorbid ASD and ID, CBI would not be the treatment of choice due to the barriers in obtaining insight into their cognitions and behaviors; however, those with mild (and even moderate) intellectual disabilities may benefit from CBI depending on verbal abilities and successful adaptations.

Naturalistic Interventions

Another group of evidence-based treatments commonly used in a population with overlapping ASD and ID diagnoses are naturalistic interventions. Those interventions are based on traditional ABA practices, utilizing behavioral treatment components such as reinforcement and modeling. However, compared to the traditional ABA approaches, naturalistic interventions are more interactive and developmentally oriented (Schreibman et al., 2015) and focus on learning that occurs in the child's natural environment.

Naturalistic interventions build on the ideas of famous developmental psychologists such as Lev Vygotsky and Jean Piaget, who proposed that children are active agents in their environment and that learning is most effectively facilitated through instructional scaffolding. They aim to enhance the naturally occurring learning process through gradual exposure to new skill sets as explained by Vygotsky's Zone of Proximal Development theory (Schreibman et al., 2015). The relationship between the trainer and the client is interactive and fluid, depending on the client's interests, motivation, and achievements. Because of this interactive structure, naturalistic interventions are mainly designed to address difficulties with social behaviors and communication, which are commonly found in individuals with comorbid ASD and ID diagnoses. Clients are also being reinforced for initiative, attention, and progress which further facilitates learning.

Advantageously, naturalistic interventions can be implemented at a very early age regardless of the client's level of language proficiency (Schreibman et al., 2015). In fact, clients receiving naturalistic interventions in early childhood were found to achieve significant improvement in specific learning as well as enhanced ability to generalize the learned knowledge in different situations (Carr & Kologinsky, 1983; McGee, Krantz, Mason, & McClannahan, 1983; McGee, Krantz, & McClannahan, 1985). Children diagnosed with ASD were also found to learn better when associations between the targeted behaviors and reinforces were natural and interrelated (e.g., saying "car" and receiving a car to play with versus saying "car" and receiving a piece of candy for correct labeling of the car; Schreibman et al., 2015; McGee et al., 1985).

Another advantage of naturalistic interventions is that they can be implemented by a broad team including not only the clinicians but also the caregivers, siblings, peers, and teachers. The results of a systematic review done by Trembath, Madler, and Hurdy (2016) support the idea that, for children with several types of disabilities, parents can effectively implement many different naturalistic interventions, leading to improvements in receptive and expressive language skills.

The umbrella of naturalistic interventions includes natural language teaching paradigm, incidental teaching, and pivotal response training (PRT). Natural language teaching paradigm traditionally relies on activities and play during which the trainer models usage of proper language to the client. While incidental learning typically focuses on the promotion of specific communication intent such as making a request for food, Pivotal Response Training takes interest in broader, "pivotal" areas of human development such as skills related to motivation and self-management. Researchers have found that children who underwent Pivotal Response Training exhibited improvements in self-management, engagement in peer interaction and symbolic play, creativity, and joint-attention behaviors (Pierce & Schreibman, 1995; Stahmer, 1995). In one clinical trial, Pivotal Response Training has also been found to be more effective with children diagnosed with ASD than the traditional, structured ABA approach (Mohammadzaheri, Koegel, Rezaee, & Rafiee, 2014).

The effectiveness of naturalistic interventions has been widely researched, meeting the criteria for evidence-based treatment for ID and ASD diagnoses (Wong et al., 2015). Naturalistic interventions were found to be effective in various age groups including preschool-aged children (Ingersoll, Lewis, & Kroman, 2007; Koegel, Camarata, Koegel, Ben-Tall, & Smith, 1998; McGee, Almeida, Sulzer-Azaroff, & Feldman, 1992; Yoder & Stone, 2006), school-aged children (Charlop, Schreibman, & Thibodeau, 1985; Charlop & Trasowech, 1991; Charlop & Walsh, 1986; Koegel et al., 1998; Laski, Charlop, & Schreibman, 1988; McGee et al., 1985), and adolescents (Hamilton & Snell, 1993).

There are four strategies that are key to the teaching style used by naturalistic interventions, which are not commonly present in traditional didactic teaching (McGee et al., 1983). Those strategies include waiting for the child's initiative (e.g., request for a toy), teaching in context of activities enjoyable to the child such as play, usage of stimuli and reinforces selected and preferred by the child, and promotion of language by variation of prompting strategies dependent on the child's initiating behavior (McGee et al., 1983). In addition to these four strategies, steps for implementation include: identifying the target behavior and the intervention setting, collecting baseline data, training the team members, eliciting the desired behavior through environmental rearrangement, and data collection (Franzone, 2009).

Early Interventions

The Early Start Denver Model (ESDM)

The early start Denver model (ESDM) was originally developed by Sally Rogers, Ph.D., and Geraldine Dawson, Ph.D., as an intervention suitable for clients with ASD diagnosis between ages 12 and 36 months (Rogers & Dawson, 2010). The ESDM mainly builds on four intervention approaches designed for ASD clients including the Denver Model, Dawson's social motivation hypothesis of autism, pivotal response training (PRT), and the Rogers and Pennington's model of interpersonal development in autism (Rogers & Dawson, 2010).

Similar to naturalistic interventions, the ESDM is developmentally oriented, based on traditional ABA techniques, and utilizes settings and behaviors natural for the client. However, the focus of the ESDM is more complex, addressing a variety of developmental milestones including imitation, theory of mind, play, verbal and nonverbal language, and other socially relevant abilities (Baril & Humphreys, 2017). The ESDM promotes the acquisition of these abilities through structured and intensive education, which can be modified for the needs and developmental level of the client (Rogers & Dawson, 2010). The individualized ESDM curriculum is then taught through play and activities enjoyable for the client. Components utilized by the ESDM may include prompting, fading, and chaining behaviors.

While naturalistic interventions may be primarily implemented by the caregivers and the teachers, the ESDM has to be implemented by a professional with ESDM training and certification. Implementation of the ESDM may be guided by a multidisciplinary team including psychologists, language pathologists, and physicians. The process of implementation begins with a collection of the baseline data, which provides the starting point for the individualized ESDM intervention. The ESDM Curriculum Checklist is used for the assessment of baseline abilities of the client (Rogers & Dawson, 2010). The client's abilities are typically reassessed in 12-week intervals in order to record and evaluate the client's progress and the effectiveness of the intervention (Rogers & Dawson, 2010). The caregivers may be provided with a specialized Training Manual explaining the ESDM intervention strategies.

The ESDM has a strong empirical basis and has been recommended by the National Research Council (2001) as an effective intervention for toddlers diagnosed with ASD. According to Waddington, van der Meer, and Sigafoos (2016) who created a systematic review of 15 studies with a total of 209 participants, the ESDM has been linked to positive client outcomes for language, cognitive and social skills including initiation, imitation, and attentiveness (Dawson et al., 2010, 2012; Eapen, Črnčec, & Walter, 2013; Estes et al., 2015; Fulton, Eapen, Crnčec, Walter, & Rogers, 2014; Vismara, Colombi, & Rogers, 2009; Vismara, McCormick, Young, Nadhan, & Monlux, 2013; Vismara & Rogers, 2008; Vivanti et al., 2014; Vivanti, Dissanayake, Zierhut, Rogers,, & Team, 2013). Nonetheless, the systematic review reported mixed findings regarding the effectiveness of the ESDM in relation to other adaptive behaviors as well as the severity of ASD symptoms (Waddington et al., 2016).

State Early Intervention Programs

One of the most common resources utilized and available to infants and toddlers with developmental disabilities is the individual states early intervention program. Currently, every state (and eligible territory) in the United States participates in the federal grant Early Intervention Program for Infants and Toddlers with Disabilities (0–3 years of age) which is a component (Part C) of the Individuals with Disabilities Education Act

(IDEA, 2004). Every state is responsible for developing their early intervention program following guidelines regarding structure, evaluation, assessment, and identification; however, in regard to treatment approaches, states differ quite dramatically. Although the goals of these state programs follow those established by Part C of IDEA (enhance development, reduce educational costs, minimize the need for special education and institutionalization, maximize independent living, etc.) the method by which each state works towards these goals can be quite different. Because of these differences, it is not currently possible to describe state early intervention programs as a whole, but rather to discuss individual treatment modalities that various states may incorporate into their state-run early intervention program. However, there are components and concepts that are relatively consistent across all state early intervention programs including eligibility determination, the Individualized Family Service Plan (IFSP), and transition services from early intervention (IDEA-Part C) to special education (IDEA-Part B).

Identification and eligibility are one of the goals at the forefront of state early intervention programs. IDEA requires that each state participates in a type of "Child Find" program that helps to identify and evaluate all children with disabilities between 0 and 21 years of age. While many children with ASD may not be identified in time to receive services in state early intervention programs, those with comorbid ID and ASD are more likely to be identified within this age range and qualify for services. Eligibility for services does vary from state to state and is based on the state's definition of developmental delay. Additionally, some states extend services to those found to be "at risk" for disabilities while others may not.

Once a child is found to be eligible for services, according to state guidelines, all families will receive an Individualized Family Service Plan or IFSP. The IFSP is meant to guide the early intervention process and determine which available services will be most beneficial for the child and their family. For children with ASD/ID these services may vary widely from state to state and the availability of ASD specific programming may be even further limited in many states. One of the major commonalities amongst states provided by Part C of IDEA is the push to provide services in naturalistic environments. This most often takes place in the home but could also take place in other community settings that include children without disabilities. Because of this, states that are providing ASD specific treatments as part of their early intervention programming have leaned away from less naturalistic treatments such as Discrete Trial Training and more towards naturalistic programs such as the Early Start Denver Model or similar programs as well as those that promote parent involvement and parent-child interaction.

Due to the time that it often takes to identify children with disabilities, access to services through the state early intervention program is often short-lived. A final component of these programs is to ensure an effective transition from early intervention programs into special education programs. This period of time is an area in which families often fall into gaps or lapses in service provision either due to differing eligibility criteria from early intervention to special education or due to ineffective transition planning and lack of available resources. An effective transition generally starts 4–6 months prior to the child's third birthday and includes a meeting between the early intervention program, the preschool special education program, and the family and after eligibility is determined an Individuated Education Plan (IEP) is developed to help guide the educational needs of the child into preschool.

Social Skills Training

Severe social impairments are a common concern in the ASD population. Therefore, social skill interventions are essential. Social skills interventions are treatments that focus on social behaviors, such as eye contact, appropriate speech content, and intonation, appropriate motor movements, appropriate facial affect, etc. Without effective intervention, social impairments are likely to become more severe with age (Matson,

Matson, & Rivet, 2007). A study performed by Taheri, Perry, and Minnes (2016) examined the social interaction between developing children and adolescents, those with ID, and those with ASD-ID. The study found that those with ASD-ID participated in fewer social activities than their typically developing peers and peers with ID. Typically developing participants had significantly more friends than participants with ID and ASD-ID. Finally, participants with ID were more likely to have friends or even a best friend compared to the participants with ASD-ID (Taheri et al., 2016). Minimal social interaction is common in individuals with ASD-ID; and, in order to obtain a range of basic social skills, they require intensive instruction (Plavnick, Kaid, & MacFarland, 2015).

Various interventions have been used in the treatment of social deficits in this population. Evidenced-based practices for social skills treatments include self-management, social narratives, and socials skills training. Self-management consists of instructions that focus on teaching learners with ASD to discriminate between appropriate and inappropriate behaviors. The learners are also taught to monitor and record their own behaviors accurately. When the learners behave appropriately they then reward themselves. Self-management has been found effective for learners with ASD ranging from age 3 to 22 (Wong et al., 2015 with specific studies examining its effectiveness).

A study conducted by Newman and Eyck (2005) attempted to teach three participants with ASD self-management skills. The goals were to help them learn to make initiations with others and require less interventionist supervision, and in the study, participants were able to learn to make social initiations to an adult (Newman & Eyck, 2005). Another study found self-management procedures to be effective in reducing inappropriate vocalizations in it participants (Kern, Marder, Boyajian, Elliot, & McElhattan, 1997). Koegel, Koegel, Hurley, and Frea (1992) found that lack of social responsivity can be successfully treated with self-management procedures. This is beneficial in schools, homes, and in the community because it permits less direct contact, is teachable in a short time, and provides relatively quick results (Koegel et al., 1992).

Social narratives were first introduced in 1993 by a former teacher named Carol Gray (Kokina & Kern, 2010) and typically give short descriptions of social situations. Criteria for social narratives must include several types of sentences, such as descriptive, perspective, directive, cooperative, affirmative, and control. The control sentences are written by the child in order to allow for an understanding of the child's own strategies to recall and use information. It is recommended that terms such as "usually," "sometimes," and "probably" be used (Kokina & Kern, 2010). The descriptions may include pictures and other visual aids and the learners are provided with relevant cues and examples of appropriate responding. Learners are also provided with explanations of the thoughts and feelings of others (Sam & Team, 2015). Social narratives have shown to be effective for those with ASD ranging from ages 3 to 18 years (Wong et al., 2015) with studies performed to examine the extent of their effectiveness.

Social narratives, also known as social stories, are one of the most common evidence-based procedures used in treatments for individuals diagnosed with ASD. Teachers who have used this in their classrooms have perceived social narratives to be effective in changing behavior (Leaf et al., 2016). However, meta-analyses have found limitations with research regarding social narratives (Kokina & Kern, 2010; Leaf et al., 2016). Often the studies included other procedures as well, making it difficult to distinguish the effectiveness of social narratives. Leaf et al. (2016) decided to compare one behavior intervention called the "cool vs. not cool" procedure (CNC) and social narratives with an individual diagnosed with ASD and the results indicated that CNC was more effective than social narratives. The data indicates that for the social narratives there were some improvements from the baseline level to the intervention sessions, though the participant never showed more than 80% of the steps correctly (Leaf et al., 2016). Kokina and Kern (2010) conducted a meta-analysis also examining the effectiveness of social narratives and found that social narrative interventions were more effective for targeting behavior reduction compared to teaching social skills.

Social skills training teaches people with ASD how to appropriately interact with others around them. Instructions of basic concepts, such as role-playing and feedback, are often used to help the learners obtain and practice communication and social skills. It is used to promote positive interactions with the learners' peers and has been effective for learners with ASD from age 3 to age 22 (Wong et al., 2015). A combined theory-of-mind and social skills training program was found to greatly improve positive social interactions of the participants across multiple settings (Hua, Ya-yu, Shuling, & Cartledge, 2008). Another study found that young children with ASD showed increased frequency and duration of interactions with typically developing peers after a social skills training. The participants were taught social skills that would be beneficial in sundry situations. Free play was implemented after the training to see if the training procedures were effective (Gonzalez-Lopez & Kamps, 1997). Social skill interventions are important in helping those with ASD-ID function in their lives. Self-management, social narratives, and socials skills training are just a few of the evidenced-based practices that are used to help individuals with ASD-ID. Overall, social skill interventions have been found effective in helping those with ASD-ID improve their social skills.

Language Training

Computer-Aided Instruction (CAI)

Computer-Aided Instruction (CAI), falling under a broader category of evidence-based treatments called Technology-Aided Instruction and Intervention (TAII), has been developed as an instructional method promoting the development and facilitation of interpersonal communication in individuals diagnosed with ASD and ID. CAI has been primarily designed to assist school-aged children, addressing school-readiness, academic skills, and communication. Traditionally, the implementation of CAI is led by a team including the caregivers, clinicians, and the school staff. Through the usage of a computer, CAI aims to provide the learner with systematic instructions, making the learning process easier and more achievable (Collet-Klingenberg, 2009). Various CAI programs are available on the market, depending on the learner's age and targeted skill. The following steps of CAI implementation were discussed by Collet-Klingenberg (2008):

> *Identification of the targeted skill to be learned (e.g. increased vocabulary), Collection of the baseline data, Identification, installation, and familiarization with an appropriate software, Competition of a task analysis of steps for using the selected software, Introducing the learner to software, Providing the learner with multiple opportunities to use the computer and ongoing support, and Collecting data on the acquisition of the target skill.*

The effectiveness of CAI itself has been supported by six studies, which included participants between preschool and middle-school ages with a variety of communication problems and language delays (Bosseler & Massaro, 2003; Hetzroni & Shalem, 2005; Hetzroni & Tannous, 2004; Massaro & Bosseler, 2006; Moore & Calvert, 2000; Silver & Oakes, 2001).

Nevertheless, since the number of treatments utilizing modern technologies expanded in recent years, CAI has been included into a broader Technology-Aided Instruction and Intervention (TAII) evidence-based category (Wong et al., 2015). TAII relies on the use of an electronic device, including computers, tablets, smartphones, and other technology, which can assist individuals diagnosed with ASD. The idea that an ASD population benefits from using modern technologies has been supported by 20 group-design and case studies (Beaumont & Sofronoff, 2008; Choi, O'Reilly, Sigafoos, & Lancioni, 2010; Cihak, Wright, & Ayres, 2010; Faja, Aylward, Bernier, & Dawson, 2007; Stromer, Mackay, Howell, McVay, & Flusser, 1996; Whalen et al., 2010).

Speech Generated and Communication Devices

Another sub-category of TAII evidence-based treatments suitable for individuals with comorbid ASD and ID diagnoses is Speech Generated and Communication Devices (SGCD). SGCD include a variety of electronic, portable devices whose aim is to assist the individual with daily communication. This is done through synthetic speech produced by the device across different settings. Franzone and Collet-Klingenberg (2008) discussed the following steps for implementation of SGCD:

> *Identifying and setting up the device, Identification of settings where the device will be initially used, Identification of the appropriate vocabulary, Introduction of the device to the learner, Providing as few prompts as the learner requires, Honoring the communication, Reducing prompts as soon as possible, Increasing the number of settings where the SGD is used, and Increasing vocabulary.*

Skills that were found to be effectively addressed by SGCD are the initiation of conversation, expressive language, nonverbal language, reading, and mathematics (Franzone & Collet-Klingenberg, 2008). In fact, the utility of SGCD for school-aged children has been widely supported (Olive et al., 2007; Olive, Lang, & Davis, 2008; Parsons & La Sorte, 1993; Van Acker & Grant, 1995).

Picture Exchange Communication System (PECS)

The Picture Exchange Communication System (PECS) is an augmentative communication system that uses pictures/icons (Ganz, Davis, Lund, Goodwyn, & Simpson, 2012). It is used to help initiate communicative exchanges and interaction for those with limited functional communication skills within a social context (Sam & AFIRM Team, 2016). PECS is designed to help learners with autism and other developmental disorders. It has been predominately used with children, specifically preschool-aged children (Ganz et al., 2012). There are six phases of training and they get progressively more complex. Learners with severe ASD are often only taught the first three phases (Carre, LeGrice, Blampied, & Walker, 2009; Ganz et al., 2012). While PECS is primarily picture-based, it does use sentence strips combined with pictures in more advanced phases. This is to increase complexity and potential utility of communication. It is suggested that PECS is particularly well-suited for those with ASD because of its primarily visual nature. PECS attempts to reduce the uncertainty in communication for those with ASD by using symbols that have a one-to-one ratio correspondence with objects, people, and concepts (Ganz et al., 2012). Ganz et al. (2012) also states that along with the reduction of ambiguity in communication, there is also an opportunity for recognition of meaning instead of requiring recall.

Many single case research designs have found PECS is indeed effective in improving communication skills in individuals with ASD. Not only has it been found to be effective, but for some learners PECS has also been found to be *more* effective than other forms of alternative and augmentative communication (AAC). PECS has also been found to be more effective than other forms of picture-based AAC and just as effective as speech generating devices (SGDs) (Ganz et al., 2012). PECS is a beneficial treatment in helping learners with ASD and other developmental disabilities improve their communication skills.

Parent and Peer Interventions

In addition to the many interventions used for children with ASD-ID diagnoses, two effective treatments to implement in the home or at school are Parent-Implemented Intervention (PII) and Peer-Mediated Instruction and Intervention (PMII). The emphasis on these two types of interventions is based on research indicating four characteristics of efficacious interventions for the treatment of infants and younger children with a developmental disability such as autism or intellectual/developmental delay. The characteristics described by Wallace and Rogers (2010) include:

1. Parent involvement in interaction such as continuous coaching and sensitivity to cues provided by the child.
2. Individualized intervention planning tailored to the child's specific needs.
3. Attending to a broad range of targeted stimuli.
4. Providing treatment as early in the lifespan as possible and providing treatment at least once per week for an extended duration.

Based on these qualities of an effective intervention, PII meets all of these criteria in addition to added benefits such as decreased family stress (Koegel & Schreibman, 1996). Parent-implemented intervention is a form of behaviorally based intervention in which the clinician helps to teach the parent(s) ways in which they can help their child improve specific behaviors outside of the office. With parents being the identified "agents of change," it allows the child to generalize their gains across multiple settings, the parent is able to implement the intervention(s) throughout the day, it provides the parent with a greater sense of success, it is more cost-effective, and it has even been shown to have improved gains (Ingersoll & Gergans, 2007).

The majority of the current literature on PII has focused predominantly on socially based interventions such as social communication and imitation. For example, when looking at outcomes of parents that have been coached and received reciprocal imitation training (RIT), children's correct use of imitation and descriptive language increased significantly (Zaghlawan & Ostrosky, 2016). Similarly, children whose parents received RIT and were implementing PII generalized their object imitation skills to the homes and parents reported that their child's social-communication skill had improved (Ingersoll & Gergans, 2007). Children also will experience greater gains in verbal skills, communication and daily living skills, and social communication skills when provided with individual parent-provided early social interaction in which parents are trained on ways to improve and increase the interactions with their nonverbal children with ASD (Wetherby et al., 2014). In addition to these treatments being effective for improving symptoms of ASD, PII has also been shown to be effective in treating children with developmental delays or intellectual disabilities to help improve language (Akamoglu & Meadan, 2018).

Not only have treatments been developed to be implemented by parents; peer interventions have also been shown to be effective in treating social symptoms of children with diagnoses of ASD and ID. Peer-mediated intervention (PMI) is described as a treatment that teaches typically developing peers ways to interact and increase social skills in children with a primary diagnosis of ASD (Płatos & Wojaczek, 2018). This type of treatment is beneficial in the development of social skills because most children with a diagnosis of ASD typically spend most of their time engaged in solitary play and struggle to form peer relationships. By implementing PMI, peers are taught either by trained teachers or research assistants how to use strategies such as inviting the child to play, offering assistance, offering to share, and demonstrating warmth to the child with the primary ASD diagnosis (Katz & Girolametto, 2013). This form of treatment, which has been shown to be effective across childhood, from preschool to middle school, is beneficial because it allows the child to interact with his or her same-aged peers in their natural setting (Collet-Klingenberg, Neitzel, & Laberge, 2012; Katz & Girolametto, 2013). In addition to having frequent peer interactions which provide the child with a sense of social support, research has also suggested that increased regular social interaction leads to better verbal skills as well as nonverbal skills (Allen & Marshall, 2011; Laski et al., 1988). This form of treatment can be modified for ASD/ID children by training typically developing peers on how to interact with simpler verbalizations and allow greater response time for the child. By making these modifications, an ASD/ID child can see improvements in nonverbal and verbal skills and will likely have a greater self-concept because they are increasing their social group (Agaliotis & Kalyva, 2008).

Implications and Future Directions

The treatment of ASD in the context of ID has been the focus of many child and developmental disability researchers for several decades. Many of the interventions discussed throughout this chapter were developed for infants, toddlers, and school-aged children with comorbid ASD and ID and the science supporting these treatments show promising results. The current status of the field, however, requires greater focus on the aging population of individuals with ASD and ID. Very few interventions have been developed targeting adults or even adolescents and the transitions between various phases of life are an area that interventionists and support programs have failed to successfully address. While many have attempted to adapt programs to fit the needs of adolescents and adults (and some rather successfully) further research and resources should be targeting the appropriate care of this aging population.

Though the ASD and ID treatment and support community has come a long way from the days of mass institutionalization, integration into our communities continues to be a challenge. While acceptance by employers and community members has continued to grow, appropriate support programs and legislation continue to be grossly deficient. Further program development should continue to focus on the development of work training, supported independent living, and community integration programs that are individualized to the needs and abilities of the individual. Although many such programs exist, very few have the ability to be tailored to the individual and can place unrealistic expectations and goals on the client (e.g., teaching a nonverbal adult how to manage personal finances who has not mastered counting).

Finally, treatment services for those with ASD and ID have traditionally centered around major medical universities and hospitals in urban areas; however, a large portion of this population (and possibly even the majority) live in rural area. Access to appropriate services continues to be lacking including not only treatment and support services but even diagnostic services. Further research and resources should be focused on the delivery of evidence-based interventions and services to these rural populations and may include existing technologies such as telehealth, monitoring and support systems, and cell phone apps.

Since appropriate and timely intervention in the early years of the individual's life may contribute to a reduction in severity of ASD and ID symptoms, the need for effective, evidence-based treatments suitable for this population is paramount. Even though a majority of the evidence-based treatments discussed in this chapter have been designed for and studied on preschool and school-aged children, adolescent and adult clients would likely benefit from those programs as well. More research is, however, needed to validate the effectiveness of the discussed treatments for a variety of age groups and adaptations will likely be necessary dependent on the individual client.

ADHD in Individuals with Intellectual Disability

Laura Flanigan, Emma A. Climie, Christina Gray, and Cristina Fernández Conde

Individuals with intellectual disabilities (ID) may be impacted by any number of other comorbid conditions. Indeed, those with ID may be at greater risk for co-occurring conditions such as autism spectrum disorder, learning disorders, mental health concerns, and/or other physical impairments. More recently, researchers and practitioners have become aware that individuals with ID can also be affected by attentional disorders, such as Attention-Deficit/Hyperactivity Disorder (ADHD).

This chapter will provide an overview of ADHD and ID, with a specific emphasis on both the overlap and the distinctions between the two disorders. We will begin with brief descriptions of ADHD and ID diagnoses and continue with a summary of current literature surrounding the strengths and challenges of those with a combined ID/ADHD diagnosis. The majority of the chapter will focus on reviewing and describing evidence-based recommendations and suggestions for treatment and support. Specifically, we will highlight supports in a number of domains, including social interaction, behavioral interventions, academic recommendations, adaptive challenges, and in other more general supports for adults. We will conclude by highlighting some areas of continual need for those with ID/ADHD as they transition into adulthood.

Attention-Deficit/Hyperactivity Disorder

ADHD is a neurodevelopmental disorder that is characterized by persistent symptoms of hyperactivity, impulsivity, and/or inattention that affect an individual's ability to adapt to his or her environment (American Psychiatric Association, 2013). Attention encompasses a series of mental operations that allow individuals to focus, encode, disengage, and shift their focus from diverse stimuli in their environment (Seidman, 2006). Inattention, or the lack of attention, can be observed behaviorally by disengagement with presented tasks, issues with persistence, and challenges organizing or understanding information (APA, 2013). Inattentive children may be prone to careless mistakes, losing their belongings, and missing relevant information when they are involved in play and schoolwork (Friedberg & McClure, 2015). Those who present with the hyperactive component of the disorder display inappropriate motor activity, which can present as fidgeting, garrulousness, and continual movement (APA, 2013). Impulsivity becomes evident in actions undertaken without consideration of

the environment and consequences that could result in harm (APA, 2013).

According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5), three main subtypes of ADHD are identified: predominantly inattentive presentation, predominantly hyperactive/impulsive presentation, and combined presentation (APA, 2013). Those with the predominantly inattentive presentation must demonstrate six or more inattentive behaviors (five or more if the individual is over the age of 17 years or an adult), such as lack of attention to detail, lack of sustained attention, failure to complete tasks or follow through on instructions, loses things (e.g., keys, books, pencils), or is frequently forgetful. Those with the predominantly hyperactive/impulsive presentation must demonstrate six or more hyperactive/impulsive symptoms (five symptoms for adolescents/adults), such as fidgeting, tapping, playing loudly, difficulty waiting, talking excessively, interrupting others, or blurting out answers. If an individual meets the diagnostic criteria for both inattentive and hyperactive/impulsive presentations independently, then a combined presentation diagnosis is warranted.

Identification of an ADHD subtype requires thorough observation or report of the core symptoms of inattention and hyperactivity/impulsivity to verify they are negatively impacting the individuals functioning. According to the DSM-5, symptoms must be present before age 12 years and can persist throughout the life span (APA, 2013). As well, it is noted that the challenges derived from the observed symptoms must interfere with the person's functioning in at least two settings (e.g., home and work or home and school) to ensure that there is continuity in symptom presentations and that the behaviors are not simply environmentally controlled (APA, 2013). Finally, the severity of symptomatology (e.g., mild, moderate, or severe) can also be specified (APA, 2013).

Historical Background

Symptoms of what is now referred to as ADHD were first described in 1775 in a chapter by physician Melchior Adam Weikard (Barkley & Peters, 2012). Decades later, Alexander Crichton described a child who could not control himself (Taylor, 2011). Although single cases were described in the literature, it was not until the beginning of the nineteenth century that Benjamin Rush focused on the description of impulsive behavior and lack of control in children (Nigg & Barkley, 2014; Taylor, 2011). Years later, Frederick Still provided significant description of behavior that can be linked to ADHD by describing children with difficulties in inhibitory behavioral control and attention (Taylor, 2011). He was also one of the first to identify higher prevalence in males than females (Barkley, 2014). Tredgold provided further insight on this area by highlighting that through medication and environmental changes, behavioral improvements could be observed (Barkley, 2014).

Many children that survived the encephalitis epidemic of 1917 presented with disruptive behaviors and symptoms similar to those described for ADHD. Thus, doctors started describing these children as having "postencephalitic behavior disorder" (Barkley, 2014). At this time, heightened interest existed in understanding the link between disruptive behaviors and brain dysfunction. By focusing on brain damage in the early twentieth century, ADHD became known as Minimal Brain Dysfunction (MBD) as part of a conceptualization that considered the possibility of the existence of a unitary syndrome of brain damage in young populations (Barkley, 2014; Nigg & Barkley, 2014).

In 1968, the *Diagnostic and Statistical Manual of Mental Disorders, Second Edition* (DSM-II) included a disorder called hyperkinetic reaction of childhood. In the late 1960s, questions began around understanding hyperactivity through brain damage, ultimately resulting in a shift towards considering behavioral symptoms to describe hyperactivity (Barkley, 2014). Furthermore, evidence was provided to suggest that there was not always neurological evidence to suggest the diagnosis of hyperkinesis (Barkley, 2014). It was postulated that hyperactivity could be linked to intellectual disabilities, brain damage, and psychotic disorders and other serious mental illnesses. At this point, it was believed that hyperactivity was outgrown by adolescence (Barkley, 2014).

Wender, at the beginning of the 1970s, brought to attention that individuals with hyperactivity also presented with a short attention span, impulsivity, difficulties in concentration, and challenges with learning and impulse control. However, seminal work by Virginia Douglas suggested that difficulties with attention and impulse control represented considerable challenge for hyperactive children above and beyond hyperactivity itself (Barkley, 2014). Through follow up studies, extreme variability in performance in this population was demonstrated and it was found that challenges with sustained attention and impulse control persisted into adulthood (Barkley, 2014). With the changes in research trends, Hyperkinetic Reaction of Childhood was renamed Attention Deficit Disorder (ADD) in the *Diagnostic and Statistical Manual of Mental Disorders, Third Edition* (DSM-III; Nigg & Barkley, 2014). The change in terminology showed a shift in the conceptualization of the disorder by focusing on its psychological components rather than unknown neurological causes (Taylor, 2011). Further research on ADD started showing the impact that culture, environment, and a multidisciplinary approach to treatment (e.g., use of behavioral management interventions, medication, and parent training to treat ADD) had on the affected population (Barkley, 2014).

In the revised version of the DSM-III (DSM-III-R), factor analysis indicated the presence of three symptom groups: inattention, hyperactivity, and impulsivity (Barkley, 2014; Nigg & Barkley, 2014). Thus, the hyperactive impulsive components of the disorder were highlighted by renaming the condition attention-deficit/hyperactivity disorder (Nigg & Barkley, 2014). The diagnosis further specified whether hyperactivity was present or not (e.g., ADHD with or without hyperactivity; Barkley, 2014).

Significant progress in neuroimaging and genetic research led to the fourth edition of the DSM (DSM-IV; APA, 2013) being the strongest empirical set of criteria of ADHD (Barkley, 2014). In the most current DSM edition (DSM-5; Nigg & Barkley, 2014), changes were made to include environmental considerations and symptom counts that accounted for the challenges associated with a late adolescence or adult diagnosis (Barkley, 2014). In the twenty-first century, the study of ADHD focuses not only on attention and hyperactivity-impulsivity but also in understanding comorbidity (Barkley, 2014) and executive functions, which are relevant cognitive abilities thought to underlie ADHD (Nigg & Barkley, 2014).

Etiology and Epidemiology

Etiology. There are several etiological explanations for ADHD. The disorder is highly heritable (APA, 2013), suggesting that those with relatives with ADHD are more likely to develop the disorder. Neurologically, the frontostriatal model of ADHD has focused on understanding ADHD as a disorder that affects the prefrontal cortex, a part of the brain responsible for executive control and behavioral regulation (Seidman, 2006). This theory gathered substantial support when some studies reported a smaller prefrontal cortex in children with ADHD, as well as a slight asymmetry between the left and right prefrontal cortex (Krain & Castellanos, 2006). Research has also focused on structures that have been linked to attention (cerebellum), motor control (putamen), coordination of executive functioning (basal ganglia), and white and gray matter development (Krain & Castellanos, 2006).

Currently, although there is no core consensus on the definition of executive functioning (EF), it is generally understood as an overarching control mechanism of high-order activities that encompass several subprocesses such as working memory, inhibitory control, selective attention, planning, and problem-solving (Castellanos & Tannock, 2002; Lambek et al., 2011; Miyake et al., 2000). For individuals to regulate their behaviors and organize EF, inhibitory response is especially relevant (Castellanos & Tannock, 2002). Based on this idea, Barkley hypothesized executive dysfunction as being the primary deficit in ADHD (Castellanos & Tannock, 2002). In this theory, Barkley theorized that self-regulation is dependent on the inhibition of behavioral responses through four EF components: verbal and nonverbal working memory, self-regulation of affect, motivation and arousal, and effective analysis and synthesis of behavior (Nigg & Barkley, 2014). Disinhibition and impairment in the above-mentioned EF areas affect motor responses and adaptive functioning negatively by impairing self-regulation (Nigg & Barkley, 2014).

Prevalence. Due to its neurodevelopmental nature, ADHD affects individuals over the course of their life (Abecassis, Isquith, & Roth, 2017). Estimates suggest that ADHD affects approximately 5% of school-aged children (APA, 2013; Steinberg & Drabick, 2015), making it one of the most common mental disorders in youth (Takeda, Ambrosini, deBerardinis, & Elia, 2012). The DSM-5 estimates a prevalence of 2.5% in adulthood (APA, 2013). However, prevalence rates vary in different regions of the world depending on age, with rates varying from 4 to 21% in young adults (Abecassis et al., 2017). With regards to gender, prevalence in childhood is higher in males than females (approximately 3:1 ratio), but this proportion evens out during adulthood (Nigg & Barkley, 2014).

Diagnostic methods. The primary form of diagnosis of this disorder relies on clinical judgements that are based on observations, behavioral rating scales completed by the individual and those around him/her (e.g., parents or teachers), as well as standardized measures (Climie, Mah, & Chase, 2017; Mueller, Hong, Shepard, & Moore, 2017). Based on the findings, a clinician or pediatrician may specify a predominantly inattentive, hyperactive/impulsive, or combined presentation of the disorder. To help increase diagnostic accuracy regarding ADHD, current research has focused on increasing understanding of anatomical (Krain & Castellanos, 2006) and neural circuits that could support a more specific classification of the disorder (Mueller et al., 2017) in addition to furthering the understanding of the behavioral connections to ADHD.

Developmental Presentation

It is important to study the presentation of ADHD over the life span to fully understand its characteristics and impact in different life stages, including early childhood, adolescence, and adulthood. Although the DSM-5 does not prohibit the diagnosis of ADHD prior to age 4 years, the validity of a diagnosis at such an early age is contentious (Nigg & Barkley, 2014). Most individuals with ADHD are identified at eight to 12 years of age (Nigg & Barkley, 2014). Children diagnosed with ADHD have difficulties with sustained attention (Mueller et al., 2017), working memory, and processing speed (Koziol & Budding, 2012). In a school setting, numerous studies show that students with ADHD tend to be disruptive, have difficulty staying on task, move around constantly, interrupt their teacher and peers, and are prone to leaving their seat without permission (Gaastra, Groen, Tucha, & Tucha, 2016). Furthermore, childhood ADHD can result in familial stress, and parents of children with ADHD are prone to feel less competent in their roles (Barkley et al., 2000). Thus, they are often faced with social, cognitive, familial, and occupational difficulties throughout their lives (Harvey, Breaux, & Lugo-Candelas, 2016; Nigg & Barkley, 2014).

Elevated levels of inattention and/or hyperactivity and impulsivity frequently persist into adolescence (Sibley, Kuriyan, Evans, Waxmonsky, & Smith, 2014). Challenges in social and family interactions are still present in this stage (Sibley et al., 2014). Adolescents with ADHD are at greater risk of substance abuse (Charach, Yeung, Climans, & Lillie, 2011) and risky driving practices (Thompson, Molina, Pelham, & Gnagy, 2007). For some adolescents, treatment adherence to medication is challenging and behavioral training and therapy may not be as effective as in childhood, due to adolescent or parental disengagement (Sibley et al., 2014).

Young adults with ADHD often experience numerous challenges as a result of reduced supervision and a cognitively demanding environment. Executive functioning challenges affect their academics and they may engage in risky sexual behavior (Abecassis et al., 2017). Research has shown that adults with this diagnosis tend to have job-related difficulties and family and peer conflict are still present (Magnin & Maurs, 2017). It is important to highlight that symptomatology can improve through the implementation of an appropriate treatment plan.

Intellectual Disability

The term *intellectual disability (ID)* refers to a neurodevelopmental disorder characterized by deficits in general mental abilities that result in impairments in adaptive functioning (APA, 2013). For example, an individual with intellectual disability may present with deficits in mental reasoning, problem-solving, abstract thinking, planning, and learning from academics and/or experience (APA, 2013). These general mental deficits impact daily adaptive functioning to the extent that the individual is unable to meet standards of independence and responsibility, including in the areas of communication, academic or occupational functioning, and independent living at home or in their community. Onset of ID must occur during the developmental period in an individual's life. Previously, ID has been referred to using other terms, such as *mental retardation* and *intellectual developmental disorder* (APA, 2013). At present, the term ID is most commonly used by medical professionals and across public professions (APA, 2013; World Health Organization, 2009).

Historical Background

There have been numerous changes in the conceptualization and terminology relating to ID. Historically, the term *mental retardation* (MR) was used to refer to a cluster of disorders characterized by low intelligence and associated limitations in adaptive behavior function (Carulla et al., 2011). Initially, the World Health Organization (WHO) revised the *International Classification of Diseases and Related Health Problems, Eleventh Revision* (ICD-11) to reflect updated clinical research, frameworks, and further advance a unified global classification system relating to the previously termed MR syndromes (World Health Organization, 2009). The ICD-10 conceptualization of MR was replaced with the concept of *intellectual developmental disorders* (IDD) in ICD-11 (Carulla et al., 2011). This shift away from MR towards ID has occurred not just with the ICD-11 but also in policy and legislation in many developed countries (Carulla et al., 2011).

The DSM-5 classifies ID under the neurodevelopmental disorders family (APA, 2013). Previous editions of the DSM included MR, which was later changed to align with ICD and other organizations shifting to the label ID (Mahour & Panday, 2015). The current DSM-5 criteria for ID now encompasses a focus on impact on the individual's cognitive, social, and practical adaptive functioning as well as a decreased reliance on low intelligence quotient (IQ) scores (i.e., standard score ≤ 70 on a standardized intelligence test) to rule-in a diagnosis (Mahour & Panday, 2015). These changes in the diagnostic criteria of ID in the DSM place greater emphasis on adaptive reasoning in the individual's academic, social, and practical settings rather than focusing primarily on the individual's IQ score (Mahour & Panday, 2015). The historical views of ID have progressed to allow for a less stigmatizing terminology and view towards the disorder. These changes in conceptualization of ID have been adopted across dominant tools used to guide clinicians with diagnostic processes as well as shift ID associated administrative and legislative policies.

Etiology and Epidemiology

Etiology. The causes of ID are broad and variable; however, experts generally agree that there are six categories that cover the majority of ID cases: genetics, pre-, peri-, and post-natal difficulties, illness, and environmental factors

(Mouzakitis, 2012). Approximately 5% of ID cases are caused by genetic abnormalities. Other causes include pre-, peri-, and post-natal difficulties, including improper development or injury in utero, lack of oxygen during birth, and childhood diseases such as chicken pox or measles (Mouzakitis, 2012). General illness or health concerns, such as meningitis or malnutrition, can cause IDs. Lastly, IDs can be caused by environmental factors, such as lack of stimulation caused by neglect (Mouzakitis, 2012). It is important to determine the cause of the ID, as the root cause may result in additional difficulties that also need treatment (Mouzakitis, 2012).

Prevalence. ID has a general population prevalence of 1% in high-income countries, with prevalence rates varying by age (APA, 2013; Maulik, Mascarenhas, Mathers, Dua, & Saxena, 2011). In low income countries, the prevalence is around 2% (Durkin, 2002). The prevalence for severe ID is approximately 6 per 1000 individuals (APA, 2013). The highest rates of ID have been found in lower to middle-income countries, which presents challenges in terms of resource limitations (Maulik et al., 2011). Among adults with ID, there is a widely varying prevalence of comorbid psychiatric illness that affects between 10% and 39% of individuals, depending on the diagnostic criteria used (Deb, Thomas, & Bright, 2001).

Diagnostic methods. ID is typically identified through the use of standardized intelligence measures, such as the Wechsler Adult Intelligence Scale (WAIS; Corporation, 2008) or the Stanford-Binet (Roid, 2003), as well as an assessment of adaptive skills, such as the Vineland Adaptive Behavior Scale (Sparrow, Cicchetti, & Balla, 2005). Previously, under the guidelines of the DSM-IV, ID was identified solely through IQ determined by a cognitive assessment (APA, 2013). An individual could be identified as intellectually disabled if they achieved an IQ two standard deviations below the population mean (APA, 2013). For example, if the WAIS has a population mean of 100 and a standard deviation of 15, an individual would be considered intellectually disabled if they achieved an IQ of 70 or below on this scale (APA, 2013). It is now recognized, however, that adaptive skills are just as, if not more, important than IQ in identifying IDs. The DSM-5 (APA, 2013) assesses the severity of an ID (mild, moderate, severe, profound) based on an individual's ability to complete age-appropriate skills in the conceptual (e.g., literacy), social (e.g., developing appropriate relationships), and practical (basic hygiene) domains.

Developmental Presentation

ID is a disorder that continues throughout the life span of the affected person (APA, 2013). Individuals with ID follow similar sequences of cognitive development as typically developing individuals with respect to their progression of cognitive problem-solving, reasoning, and understanding abilities. However, the progression of these stages tends to stop earlier than those without ID, prior to completion of progression in conceptual development (Harris, 2006). An individual who is appropriately diagnosed with ID will continue to be intellectually disabled throughout her or his life span, experiencing a failure of typical cognitive progression (Harris, 2006). Early cognitive development tends to be more universal and neurobiologically based, while later, more complex cognitive development may vary with social and cultural experiences for the individual with ID (Harris, 2006). Understanding the contributory conditions (e.g., genetic/familial causes, brain damage) that result in ID may be useful with determining appropriate personal supports and focused education to support the individual's needs through adolescence, adulthood, and elderly years.

Contrary to misconceptions surrounding ID, many individuals with ID live to old age, continue to work, and in many instances can live independently and make contributions in their communities (Harris, 2006). Some individuals with ID may experience premature aging, shortened life expectancy, and poor health, particularly those with severe ID and multiple disabilities (Harris, 2006). Individuals with ID tend to have a lower capacity for self-determination, independent functioning, and limitations with work and social environments, adaptations allow them to meet their potential as they age (Harris, 2006).

Co-occurring ID and ADHD

Individuals with ID are at significant risk of developing comorbid psychiatric conditions. The most common comorbid mental disorder experienced by those with ID is ADHD (Baker, Neece, Fenning, Crnic, & Blancher, 2010). However, it was only recently that it became acceptable to diagnose these two disorders simultaneously. Historically, it was believed that an individual with ID could not also have ADHD, as any inattentive, hyperactive, and/or impulsive symptoms were largely the result of the more global mental impairment associated with ID (Ahuja, Martin, Langley, & Thapar, 2013). Additionally, and for similar reasons, the majority of research on ADHD has excluded participants with lower cognitive functioning (Lindsey, 2002). This phenomenon, known as "diagnostic overshadowing," where symptoms of one disorder are explained away by the presence of another (Fuller & Sabatino, 1998), has led not only to considerable under-diagnosis of ID with comorbid ADHD, but also a dearth of research examining this population (Ahuja et al., 2013). The following section will outline what is known about the etiology/epidemiology, presentation, and primary concerns among individuals with co-occurring ID and ADHD.

Etiology and Epidemiology

Etiology. Individually, ADHD and ID both have strong genetic components (APA, 2013). No studies have examined the shared genetic variance among those with ADHD and ID; however, Aureli et al. (2010) found that specific polymorphisms of the brain-derived neurotrophic factor (BDNF, polymorphisms Val66Met and 270 C/T) are significantly associated with both ADHD and ID, and are overrepresented in these populations compared to controls. This finding suggests that these BDNF polymorphisms could play a role in the comorbidity between ADHD and ID. Kuntsi et al. (2004) found that 100% of the variance between ADHD diagnosis and IQ was the result of shared genetics.

Epidemiology. As mentioned, the most common psychiatric condition associated with ID is ADHD (Baker et al., 2010). Depending on methodological variables, ADHD is associated with ID in 8–39% of cases (Baker et al., 2010; Dekker & Koot, 2003), notably higher than that expected in individuals without ID (approximately 5–7%; APA, 2013). Voigt, Barbaresi, Colligan, Weaver, and Katusic (2006) found an odds ratio of co-occurring ADHD with versus without ID to be 6.3, suggesting that those with ID are at a higher risk of also having ADHD. Both ADHD and ID, individually, occur much more frequently in males than females (APA, 2013); however, it is not known how this compares to populations with co-occurring ADHD and ID, although it is likely that ID/ADHD is more prevalent in males.

Presentation

To be diagnosed with ADHD in addition to ID, the individual must display symptoms of inattention, hyperactivity, and/or impulsivity over and above what would be expected from someone with ID alone (APA, 2013). Additionally, as per the diagnostic criteria for ADHD, the individual must display these symptoms in multiple settings, have displayed these symptoms since before age 12, and experience significant impairment in multiple domains of functioning as a result of the symptoms of ADHD (APA, 2013). Individuals with ID who meet criteria for ADHD may represent a distinct group in terms of their presentation and associated comorbid conditions.

Symptomology. Ahuja et al. (2013) found that children with both ADHD and ID had significantly lower IQs than those with ID-only. Interestingly, research suggests that there are no differences in the total number of ADHD symptoms displayed by those with ADHD and ID

(Ahuja et al., 2013; Johnson, Lubetsky, & Sacco, 1995), or in the presentations of ADHD (e.g., predominantly inattentive or hyperactive-impulsive; Baker et al., 2010) compared to ADHD-only. However, Neece, Baker, Blacher, and Crnic (2011) found that ADHD diagnoses appeared earlier and remained more stable among children with ID than without ID. Interestingly, individuals with ADHD and ID may be less responsive to medication and experience more side effects than those with only ADHD (Hässler & Thome, 2012).

Additional comorbid conditions. Ahuja et al. (2013) found that youth with both ADHD and ID, compared to youth with only ADHD and only ID, had higher symptoms and diagnoses of Oppositional Defiant Disorder (ODD) and Conduct Disorder (CD), potentially due to the increased level of impulsivity and lower social skills among those with ADHD/ID. Children with ADHD and ID were similar in their symptoms and diagnoses of depression and anxiety, compared to those with ADHD-only and ID-only. However, Aman, Armstrong, Buican, and Sillick (2002) found that adolescents with ADHD and ID had increased rates of separation anxiety disorder than those with ADHD only.

Primary Concerns

It is recognized that individuals with both ID and ADHD experience a "double deficit," whereby they experience significantly more impairment in functioning than either ADHD or ID alone (Carmeli, Klein, & Sohn, 2007). Specifically, Pearson et al. (2000) found that adolescents with ID and ADHD experienced significantly more depression, family conflict, defiance, anxiety, social skill deficits, and academic difficulties than adolescents with ID without ADHD. Carmeli et al. (2007) compared males with ID, ADHD, and co-occuring ID and ADHD and found that those with co-occurring ID and ADHD had significantly higher impairment in social skills than those with ID or ADHD only. Youth with ID and ADHD tend to have greater rates of behavioral problems than those with ADHD or ID alone (Aman et al., 2002; Carmeli et al., 2007). Additionally, hyperactivity among adolescents with ID is associated with bullying and violent behavior (Reiter, Bryen, & Shachar, 2007). Interestingly, Di Nuovo and Buono (2007) described that the co-occurrence of ID with ADHD has less of an impact on motor skills, verbal communication, and visual spatial skills than it does on areas that require judgment, reasoning, and memory. They did not find any differences in adaptive functioning between those with both ID and ADHD and ID only.

Treatment of Individuals with ID/ ADHD

This section outlines a number of areas in which those with ID/ADHD may benefit from treatment or support. Although the following intervention suggestions are not exhaustive, they may provide practitioners and families with some guidance as to how to support those with co-occurring ID/ADHD. This section specifically outlines evidence-based interventions related to four key domains: social, behavioral, academic, and adaptive support. Additionally, we have included a final section that notes a number of other interventions that may be beneficial specifically for adults with ID/ADHD.

Social Interventions

The development of appropriate peer interactions is one area in which those with ID or ADHD may have difficulties. For example, those with ID often struggle to engage conversationally with their peers, as their ability to keep up with or discuss age-appropriate topics may be limited by their cognitive skills. For those with ADHD, the inattentive and impulsive symptoms associated with the disorder may frequently impact a child's ability to follow a conversation or provide meaningful input at appropriate times (i.e., without blurting out or interrupting others). Together, when individuals are impacted by the challenges associated with both ID and ADHD, the social difficulties may multiply. Consequently, these individuals may not only struggle to find areas of common ground with peers, but may also have difficulties with the social norms related to conversational turn taking.

Broadly speaking, having close relationships with others and meaningful social interaction is linked to emotional well-being (Emerson & McVilly, 2004). Furthermore, within the ID population specifically, peer friendships have been found to be related to a number of additional beneficial outcomes, including increased adaptive skills and lower levels of severe behaviors (Kozma, Mansell, & Beadle-Brown, 2009). Those with ADHD are also known to have social challenges, with making and maintaining appropriate peers relationships among the primary concerns noted by parents and teachers (e.g., Hoza, 2007). Given the necessary link between social skills and peer relationships, those with ID/ADHD may benefit from additional social supports that may allow them to build skills and, more importantly, apply these skills consistently, effectively, and appropriately.

Building appropriate peer relations. One area in which children with ID/ADHD may benefit from additional supports is in the direct instruction of social skills, often achieved through social skill training program. Social skills training programs are often the primary manner in which individuals are taught skills that they may otherwise be lacking. However, as Gresham, Sugai, and Horner (2001) note, it is important to understand that those with greater levels of disability also require more frequent and intense instruction. A one hour per week social skills training group is unlikely to provide any significant change and may not show any sustained long-term benefit. Instead, more intensive or targeting intervention may produce more effective results, allowing those with disabilities the opportunity to build their skills more readily.

As well, those with ID/ADHD may benefit from additional support while building their social skills, rather than simply relying on group training. For example, including parents in the social skills training process may allow parents to understand the skills their children are being taught and help them work on those skills outside of the training sessions. As well, the inclusion of parent–child homework (e.g., social tasks that the parent helps the child complete, such as inviting another child to a play date) may help to generalize some of these skills to new or novel situations. This parent-inclusion model has been shown to be beneficial for those individuals on the autism spectrum, such as through the UCLA PEERS program (Laugeson, Frankel, Gantman, Dillon, & Mogil, 2012; Laugeson, Frankel, Mogil, & Dillon, 2009) and for those with ADHD (Frankel, Myatt, Cantwell, & Feinberg, 1997) individually. Tenets of these programs may also be particularly applicable to those with ID/ADHD, as the increased support provided by these models may create greater opportunities for success.

Understanding social conventions. Social conventions or social cooperation skills incorporate the ability to understand and abide by social rules, adhere to social structure, and attune to social expectations (Merrell & Wolfe, 1998). These skills may include things like sharing, turn taking, addressing adults, making polite requests (e.g., the use of “please” and “thank you”), appropriate greetings (e.g., with a peer or adult), or joining an existing conversation. While many typically developing children pick up these skills through experience and exposure, the challenges associated with ID and/or ADHD may make this experiential learning more difficult for those with the disorder.

These social conventions are often particularly difficult for those with ADHD, as their impulsivity often impedes their ability to communicate appropriately. Additionally, children with ID/ADHD may require direct instruction in the area of understanding social conventions so as to build appropriate skills as well as to generalize these skills to new or novel situations. It is important to remember that these individuals may require significant practice and repetition and that their ability to extrapolate from one situation to another may be limited.

A number of techniques may be used to help teach students social convention skills. For example, at the most basic level, the use of modeling can be beneficial. If a teacher or student is able to model appropriate interaction skills, it provides a strong visual example for students who are weaker in this area. However, a more effective technique is to allow students the opportunity to practice the skills themselves through role-playing scenarios (Spence, 2003). In these situations, students are able to mimic situations in which they may find themselves and provide in-the-moment responses to the scenarios. For example, a student may practice beginning a conversation appropriately, allowing for conversational turn taking. As well, more advanced topics may be incorporated, such as responding appropriately or confidently to bully or peer pressure situations.

Together, the building of social skills may allow those with ID/ADHD a greater opportunity to engage with their peers at home, at school, and in their communities. Given the positive long-term outcomes related to friendships, ensuring that these children develop the necessarily skills for appropriate peer interaction should be an important consideration in support planning.

Behavioral Interventions

Behavioral interventions are also central to the treatment and skill building of individuals with ID and ADHD; they allow for an improvement in daily living skills and reduction of maladaptive behaviors (Benson & Havercamp, 2007). While there is limited research examining behavioral interventions among individuals with comorbid ID and ADHD, behavioral interventions commonly used to support individuals with ID can be easily adapted to accommodate for ADHD-related behaviors. The following section will discuss some effective behavioral interventions for individuals with ID or ADHD, including reinforcement, token economy, and relaxation training, and how they can be adapted to accommodate co-occurring ID/ADHD.

Reinforcement. The concept of reinforcement forms the basis for most behavioral interventions. A reinforcer is a stimulus that increases some form of behavior or outcome (Benson & Havercamp, 2007). Positive reinforcement, then, is rewarding positive or desired behavior with a motivating stimulus or outcome (Miltenberger, 2001). For example, a child may be more inclined to clean his or her room with the knowledge that he or she may be rewarded upon completion of the task (e.g., they may get a new toy or have an ice cream treat). Individuals with ID and ADHD (individually) both react well to positive reinforcement (Benson & Havercamp, 2007; Pfiffner & Haack, 2014). However, for positive reinforcement to work effectively, the outcome must be particularly rewarding for the individual. For some children, ice cream may be a strong motivator, but for others, it may have little to no motivating power. Consequently, it may be beneficial to conduct a preference assessment with an individual prior to using a positive reinforcement paradigm. Sturmey, Lee, Reyer, and Robek (2003) created the Choice Assessment Scale, which may be used to identify potential reinforcers for individuals with ID. The reinforcer should also be received or administered in close succession to the desired behavior, as individuals with ID and ADHD struggle to understand and appreciate delayed gratification (Pfiffner & Haack, 2014).

Negative reinforcement, or the encouraging a behavior by stopping or removing a stimulus, may also be used. For example, allowing a child to come out of a time out after they apologize may help to increase apologizing behavior. However, although negative reinforcement has some effect, it is often less motivating for individuals with ID and ADHD (Pfiffner & Haack, 2014); therefore, it may be more beneficial to use positive reinforcement more frequently.

Token economy. Token economy is a popular form of reinforcement used to support individuals with ID and ADHD. The reinforcer, or "token," acts in a similar manner to traditional money: it can be exchanged for a desired stimulus or outcome in the future (Benson & Havercamp, 2007). For example, if a child receives a marble for demonstrating good behavior, he or she can "save" the marbles until a marble jar is full. After that time, the full marble jar can be exchanged for a reward of his or her choosing. There are numerous benefits to using a token system: they are tangible, received immediately, and can be collected to earn a greater future reward (Benson & Havercamp, 2007).

To create an effective token economy, choose a negative behavior to be changed and a positive behavior to replace the negative behavior (e.g., stealing food from the cupboard should be replaced with asking for a snack). Tokens should be given based on predetermined intervals or outcomes. For example, a token could be given each time a positive replacement behavior is observed (i.e., the child asks for a snack). Once enough tokens have been earned (based on a predetermined threshold), they can then be exchanged for some greater reward (Pfiffner & Haack, 2014), such as a trip to the ice cream store. Token economy is an effective strategy for children, adolescents, and adults with ADHD and ID (Benson & Havercamp, 2007; Pfiffner & Haack, 2014). Matson (1982), for example, provided tokens to adult men with mild ID for each minute out of 30 that a target behavior (repetitive clothes checking) did not occur. That token could be later exchanged for snacks. Over time, the occurrences of the undesirable behavior reduced.

Relaxation training. Relaxation training, meant to reduce symptoms of anxiety, is an effective behavioral strategy for both children and adults (Benson & Havercamp, 2007). Individuals with both ADHD and ID experience tension and anxiety due to difficulty meeting the demands of their environment (Lim, 2009; Pfiffner & Haack, 2014). With appropriate accommodations, relaxation training can reduce aggressive and disruptive behaviors, hyperactivity, and anxiety in individuals with ID (Lim, 2009). It can also help to improve concentration and attention to tasks, an important component for those with ADHD (Lim, 2009). Lim (2009) completed a relaxation training program with teenagers with mild ID, some of whom also had ADHD. The relaxation exercises include deep breathing, listening to calming music, progressive muscle relaxation, and picturing a special place. Lim (2009) reported reductions in anger, and greater feelings of calmness, relaxation, and concentration.

One of the most common forms of relaxation training is that of progressive muscle relaxation, where the individual tenses, holds, and relaxes muscle groups (Sturmey, Lindsay, Vause, & Neil, 2014). Progressive muscle relaxation has been adapted to accommodate the needs of individuals with ID, and is referred to as abbreviated progressive muscle relaxation (APMR). Here, the instructor models and guides the individual through the movements, providing manual instructions and prompts as necessary. Progressive muscle relaxation can be further accommodated for the needs of those with ADHD by conducting the exercise in very short bursts, by allowing for “inattentive relaxation,” or by allowing movement during the activity (Pfiffner & Haack, 2014).

Academic Interventions

Given that success on academic tasks is strongly predicted by attentional abilities (e.g., Kirk, Gray, Ellis, Taffe, & Cornish, 2016), researchers have acknowledged the importance of studying evidence-based interventions that specifically support the success of those students who struggle academically and/or with attention (Roording-Ragetlie, Klip, Buitelaar, & Slaats-Willemse, 2017). Furthermore, changes in legislation that have made inclusion a priority in education have increased the need to create academic interventions that allow for greater access to education for diverse learners (Snodgrass, Israel, & Reese, 2016). Although many academic supports can be applicable for the ID/ADHD population, this section will highlight two of the most relevant and evidence-based techniques: Computer-Based Interventions, also known as Computer-Assisted Instruction, and Peer Tutoring.

Computer Assisted Instruction (CAI). CAI shows promise as an academic intervention to target attention and working memory (Weng, Maeda, & Bouck, 2014). Also known as Computer Based Learning or Computer Based Teaching, CAI is defined as educational technology in which instruction can be delivered through computer programs or other type of computer-based technology (Weng et al., 2014). Four primary types of CAI exist: Visual, Auditory, Mobile, and Cognitive skills-based (Weng et al., 2014). Visual and auditory computer assisted instruction can provide support for students that need computer devices to complete academic tasks. Examples of these computer-based interventions include speech-to-text software (Van Laere & van Braak, 2017). Mobile CAI includes the use of tablets, which have generated interest in educational settings because they can be easily transported and their use is simple and interactive (Weng et al., 2014). Mobile technologies have been used with students with autism spectrum disorder as well as moderate and severe intellectual disabilities to teach life skills such as cooking, time and behavioral management (Ayres, Mechling, & Sansosti, 2013). Cognitive skills-based CAI has shown to be the most effective for children with attentional concerns. Specifically, studies have shown that children with ADHD who use CAI tend to spend less time in off-task behaviors and appear to be more actively engaged compared to other methods (Murray & Rabiner, 2014), such as handwritten note-taking or just looking at information explained by drawing or writing on a whiteboard.

Furthermore, computer-based technologies also seemed to be preferred by individuals with intellectual disabilities, as the immediate and direct feedback provided by computer games and programs helps to maintain attention and engagement in the program (Kirk et al., 2016). Through CAI, the intensity or length of intervention can be reduced and, because software access is becoming more accessible, the duration of interventions can be extended of longer periods of time (Roording-Ragetlie et al., 2017). This increasing duration is important because prolonging the use of an intervention to reduce cognitive load may be beneficial for children with mild IDs and neuropsychiatric disorders (Roording-Ragetlie et al., 2017). Although CAI has also been used to develop academic skills in students with ADHD, including reading and mathematics (DuPaul et al., 2006; Mautone, DuPaul, & Jitendra, 2005), few studies have examined the use of CAI solely in the ID population. A recent study in Brazil targeted reading and writing skills with parents as monitors of the CAI intervention (Benitez & Domeniconi, 2016). The reading and writing program was available to students from a home computer and a high-school graduated family member was trained to provide monitoring during sessions (20 to 30 minutes, three times a week, before or after school). All students improved the target reading and writing skills after the intervention (Benitez & Domeniconi, 2016). These results suggest that academic interventions targeting reading and writing could also be effective in this population when they receive support from their caregivers or support workers.

Literature reviews aiming to identify the effectiveness of CAI programs in students with ADHD or other disorders have shown small effect sizes (Ramdoss et al., 2012; Weng et al., 2014). Some of the issues with the implementation of Cognitive training in research have been inconsistencies in training regimes (e.g., lack of clarity in the frequency of implementation; Kirk, Gray, Riby, & Cornish, 2015) as well as significant heterogeneity in the targeted skills: some studies have targeted cognitive skills like attention and memory, while others have focused on teaching basic living skills, mathematical, reading, or writing skills (Weng et al., 2014). With the broad range of skills that are being targeted, it is difficult to identify the academic areas cognitive training has a positive impact on. Research is still needed to establish CAI as an effective and evidence-based intervention for children and youth with comorbid ADHD/ID.

Peer tutoring. This instructional strategy involves two students collaborating in an academic activity by teaching, assisting, and providing feedback on an academic task (DuPaul, Ervin, Hook, & McGoey, 1998). Peer-assisted learning focuses on enhancing learning and motivation by recognizing that peers are able to instruct each other or act as positive academic models for academic tasks (Rohrbeck, Ginsburg-Block, Fantuzzo, & Miller, 2003). Some evidence of effectiveness of the use of peer tutoring with children with ADHD to learn academic material has been found (Raggi & Chronis, 2006; Richardson et al., 2015). However, few studies have researched its effectiveness for students with ID specifically and no literature has explored this technique for the ID/ADHD population. However, class-wide peer tutoring to improve spelling has been used in regular education classrooms by pairing typically developing children with students with disabilities (Mortweet et al., 1999). All of the children, including those with a either mild intellectual disabilities or ADHD, improved their spelling scores by the end of the intervention (Mortweet et al., 1999), suggesting that there may be benefits for using this type of intervention support to build academic skills in the ID/ADHD population.

Adaptive Supports

Individuals with ID show similar sequences of development to typically developing children; consequently, an understanding of universal sequences in development is essential for intervention with the ID/ADHD population (Harris, 2006). Adopting a developmental approach to ID will allow for emphasizing where the individual with ID/ADHD is at developmentally and then build upon existing skills across multiple domains. Given that individuals with ID/ADHD face a number of challenges relating to adaptive functioning across conceptual, practical, and academic domains, successful treatment requires adaptive supports to address challenges across these domains. When adaptive behaviors are assessed, the individual's behavior is compared to expectations based on culture and age, generally to national norm groups by age (Fiorello & Jenkins, 2018). Thus, adaptive supports may be most beneficially applied when consideration is given to the age and culturally based expectations that are relevant for the individual with ID/ADHD. These expectations for adaptive functioning will vary for children, adolescents, and adults with ID/ADHD.

Children. Children with ID/ADHD must demonstrate mastery of skills for there to be growth and development across adaptive functioning domains (Harris, 2006). For example, a child with ID/ADHD who has difficulty with their verbal comprehension and language skills has gaps in these foundational skill areas that may impact their adaptive functioning relating to academics, making it difficult for them to understand what they read and understand reading-based material in and outside of school. Demonstration of prerequisite skills is necessary for further development in other domains and allow for setting goals for next steps in treatment plans.

Across conceptual, practical, and social domains, the level of adaptive supports provided to target challenges across these areas will depend on the severity of intellectual disability that the child has as well as the type and severity of comorbid ADHD. In terms of the conceptual adaptive domain, school-age children with ID/ADHD will tend to have slower progress in reading, writing, and mathematics and understanding is markedly limited compared to peers (APA, 2013). Adaptive supports that address these challenges in the conceptual domain require educational supports with simplifying academic material, provisions of extra time to complete academic work, as well as use of a scribe, computer, calculator and other technological supports to accompany teaching strategies. With the social domain, the spoken language of a child with ID/ADHD may be less complex that that of peers, there may be challenges with perceiving or interpreting social cues accurately, and social judgment and decision-making is limited (APA, 2013). Adaptive supports to address challenges in the social domain will require that the child be explicitly taught about social concepts such as trust, how to be a good friend, and simple approaches for how to navigate social conflict, such as a friend hurting one's feelings. The practical domain includes challenges relating to one's capacity to meet his or her own personal needs involving dressing, eating, elimination, and hygiene (APA, 2013). Depending on the severity of adaptive functioning deficits experienced by the child with ID/ADHD, he or she may require daily support from a caregiver or aide with meeting their personal needs. Some children with milder ID/ADHD will require adaptive support in the form of modeling and one-on-one teaching with visual reminders for how to carry out personal care steps, such as how to get dressed and how to brush teeth.

Adolescents and adults. A child with ID/ADHD who enters adolescence may present as developmentally younger in comparison to their peers across conceptual, social, and practical domains of adaptive functioning. Unfortunately, the demands of social relationships, academics, and expectations for autonomy and independence increase from childhood into adolescence, which are difficult for a youth with ID/ADHD to meet. Adaptive supports in the form of an assistive aid worker within the home/school or living in a residential treatment program from childhood may have to continue to be in place for the adolescent with progression towards teaching specific skills for adulthood, such as employment and money-managing skills. For older adolescents, the transitional periods from school completion into adult life is difficult if the youth is in a position where they are leaving a monitored, individualized program with same-age peers to adult programming that encompasses a range of ages and diagnoses (Harris, 2006). Consideration of provincial funding eligibility options and program placement may be informed through formal assessment of adaptive functioning through social work and psychological services.

Other Adult Supports

As individuals with ID/ADHD age out of the youth system, their needs do not dissipate. Indeed, they may actually require more intensive support, as they are often not able to manage the typical expectations of being an adult, such as independent living, maintaining employment, and self-advocacy. This section will outline some relevant supports that may be beneficial when transition planning or when supporting adults with ID/ADHD in their homes, communities, and places of employment.

Occupational supports. Those with ID/ADHD often find satisfaction when they have some kind of meaningful employment. These individuals note that they enjoy the opportunity to connect with others, enjoy the benefits of pay, develop feelings of pride and satisfaction, and have the opportunity to develop new learning experiences (Lysaght, Ouellette-Kuntz, & Lin, 2012). Additionally, in some workplaces, these individuals may be valued for their contributions to the workplace, although there are often challenges to the integration of those with disabilities into the workforce (Lysaght et al., 2012).

For individuals with ID/ADHD, they may be supported through a number of means. For example, the use of agency partnerships may help to bridge the challenges that those with ID/ADHD may experience (Lysaght et al., 2012). These agencies may be able to provide an organization with training and guidance for their staff regarding the supports that individuals with ID/ADHD may need to be successful in the workplace (e.g., social supports, physical supports; Lysaght & Larmour-Trode, 2008) and help to manage any problems that arise. Having this outside support may be invaluable for ensuring that the individual with ID/ADHD is not only accepted into the workplace but can be a productive and contributing member of the work team.

As well, having a greater connection between K-12 schooling and occupational opportunities may be particularly beneficial for those with ID/ADHD. For example, allowing and encouraging those with ID/ADHD to become involved with vocational or work training programs while still in school may allow them to build occupational skills as well as develop connections with local organizations (Beyer & Kaehne, 2008). If schools are able to build collaborative connections with community agencies and partners, then vocational preparation may begin at an earlier age. As well, the range of opportunities available to these individuals may be expanded (Lysaght et al., 2012). For example, job shadowing or workplace visitations/observations may encourage these students to further explore educational opportunities beyond high school completion. As well, those with ID/ADHD may gain a greater awareness of employment opportunities available to them, which may increase their motivation to complete their high school coursework.

Independent living supports. As to be expected, those with ID/ADHD vary in their ability to live independently; most of these individuals have some desire to live as independently as possible, with some autonomy in their decision making (Kozma et al., 2009; Shaw, Cartwright, & Craig, 2011). Some individuals may be able to be more independent than others, depending on their level of ID. For example, some may be successful with minimal supports, such as with a supportive roommate or in a supported living facility, while others may require more intensive support, such as in a group or residential home with higher levels of supervision and guidance. In a review of placement settings, Kozma et al. (2009) report that a majority of studies indicated that deinstitutionalized placements, such as those offered through community care arrangements, had greater benefits than group living arrangements, although the needs of the individual, particularly around safety, must be considered. Either way, these individuals will require personalized planning to ensure that they are able to live as independently as possible, taking into consideration their strengths, limitations, needs, and desires.

As previously noted, building social skills in this population may have protective benefits. The development of social skills can also have an impact on an individual's quality of life, particularly in relation to independent living skills (Wehmeyer & Garner, 2003). As well, connectedness with others has been frequently linked to better quality of life, with those who live in supported living arrangements having a greater number of friends and visitors and are more likely to be known by those who live around them than those who live alone (Kozma et al., 2009). Ensuring that those in the ID/ADHD community have the opportunity to connect with others with ID, as well as have positive interactions in the community may help to foster their skills in these areas.

Finally, it should also be noted that working with individuals with ID/ADHD from a person-centered approach is also recommended. This approach acknowledges the preferences and desires of those with a disability and their caregivers in making placement decisions. As well, this approach encourages those with ID/ADHD to become active and involved in their own decision making and planning when choosing housing and support services. Individuals are more likely to enjoy their living arrangements when they feel as though they have had some input into the process.

Self-advocacy. Building on the idea of the person-centered approach, an additional area of persistent need is to ensure that those with ID/ADHD continue to build skills in the area of self-advocacy (Shogren & Plotner, 2012). The ability to advocate for oneself is a critical skill to ensure that those with ID/ADHD have a say in decisions that have direct impact on them. There have been a number of suggestions as to how to build leadership and self-advocacy skills in those with ID, although many of these recommendations would also apply to those with ID/ADHD. One manner in which to build self-advocacy skills is to encourage those with ID/ADHD to participate in volunteering or other community service opportunities (Caldwell, 2010). For example, involvement in one-off special community events (e.g., fun runs, celebration events) or more long-term volunteering opportunities (e.g., weekly shifts at the local humane society), based on the individual's interests or desires, may help to increase feelings of competence and independence. Enhancing leadership opportunities for this population may allow them to develop stronger communication, social, and life skills, all of which may lead to enhancement of their self-advocacy skills.

Additionally, those with ID/ADHD should be encouraged to participate on relevant boards or committees, particularly those who may benefit from the presence of someone who lives with a disability (Caldwell, 2010). For example, involvement on organizations associated with supporting those with disabilities (e.g., learning disability associations, independent living support groups) may provide valuable experience for both the organization and the individual. Encouraging those with ID/ADHD to provide direct input to decision making bodies allows them to develop a stronger sense of self-worth and importance and provide an opportunity for them to give honest and practical feedback that may have important and policy-related outcomes.

Finally, encouraging those with ID/ADHD to pursue some form of post-secondary education may also contribute to their ability to self-advocate (Caldwell, 2010). There is currently a greater push for accessibility supports for those with exceptional learning needs of all varieties within post-secondary environments. Consequently, encouraging the pursuit of higher education in areas of interest and ability may significantly benefit the lives of those with ID/ADHD. These educational skills may also have secondary benefits, such as an increase in the employment prospects of these individuals or additional opportunities to build social skills.

Conclusions and Future Directions

Together, this chapter highlights the unique needs of individuals with comorbid ID and ADHD. Due to issues such as diagnostic overshadowing, research examining the co-occurrence of ID and ADHD is extremely limited, and it is only with the recent iteration of the DSM that the possibility of both an ID and an ADHD diagnosis is available. However, it is clear that individuals with both disorders are at greater risk of numerous negative outcomes (e.g., depression, anxiety, aggression; Carmeli et al., 2007) than those with ID or ADHD alone, and thus the importance of specific, targeted, and individualized interventions should not be overlooked.

Although those with ID/ADHD may benefit from support in childhood and adolescence, as we highlighted above, the needs of these individuals as they transition from the youth system to the adult system remain high. Currently the ability to provide this wrap-around care and support as individuals make this transition is limited, sometimes resulting in individuals falling through the proverbial "crack" and ending up on a negative path. Continuing to advocate for supports and resources not only for adults but also to support and guide the transition to adulthood may be extremely beneficial. More specifically, building capacity to allow those with ID/ADHD to advocate for themselves would provide long term benefit for those with the disability as well as their families (Carter, Brock, & Trainor, 2014; Shogren & Plotner, 2012).

In summary, it is necessary to understand the unique and individual needs of those with a combined ID/ADHD diagnosis, as they may benefit from some interventions and recommendation relevant to the ID population as well as those more pertinent to individuals with ADHD. As with all intervention planning, providing individualized support and guidance is key to ensuring that each person can achieve to their potential.

Wendy Aertssen, and Reint Geuze

Introduction

The Importance of Motor Development in ID

Imagine humans without a voluntary motor system. We would not be able to communicate or interact with the environment. How would we ever function? This illustrates that movement—being able to act and react—is a basic capacity of human functioning. Very early in development, around the eighth week of gestation, the first movements of the fetus may be observed. Gradually the movement repertoire is extended and becomes more complex (Timor-Tritsch et al., 1988). The developing nervous system contacts the contracting tissues and help shape the bones and joints in a self-organized way. At some stage during later pregnancy, functional connections in the nervous system are strengthened, whereas the nonfunctional ones are removed again. After birth development continues. Major changes are the exposure to the environment (gravity, sounds, visual stimuli, object characteristics) and the possibility to explore and interact with the environment as far as the sensory and motor systems of the newborn allow. Interaction with the environment through movement elicits sensory consequences, facilitating calibration of the motor system with the varied sensory systems. Learning by active exploration of the environment is a major drive for cognitive development. Thus, cognitive and motor development should be seen as a dynamic interactive process (Crone & Ridderinkhof, 2011). Another domain of functioning where cognitive and motor capacities meet is planning and control of complex motor tasks. For example, in learning to write, language needs to be transferred to finger movements that produce a written text (Van Galen & Morasso, 1998).

What will happen in case of nonoptimal development of the nervous system? Lesions in the motor areas of the brain will likely result in reduced motor skills [e.g., children with cerebral palsy or developmental coordination disorder (DCD) with normal IQ], and lesions in the cognitive areas in reduced cognitive function (e.g., children with ID). However, developmental disorders often cannot be localized so clearly and functions are likely to be sub-served by parts of overlapping brain networks. If the brain networks are nonoptimal and involved in several functions, overlapping

functional limitations may occur such as ADHD and autism, or ID and poor motor skills.

The message to be taken from this part of the introduction is that although motor capacities and ID seem separate domains of functioning, they are related in varied ways during development and in cognitive-motor tasks that require cognitive planning and control.

Importantly, motor coordination problems cause individuals to struggle with everyday functional tasks and to participate less in physical activity (Mandich, Polatajko, & Rodger, 2003). These motor problems make participating in sport and daily outdoor activities more difficult (Barr & Shields, 2011) leading to more sedentary lifestyle, lower levels of physical activity and poor fitness (Lin & Wuang, 2012; Philips & Holland, 2011). Consequently, it impacts their capacity to execute everyday activities and their health-related fitness. Intellectual disability provides an additional barrier to an active lifestyle and this may lead to the underdevelopment or loss of independence, increased risk of noncommunicable diseases, and health complications later in adulthood (Ells et al., 2006). This suggests that designing specific interventions to address motor impairments, activity limitations and participation restrictions are needed to avert the adverse effect of poor motor coordination and its health complications in ID.

Developmental Coordination Disorder (DCD)

Children develop a range of movement skills through various forms of playful activities and exploration. However, not every child is able to develop adequate motor skills required for everyday activities. Difficulties acquiring movement skills is one of the most common issues in children (Henderson & Henderson, 2002). This group of children has been identified with different kinds of names in the literature. These included clumsiness, motor dyspraxia, minimal brain damage, and perceptual-motor dysfunction. If the motor difficulties are evident from an early age, affect activities of daily living, and are not associated with a known medical condition (cerebral palsy, muscular dystrophy, etc.) the preferred term today is Developmental Coordination Disorder (DCD) (DSM-5, American Psychiatric Association, 2013). DCD is a condition that affects around 5–6 percent of all children (Smits-Engelsman, Magalhães, Oliveira, & Wilson, 2015), with more boys than girls being affected. DCD is characterized by motor difficulties in performing essential movement-based activities. Movements seem clumsy, slow and lack accuracy and balance may be poor. Performing age appropriate activities of daily living often is difficult for children with DCD. However, the manifestation of symptoms tends to vary from one child to another and also across the developmental time, demonstrating heterogeneity. In addition, the signs and symptoms of DCD can show persistence from childhood through adulthood when treatment is not provided.

Skilled motor function is a prerequisite for the performance of activities of daily living (ADL) and (pre)vocational activities. While most children learn seamlessly the motor skills that prepare them well for later school achievement and participation, a significant proportion do not, which places them at a significant disadvantage relative to their peers (Bult, Verschuren, Jongmans, Lindeman, & Ketelaar, 2011). Hence DCD, affects their participation in daily activities (Barnhart, Davenport, Epps, & Nordquist, 2003) Moreover, motor skill difficulties have developmental consequences beyond just motor function and place the child at a significant risk for social, psychological, and health-related issues, even into adulthood (Hellgren, Gillberg, Gillberg, & Enerskog, 1993; Rasmussen & Gillberg, 2000). Thus, there is a pressing need to optimize therapeutic approaches such that motor function and participation of this group of children is promoted (Smits-Engelsman et al., 2018).

It is currently unclear if children with DCD have a pure motor coordination deficit or a motor learning deficit or "only" a motor developmental delay. Most children do not "grow out of it," but some 30–50% do (Geuze, 2007, p. 18), suggesting a developmental delay, whereas the others may have deficit or even a genetic basis for their motor problems (Martin, Piek, & Hay, 2006). Thus, as mentioned, children with DCD constitute a very heterogeneous group (Wilson et al., 2017).

DCD is classified in the *Diagnostic and Statistical Manual for Mental Disorders Fifth Edition* (DSM-5) and is subcategorized within the broader category of "neuro-developmental disorders." Table 49.1 lists the criteria for the classification of DCD in DSM-5.

The criteria for DCD are quite clear. However, DSM does not provide an operationalization for the criteria (Smits-Engelsman, Schoemaker, Delabastita, Hoskens, & Geuze, 2015). For example, for criterion A, it is not specified how to assess "the acquisition and execution of coordinated motor skills is substantially below that expected given the individual's chronological age and opportunity for skill learning and use." Operationalization of the criteria should therefore follow the protocol developed by an international working group that developed the International Clinical Practice Recommendations of Developmental Coordination Disorder (Blank et al., 2019), based on extensive reviews of the literature and consensus between experts.

Table 49.1 Diagnostic criteria specified in the Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5) of the American Psychiatric Association, (2013)

A. The acquisition and execution of coordinated motor skills is substantially below that expected given the individual's chronological age and opportunity for skill learning and use. Difficulties are manifested as clumsiness (e.g., dropping or bumping into objects) as well as slowness and inaccuracy of performance of motor skills (e.g., catching an object, using scissors or cutlery, handwriting, riding a bike, or participating in sports)
B. The motor skills deficit in Criterion A significantly and persistently interferes with activities of daily living appropriate to chronological age (e.g., self-care and self-maintenance) and impacts academic/school productivity, prevocational and vocational activities, leisure, and play
C. Onset of symptoms is in the early developmental period
D. The *motor skills deficits are not better explained by intellectual disability* (intellectual developmental disorder) or visual impairment and are not attributable to a neurological condition affecting movement (e.g., cerebral palsy, muscular dystrophy, degenerative disorder)

International Clinical Practice Recommendations of Developmental Coordination Disorder

The Clinical Practice Recommendations (CPR) for DCD decomposes each of the criteria into parts, and recommendations are provided on how to operationalize these. For example, for the assessment of motor skills (Criterion A), the CPR recommends the use of reliable and valid motor tests that have standardized norms derived from the population; and for excluding the neurological conditions specified in Criterion D, the CPR recommends a medical assessment preferably by a pediatrician.

Interestingly, the DSM in Criterion D (Table 49.1) suggests that intellectual disability is expected to have an impact on the motor skills deficit. Therefore, in most studies children with an IQ below 70 have been excluded. Indeed, the study by Smits-Engelsman and Hill (2012) shows a linear relationship between IQ and motor skill in a group of 460 children identified with/without motor difficulties from both clinical and educational settings.

On the Criteria for DCD

As for criterion A, "… expected given the individual's chronological age and opportunity for skill learning and use," two cutoff values have been internationally accepted: the fifth and the 15/16th percentile on a standardized motor test (See Subheading Assessment of Primary and Secondary Movement-Related Problems). Few of these tests have been widely accepted or have good validity and reliability. With respect to the opportunities for skill-learning, these may have been less in children with DCD and even more so in children with ID, due to cognitive and social restrictions, making it difficult to estimate how much of the poor coordinated motor skills are to be ascribed to lack of experience. In addition, cognition and social restriction of children with ID also play a role in skill acquisition and when testing a child with ID.

With respect to criterion B, the impact of the motor problems on daily life and academic achievement may be different between children with DCD and DCD-ID. In children with DCD it is already difficult to disentangle language, comprehension and motor contributions in the handwriting difficulties, in children with DCD and mild ID this will be even harder.

Criterion C refers to onset in the developmental period. For older children, adolescents and adults this may be checked retrospectively. Very early diagnosis—say under the age of 6 years—is, however, not recommended because of the instability of early motor development. Young children who may seem atypical may catch up a few months later. Therefore, the CPR recommends to retest young children (<5 years) who seem atypical after half a year.

Criterion D refers to ID. In the working group for the International Clinical Practice Recommendations of Developmental Coordination Disorder (DCD) (Blank et al., 2019) the problem of diagnosing DCD in children with severe cognitive delays or intellectual disorder (ID) has been discussed thoroughly. It was recognized that defining a specific IQ score below which the diagnosis of DCD is precluded seems artificial. Given the complexities of arbitrating between cutoffs and determining discrepancy scores, it is recognized that categorical decisions (above or below a specific IQ score) may be extremely difficult. Looking at the meta-analysis on underlying mechanisms of DCD, a specific IQ score does not seem to be helpful to distinguish between children with DCD and children with coordination problems due to ID, as the construct of DCD is nowadays increasingly supported by neurobiological and neurophysiological findings and not restricted to global intellectual abilities (Wilson et al., 2017). Hence, it was agreed that the motor dysfunction in ID should be defined as DCD if the other criteria are fulfilled and if clinical history and examination cannot explain the motor problems and their impact on daily activities by cognitive status. It is recommended that the complete DCD assessment considers ADL (i.e., self-care and self-maintenance), academic/school productivity, prevocational or vocational activities, leisure, sports, and play.

It is also recommended that the child be checked for visual impairment and neurological conditions affecting movement. For DCD-ID this will exclude all children with such conditions. A future problem may be that refined brain imaging will show that all children will exhibit subtle to more substantial degrees of abnormalities in brain structure and activity, thus rendering this part (no neurological condition) of the criteria questionable. Frequently occurring health problems, such as a congenital heart defects or visual defects, can also influence motor development.

Co-occurring Developmental Disorders

Children with DCD often have co-occurring disorders such as ADHD (Loh, Piek, & Barrett, 2011), and children with developmental disorders such as specific language disorders often have co-occurring motor problems (Pieters et al., 2012). It is known that comorbidity in children with ID is large for disorders such as anxiety, depression, schizophrenia, epilepsy, obesity, chronic pain, ADHD, autism, and cardiovascular and muscular anomalies. These have to be taken into account in diagnosing the co-occurrence of ID and DCD. More specifically, when diagnosing DCD one should check for coexisting disorders and set priorities for treatment and support. In case of ID as a coexisting condition, the measured delay in motor development should not be attributable to a neurological condition affecting movement.

Assessment of Primary and Secondary Movement-Related Problems

Motor Competence

Motor competency should be measured by using an appropriate motor test that measures the different areas of motor competence, and have good reliability and validity and a population-based standardization (appropriately norm-referenced for that specific population). Motor performance tests recommended in the international CPR to diagnose DCD "Criterion A" are the Movement Assessment for Children—second edition (MABC2; Henderson, Sugden, & Barnett, 2007) and the Bruininks–Oseretsky test—second edition (BOT-2; Bruininks & Bruininks, 2005). Most of the tests have not been investigated for children with mild ID (IQ = 50–70) and may only be partly suitable. It follows that reference norms and cut-off points for children with ID are lacking.

A test for motor performance that has been used in children with ID is the Bruininks–Oseretsky test—second edition (BOT-2). The BOT-2 consists of eight subsets (fine motor skills, manual dexterity, bilateral coordination, balance, strength, upper limb coordination, running speed and agility) and is a reliable and valid measure in children with mild ID (Wuang & Su, 2009a, b).

The Test of Gross Motor Development-II (TGMD-2) is an assessment of locomotor function and object control that has been reported to be a reliable and valid measure in children with ID (Capio, Eguia, & Simons, 2016; Simons et al., 2008; Ulrich, 2000). Reference norms are available for the TGMD-2 for children with Down Syndrome. It is important to mention that validity of the BOT2 and the TGMD for these target groups was only investigated by group and age comparison and not compared with another measure.

The Developmental Test of Visual-Motor Integration (VMI) has also been adapted for children with ID and is a reliable and valid measure for identifying perceptual-fine motor deficits (Wuang & Su, 2009a, b).

To measure functional mobility, balance, and postural control, the timed up and go test (TUG) is a commonly used test in elderly, but it has also been investigated in children with ID. In the adapted version for children, children must stand up from a chair, walk as quickly as possible across a 3-meter distance, touch a target on a wall, then walk back and sit down on the chair. Research has shown that the TUG is valid and reliable tool for children with ID and there are norms available for TD children (Martin, Natarus, Martin, & Henderson, 2017; Nicolini-Panisson & Donadio, 2014).

The Gross Motor Function Measure-88 (GMFM-88) is a tool for motor function and consists of five domains: lying and rolling, sitting, crawling and kneeling, standing, walking–running–jumping. It was developed for children with cerebral palsy and adapted for children with Down Syndrome (DS). There is evidence to show that it is a reliable and valid tool for children with DS (Russel, Palisano, & Walter, 1998; Russel, Rosenbaum, Avery, & Lane, 2002).

To assess DCD criterion B, questionnaires are used to determine problems in daily living activities and school performance, (pre)vocational activities, leisure and play. The DCD-Q (Wilson, Crawford, Roberts, & Kaplan, 2006) is the most commonly used questionnaire for this purpose, but has not been investigated in children with mild ID. The Pediatric Evaluation Disability Inventory (PEDI) is a parent interview and consists of three domains (self-care, mobility, and social functioning) for which scale scores can be calculated. The PEDI is a reliable and valid tool and is able to discriminate between disabled children and TD children (Custers et al., 2003; Helders, 2003; Volman, Visser, & Lensvelt-Mulders, 2007).

Physical Fitness

The American College of Sports Medicine (2014) divides physical fitness into five different components: body composition, muscle strength, muscle endurance, cardiorespiratory fitness, and flexibility.

Body Composition

It is known that high BMI has a negative impact on physical fitness and motor abilities in children (Graf et al., 2004). Obesity in children with ID is frequently seen (O'Shea, O'Shea, Gibson, Leo, & Carty, 2018; Wang et al., 2018). For body composition, BMI and skinfold measures are reliable and valid measures in children with mild ID (Bandini, Fleming, Scampini, Gleason, & Must, 2013; MacDonncha, Watson, McSweeney, & O'Donovan, 1999; Tejero-Gonzalez et al., 2013). Waist circumference is also a reliable measure, but information concerning validity is lacking (Wouters, Evenhuis, & Hilgenkamp, 2017).

Muscle Strength and Muscle Endurance

Children with ID are known to have lower levels of muscle strength and muscle endurance (Hartman, Smith, Westendorp, & Visscher, 2015;

Hassani et al., 2014; Tejero-Gonzalez et al., 2013). In addition to the pathophysiological aspects (Dey et al., 2013), the lower level of physical activity and the fact that these children participate less in outdoor activities and sports (Barr & Shields, 2011) are seen as important factors for the lower level of muscle fitness. Few measures that evaluate muscle strength and muscle endurance in children with mild ID have been well investigated on psychometrics (Wouters et al., 2017). Grip strength, hand-held dynamometry (HHD), standing long jump and arm hang are seen as reliable muscle strength measures, but information concerning validity is lacking. The subset strength of the BOT-2 is reported to be a reliable and valid measure for children with ID (Wuang & Su, 2009a, b) and consists of five items for functional strength, mostly core muscles (long jump, sit-up, push up, wall sit and v-up). Similar tests considered valid and reliable in youth with and without ID are the 1 min sit-up and the isometric push-up protocol.

Also the Functional Strength Measurement for children with ID (FSM-ID) is a reliable and valid measure in this group of children and consist eight items measuring explosive power and muscle endurance in upper and lower extremities (overarm throwing, standing long jump, underarm throwing, lateral step up, chest pass, sit to stand, lifting a box and stair climbing) (Aertssen, Steenbergen, & Smits-Engelsman, 2018).

Cardiorespiratory Fitness

Children with ID have lower levels of cardiorespiratory fitness with lower VO2max and peak heart rate (Hartman et al., 2015; Oppewal, Hilgenkamp, van Wijck, & Evenhuis, 2013). The lower level of physical activity is mentioned as one of the explanations, but the pathophysiological features (e.g., chronotropic incompetence) also contribute to decreased cardiorespiratory fitness.

To measure cardiorespiratory fitness in children with mild ID several tools are available. Treadmill testing is a reliable and valid way to test cardiorespiratory fitness in children with mild ID (Oppewal et al., 2013). Additionally, field-based tests are available to estimate the cardiorespiratory fitness, measuring performance on a fixed running distance such as 300, 500, 880 yards and 1 mile run. These measures are seen as reliable and valid. The 6 min walk test measures cardiorespiratory fitness with a fixed time and measured distance, which is a reliable and valid measure in children with mild ID (Casey, Wang, & Osterling, 2012; Elmahgoub, Van de Velde, Peersman, Cambier, & Calders, 2012). Casey et al. (2012) found a learning effect after two practice trials in children with DS. Two types of shuttle run tests have been investigated in children with mild ID. The 16-meter Shuttle run and the 20-meter Shuttle Run and both are seen as reliable and valid measures (Agiovlasitis, Pitetti, Guerra, & Fernhall, 2011; Beets, Pitetti, & Fernhall, 2005; Fernhall et al., 1998).

(Hyper)flexibility

For flexibility, the Beighton score is a feasible and reliable measure in children with mild ID (Pitetti, Miller, & Beets, 2015). The Beighton test consists of five items (dorsal flexion of the fifth MCP, opposition of the thumb, hyperextension of elbow, hyperextension of the knees, hands flat on floor with straight knees).

Motor Fitness

The EUROFIT test battery is a worldwide used test battery to assess physical fitness in youth and adolescents. It consists of items for endurance, muscle strength, muscle endurance, speed, flexibility and balance. It was adapted for youth and adolescents with ID by removing or replacing items. The adapted version, EUROFIT-Special, consists of items for strength (long jump, pushing a medicine ball), muscle endurance (30 s sit up), speed (25 m run), flexibility (sit and reach test), and balance (balance walk) (Skowronski, Horvat, Nocera, Roswal, & Croce, 2009).

Physical Activity

Children and adolescents with mild ID are known to have lower levels of physical activity (PA) (Wouters, Evenhuis, & Hilgenkamp, 2018). Objective PA measurement may be helpful in providing a more accurate profile of PA levels in children with ID and in assessing effectiveness of intervention programs. To measure levels of physical activity questionnaires, pedometers and other accelerometers have been used. The Physical Activity Questionnaire for older children (PAQ-C) and the Physical Activity Questionnaire for adolescents (PAQ-A) are questionnaires regarding sports, games and physical activity during school time, and leisure time. These questionnaires have been used in different studies in children and adolescents with ID with findings of decreased levels of physical activity (Wyszyńska, Podgórska-Bednarz, Dereń, & Mazur, 2017). Although these questionnaires are used in children with ID, information regarding reliability and validity is lacking.

The pedometer measures the number of steps per day. It has also been used to investigate the level of physical activity in children with ID. Research has shown a lower amount of steps in children with Down Syndrome compared to the TD children (Alhusaini, Ali Al-Walah, Melam, & Buragadda, 2017; Beets & Pitetti, 2011). Also different kinds of accelerometers were used in children with ID (Izquierdo-Gomez et al., 2017; Pitchford, Adkins, Hasson, Hornyak, & Ulrich, 2018), but standardized protocol, cut-off points or information regarding reliability and validity in children with ID is lacking (Leung, Siebert, & Yun, 2017).

ID and Motor Performance

ID and Fundamental Motor Skills

Motor behavior of children with ID differs substantially from that of non-disabled children. It is evident that their motor ability develops relatively slowly and that motor milestones are achieved later (Peuschel, 1987; Ulrich, Ulrich, & Collier, 1992). Many children with intellectual disability have been reported to have deficiencies in fundamental motor skills and physical activity behaviors, which are essential requirements to lead healthy active lifestyles. The high rates of inactivity (Hinckson & Curtis, 2013) are likely to lead to obesity (Ells et al., 2006) and declining physical fitness levels (Wouters et al., 2018; Wyszyńska et al., 2017). New programs and interventions are being implemented to promote active behavior. Enriched environment can create the opportunity for motor learning given the capacity of the child. Aiming at optimal fundamental motor skills or movement literacy (the ability to plan and execute basic motor skills—walk, run, jump, catch, kick, and throw with agility, balance, and coordination) is important for ADL and participation in play and recreational activities.

Fundamental motor skills are related to physical activity (PA) (Cheng et al., 2016; Larouche, Boyer, Tremblay, & Longmuir, 2014). PA is related to physical fitness (Tsiros et al., 2014; Vasconcellos et al., 2014) and motor skills are likewise related to physical fitness (Carroll-Scott et al., 2013; Lai et al., 2014).

The relationship between motor proficiency and physical fitness requires consideration as children with motor deficiencies are less likely to participate in PA (Cairney, Rigoli, & Piek, 2013). It would appear that the reduced motor skills may be one of the characteristics of children with ID that early interventions should focus on.

ID and Physical Fitness

Low levels of motor development are associated with lower levels of physical activity. A systematic review of PA measures in children with ID was undertaken using the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines (Hinckson & Curtis, 2013). The review identified deficiencies on a number of valid and reliable tools used to quantify PA. Despite the differences in study design and methodological quality, there was agreement among studies that children with ID were significantly less active compared to children without ID.

Regular participation in PA enhances body composition (LeMura & Maziekas, 2002), bone health (Morris, Naughton, Gibbs, Carlson, & Wark, 1997), psychological health (Wilkinson, 1983), and promotes social engagement (Jobling, 2001). Key facilitators for PA participation are enjoyment and unstructured activities, social interactions, parental support and increasing level of independence. Such facilitators may have beneficial effects for PA participation in later life (Downs, Boddy, Knowles, Fairclough, & Stratton, 2013). However, children with ID may enjoy PA less, as they have less proficiency in balance and coordination and poor cardiovascular fitness compared to their TD peers (Heah, Case, McGuire, & Law, 2007) The barriers for participation include lack of knowledge and skills, fear, non-stimulating parental behavior, adverse attitudes to disability, scarce facilities, lack of transport, deficient programs and staff capacity, increased cost, functional limitations, unsafe environment, and lack of facilities or programs at close proximity to facilitate access (Stanish et al., 2016).

Environmental Factors

Environmental factors are those aspects that surround children and influence their food intake and physical activity, and include home, school, and community (Karnik, 2015; Sehm, Warschburger, & Abnorm, 2015). It is therefore important to identify environmental conditions that may be optimized to support development and participation of children with ID and promote a healthy life style, within the limits of parental and professional support. The environment should also be supportive so that associated problems are effectively managed. Where there is decreased energy demand (with increased motorized transport to school, etc.) and increased consumption of energy (such as snacks, fast food, and soft drinks), the setting is often referred to as the "obesogenic environment" (Shrivastava, Shrivastava, & Ramasamy, 2016) (p. 430). A recent systematic review supports the vital role of the microenvironment created at home, where the household setting is of significant importance in determining the risk of parental PA levels, eating habits and television viewing behavior. This would apply to all children (with DCD, ID, and TD children) associated with obesity (Kaushal & Rhodes, 2014).

Home Environment

Home is the primary environment for motor development and skill-acquisition for all children. Parents offer the child opportunities for learning and improving skills. The child learns by exploration, trial and error, imitation, feedback and instruction during play and ADL tasks. Parents are the first to note if their child's motor development seems different.

Role-modelling and parental support was the strongest predictor of PA levels in TD children and PA levels of children with ID were highest when parents participated in PA with their children, provided transport (to spaces for recreation, when neighborhoods were non-conducive to PA) or gave them encouragement and support (Fitzgerald, Fitzgerald, & Aherne, 2012). One of the identified barriers to participation was that parents did not value sport and PA for their children (Syrad et al., 2015). The children themselves cited barriers such as time constraints to complete their school homework, lack of physical skills and equipment, and the fact that PA made them sweat, while enjoyment and recognizing health benefits were positively associated with PA (Kubbayi, Jooste, Toriola, & Paul, 2014).

School Environment

Schools offer a stimulating environment for structured learning new motor skills such as writing and physical education (PE) for TD and ID children. Schools have facilities that differ from home, such as proper furniture, objects and instruments for PE and sports grounds, and playgrounds. The children should learn and improve not only by instruction and feedback from the teacher but also by interaction with and imitation of peers in the playground. This provides the extremely important chance to exercise and improve their fine and gross motor skills. Teachers will often note if a child's fine (writing or drawing) or gross motor (playground, PE) are awkward. Teachers play an important role negotiating extra help when the child has special needs.

Additionally, by implementing health and physical education (PE) in school-settings children become aware of the importance of PA and healthy food consumption (Heelan, Bartee, & Nihiser, 2015). These studies support the school environment as a model environment to teach children how to espouse and maintain a healthy and active lifestyle. However, the extent of the successful implementation between schools may vary and school category (with reference to socio-economic status and resources) was found to be significant in the prediction of childhood obesity (Centers for Disease Control, 2013). Emerging research has documented the associations between PA, physical education (PE) and nutrition programs, and academic performance (Muthuri, Wachira, Onywera, & Tremblay, 2014).

Several small-scale studies evaluated enhanced PE interventions or whole-of-school curriculum-based programs, with mixed results. In some cases PA was shown to increase (Minnaar, Grant, & Fletcher, 2016), whereas in other studies, PA and physical fitness remained largely unchanged (Tian, du Toit, & Toriola, 2015). There is a need to further explore the relationship between socioeconomic status (SES), BMI and motor skills, as this would assist in appropriate targeting of school-based interventions. Resources to promote healthy behaviors at schools have also been cited to positively influence implementation of interventions.

Socioeconomic Status

Living conditions and parental behavior affect children's opportunities for (motor) learning, activity and health. Family household factors including SES are associated with parental activity levels and weight status (de Villiers et al., 2012). Parental obesity is a principal risk factor for childhood obesity and poor motor skills. Children raised in socioeconomically disadvantaged conditions are at an increased risk of the development of obesity (Keane, Layte, Harrington, Kearney, & Perry, 2012) and this is attributed mainly to decreased PA and poor-quality diet (Igel, Romppel, Baar, Brähler, & Grande, 2016). In general, the increased accessibility of SES groups to energy-dense foods (including low-SES groups in high-income countries and high-SES groups in low-to-middle-income countries), carry a higher risk of obesity than their counterparts (Mchunu & Le Roux, 2010). More research is needed to understand why children with ID, even more so than TD children, experience such disparities in BMI status and to develop health promotion initiatives targeted at this population.

Role of Physical Activity Participation in ID and DCD

Physical activity is an essential component in the physical, mental, social, and cognitive development of children (Steyn, Nel, Labadarios, Maunder, & Kruger, 2014). Children with ID, being less active, do not engage in PA for the recommended PA duration (Draper et al., 2017). A large proportion of children with DCD also avoid PA because they are excluded by peers, frustrated because they do not master the necessary skills for participation.

The family environment plays an important role and may have significant impact on self-esteem, PA, self-efficacy and physical fitness. The barriers most frequently identified to the active participation in sports and physical recreation of children with disabilities are functional limitations, high costs, unsafe environment and the lack of nearby facilities or programs (Brown et al., 2016). Additional barriers to PA participation are perceived self-competence, time, societal sustenance from schools and communities, and family demographics (Nock et al., 2016).

Intervention and Support

Once the diagnosis DCD has been confirmed and treatment is indicated several options for intervention are available aimed at improving motor

Table 49.2 Main characteristics of task-oriented interventions (TOI)

Characteristics of task-oriented interventions (TOI)
1. Client oriented (meaningful for the client)
2. Goal oriented (aiming at activities and participation as described ICF-CY)
3. Task and context-specific (similar to the goal)
4. Active role of the client
5. Aiming at functionality not at normality (participation is the aim)
6. Active involvement of parent(s)/caretakers to enable transfer and maintenance

performance. For children with DCD without ID task-oriented intervention methods are supported by many review publications (see Table 49.2). Most of these evidence-based methods have the potential to be applied in the treatment of children with ID diagnosed with a motor delay that is larger than expected for their ID (DCD-ID). Such intervention plans should take into account not only the ID but also comorbidities since they have major consequences for the *instruction* (hearing deficit, severe refractive errors and comprehension), the ways to demonstrate and motivate (communication skills), and the *intensity* of exercise (heart conditions, obesity, cervical spine abnormalities, ligamentous laxity joint instability, hypotonia, increased risk of thyroid disease, type 2 diabetes, obesity, seizures). Although treatment programs, so called task-oriented intervention, for children with motor difficulties are available (Preston et al., 2017) it is important to be aware that these children constitute a very heterogeneous group. Hence tailored intervention in addition to and in conjunction with general stimulation for participation in PA is often needed.

Three main goals for intervention are important: (1) Movement literacy, which is the ability to plan and execute basic motor skills—run, jump, catch, kick and throw with agility, balance and coordination; (2) ADL and practical life skills; and (3) to create opportunities for physical activity to develop and maintain physical skills, self-confidence, socialization and prevent non-communicable diseases.

A recent example of a task-oriented intervention is neuromotor task training (NTT). NTT is based upon motor learning theory and an ecological approach. The first step in this method is the identification of those tasks and activities related to participation, which are of greatest concern to the child and his family—these are then the targets of treatment. NTT uses several motor teaching strategies such as implicit learning and external focus of attention suited for children with ID. By using motor teaching strategies therapists guide children through the different phases of motor skill learning by gradually changing task demands, which avoids failure and keeps the children motivated. Tasks and environmental constraints that impede successful task performance are identified and adapted. Task constraints refer to aspects of the task that restrain successful completion of a motor activity, such as when a child cannot catch a tennis ball or cannot close a shirt with very small buttons. Environmental constraints refer to aspects of the environment that impede performance, for instance when a child tries to tricycle on rough terrain. These task and environmental constraints are manipulated in the NTT intervention sessions to provide ample opportunity to practice and improve the deficient motor skills. In the early phase of learning, providing simple demonstration, exploration, and verbal instruction as to the intended outcome of the skill may be adequate to stimulate practice. Next, by repeating the task the child is provided with feedback (information about their performance from the therapist or from other external sources, from the success or failure of the attempt and how to adapt to the different contexts (action-perception coupling) so that they can improve performance on subsequent practice attempts. Techniques such as guided discovery—limiting the exploration space so they find the optimal solution sooner—are applied to promote efficient learning, to ensure development of the skill, and to motivate the child to persist with practice (Smits-Engelsman et al., 2018).

It is important to know that task-oriented training aims at training skills toward the levels and in actual context the task will be performed in later. This is of extra value in children with ID since transfer of skills to other contexts may be limited. Motor tasks in NTT are defined as movements or actions that are executed in order to achieve a goal. These tasks differ with respect to the number of actions needed to complete the task, as well as the degree to which the motor actions need to be integrated with events occurring in the environment. Many tasks require adapting task execution to either static or changing events in the environment. When the people or objects in the room are static, task execution involves integrating information about size, shape, and relative position to plan the movements/actions. When the people or objects are moving, motor planning also involves predicting how and where they will change position in the environment. Tasks, which comprise several separate subtasks, make additional demands on knowledge of the sequence, working memory, ability to persist and stay on task and completing the task within a reasonable/specified time frame. So the fact that a child with ID can walk or catch does not mean that the motor task will be performed adequately under more complicated circumstances, for instance in a game. Especially in children with ID, training the task in the actual context it will be performed in later is needed.

Once a skill is mastered to a certain extent it needs to be integrated into activities of daily living. In several studies, factors are mentioned that facilitate participation in physical activities related to personal aspects (e.g., social interaction, rewarded for participation) and environmental aspects (fun level of the activities, activity program meeting individual need, family support). Also barriers for participating in physical activities are described related to personal aspects (health issues, lack of motivation for physical activity, inadequate level of motor skills) and environmental aspects (financial aspects, limited options for physical activities, transportation, time limit parents, negative social aspect) (Alwhaibi & Aldugahishem, 2018; Bossink, van der Putten, & Vlaskamp, 2017). The importance of developing general motor skills in children with borderline and mild ID, especially with regard to ball skills might contribute positively to their sports participation (Westendorp, Houwen, & Hartman, 2011). Acquiring motor skills is also important in development due to the influence on social and emotional skills.

Stable and competent performance of general motor skills forms the basis for more complex motor skills control (Ulrich, Burghardt, Lloyd, Tiernan, & Hornyak, 2011). These skills are utilized by children when interacting with other children while playing and in other activities. Children with deficient motor skills are often ostracized or they may avoid play in school and neighborhood settings (Pienaar, van Reenen, & Weber, 2016). Play and recreational sports in children with and without disabilities are vital enablers in acquiring functional skills (Lee et al., 2015). The data from limited research studies suggest that deficiencies in the development of motor skills are more likely to be accountable for low PA levels, which are often demonstrated in later life, than is an inherent tendency toward physical inactivity (Lee et al., 2015). There may be a positive influence from early interventions to facilitate the development of competent functional motor control, which will in turn facilitate motor skills.

The physical activity habits of children with intellectual disabilities have been studied far less meticulously than those of typically developing children. There is evidence that children with disabilities are less active because they lack social skills and have inefficient motor skills to support physical activity (Eguia, Capio, & Simons, 2015; Westendorp et al., 2011). Interventions to improve this situation should target these areas. There is a scarcity of published literature on ways to improve physical activity in children with ID. Those studies that have been completed generally lack rigor with small sample sizes and short duration of intervention. Conducting research on children with ID is challenging, and it is recommended that large-scale, multi-site studies be conducted to support increased sample size and adequate study design. Including family support structures and teacher support with regards to education of both teachers and family on health and nutrition, and the inclusion of the benefits of exercise with the participation of families as motivation should be included in intervention programs.

Conclusion

Children with ID may have motor symptoms similar to those of children with DCD. The motor problems are likely to aggravate their lesser opportunities for participation and may lead to developmental and health issues due to inactivity. Gross motor skill proficiency is essential for engagement in sports and physical play and for the development of a healthy lifestyle. Their motor skills may be tested using the validated instruments for children with DCD, adapting the instruction and other cognitive demands if needed, but normative data for this population is lacking. There is real need to improve the motor skill deficiencies in children with ID; task-oriented interventions provide the best-researched opportunity to improve motor skills in DCD. It is recommended that intervention programs also include aspects to influence weight status in ID children. Existing intervention programs to improve selected motor skills and to promote physical activity and health may be adapted from evidence-based programs for children with motor problems. Future research should validate these.

Substance Use Disorders

50

Joanne E. L. VanDerNagel, Neomi van Duijvenbode,
and Robert Didden

Introduction

Substance use disorders (SUD) are among the most common mental disorders in the adult population (Substance Abuse and Mental Health Services Administration [SAMHSA], 2017). Results from a national survey in the USA indicate that 7.5% of the people aged 12 and older have had an SUD in the past year. Individuals with intellectual disabilities (ID) are considered at risk for developing SUD. In this first paragraph, we discuss the core features of SUD, and its diagnostic classification according to the DSM-5. In the remainder of this chapter, we discuss the prevalence of SUD among individuals with ID, its risk factors, and methods for screening, assessment, and treatment of SUD among individuals with ID.

Substance Use and Substance Use Disorders

Substances are being used by many individuals and they are part of their daily lives. Indeed, according to a national survey in the USA (SAMHSA, 2017), in 2016 28.6 million people (10.6%) aged 12 or older used an illicit drug in the past 30 days, 136.7 million used alcohol (50.7%), and 51.3 million used tobacco (19%). For some, the use of substances becomes problematic and they develop an SUD. Results from the same national survey indicate that there were 15.1 million individuals with an alcohol use disorder and 7.4 million individuals with an illicit drug use disorder (SAMHSA, 2017).

According to the American Psychiatric Association (2013), a substance use disorder (SUD) is characterized by a persistent desire to use and the inability to cut down or control substance use, even in the face of severe negative consequences (i.e., physical, psychological, social, or interpersonal problems). This "paradox of addiction" is explained by disruptions in

motivational, reward, and inhibitory control brain regions. These disruptions result in the over-evaluation of substance use-related stimuli, and reduction of inhibitory control. In other words, substance use-related stimuli “grab” the attention, seem attractive, and elicit approach behavior. At the same time, executive functions such as working memory capacity, the ability to delay gratification and behavioral control is deteriorating. Behavior of individuals with SUD is therefore increasingly influenced by automatic processes, indicating a growing loss of control over substance use (Koob, 2013; Volkow, Wang, Tomasi, & Baler, 2013).

In the Diagnostic and Statistical Manual of mental disorders, fifth edition (DSM-5; American Psychiatric Association [APA], 2013), an SUD is assessed on a continuum from mild to severe, using 11 criteria related to (1) impaired control over quantity and duration of substance use (criteria 1–4); (2) social impairment due to substance use (criteria 5–7); (3) risky substance use (criteria 8–9); and (4) tolerance and withdrawal (criteria 10–11). SUD severity is mild when two to three symptoms are met, moderate if four to five symptoms are met, or severe if six or more symptoms are met. It should be noted that severity can change over time. The DSM-5 identifies 10 classes of substances that are commonly found to have addictive potential for a large number of individuals of the general population. These substances are alcohol; caffeine; cannabis; hallucinogens (such as LSD); inhalants; opioids; sedatives, hypnotics, and anxiolytics; stimulants (e.g., amphetamine and cocaine); tobacco; and other (or unknown) substances. Although all of these types have common effects on the brain systems mentioned above, they may differ in other effects (see Box 50.1).

Box 50.1: Types of Substances

There are different methods to classify substances into groups. These methods coexist and serve different purposes, such as diagnosis, legal purposes, and clinical use.

A first distinction is legal versus illegal, or scheduled/non-scheduled. Within the latter system, schedule I drugs are regarded as the most harmful, with high abuse potential and no registered medical use. These drugs include for instance heroin, cocaine, and LSD. Schedule II drugs also have a high abuse and dependency potential, but with medical uses. These drugs include opioids such as methadone and morphine but also methamphetamine. Schedule III–V drugs mainly have medical use, with lower risks for abuse or dependency. Alcohol and tobacco—despite their highly addictive qualities and severe medical, mental, and social consequences—are not classified within this system, which is a downside to this classification system.

A second distinction can be made based to the psychoactive effects. Substances can be stimulating, depressant, hallucinogenic, or a combination of these. Stimulants (“uppers”) increase the activity of the central nervous system and body, and are widely used (prescribed or non-prescribed, legal and illicit) as performance enhancing, mood elevating drugs. Stimulants include substances such as caffeine and tobacco but also methylphenidate, amphetamines, and cocaine. When overdosed, these substances cause symptoms of physical and mental overstimulation, such as restlessness, sleeplessness, tachycardia, hypertension, muscle spasms, irritability, and psychosis. Depressants (“downers”) are substances that reduce arousal and activity, and cause anxiolysis, sedation, pain relief, muscle relaxation, but also somnolence, cognitive impairment, and complete anesthesia or even coma. These substances include alcohol but also opioids and sedatives/anxiolytics. Hallucinogens can cause hallucinations and other changes in cognition. A classic example of hallucinogens is LSD. Cannabis has both hallucinogenic and depressant effects. The distinction between stimulant, depressant, and hallucinogenic properties provides the most help for clinical management during intoxication or withdrawal, even when the exact type of substance that was used remains unclear.

Substance Use (Disorder) in Individuals with Intellectual Disabilities

Prevalence of SUD in Individuals with ID

In 2003, based on the limited number of studies at that time, Sturmey, Reyer, Lee, and Robek (2003) estimated the overall prevalence rate of SUD to be around 0.5–2% of the total population of individuals with ID. In 2010, using a large sample of Medicaid data, Slayter (2010a) found that individuals with ID and SUD constituted 2.6% of all people with ID. Also, using data from the Health Care Access Research and Developmental Disabilities (H-CARDD) cohort, Lin et al. (2016) found 6.4% SUD in adults with ID. It should be mentioned that rates of SUD vary between samples, with higher prevalence rates in populations with psychiatric comorbidity (e.g., Didden, Embregts, Van der Toorn, & Laarhoven, 2009; Plant, McDermott, Chester, & Alexander, 2011) and forensic populations (e.g., Lindsay et al., 2013). As expected, the prevalence rates among individuals with mild ID are much higher compared to those with more severe ID (e.g., Slayter, 2010a). However, given the scarcity of large-scale studies, it remains unclear what "the" prevalence of SUD is in individuals with ID. Given the variety in methodology, results from different studies are difficult if not impossible to compare. At present, we therefore are unable to substantiate (or falsify) the observation that the prevalence of SUD in individuals with ID is rising.

Despite a scarcity of studies, it now is recognized that individuals with ID do use substances, that this substance use (SU) can lead to SUD and that this warrants attention from clinicians and researchers. Several European studies showed that alcohol is the main substance used in adults and adolescents with ID, although prevalence rates are generally lower compared to those in the general population (Emerson & Turnbull, 2005; Pacoricona Alfaro et al., 2017; Reis, Wetzel, & Haßler, 2017; To, Neirynck, Vanderplasschen, Vanheule, & Vandevelde, 2014; VanDerNagel et al., 2017; VanDerNagel, Kiewik, Buitelaar, & De Jong, 2011). Smoking rates, however, are higher in adults and adolecents with ID than those in the general population (Emerson & Turnbull, 2005; Pacoricona Alfaro et al., 2017; Swerts et al., 2017; VanDerNagel et al., 2017). Regarding illicit drug use, studies provide conflicting evidence, with lower prevalence in some studies (e.g., Swerts et al., 2017) and higher prevalence in others (e.g., Pacoricona Alfaro et al., 2017; VanDerNagel et al., 2017). Overall, it can be concluded that substances are used by many individuals with ID, especially those with mild ID and those with comorbid problems.

Prevalence of ID Within Addiction Services

What is even much less known is the prevalence rate of individuals with ID within addiction services. In a survey among staff members, 5.7% of the patients in a Dutch addiction facility were identified as having a mild to borderline intellectual functioning (MID-BIF, IQ 50-85). The authors comment that this is probably an underestimation of the true prevalence of individuals with MID-BIF in SUD samples (VanDerNagel et al., 2014). Based on client related measurements, using the Wechsler Adult Intelligence Scale III (WAIS-III; Wechsler, 2004), To, Vanheule, Vanderplasschen, Audenaert, and Vandevelde (2015) found that the average IQ in a sample of 90 clients with SUD was 89, with 11 clients (12%) having a total IQ score below 70. In another study, an almost identical average IQ (88) was found in a sample of forensic addiction inpatients, with 39% of the sample being identified as having MID-BIF (Luteijn, Didden, & VanDerNagel, 2017).

Challenges in Prevalence Estimations

As illustrated above, it is challenging to provide reliable SU and SUD prevalence rates in individuals with ID (also see Van Duijvenbode et al., 2015). Differences between samples (e.g., community based, institutionalized), subgroups (e.g., forensic, psychiatric), definitions of SU(D), and methodological and measurement issues will result in different rates of SU(D). In addition, the rates may vary between countries, cultures, and regions. Another explanation is that the majority of individuals with mild ID—one of the groups at risk for SU and SUD—is generally housed within the community and may not be known to ID services. Some of these individuals may be known to addiction services, even without being identified as a person with an ID. In fact, adaptive skills deficits in this group may be (wrongfully) ascribed to the SUD instead of to the ID. Last but not least, SU and SUD are under recognized. Both client factors (such as reluctance to admit having a SU related problem), and non-client factors (preconceptions about individuals with ID not using substances, lack of screening) contribute to this lack of timely case identification. Thus, representative and large-scale studies on SU(D) in ID are hindered by practical and methodological challenges. Those identified with SUD are probably the "tip of the iceberg" and may not be representative for the total population (Van Duijvenbode et al., 2015).

Risk Factors for SUD

In addiction medicine, SUD is regarded as a complex and multifaceted brain disorder, with biological, psychological and social risk- and protective factors. These factors and their relationships to SUD have been mostly investigated in the general population. However, these is no reason to assume that the relationships and mechanisms do not apply to individuals with ID. In fact, social and psychological risk factors for SU(D) seem to accumulate in individuals with ID and which may put them at increased risk for SUD (see for example Van Duijvenbode et al., 2015). For example, general risk factors for SUD such as adverse life events, inadequate coping strategies, social isolation, and a low socioeconomical status are often more prevalent in individuals with ID.

In addition to these general risk factors, factors related to the ID, such as lack of basic substance (risk) knowledge and insight in its consequences, lack of delay gratification ability, the desire to "fit in," increased susceptibility to peer pressure, and low self-esteem, may further contribute to SU initiation and the development of SUD in individuals with ID. For instance, individuals with ID are reported to misinterpret the rather "liberal" cannabis policy in the Netherlands and (wrongly) conclude that cannabis use is both legal and safe (VanDerNagel et al., 2017). The relatively high prevalence of co-occurring use of prescribed psychotropic medication and psychiatric disorders further increase this risk. Also, a lack of awareness of SU risks, and recognition of early signs and symptoms of SU by caregivers, as well as barriers in access to preventative and treatment services, may further contribute to the progression of SU into SUD (e.g., Slayter, 2010b; VanDerNagel, Kemna, & Didden, 2013).

Screening and Assessment

Issues in Screening and Assessment

Diagnosis of SUD in individuals with ID is not so much hindered by the complexity of the disorder, but more by the lack of reliable information regarding quantity and duration of SU and its consequences (Mikkelsen, VanDerNagel, & Lindsay, 2016). Both individuals with and without ID may be inclined to underreport their SU, because of fear of stigma and consequences. In individuals with ID, the lack of knowledge about SU risks, including misinterpretation of what can be regarded as safe SU practices, as well as their dependence on others who may judge their SU taking behavior, may contribute to their failure to be forthcoming.

In addition, signs and symptoms of SUD can remain undetected by caregivers for prolonged periods of time. As many of these signs are not specific for SUD, they can be easily misinterpreted as tokens of other problems such as mental or somatic comorbidity or those related to the ID itself (e.g., Van Duijvenbode et al., 2015; VanDerNagel et al., 2013). Such signs may include physical symptoms (e.g., altered consciousness, weight loss, poor general health), psychological symptoms (e.g., behavioural issues, mood swings, impulsiveness), and social problems (e.g., work- or school-related problems, forensic involvement, debts).

The lack of both validated questionnaires and systematic screening procedures further contributes to the underdiagnosis of SU(D) in individuals with ID (VanDerNagel et al., 2013). Widely used mainstream screening instruments for SU(D) such as the AUDIT (Alcohol Use Disorder Identification Test; Babor, Higgins-Biddle, Saunders, & Monteiro, 2001) may not be suitable for individuals with ID. They often rely on a relatively high level of self-reflection, recall, and cause-effect relationships, and may contain complex sentences and difficult wording. Items such as “How often during the last year have you failed to do what was normally expected of you because of drinking” (AUDIT, item 5), and their rating scales (never, monthly or less, 2–4 times a month, 2–3 times a week, and 4 or more times a week) may surpass the cognitive skills of the individual with ID. In addition, screening instruments are generally short, and therefore have a relatively straightforward focus that may evoke evasive responses. Using such a test in individuals with ID may result in both high levels of underreport and overreport (VanDerNagel et al., 2013).

Screening and Assessment Methods

As the diagnosis of SUD mostly relies on information on lack of control over use, social impairment due to SU, and risky use, self-reported information—even in the light of tendencies to underreport—is the cornerstone of SUD assessment. Collateral information, such as reports from family members or professional caregivers, as well as biomarker analysis (such as breath, blood, or urine analysis), can contributute to the assessment. Though the use of the latter is often found appealing (given the presumed “objective” diagnosis), biomarker analysis has some serious limitations, such as false-positive and false-negative testing, as well as a limited window of detection depending on the type of biomarker. In addition, biomarker testing is costly, and generally depends on the subject’s consent and cooperation (e.g., De Beaurepaire et al., 2007). But foremost, though biomarker testing can contribute to assessing SU (and to some extent to assessing amounts of use), it does not provide information on consequences of SU or control over SU.

Strategies that promote timely case-identification are discussing SU in an open, non-confrontational style, preferably before problems arise. Thus, SU should be the topic of conversation in a wide, non-selected population, and skills to adress it, should be present in professionals working with individuals with ID. In subgroups with a higher a priori risk for SUD, such as those with MID-BIF, and individuals with psychiatric, behavioural, or forensic comorbidity, periodically systematic screening should be in place (VanDerNagel et al., 2013). To do this, some authors (e.g., Pezzoni & Kouimtsidis, 2015; Van Duijvenbode, Didden, Korzilius, & Engels, 2017) have used mainstream screening and assessment instruments, that were adapted to the needs of individuals with ID. For example, by using an interview rather than self-report format or by using pictures to assist in differentiating between answer categories. To date, there is only one instrument specifically designed to assess SU(D) among individuals with ID (Box 50.2). Another line of research has been specifically focused on the potential use of implicit measures for the screening, assessment and treatment of SUD among individuals with ID (Box 50.3).

Box 50.2: The Substance Use and Misuse in Intellectual Disability Questionnaire

To our knowledge, the Substance use and misuse in Intellectual Disability Questionnaire (SumID-Q) is the first and only instrument specifically designed to assess SU(D) in individuals with ID (VanDerNagel, Kiewik, Van Dijk, De Jong,

(continued)

Box 50.2 (continued)

& Didden, 2011). It is used in an interview format with the client. The SumID-Q was developed and validated in Dutch, and translated in several other languages. The SumID-Q consists of several steps:

Step 0: Establish a good working relationship with the client, and be willing to discuss substance use in an open, empathetic way. Maintain this neutral stance and an inquisitive attitude during the whole interview.

Step 1: Assess the client's familiarity with substances, using pictures. In this step, the client is playfully confronted with a standardized set of pictures, depicting various products and types of use of tobacco, alcohol, cannabis, and other drugs. Key to this phase of the assessment is to elicit responses indicative for the client's familiarity with the substance, as well as his or her terminology for it. This may include common, but also peculiar slang words for various substances and methods of usage. In the remainder of the interview, the client's terminology is adopted and incorporated in the questions. Though this phase often elicits spontaneous responses indicating the client's SU (such as "I never smoke cigars, I prefer cigarettes"), the client is not pressed to elaborate on his or her experiences yet.

For each of the substances the client is familiar with, steps 2–4 are repeated.

Step 2: Discuss substances and SU in general. Assess the client's knowledge of and attitude towards each type of substance, using the predefined set of questions for each substance. To assist with answer categories, the SumID-Q contains pictures and symbols. During this phase, the interviewer should remain interested in the client's opinion and does not correct or confront him/her. Further assess SU in the client's social environment, by using the standardized questions on substance use among peers, family members, and staff members ("Do your friends smoke cigarettes?" etc.).

Step 3: Enquire about client's own experiences with substance use. After the set of questions regarding SU in the client's social environment, the question "Did you ever use … yourself?" can follow naturally. During this step, it is important to retain a neutral stance. Try to be interested without being inquisitive. Accept whatever answer was given, without questioning its validity.

Step 4: Further inquire about the use of this type of substance. Assess age of first use, patterns of SU (frequency, quantity), SU circumstances (alone/with others, at home or somewhere else), and SU effects (positive and negative). In this phase it remains important to keep a genuine interest in the client's story. Using pictures and focusing on the "how," "what," 'when," "with whom," and "to what effect" help to do so. Try to avoid "why" questions.

Box 50.3: Implicit Measurements

Another avenue that is currently explored to assess SU in individuals with ID, is the use of implicit measurements. SUD is characterized by disruptions in motivational, reward, and inhibitory control processes and subsequent deficiencies in information processing (Hyman, Malenka, & Nestler, 2006; Koob, 2013). More specifically, SUD has been associated with several cognitive biases, including biases in attention, action tendencies, and memory associations (Robinson & Berridge, 2008). This means that substance-related stimuli have gained "incentive salience" and, as a result, "grab the attention," seem attractive and elicit approach behavior. SUD has also been associated with executive dysfunctioning,

(continued)

Box 50.3 (continued)

reflected in a smaller working memory capacity, difficulties in delaying gratification, and less behavioral control in problematic substance users compared to non-problematic substance users (Hyman et al., 2006). Implicit measures are used to assess these neuropsychological changes. In theory, all of these neuropsychological changes can serve as markers for SUD and could therefore be incorporated in screening and assessment procedures.

However, a series of studies of cognitive biases in individuals with ID with alcohol use disorder provided inconclusive results (Van Duijvenbode et al., 2017). Overall, attentional and approach biases were not found. Problematic drinkers with ID did show a so-called interpretation or association bias. In a word association task, subjects were required to finish ambiguous scenarios such as "*Movie night at your friend's house. "One More?" one of your friends asks. You cannot resist the temptation and reach for ....*" Individuals with alcohol use disorders were more inclined to finish these scenarios with alcohol-related answers ("a beer") rather than neutral answers (e.g., "a new film").

The authors hypothesize that in individuals with ID and SUD, the same neuropsychological changes are present as in individuals with SUD without ID, but methodological challenges contributed to the lack of attentional and approach biases. These methodological challenges need to be addressed. The authors therefore discourage the use of currently available, indirect, reaction time-based cognitive bias measurements for clinical purposes but regard word-association tasks as an opportunity to identify high-risk situations for SU.

Diagnosis of SUD is relatively straightforward when basic information regarding SU patterns, behaviors and consequences is available. When an SUD is suspected or confirmed, it is important to assess usage of other substances (past and present) as well. Many substance users combine multiple substances, leading to increased somatic and psychiatric risks as well as potentially specific treatment needs. Smoking requires special attention, being a highly prevalent but often ignored addiction with severe physical and psychiatric complications. Past SU can be relevant both to assess the length of SU history, its complexity (e.g., with shifting combinations of SU), as well as potential risks for current health (including the risk of infections in former intravenous drug users and risks of neurological damage in former alcohol users). Differential diagnosis of a specific type of SUD consists mainly of 1. other SUD (i.e., symptoms ascribed to a stimulant use disorder, can also be caused by new substances such as "designer drugs"), and 2 of the same SUD with a different specifier for severity (e.g., "mild" versus "severe") or stage (e.g., "in early remission"). In addition, related to the direct effects of substances, SU intoxication or withdrawal can be scored (APA, 2013).

Screening and Assessment of Comorbidity

As SUD is often complicated by somatic and psychiatric comorbidity, as well as social issues, a wider assessment of problems is warranted. Instruments such as the Addiction Severity Index (ASI, McLellan, Luborsky, O'Brien, & Woody, 1980) addresses several problem areas such as medical status, employment and social support, drug and alcohol use, legal status, family/social status, and psychiatric status. The ASI requires an interview with a trained profession of about 1 h. For individuals with ID, these standardized questionnaires have the same issues as screening instruments for SUD, with the additional problem of their length. Therefore, screening for and assessing of comorbidity in individuals with ID and SUD often relies on non-standardized methods. In this process, several topics warrant attention: past and present medication use (including over the counter medication, as well as prescribed and non-prescribed opioids, benzodiazepines, and other psychoactive and non-psychoactive medication), medical history and current complaints, psychiatric history and current complaints, as well as assessment of psychosocial functioning. A full assessment should also include a physical and psychiatric examination, as well as a laboratory screening (hematology, liver- and kidney functioning, vitamin B1, B12, D, and thyroid functioning). Urine or saliva drug screening can be used to confirm and monitor (recent) SU but are not to be considered an alternative for an ongoing conversation with the individual about their substance use.

Prevention, Treatment, and Rehabilitation

As SU can have negative effects and may progress into SUD that warrants clinical attention, a variety of interventions is needed in prevention, treatment and rehabilitation. Unfortunately, there is a huge treatment gap: only about 10% of the people who needed substance use treatment received such treatment at a specialized facility in the past year (SAMSHA, 2017). For individuals with ID, access to such services may be even more limited for reasons we discussed earlier.

Prevention

Awareness of the risks for SU(D) in individuals with ID is a prerequisite for adequate preventative interventions. Such interventions may include identifying and reducing risk factors for SU (e.g., addressing mental health issues, inadequate coping, stress), promotion of a positive, healthy and socially inclusive lifestyle (adequate daytime activities, sufficient social and practical support), and reducing external risk factors (e.g., providing a smoke-free living environment, including regulations to prevent caregivers from using substances such as alcohol or tobacco in the presence of clients). Prohibition of and punishment for SU (including withholding care or limiting personal freedom) may have some temporary effects, but in the long run such measures causes serious and unwanted side-effects (e.g., secretive use). As the prison system and the “war on drugs” have proven: eradication of SU through restrictive measurements is unfeasible at best, and comes at a high cost.

Effects of education about the risks of SU as a sole intervention is not an effective strategy to prevent SU, neither in those with or in those without ID (see Kerr, Lawrence, Darbyshire, Middleton, & Fitzsimmons, 2013; Kiewik, VanDerNagel, Engels, & De Jong, 2017). However, both users and nonusers may have a need for factual information on SU to make informed decisions and to communicate with their caregivers. Direct caregivers (including family members and professional staff) are centerpiece in both primary prevention (prevention of SU), secondary prevention (timely case identification), and tertiary prevention (preventing further harm from SU). Therefore, one important preventative intervention is not so much to educate clients with ID but to educate their caregivers.

Treatment of SUD

In less progressed cases, SUD can be treated with relatively short interventions, such as the advice of a general practitioner (or family member/professional caregiver) to cut down on alcohol or benzodiazepine use or to quit smoking. Unfortunately, many clients with SUD are unable to control or cease their SU, even while they are aware of its risks and consequences (e.g., Van Duijvenbode et al., 2015). In those instances, SUD is a complex, chronic, relapsing, and remitting condition that warrants more complex and often multimodal interventions. These may include a combination of motivational strategies, detoxification, cognitive behavioral therapy, relapse prevention, and treatment of comorbidity.

Though SUD poses a threat to the health and well-being of the individual, treatment can be complicated with severe negative health effect. For instance, the detoxification of gamma hydroxy butyric acid (GHB) is associated with serious agitation and delirium, even in clients in specialized addiction services. Alcohol withdrawal symptoms (when not properly managed by benzodiazepine prescription) can lead to seizures and delirium. And restoration of normal dietary intake in malnourished alcoholics can lead to acute and severe neurological problems (Wernicke's syndrome) due to acute vitamin B1 deficiency (as vitamin B1 is utilized in digesting carbohydrates). All of these complications of SUD treatment can be avoided with appropriate medical interventions. Thus, treatment of SUD often requires specialized addiction knowledge and services. Inpatient treatment is needed when the patient requires permanent supervision and when complications within the treatment process are expected. These problems could include the aforementioned medical complications during detoxification but also behavioral or psychological issues, somatic or psychiatric comorbidity, or the inability of the client to complete an outpatient treatment.

SUD Treatment in Individuals with ID

In individuals with ID, a close collaboration between ID service providers and SUD treatment providers is warranted (see Slayter, 2010b; Van Duijvenbode et al., 2015; 2017). Ideally, both types of services know each other's qualities and limitations, and work collaboratively to provide a treatment program tailored to the needs of the individual patient.

General Adaptations

One of the main and common adaptations is the use of a trusted proxy (e.g., family member or professional caregiver) within the treatment program. Such a person can be of utmost value to reassure the client with SUD and ID, to help overcome misunderstandings, to follow through with the program, and to assist practicing newly learned behavior in daily life. Treatment providers in addiction medicine who treat clients with ID need to adapt their language and treatment protocol to the cognitive and adaptive abilities of these clients. Use of pictures, drawings and props as well as real-life examples are helpful. Generally, the client with SUD and ID will require more, but shorter sessions, a more prolonged treatment plan, and—last but not least—a more supportive than confrontational approach.

Motivational Interviewing

Motivational interviewing can help the client to consider the benefits of changing SU, and to explore his or her options how to achieve this change. Several studies suggest that this strategy is feasible for individuals with ID and SUD (e.g., Frielink & Embregts, 2013; Kouimtsidis et al., 2017; Mendel & Hipkins, 2002).

Cognitive Behavioral Therapy

Cognitive behavioral therapy (CBT) is the core of many addiction programs, aiming to increase self-control and improve alternative behavior. Preliminary data suggest that CBT can be sucessfully used in individuals with ID, either in brief extended interventions (Kouimtsidis et al., 2017) or in full CBT protocols (VanDerNagel & Kiewik, 2016). In addiction treatment centers, CBT often is offered in groups. This may not always be suitable for individuals with ID, unless they are placed in more or less homogeneous groups, in which communication and group interactions are correspondent to their abilities.

Inpatient Treatment

Inpatient detoxification may be required more often in individuals with ID, given their higher rates of comorbidity, and their limited cognitive and adaptive skills that may hinder treatment. As detoxification generally is a rather short, medically oriented intervention, providing this type of care to individuals with ID does not imply major adaptations.

Prolonged inpatient treatment may last up to several months, and often uses group therapy as a major intervention. As mentioned above, this may be a hindrance for individuals with ID. Also, individuals with ID may not profit from this type of intervention if they are mixed in mainstream groups. Group interactions—even outside therapy sessions—may be too complicated, the level of staff support in day to day functioning may be too little and vulnerable individuals with ID may be exploited or negatively influenced by group members.

To overcome these issues, several clinics in the Netherlands have established specialized wards for SUD treatment for individuals with ID. Within these wards, the focus is not only on the SUD but also on the development of daily living skills, restoration of daily structure and activities, as well as gradual rehabilitation into outpatient or community facilities.

Relapse Prevention

Given the chronic character of SUD and its associated changes in brain functioning, relapse prevention needs to be integral part of any SUD treatment program. Aim of this type of prevention is not so much eradication of relapse (which is probably unfeasible), but reducing the number and severity of relapses, and to prevent complications. Some clients with SUD in remission and their caregivers may not be very willing to engage in such a program, as they may regard SUD as a problem of the past. A program that focuses on positive goals for the future may be more acceptable to these groups, and achieve the same results as a relapse prevention program per se.

Medication

Prescribed medication can be used during detoxification (to prevent withdrawal), during maintenance treatment and relapse prevention, and to treat somatic and psychiatric comorbidity. Generally, treatment strategies, their indications and contraindications, do not differ between individuals with and without ID. However, clinicians should be aware that individuals with ID may respond differently (i.e., with an increase, decreased, or “paradoxical” effect) to psychoactive medication. Also, the use of aversive drugs (that induce very unpleasant and even dangerous effects when taken together with alcohol), warrant close scrutiny. Though clients with ID may benefit from such drugs (knowing they cannot use alcohol, for the risk of getting unwell), their safe use requires both a level of insight and self-control that may not be present in all individuals with ID.

Rehabilitation

Some clients may not be able to stop or control their SU for a prolonged time. In this group, tertiary prevention interventions (also called “harm reduction”) are needed. These include prevention of somatic complications (e.g., in needle exchange programs), monitoring of general and mental health, and providing social support (including housing, daytime activities and counselling). In all of these interventions, knowledge and skills of ID service providers is needed, as withholding these services may contribute to deterioration of the client’s condition.

Treatment of Comorbidity

Treatment of comorbid somatic and mental health conditions may contribute to the reduction of risk for (prolonged) SU. However, comorbid disorders generally require treatment of both conditions. In the case of substance use induced mental health disorders, symptomatic treatment may be required for the psychiatric symptoms, even though recovery after prolonged abstinence is to be expected. Special consideration should be given to the risk of increasing symptoms of one of the conditions as a result of the treatment of the other condition. Examples of these include relapse or worsening of symptoms of posttraumatic stress disorder (such as irritability or sleeplessness) after abstinence of cannabis, and increasing risks of SU by treating ADHD or pain with poorly monitored prescription medication. However, as mentioned earlier, withholding adequate treatment and support for comorbidity will not help to reduce symptoms and consequences of SUD.

Conclusion

Substance use disorders (SUD) are among the most common mental disorders in the adult population. Substance use (disorders) among individuals with intellectual disabilities (ID) has gained increasing attention, with a growing number of studies on prevalence, assessment, prevention, and treatment of SUD in this population. Although it is still challenging to provide reliable SU and SUD prevalence rates in individuals with ID, it is generally accepted that individuals with ID are at risk for developing SUD and experience more severe negative consequences from SU.

A number of suggestions for policy and practice to further improve the care for individuals with SUD and ID can be made. First, systematic screening and assessment of SU(D) among individuals with ID is essential for timely case identification and increasing the opportunities to intervene in an early phase. Second, professionals need to be aware of possible comorbidity with other medical, mental health, and psychosocial problems. These issues should be included in the assessment and treatment. Third, individuals with ID require specialized care from multidisciplinary teams in which knowledge and expertise regarding both ID and SUD is present. Collaboration and fertilization between addiction medicine and ID service providers are key factors in achieving this. Initiatives such as adapted assessment and treatment protocols (see for example Box 50.2 and 50.3) are therefore welcomed and are in fact becoming increasingly available.

Dementia and Intellectual Disability: Prevalence, Assessment and Post-Diagnostic Support

Eimear McGlinchey, Evelyn Reilly,
Philip McCallion, Pamela Dunne, Niamh Mulryan,
Rachael Carroll, and Mary McCarron

Chapter Overview

This chapter will focus on dementia in people with an intellectual disability. Because for this group a genetic risk factor for Alzheimer's disease leads to higher and earlier incidence, the majority of research to date into dementia in people with an intellectual disability has focused on Alzheimer's disease in those with Down syndrome.

This chapter will discuss the prevalence of dementia in people with Down syndrome, and for people with ID and without Down syndrome. The presentation of dementia will be discussed, along with the assessment of dementia and challenges to assessment due to pre-existing intellectual disability. Post-diagnostic support will be illustrated using a case study highlighting best practice dementia standards in an intellectual disability specialised memory clinic.

Throughout the chapter, key points will be supported using data from the Intellectual Disability Supplement to the Irish Longitudinal Study on Ageing (IDS-TILDA) and from a 20-year longitudinal follow-up study on incidence of dementia in people with Down syndrome.

The Intellectual Disability Supplement to the Irish Longitudinal Study on Ageing (IDS-TILDA) is a unique nationally representative longitudinal study. It is the only study of its kind where people with an intellectual disability over the age of 40 are followed longitudinally in tandem with the general population. Both studies gather data on a wide range of issues, including, social participation and connection, health, mental health, health care utilisation, cognitive health and level of functioning. This allows for direct comparison of the ageing experiences of people with an intellectual disability to those of the general ageing population. Data collected includes dementia diagnosis, ADLs, chronic health conditions, and objective measures of cognitive function. The study has been ongoing since 2009, and has published three waves of data to date. In Wave 1 of IDS-TILDA, there were 753 people with an intellectual disability, of which 149 had Down

syndrome. In Wave 3, there were 609 individuals, of which 109 had Down syndrome, with the majority of attrition attributed to deaths.

The second study is a prospective 20-year longitudinal study on the incidence of dementia, co morbidities, and mortality, in 77 people with Down syndrome, in a dementia specific service (McCarron, McCallion, Reilly, & Mulryan, 2014a, McCarron et al., 2017). For the 77 individuals enrolled in the study, there was a comprehensive baseline screening, with annual follow-up of both cognitive and physical functioning.

Dementia and Alzheimer's

As much of the research focuses on people with Down syndrome, so too does much of it focus on Alzheimer's disease rather than other types of dementia.

Dementia in the general population given it coincides with increases in longevity and reductions of premature deaths (Livingston et al., 2017) is increasingly reported to be the greatest global challenge for health and social care, with the number of people with dementia expected to triple by 2050. The estimated global cost of dementia in 2015 was $818 billion dollars (Prince et al., 2017), a 35% increase over 2010 estimates (Wimo et al., 2017). It should be noted that a progressive decline in the incidence of dementia since the 1970s in the general population has been noted (Satizabal et al., 2016). The reasons for this are not fully understood; however, the earlier diagnosis and more effective treatment of stroke and heart disease may have played a role (Satizabal et al., 2016).

Alzheimer's Disease

Alzheimer's disease is the most common form of dementia, and is the cause of approximately 50–70% of all dementias (Alzheimer's Association, 2018). In the 1984 diagnostic guidelines, to be diagnosed with Alzheimer's disease, symptoms of dementia must be present. This was changed in the 2011 guidelines, where Alzheimer's disease now includes the continuum from initial changes in brain pathology, with or without symptoms, through to dementia. What was previously classified as Alzheimer's disease is now referred to as Alzheimer's dementia, or dementia due to Alzheimer's, and is the phase in the continuum where symptoms of dementia are present (Alzheimer's Association, 2018).

Neuropathology of Alzheimer's and Specific Risk for People with Down Syndrome

Since the discovery of Alzheimer's disease, the only definitive diagnosis was and is at autopsy. Alzheimer's disease is characterised by positive B amyloid neuritic plaques and phosphorylated-tau neurofibrillary tangles (NFT), along with neuronal and synaptic loss (Theofilas et al., 2018).

People with Down syndrome have a genetic risk for developing Alzheimer's disease. A number of studies have shown that by the age of 40, all people with Down syndrome will have the neuropathology of Alzheimer's disease (Lamar et al., 2011; Schupf et al., 2010). The most common cause of Down syndrome is trisomy 21—a triplication of chromosome 21. The amyloid precursor protein (APP) gene is located on chromosome 21, and thus, due to trisomy 21, people with Down syndrome have 4–5 times overexpression of APP (Jennings et al., 2015). This increase in the APP expression leads to an increase in ß-amyloid deposition. The amyloid cascade hypothesis (Hardy & Higgins, 1992; Selkoe, 1991) suggests that the deposition of amyloid ß plays a critical role in the development of AD pathology, with Aß40 and Aß42 being the two major species generated by the amyloid precursor protein (APP) (Schupf et al., 2010). Plasma levels of Aß42 and Aß40 have been found to be higher at all ages in individuals with DS compared to age matched peers (Prasher, Sajith, Mehta, Zigman, & Schupf, 2010).

Tau protein has also been the focus of explanations for the neuropathology of Alzheimer's disease in people with Down syndrome possibly helping to explain neuronal death (Butterfield, Di Domenico, Tramutola, Head, &

Perluigi, 2017). Individuals with Alzheimer's disease are identifiable based on amounts of insoluble tau protein and phosphorylated tau species (Mukaetova-Ladinska, Harrington, Roth, & Wischik, 1993). Changes in tau pathology begin in the outer layer of the hippocampus, with neurofibrillary tangles in the hippocampal CA1 region then found with neuronal loss in the entorhinal cortex (Head et al., 2003). There is also a higher density of neurofibrillary tangles in those with Down syndrome compared to people in the general population (Head, Lott, Wilcock, & Lemere, 2016).

Prevalence, Incidence, Duration, Age of Onset of Dementia

Prevalence

A number of population based studies have focused on the prevalence of Alzheimer's dementia in people with Down syndrome, with the consensus that dementia is far more prevalent in people with Down syndrome than is found in people with intellectual disability from other aetiologies or for people in the general population.

A review of population prevalence based studies was conducted in 2010 (Strydom et al., 2010), with prevalence listed in Table 51.1.

A number of studies have also calculated the age specific risk of dementia in people with Down syndrome. Coppus et al. (2006) reported that, from the age of 45, dementia prevalence doubled with each 5-year interval, up to the age of 60. In this study, prevalence was then reported to decline after the age of 60, most likely due to the higher mortality rates in this age group, as there was no decrease in incidence of dementia over the age of 60.

Table 51.1 Prevalence of dementia in people with Down syndrome; review of studies

Author	Year	Percent
Cooper et al.	1997	21.6
Sekijima et al.	1998	15.1
Holland et al.	1998	24
Tyrell et al.	2001	13.3
Coppus et al.	2006	16.8
Strydom et al.	2007	13.1
Nieuwenhuis-mark	2009	15

In a 20-year longitudinal study in Ireland, age specific risk of developing dementia in a group of women with Down syndrome using incidence rates (McCarron et al., 2017) was calculated as 23% at age 50 years, 45% at age 55 years and 88% at age 65 years. Over 20 years, 97.4% of participants with Down syndrome developed dementia.

In Ireland in Wave 1 of IDS-TILDA, reported overall prevalence of dementia for participants with ID was 5.8%. As the sample aged, this had risen to 9% in Wave 2 and 9.1% in Wave 3. The graph below shows the prevalence of dementia for the overall sample in IDS-TILDA compared to the sub sample with Down syndrome. In Wave 1, 15.8% of those with Down syndrome over the age of 40 had a diagnosis of dementia, compared to 2% of those with non-DS-ID. By Wave 3, this had more than doubled, with 35.5% of those with Down syndrome reporting a diagnosis of dementia; this compared to 3.4% of those with an intellectual disability but without Down syndrome. These figures, however, are likely to be an underestimation, as it was found of those without a diagnosis of dementia, 47% had never had a dementia assessment (McCarron et al., 2017) (Fig. 51.1).

Mean Age of Onset and Duration of Dementia

Understanding the age at which dementia is likely to occur and the number of years with which one will live with dementia has serious implications for individual quality of life, service provision, planning and training needs.

In the same 20-year follow-up study, all 77 participants were screened annually for dementia, and when changes were noted, they were formally assessed with a multidisciplinary team arriving at a consensus diagnosis. The average age of onset in the 20-year study was 55 years, with an average duration of 5.6 years and a median duration of 7 years (McCarron et al., 2017). For those with pre-existing severe or profound ID, survival post diagnosis was 8.6 years.

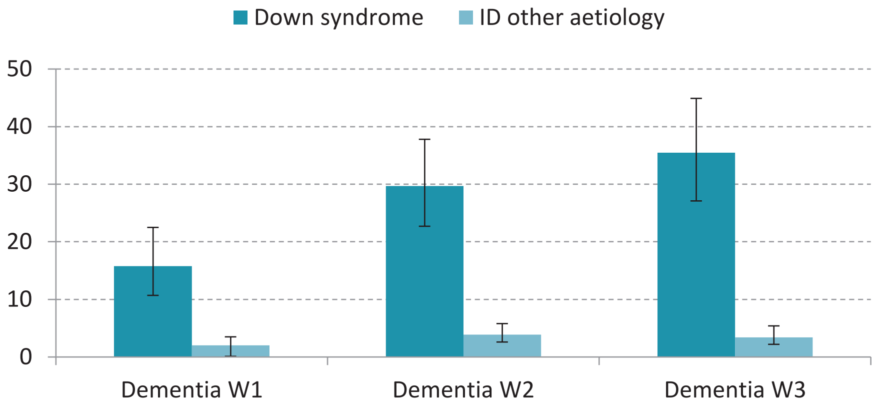

Fig. 51.1 Prevalence of dementia in IDS-TILDA. Wave 1 *n* = 752; Missing Obvs = 1; Wave 2 *n* = 705; Missing Obvs = 3; Wave 3 *n* = 604; Missing obvs = 5; Error bars correspond to 95% confidence intervals

Findings here were similar to those from a study of data extracted from clinical records of 839 individuals (254 with dementia) referred for memory screening. Here the average age of diagnosis was 55.8 years with a duration of 3.78 years and approximately 50% were diagnosed in their sixth decade (Sinai et al., 2017). Those living with family were diagnosed 4.5 years earlier than those who were living away from family.

Despite differences in methodology, there is agreement on age of diagnosis at 55 years in both studies, confirming previous findings of average age of onset of between 51 and 55 years (Lai & Williams, 1989; Prasher & Krishnan, 1993). No significant difference was noted in age of onset for those with mild/moderate or severe/profound intellectual disability (McCarron et al., 2017; Strydom, Hassiotis, King, & Livingston, 2009).

Prevalence of Alzheimer's in Non-DS ID

Prevalence rates for people with intellectual disability but without Down syndrome are not as well established. There has been no consensus on the prevalence with one study showing that prevalence was higher than the general population at 21.6% (Cooper, 1997), and others showing that it was similar to what is found in the general population at 9% in those aged 65 and over (Zigman et al., 2004). In the most recent study to examine prevalence in people with intellectual disability without Down syndrome, it was reported that incidence of dementia is up to five times higher for people with intellectual disability than is found in the general population (Strydom, Chan, King, Hassiotis, & Livingston, 2013).

Presentation of Dementia

Presentation in People with Down Syndrome

Previous literature has shown that all individuals with Down syndrome will have neuropathological and neuro-imaging features of Alzheimer's disease by the age of 40 (Lamar et al., 2011; Roizen & Patterson, 2003; Schupf et al., 2010). Furthermore, it has been shown that age related atrophy in Down syndrome is similar to the atrophy observed in early stages of Alzheimer's disease in those without Down syndrome (Carr & Collins, 2018; Teipel & Hampel, 2006). Nevertheless, presentation can vary largely between individuals and the subsequent rate of decline, although the reasons for this are not fully understood (Lautarescu, Holland, & Zaman, 2017).

Despite the neuropathology being present, it is important to understand that dementia and presentation of clinical symptoms is not inevitable for everyone with Down syndrome. It is essential therefore to understand the unique presentation and progression of dementia in this population so that dementia is not diagnosed when there are other causes of the symptoms observed that may be manageable or treatable (O'Caoimh, Clune, & Molloy, 2013).

The presentation of the later stages of dementia is reportedly similar to that seen in the general population (McCarron et al., 2018; Strydom et al., 2010). The early stages of dementia in people with Down syndrome, however, are believed to be atypical (Lautarescu et al., 2017). While there is some overlap in symptoms such as memory loss, confusion, deterioration in speech, the earliest changes noticed appear to be personality and behavioural changes associated with executive dysfunction, rather than the short-term memory loss that is seen in the general population (Ball et al., 2006). In a systematic review of the early presentation of dementia in people with Down syndrome, 9 of the 15 studies identified "frontal-like symptoms" as the earliest change (Lautarescu et al., 2017).

Behavioural changes may be misdiagnosed as new onset behavioural disorder or depression. Yet, Holland, Hon, Huppert, Stevens, and Watson (1998) reported that behavioural changes noted by carers retrospectively such as apathy, stubbornness, withdrawal were the earliest changes noticed prior to a clinical diagnosis. Behavioural changes have been described by Ball et al. (2006) as being more typical of dementia of the frontal type, and may be seen as preclinical Alzheimer's, which occurs before the continued progression to clinical dementia. For 48% of persons observed in one study, the deterioration of activities of daily living (ADL) were noted as trigger symptoms, with deterioration first noted in personal hygiene and later in spatial disorientation (Cosgrave, Tyrrell, McCarron, Gill, & Lawlor, 2000).

Behavioural and Psychological Symptoms of Dementia (BPSD) are defined as a "heterogeneous range of psychological reactions, psychiatric symptoms and behaviours resulting from the presence of dementia" (Finkel, 2001). BPSD have been studied intensively over the past two decades in the general population, using scales such as the Behavioural Pathology in AD Rating Scale (BEHAVE-AD) (Reisberg, Auer, & Monteiro, 1997) and the Neuropsychiatric Inventory (Cummings et al., 1994). However, despite increased reported prevalence of psychological and behavioural symptoms of dementia, these scales have not been adapted or validated for people with an intellectual disability (Dekker et al., 2015).

Presentation in People with Non-DS ID

For people with intellectual disability without Down syndrome, decline in general functioning along with emotional and behavioural changes are frequently reported with aggression seen more often in those with intellectual disability without Down syndrome, and a higher rate of other behavioural changes noted for those with Down syndrome (Strydom et al., 2010).

Assessment and Assessment Challenges

In this section, assessment for dementia and the challenges in assessment and diagnosis will be highlighted. In discussing the cognitive assessments available and the challenges associated with diagnosis, no differentiation will be made between those with and those without Down syndrome as the same issues appear to apply to all people with intellectual disability regardless of aetiology. However, the use of neuroimaging in diagnosis will be discussed for those with Down syndrome.

In the general population, the diagnosis of dementia depends on reliable clinical history (Bayer, 2018) and includes assessment of core clinical criteria that include

- Interference with ability to work or function.
- Decline from previous function.
- Not explained by major psychiatric episode.
- Cognitive impairment detected and diagnosed through.
  - History taking from patient and reliable informant.
  - Objective cognitive assessment.
- Impairment includes two or more of the following.
  - Impaired ability to acquire or learn new information.
  - Impaired reasoning or handling of complex tasks.
  - Impaired visuospatial abilities.
  - Impaired language function.
  - Changes in personality or behaviour.

    (McKhann et al., 2011)

The International Classification of Diseases (ICD-10) (World Health Organization, 2004) and the Diagnostic and Statistical Manual of Mental Disorders (DSM-V) (American Psychiatric Association, 2013) lay out criteria that need to be met in order to dementia to be diagnosed. There are some differences in the criteria depending on which is used, where the ICD-10 puts emphasis on emotional changes, where the DSM-V does not.

Usefulness of Criteria for Dementia and Mild Cognitive Impairment for People with Intellectual Disability

There are no specific guidelines in the ICD-10 (World Health Organization, 2004) or the DSM-V (American Psychiatric Association, 2013) for diagnosing dementia in people with intellectual disability (O'Caoimh et al., 2013). The same criteria, however, can be used for people with intellectual disability as are used in the general population, as long as it is understood that any observed decline is relative to baseline functioning levels, rather than impairment to "normal" functioning (Ball et al., 2004). The Diagnostic Criteria for use with adults with Learning Disabilities (DC-LD) was developed in 2003 to compliment the ICD-10 and to improve accuracy of diagnosis in people with an intellectual disability (Royal College of Psychiatrists, 2001). It was found that there was some discrepancy between rates of diagnosis using the DC-LD compared to previous diagnoses using the ICD-10, including discrepancy in prevalence of dementia, but that the DC-LD was useful in aiding the diagnosis in this population (Tully, Schirliu, & Moran, 2012).

It is essential that criteria for diagnosing dementia are able to differentiate between deficits due to dementia and those due to other cognitive deficits, such as is found in intellectual disability. One study examining the predictive validity and reliability of the DSM-IV and the ICS-10 criteria when used in a one-off assessment with people with intellectual disability (Strydom et al., 2013) found that, although validity and reliability were satisfactory, results were less stable than reported in the general population. This was particularly true for people with severe or profound intellectual disability.

There is no consensus on whether the ICD-10 or the DSM-IV criteria are more useful for people with intellectual disability (Aylward, Burt, Thorpe, Lai, & Dalton, 1997). Prior to the DSM IV, the ICD-10 criteria was recommended for use with people with an intellectual disability as there is greater emphasis on the emotional, or "non-cognitive" aspects of dementia, which are often the earliest signs reported by people with an intellectual disability. In a more recent study, the DSM-IV criteria were found to be more inclusive of people with an intellectual disability with moderate to severe dementia (Strydom et al., 2007). More work is needed to see if this also holds for use of DSM V criteria.

Challenges in Assessment

The presentation of the early stages of dementia in people with intellectual disability can differ from early symptoms in the general population. Difficulties in diagnosis may be due to the pre-existing intellectual disability (Aylward et al., 1997) and the fact that individuals do not reach the same cognitive ability as individuals without an intellectual disability, thus it may be more difficult to identify decline due to dementia, rather than pre-existing intellectual disability (Rowe, Lavender, & Turk, 2006). For people with Down syndrome, it has also been found that by age 50, scores decline on tests even for those without dementia—suggesting there is a confounding age related decline in people with Down syndrome that is not due to dementia (Carr & Collins, 2018). Non-dementia age-related cognitive decline has similarly been documented in the ageing general population (Grady, 2008). For instance, older individuals regularly perform at a lower level than their younger counterparts when engaged in cognitive tests that require working memory, task switching and attention, all of which are largely associated with executive functioning. It should be noted, however, that these effects seem to occur at a later stage in the general population, with most research in this field tending to focus on those in their seventh decade.

In the general population, dementia diagnosis relies on the integration of history, physical examination and cognitive testing (Feldman et al., 2008). While this is true also for those with intellectual disability, a number of challenges pose unique difficulties for diagnosis:

- Difficulties in communication.
- Lack of baseline measurements.
- Difficulties in using standardised tests.
- High staff turnover.
- Lack of awareness of caregivers of the significance of decline.

(McCallion & McCarron, 2004; McCarron & Lawlor, 2003).

A Model of Best Practice for Diagnosis

An international consensus group developed a model of best practice for the diagnosis of people with intellectual disability in order to overcome these challenges (Burt & Aylward, 2000). They recommended a baseline assessment of people with Down syndrome >35 and for others with an intellectual disability >50 and an annual follow-up assessment with agreed and validate measures. This model continues to be refined with guidance for a comprehensive diagnostic workup if an initial decline is noted and a person centred approach to subsequent care including specialist staff training, standardised assessments, and further research (McCarron et al., 2014a; McCarron et al., 2017; Wilkinson & Janicki, 2002). These recommendations continue to be endorsed, with the British Psychological Society continuing to recommend reactive screening and prospective monitoring (British Psychological Society and Royal College of Psychiatrists, 2015; Jokinen, Janicki, Keller, McCallion, & Force, 2013).

Assessment Process

Based on the model of best practice, the recommended assessment process is:

Baseline Assessment

A baseline assessment should be completed for adults with Down syndrome by age 35 and for adults with intellectual disability from other aetiologies by age 50 (Aylward et al., 1997). It is more straightforward to measure pre-morbid level of functioning in the general population through self-report or employment history; however, this is not always the case with an individual with intellectual disability, making baseline screening more important in this population. Measurement of a pre-dementia baseline is needed against which deterioration later in life may be measured avoiding reliance on a "normative" level for an assessment instrument, which likely does not apply for a person with an intellectual disability.

Data from the IDS-TILDA study shows that the percentage of the overall intellectual disability population in Ireland who had ever had a dementia assessment increased from 14.3% in wave 1–30% in Wave 3 (6 years later), and from 13.9% to 61.4% for those with Down syndrome.

While this increase in screening is positive, the data also shows that 47% of those with Down syndrome who did not have a diagnosis of dementia at wave 3 had never had a dementia assessment. This finding highlights that prevalence figures may be underestimated due to lack of baseline screening.

Monitoring

Annual screening after baseline screening is recommended so that any change is picked up at the earliest possible stage. Annual screening should also include information on any other changes noted in everyday functioning.

Regular monitoring ensures that (1) changes due to dementia are noted early in the course of the illness, (2) any other health conditions that may mimic symptoms of dementia, but are treatable are noted and addressed and (3) care plans are adapted if medical, psychosocial or environmental interventions need to be put in place.

Dementia Assessment and Diagnostic Work Up

If changes are noted in the screening process, a dementia assessment is recommended. The initial step is to rule out other physical causes that could mimic the symptoms of dementia. Physical, psychiatric, neurological and audiology assessments are needed (McCarron & Lawlor, 2003).

Recommended physical checks include

- Full blood count.
- Urea and electrolytes.
- Blood sugar.
- Thyroid function tests.
- Liver function tests.
- Folate and B12.
- Lipid levels.
- Sensory screening—vision and hearing.

(British Psychological Society & Royal College of Psychiatrists, 2015)

A dementia diagnosis should result from a multidisciplinary team coming to a consensus agreement on diagnosis after considering assessment data on the individual's physical, cognitive, emotional and mental state, along reviewing possible environmental influences and external life events that may have contributed to the change.

Assessment Instruments

Assessment of cognitive function is essential in the field of dementia study, both for timely diagnosis, and for symptom measurement following treatment using anti-dementia drugs. While the Montreal Cognitive Assessment (MOCA) (Nasreddine et al., 2005) and the Dementia Rating Scale (DRS) (Mattis, 1988) are standardised and validated in the general population, they are not suitable for use with people with an intellectual disability, particularly for those with moderate or more severe level of intellectual disability. For example, it has been found in one study that three quarters of people with ID who might be classified as having dementia based on Mini Mental State Examination (MMSE) score did have a diagnosis of dementia when other criteria were applied (Deb & Braganza, 1999).

One difficulty in diagnosing dementia in this population is the lack of an agreed battery of instruments. The benefits of having such standardised tests for use with a population with intellectual disability would include results being directly comparable, and it would facilitate communication between clinicians (Zeilinger, Stiehl, & Weber, 2013). In a systematic review on assessment instruments for dementia for people with an intellectual disability, 114 different tools were identified by Zeilinger et al. (2013).

Administration of neuropsychological assessments can be challenging to administer, due to communication difficulties and pre-existing intellectual impairment, particularly for those with severe or profound intellectual disability (McCarron et al., 2017). Due to these challenges, there is often a reliance on informant measures, where information on an individual's functioning

Table 51.2 Informant and objective measures of dementia for people with an intellectual disability (Strydom & Hassiotis, 2003; Zeilinger et al., 2013)

Informant		
Dementia Questionnaire for People with Learning Disability (DLD)	Evenhuis et al. (2007)	The *DLD*, an informant-based questionnaire, consists of 50 items and eight subscales. It measures specific cognitive deterioration as a result of dementia, as well as functional deterioration as a result of dementia severe sensory or psychiatric problems
IQ Code	Jorm (1994)	An informant tool that determines whether there is a decline in cognitive functioning
Dementia Scale for Down syndrome (DSDS)	Gedye (1995)	Test to determine the presence of dementia. Can only be administered by psychologists or psychometrists
Cambridge examination for Mental Disorders of the Elderly, modified for use for assessing people with Down syndrome (CAMDEX-DS)	Ball et al. (2004)	An informant assessment tool for diagnosis dementia in people with Down syndrome. Emphasis is placed on change from person's previous best of functioning
Dementia Screening Questionnaire for Individuals with intellectual Disability (DSQIID)	Deb et al. (2007)	The 53 items of the DSQIID cover areas such as loss of memory, confusion, loss of skills, social withdrawal, behavioural changes, psychological symptoms, physical symptoms, sleep logical symptoms, physical symptoms, sleep disturbance and speech abnormalities
Adaptive Behaviour Dementia Questionnaire (ABDQ)	Prasher et al. (2004)	15-item questionnaire to detect change in adaptive behaviour
Objective		
Test for Severe Impairment	Albert and Cohen (1992)	The Test for Severe Impairment (TSI) is a 24-item scale that measures a range of cognitive functions including motor performance, language production, language comprehension, memory, conceptualisation, and general knowledge
Down syndrome mental status examination (DSMSE)	Haxby (1989)	Objective measure of memory, orientation, language, visual perception, spatial ability, praxis
Neuropsychological Assessment of Dementia in Adults with intellectual Disability (NAID)	Crayton et al. (1998)	Simple battery of tests covering memory, orientation, language and praxis
Brief Praxis Test	Dalton and Fedor (1997)	The BPT is a 24-item non-verbal cognitive test. It requires simple behavioural responses with minimal language demands
Modified FULD object memory Test	Seltzer (1997)	Memory is one of the key changes in dementia. The Modified Fuld Object-Memory Test assesses recognition/naming and learning/recall. The test includes the use of objects rather than pictures to improve salience, and inclusion of multiple presentations as well as a recognition trial

over a period of time can be gathered by someone who knows the person well (McKenzie, Metcalfe, & Murray, 2018). In order to complete a dementia assessment in this population, it is recommended that that both objective and informant measures are used. Table 51.2 summarises some of the measures that have been found valid and useful for a population with an intellectual disability.

Evidence from Research

20-Year Follow-Up Study

In a longitudinal 20-year follow-up study in Ireland, at a specialist memory service for people with an intellectual disability, dementia assessments were completed for all 77 participants with Down syndrome on an annual basis. These assessments included the Test for Severe

Impairment (Albert & Cohen), The Down syndrome Mental State Examination (DSMSE) (Haxby, 1989), The Dementia Questionnaire for People with Learning Disability (DLD) (Evenhuis, Kengen, & Eurlings, 2007), and the Daily Living Skills Questionnaire (National Institute of Aging 1989). As of 2017, 75 of the 77 (97.4%) had developed dementia. Data is available on the annual cognitive assessments. The graph below shows scores on the four instruments 5 years prior to diagnosis and 5 years post diagnosis. An increase in scores on the DLD indicates lower level of functioning with DLD scores plotted on the secondary axis on the graph below (Fig. 51.2).

As can be seen on this graph, scores on the DLD show the earliest signs of decline, suggesting this is the most sensitive instrument used, with decline seen over a period of 5 years pre diagnosis. The DLSQ measures activities of daily living and identified changes 3–4 years prior to diagnosis. The TSI and DSMSE appeared less sensitive to change prior to diagnosis, (McCarron et al., 2017). When changes in scores were mapped by level of intellectual disability, greater change was seen for those with a moderate level of intellectual disability as compared to those with a severe level of intellectual disability; perhaps when scores are higher at baseline, greater change can be seen over time (McCarron et al., 2017)

IDS-TILDA

IDS-TILDA has cognitive scale data on 609 people who have completed the TSI for all three waves of the study to date. As is shown on the graph below, scores for those with a diagnosis of dementia in Wave 1 declined more over time than for those without a diagnosis, lending further confirmation to the sensitivity of the instrument (Fig. 51.3).

Neuroimaging and Assessment in People with Down Syndrome

There are findings that people with Down syndrome show accelerated ageing in the brain, with an adjusted brain predicted age increase of 7.69 years (Cole et al., 2017) and greater age related reduction in the frontal, temporal, and parietal lobes compared to the general ageing population (Beacher et al., 2009). The most consistent structural change seen early in Alzheimer's disease is atrophy of the temporal medial lobe. Neuroimaging studies have found that atrophy is present in the temporal medial lobe in people with Down syndrome even without a diagnosis if dementia and no normative values have been established for people with Down syndrome (British Psychological Society & Royal College of Psychiatrists, 2015). Some MRI studies with people with Down syndrome have shown signifi-

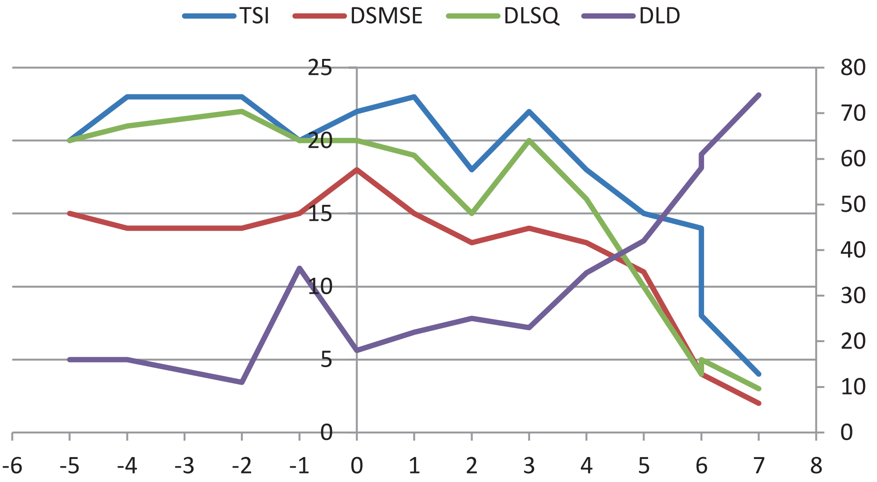

Fig. 51.2 Scores on cognitive assessments in 20-year follow-up study in people with Down syndrome

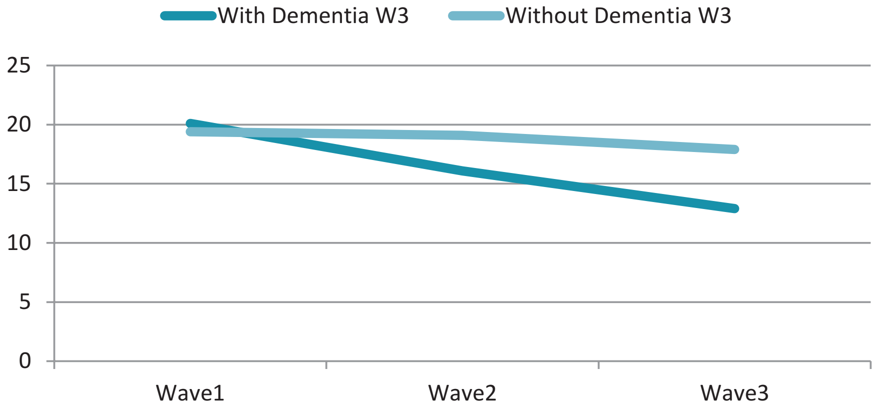

Fig. 51.3 Change in score in TSI for those with and without dementia diagnosis in IDS-TILDA

cant reduction in volume in the temporal lobe and hippocampus in individuals with Alzheimer's compared to those without Alzheimer's; however, the samples were small and those with Alzheimer's were significantly older than the controls without Alzheimer's (Kesslak, Nagata, Lott, & Nalcioglu, 1994; Pearlson et al., 1998).

In a more recent study, however, it was found that, when adjusted for head size, age and gender, volume size of the hippocampus, striatal structures and amygdala was significantly smaller in those with Down syndrome and Alzheimer's compared to those with Down syndrome without Alzheimer's. The volume of the hippocampus and the caudate nuclei (dorsal striatum) appeared to distinguish between people with Down syndrome with and without Alzheimer's with 90% specificity and 80% sensitivity (Beacher et al., 2009). This is an important finding but clinical use is limited, as cross sectional data does not address time course changes. Longitudinal studies are therefore needed to better distinguish brain changes associated with Alzheimer's from anomalies associated with Down syndrome (Neale, Padilla, Fonseca, Holland, & Zaman, 2018).

Co-morbidities

Co-morbidities in People with Down Syndrome

Frequency and severity of co-morbidities appear to be associated both with presence of Alzheimer's and with the stage of Alzheimer's in people with Down syndrome (McCarron, Gill, McCallion, & Begley, 2005). Among participants in the 20-year follow-up study in Ireland, co-morbidities were common (see Fig. 51.4) with vision impairment the most commonly reported, at 93.3%, and hearing impairment at 61.3%. Epilepsy was also common.

Epilepsy in People with Down Syndrome and Dementia

In the IDS-TILDA study, 77.9% of participants had epilepsy, and all participants with epilepsy had a diagnosis of dementia. Diagnoses of epilepsy and dementia were highly associated, and a diagnosis of epilepsy came on average 0.57 years after a diagnosis of dementia. This is in keeping with previous research on epilepsy and dementia in a population with Down syndrome. It has previously been reported that 80% of people with Down syndrome and dementia will develop epilepsy, and younger age of onset of dementia is associated with greater risk of seizures (Menéndez, 2005). Finding in the Irish longitudinal follow-up confirm these earlier reports.

Co-morbidities Common in All People with Intellectual Disability and Dementia

In addition to the co-morbidities found in the study above for people with Down syndrome, sleep disorders, gastrointestinal disorders, infec-

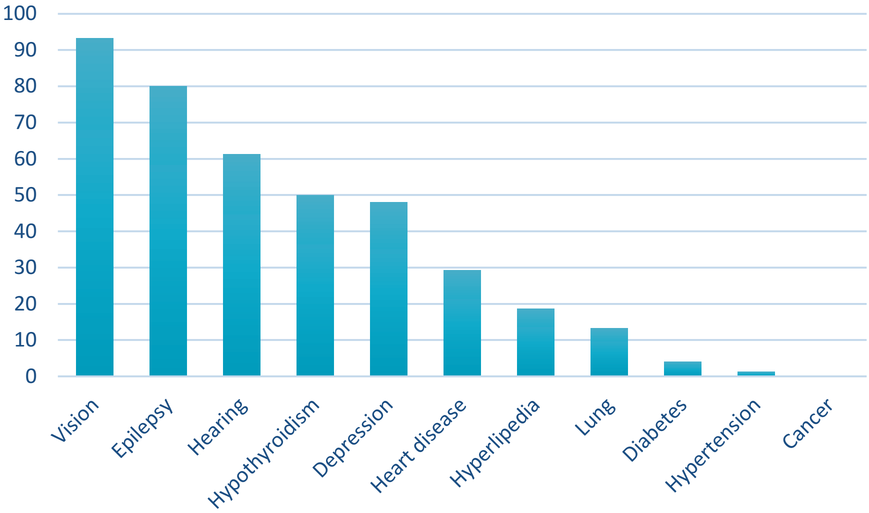

Fig. 51.4 Health co-morbidities of dementia in people with Down syndrome in 20-year follow-up study

tions and pain have been recognised as common co morbidities associated with dementia for people with an intellectual disability (British Psychological Society & Royal College of Psychiatrists, 2015).

It was been highlighted that pain can go unrecognised in this population. In one study examining staff knowledge and experience in working with people with intellectual disability and dementia, it was found that pain often went undetected and unmanaged, and where behaviours were assigned as "challenging" rather than associated with pain (Wilkinson, Kerr, & Cunningham, 2005).

Diagnosing pain in people with intellectual disability and dementia can also be challenging due to:

- Diagnostic overshadowing.
- Communication challenges.
- High turnover of staff.
- Carer beliefs about pain thresholds in people with ID.

(British Psychological Society & Royal College of Psychiatrists, 2015; McCarron et al., 2014b)

Post-diagnostic Support

Good quality post-diagnostic support is essential for people with intellectual disability who develop dementia. It is acknowledged that environmental features that do not meet the needs of older adults can trigger confusion and result in agitation and disruptive behaviours (Brawley, 2001). Also, in the general population, of the estimated $818 billion spent on dementia care, it is estimated that 85% of costs are related to family and social care rather than medical care (Livingston et al., 2017).

There are numerous definitions of post-diagnostic support where some place emphasis on planning, support, information and maintaining independence (World Health Organization, 2012), and others place more emphasis on psychosocial interventions (Watts, Cheston, Moniz-Cook, Burley, & Guss, 2013). The British Psychological Society focus the definition of post-diagnostic support on the person, rather than the disease and place emphasis on things that help the person to live well (British Psychological Society, 2015). This includes ensuring that the individual feels a sense of belonging to their family or community, and being able to contribute and participate meaningfully to their community. Post-diagnostic care refers to care from this time a dementia diagnosis is highly suspected through to end of life stage of dementia. Thus, there is a recognition also that any definition of post-diagnostic care needs to be flexible enough to adapt to the changing demands and needs of the individual as dementia progresses (Dodd et al., 2017).

The first stage of post-diagnostic support is helping the individual to understand and to come to terms with the diagnosis. As with all care for the individual with intellectual disability, the approach should be individualised and person centred, where the carer best known to the person and family members should lead in sharing information to share, and in understanding what the individual is experiencing (Jokinen et al., 2013; Tuffrey-Wijne & Watchman, 2014).

Stages of Dementia

Early Stage Dementia

In the early stages of dementia, subtle changes in behaviour and mood may be seen, with difficulties in memory for recent events, completing everyday tasks and learning new information, declines in social and daily living skills, and disorientation.

The emphasis at this stage is to support the individual to maintain their skills while gradually increasing support to the individual as needs change. This may also involve simplifying elements of support, such as communication, routines and tasks.

Suggested activities for this stage include arts and crafts, board games, discussion about people and places, use of visual planners (Jokinen et al., 2013; Watchman, 2014).

International guidelines recommend the use of non-pharmacological interventions at this stage, to deal behavioural or psychological symptoms of dementia; however, there is a lack of evidence base to suggest which non-pharmacological interventions to use (Kales, Gitlin, & Lyketsos, 2015).

Mid Stage Dementia

Mid stage dementia is characterised by further memory loss including of names of familiar people, declines in language, difficulties with self-care, personality or mood changes, problems with eating and drinking, disturbed sleep patterns and increased incontinence (British Psychological Society & Royal College of Psychiatrists, 2015).

The focus of care at this stage is to reduce stress and anxiety, interventions to preserve abilities while ensuring safety, comfort and dignity. Excessive demands on the individual should be reduced, with clear routines and with as little change as possible especially with respect to health and social care services (Dodd et al., 2017; Jokinen et al., 2013).

There should be a focus at this stage should focus on finding failure free activities; music therapy, aromatherapy, reminiscence, movement and exercise, one-step gardening such as watering plants, massage (Watchman, 2014).

Late Stage Dementia

Myoclonus and epilepsy are common in late stage dementia, incontinence is prevalent, along with loss of eating/drinking skills, difficulty recognising people, will require 24 h care, will be bedridden and there is greater risk of infections, particularly pneumonia (British Psychological Society & Royal College of Psychiatrists, 2015; McCarron et al., 2018).

Health monitoring is essential at this stage, with attention to weight, nutrition and hydration, continence, pain and epilepsy (British Psychological Society & Royal College of Psychiatrists, 2015; Jokinen et al., 2013).

Activities at this stage include smiling and laughing, singing, stroking, holding, gentle rocking (Watchman, 2014).

End of Life Care

Defining end of life is difficult in any situation, but is further complicated in people with an intellectual disability. Scales used in the general population such as the Global deterioration scale (Reisberg, Ferris, Leon, & Crook, 1982) or the Functional Assessment Staging Tool (FAST) scale (Reisberg, 1988) are of limited use with people with intellectual disability, as some people may not have had the stated capabilities to begin with. There are consensus recommendations that the FAST scale supplemented with findings of acute medical complications, recurrent infections, pneumonia, pressure sore and/or pressure sores is indicative that life expectancy is of 6 months or less, and care should move to specialised end of life care (McCallion et al., 2017).

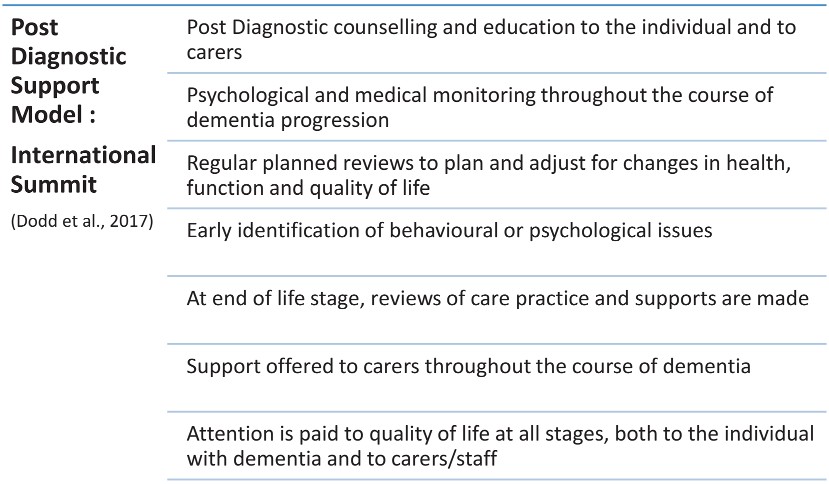
Understanding the characteristics of advanced dementia in people with Down syndrome and/or other ID is critical to understanding when transitions must be initiated from active curative care to supportive comfort care that is palliative care (McCarron et al., 2018). It is essential that person-centred approaches embedded in prior care are continued, and that there is genuine collaboration between ID services and hospice/palliative care with planning that involves the person with ID their families, other carers and their peers. The history and the voice of the person with an intellectual disability must continue to be heard (McCallion et al., 2017; McCarron et al., 2018).

A consensus statement of the international summit on intellectual disability and dementia recommended that post-diagnostic support needs to be individualised and adapted to the person's needs as dementia progresses (Dodd et al., 2017). This statement also highlighted that models of post-diagnostic support for people with an intellectual disability generally mirror those for the general population. The main differences noted were that many people with intellectual disability are part of a service prior to diagnosis, and thus post-diagnostic support tends to be an extension of this service, adapted to serve specific dementia needs. Specific consensus group recommendations (see Table 51.3) addressed care across the stages of dementia, regular reviews and attention to needs of carers.

It was also noted that because people with intellectual disability are often attached to formal services prior to the dementia diagnosis, approaches to post-diagnostic support tend to be more person centred than in general dementia care. Care goals are often to adapt the service that was already in place for the individual to ensure that changing needs are better supported (Dodd et al., 2017; McCallion et al., 2017; McCarron et al., 2018).

Supports and interventions are individualised and tailored to both the person's pre-existing level of intellectual disability and stage of dementia with an emphasis on the psychological wellbeing of the individual and the minimisation of the impact of changes for the individual with

Table 51.3 Model of post-diagnostic support for people with an intellectual disability and dementia



Post Diagnostic Support Model : **International Summit** (Dodd et al., 2017)	Post Diagnostic counselling and education to the individual and to carers
	Psychological and medical monitoring throughout the course of dementia progression
	Regular planned reviews to plan and adjust for changes in health, function and quality of life
	Early identification of behavioural or psychological issues
	At end of life stage, reviews of care practice and supports are made
	Support offered to carers throughout the course of dementia
	Attention is paid to quality of life at all stages, both to the individual with dementia and to carers/staff

dementia and their carers (British Psychological Society & Royal College of Psychiatrists, 2015; Jokinen et al., 2013).

These theories of post-diagnostic support have been brought together in a practical way in the Standards of dementia care (McCarron & Reilly, 2010) developed at the Daughters of Charity Service.

The Daughters of Charity Disability Support Services

The Daughters of Charity Disability Services provides a wide range of services to with intellectual disability in Ireland. A dementia specialist clinic was established to respond to

1. The changing demographics of the service users.
2. An ageing population with Down syndrome.
3. The need to restructure residential and day programmes.
4. The need to upskill staff at all levels of the organisation.
5. To address end of life care concerns.
   (McCarron, McCallion, Reilly, & Mulryan, 2014b)

The memory clinic is run by two clinical nurse specialists in dementia. Baseline screening for dementia is completed with all adults with Down syndrome over the age of 35 and with individuals with intellectual disability from other aetiologies from the age of 55. Annual screening is then completed, using a mixture of objective and informant measures.

In 2011, two purpose built dementia homes were built; an eight bedded home specifically to accommodate the needs of those with mid stage dementia and a six bedded home adapted to accommodate people with end stage dementia (McCarron & Reilly, 2010). The houses were designed to support the changing needs of individuals with intellectual disability across the continuum of dementia with features of the design selected to minimise stress, and to compensate for the loss of abilities with the aim of empowering the individual to use their remaining abilities to the greatest extent.

Features of the home include

- Familiar features and a homely style.
- Curved corridors with strategic seating to promote wandering and to cue to rest.
- Open plan kitchen to allow for involvement in cooking activities.
- Good signage and "cueing" with good visual access.
- Large central garden area to support gardening activities, found to be therapeutic.
- Supports unplanned activities between staff and service users, such as taking a walk in the garden.
- The ability for staff to be able to discreetly observe service users, without encroaching on their space.

Standards of Dementia Care

Within the context of a memory clinic, specialised residential facilities and ongoing support for ageing in place for many individuals with Down syndrome and dementia standards of dementia care were established to formalise the essential elements that are needed to provide a consistent quality approach to dementia care (McCarron & Reilly, 2010).

The six standards recognise the uniqueness of each person's experience of dementia (Fig. 51.5).

Standard 1: Appropriately Trained Staff and Service Development

It is essential that people with dementia receive care and support from staff that have sufficient and correct knowledge to care effectively. Education on dementia is also recommended for peers with an intellectual disability, which is tailored to their needs. Information is also offered to families of the individual with dementia in relation to dementia care.

Standard 2: Memory Assessment Service

All individuals with intellectual disability have access to baseline screening, following up assessment and timely diagnosis of dementia. The memory clinic model offers systematic screening, assessment, diagnosis, including a compre-

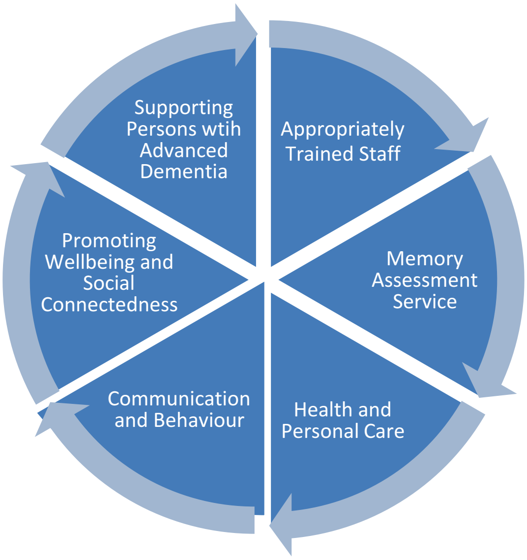


Fig. 51.5 Standards of dementia care

hensive diagnostic work-up and post-diagnostic support and treatment.

Standard 3: Health and Personal Care

Individuals are encouraged to continue with previous level of personal care to the greatest extent possible. Person centredness underpins all physical care activities with focus on dignity, privacy and the person's preferences. Optimum physical and mental care is essential using a multi-disciplinary approach and in partnership with the individuals with dementia, their carers, family and healthcare team.

Standard 4: Communication and Behaviour

Effective communication is essential in order to maintain the individual's personhood and well-being, and to minimise stress for the person with dementia. Non-cognitive symptoms that cause distress are assessed in a timely manner to alleviate aggravating factors. Every effort is made to support ageing in the home of choice for the individual, but that procedures are in place should the changing needs become too great where a change in living circumstances is recommended.

Standard 5: Promoting Well-Being and Social Connectedness

Relationships between the person with dementia and to those important to them are encouraged, and supported. Activities that reflect the person's lifelong interests are maintained as much as possible, and are adapted to support changing needs of the person.

Standard 6: Supporting Persons with Advanced Dementia: Addressing Palliative Care and End of Life Needs

Care is appropriate to the needs of the individual and adapted as necessary. Every effort is made to optimise the person's quality of life by providing the best end of life and palliative care. End of life plans take in to account the person's religious, cultural and spiritual needs. The family and staff who best know the person with dementia have the opportunity to discuss and partake in decisions relating to end of life.

Case Study of Best Practice in Dementia Care for individual with Down syndrome and Dementia

Paula∗ was born in 1962 with Down syndrome and a moderate intellectual disability. In her adult years, she lived in a community home with other people who had an intellectual disability within a large disability organisation in Dublin. Paula was an independent person. She mastered many home making skills, travelled independently, worked a few hours weekly in her local supermarket and had an active social life competing in swimming and bowling at Special Olympics both nationally and internationally.

The organisation Paula attended has a specialist Memory Clinic and in line with international best practice, Paula received a baseline neuropsychological screening at age 35 years. This screening entailed completing a variety of cognitive tests and with informants in her both community home and work placement, giving information on her functional, cognitive and social skills. The Clinical Nurse specialist (CNS) in dementia who completed the screening process documented in detail Paula's functional, cognitive and social abilities. Over the following years, these assessment scales were repeated and compared along with an overview of Paula's physical health profile.

In 2009 when Paula was aged 47 years, the first perceptible changes were noted at her annual screening. Staff in her home described that Paula was more irritable with her peers and she was more argumentative. They described "door banging" and episodes of weepiness. Paula had become more apathetic and was declining to participate in previously enjoyed activities. Staff were requested to seek a mental health review to rule out depression. There was no decline noted in Neuropsychological assessment scores and no change to functional skills. Staff had observed no changes to her short-term memory. Despite this, the CNS was alerted to the change in personality. Frontal temporal type changes are often first observed as prodromal dementia changes; however, it is vital at this stage to rule out environmental/mental health contributory factors as these can mimic early dementia type changes.

Over the following 18 months, the following changes were observed. Staff noted that they had to repeat their instructions more often and Paula started to require verbal prompts to keep her orientated to her weekly routine. She insisted on making her lunch for work at weekends and found it difficult to adapt to a change in routine. She misplaced her house keys and when something was misplaced, she blamed her peers, which escalated arguments within the home. In 2011, a consensus meeting with the Psychiatrist, CNS dementia and key support staff agreed the presentation typical of Alzheimer's type dementia in people with Down syndrome and a full physical work up to rule out differential diagnosis was undertaken. Following this work-up, a formal diagnosis of Alzheimer's dementia was made and a trial of cognitive medication was commenced.

Supports were put in place to enable Paula to continue to engage in her day-to-day activities of living and her diagnosis was shared with her in a way that was meaningful to her. The CNS spoke to her of having problems with her memory and encouraged her to use her diary and visual pictures to help keep her orientated to her daily activities. Family and staff also helped Paula to create her life story in a photo album and Paula found this very enjoyable. Staff training guided practice consistent with the Dementia Care standards (McCarron & Reilly, 2010).

The CNS continued to repeat the neuropsychological assessment tools to support Paula, her family, peers and staff through the stages of dementia.

In 2013, Paula had increased problems with her communication and she had great difficulty in expressing herself verbally. Her short-term memory was very impaired and she could not remember an instruction given moments before. Her cognitive test scores plummeted and she required support in all activities of daily living, dressing, showering and feeding. Staff provided an increased level of verbal and physical prompts and they endeavoured to support Paula to maintain each skill for as long as was possible. In this, the mid stage of dementia typical issues emerged as Paula tried to make sense of her world. With increased confusion and declining emotional control, she would hit out at peers and staff showing evidence of hyperacusis, an increased sensitivity to noise. Staff used her life biography to support their care practice and reminiscence provided a valuable tool for redirection when Paula became overwhelmed in day-to-day situations While supporting Paula to the extent possible in her existing home Paula was also introduced to a specialist home supporting people at mid stage dementia. In October 2013, she commenced respite there, initially for afternoon visits progressing to overnights and then weekly stays. This allowed a break for her peers who found it difficult living with their friend who had now become very vocal at times screaming at them for no apparent reason. It was important to engage her peers understanding of what was happening for Paula and through a series of peer support sessions using resources from Dementia Scotland the CNS offered education on supporting their friend with dementia.

Staff in her long-time home wished to continue to provide care for Paula but this became increasingly difficult when problems emerged with depth perception and mobility. Paula lived in a two storey home with no downstairs sleeping accommodation. In 2014, she started to have difficulty getting on and off the bus and staff was concerned in relation to her safety when using the stairs Family and key support people's views were considered and it was decided that the specialist home could best support her current and future care needs and a detailed transition plan was developed.

Behaviours that arose in her community home were less evident in specialist home for people with mid stage dementia and Paula was supported to maintain previously important relationships as is detailed in standard 5 of the dementia care standards.

In 2015, Paula developed new onset seizure activity. Despite being well managed through anticonvulsant medication, the development of seizure activity corresponded with a further decline in her dementia. Issues of incontinence and immobility became a further issue. Paula had access to an Occupational therapist, Physiotherapist, Speech and Language therapist and dietician and their combined skills provided expertise in managing her safety and comfort as dementia progressed. Paula's dementia assessment review pointed towards late stage dementia and as the year progressed, she had an increase in respiratory and urinary tract infections. Paula moved to a specialist home that supports the advanced palliative care needs of people with an advanced dementia in 2016. Its environment is quieter than her previous home and best supports the needs of a person with advanced dementia.

Advance care planning had been discussed with family and this conversation was further progressed when Paula moved to the specialist home for advanced dementia. Family, Paula's GP, CNS dementia and key support staff discussed what was in Paula's best interest and her prior expressed wishes in terms of supporting her health needs as her dementia further progressed. Resources from the Irish Hospice foundation and palliative care guidelines were used as a framework for discussions. Family had built a relationship of trust with Paula's care professionals and all decisions were made supporting a palliative approach to care.

In June 2017 surrounded by family and friends, Paula passed away peacefully in this home. Her life was celebrated and her loving memory lives on.

Issues of Sexuality and Relationships

Nathan J. Wilson, Patsie Frawley,

Judith McKenzie, and David Charnock

Background

Sexuality in the lives of people with intellectual disability is almost always conflated with sexual abuse, sexual behaviours, sexual knowledge and questions about capacity to "be" sexual. Rarely is sexuality discussed in a more holistic way that acknowledges pleasure, desire, identity and "self-authored" sexual expression. Writers like Michael Gill (2015) suggested this is due to sexual ableism which he defined as "the system of imbuing sexuality with determinations of qualification to be sexual based on criteria of ability, intellect, morality, physicality, appearance …" (p. 3). Through this lens, sexuality in the lives of people with intellectual disability is mediated by ideas about capacity and competence, assumptions of desirability and overshadowed by a discourse of risk and vulnerability. Foley (2017) reported that underpinning this discourse is a "paternalistic regime" whereby the sexual lives of people with intellectual disability are strongly surveilled, often by parents or other caregivers. He described this regime as being played out where people with intellectual disability, despite their chronological adulthood, "either must ask permission and/or are prevented by their parents from taking control over their social/sexual lives" (p. 6).

Lost in this discourse are opportunities to consider sexuality as a humanly intrinsic part of life and a right for people with intellectual disability as it is for their peers who do not have the

restrictive label of intellectual disability. Michael Perlin, a noted scholar in disability and human rights law, noted that "One of the most controversial social policy issues that remains dramatically under-discussed in scholarly literature is the sexual autonomy of persons with psychosocial and intellectual disabilities" (Perlin & Lynch, 2015, p. 10). The absence of a codified right to "be sexual" in society's most progressive and unifying international law on the rights of people with intellectual disability, the United Nations Convention on the Rights of Persons with Disabilities (CRPD) speaks loudly about the way sexuality is positioned in relation to other rights.

Evidence from reviews of the CRPD committee's deliberations about sexuality indicate that a sense of "moral panic" from conservative religious and cultural nations has ensured sexual rights are not included in the Convention (Ruiz, 2017; Schaaf, 2012). Although a number of the articles in the Convention give a nod to sexuality, no single article exists asserting this right, therefore there is no requirement for signatory nations to focus their attention on how to progress this right. While Article 23 asserts the right to "form a family", there is no recognition of how you might do this by being sexual. Likewise, although Article 25 refers to sexual health there is no clear reference to the link between "being sexual" and sexual health. With the CRPD lacking this clear reference to sexuality rights signatory nations can easily overlook sexuality and sexuality rights in their domestic laws and policies. It is important to recognise this absence and its implications as Article 4 of the Convention requires that signatory nations "engage themselves to develop and carry out policies, laws and administrative measures for securing the rights recognized in the Convention and abolish laws, regulations, customs and practices that constitute discrimination" (UN General Assembly, 2007). Rather than the Convention providing a template for the progression of sexual rights for signatory countries, there is greyness about the place of sex in the lives of people with disabilities.

Sexual health is referred to in the CRPD, where Article 25 notes State Parties shall "Provide persons with disabilities with the same range, quality and standard of free or affordable health care and programmes as provided to other persons, including in the area of sexual and reproductive health and population-based public health programmes" (UN General Assembly, 2007). The inclusion of sexual health is important as it acknowledges, albeit secondarily, that people with disabilities are sexual and that their sexual health along with physical and mental health is a significant health area. Very little research is available about the sexual health status of people with intellectual disability with reports generally referring to "disability" more broadly. The research that is available suggests that people with disabilities are experiencing rates of STIs and HIV/AIDS in particular at higher rates than the general population (WHO/UNFPA, 2009).

A report by WHO/UNFPA in 2009 cited the link between poverty and disability as a significant factor in suboptimal sexual health outcomes for people with disabilities (WHO/UNFPA, 2009). This report suggested the need for an intersectional approach to understanding and responding to sexual health in the lives of people with intellectual disability. It makes the following five recommendations for addressing sexual health:

1. Establish partnerships with people with disabilities to address sexual health,
2. Raise awareness and increase accessibility in mainstream health and sexual health services,
3. Ensure all sexual and reproductive health programmes reach and serve persons with disabilities,
4. Address disability in national sexual and reproductive health policy, laws, and budgets, and
5. Promote research on sexual and reproductive health of persons with disabilities at local, national and international levels (p. 1).

This framework provides guidance to signatory countries to the CRPD in how to work towards recognising the right to optimal and equal sexual health for people with disabilities, but it requires that national and international disability advocacy continues to pick this issue up and progress it.

For example, in Australia, the peak women's disability advocacy organisation Women with Disabilities Australia (WWDA) have taken the lead in this area. In their latest work they reported on research they undertook with women with disabilities about access to health services where sexual health was a key focus. In addition to issues of general inaccessibility reported in this research, the report makes an important point about the need for an acknowledgement of the sexuality of people with intellectual disability to ensure access to sexual health services. In this research they also found that gender was a key site of discrimination in relation to accessing sexual health services. This is captured strongly by one woman who noted "My doctor refused to believe me about my sex life" (Women with Disabilities Australia (WWDA), 2018 p. 7).

Many people with intellectual disability live at home with family caregivers, who themselves face a range of issues in supporting access to sexual health supports and services for their family member who has intellectual disability. It is important to understand these issues and to be aware of the underlying issues families deal with. As Foley (2017) noted, the way families see and respond to the sexuality of their family member with intellectual disability are informed by their paternal/maternal frame of protection.

Family Caregiver Roles—Risk Versus Protection

The role of families in supporting the sexuality of their family members with intellectual disability has only received minimal attention in research, practice and theorisation. What has been researched shows that the issue of sexuality is fraught with challenges for families at conceptual, moral and practical levels and that these challenges are similar across cultural contexts (O'Neill, Lima, Thomson Bowe, & Newall, 2015; Rogers, 2010). For example, family caregivers, especially parents, sometimes struggle to accept and understand that their adult children with intellectual disability have sexual needs as their focus tends to be more about the adult's limitations and the moral and practical responsibilities of ensuring the safety of their adult child.

The continued dependency of people with intellectual disability on family caregivers raises conflicts for the family caregivers of how much protection and how much support to give to the family member with intellectual disability in the area of sexuality (Dupras & Dionne, 2014). For example, Foley (2013) described the mothers in his study as "reluctant jailors" in order to illustrate the tension of trying to create a balance between their children's need for sexual empowerment and the maternal desire to offer protection from harm. Although Foley (2013) only sought the views of ten mothers, the quandary faced by these mothers is a common experience (Pownall, Jahoda, Hastings, & Kerr, 2011; Rushbrooke, Murray, & Townsend, 2014).

The responsibilities and emotional attachment that comes with such a caring relationship often pushes family caregivers towards a more conservative outlook as compared to paid caregivers, professionals and other people who do not have that day-to-day responsibility (Aunos & Feldman, 2002; Brown & Pirtle, 2008; Rushbrooke et al., 2014). For example, an Irish study by Evans, McGuire, Healy, and Carley (2009) compared the attitudes of paid and family (i.e. unpaid) caregivers to the sexuality of people with intellectual disability and found that the attitudes of paid caregivers aligned more closely with the rights-based approach. In a recent South African study, although family caregivers had some conceptual understanding of sexuality as a human rights issue, it appeared much more limited and conservative (Kahonde, 2016). These attitudes, in turn, impact upon the type of sexuality education that the family member with intellectual disability may, or may not, receive.

When comparing the family caregivers' perceived role as sexuality educators for their children with and without intellectual disability, there is evidence that the way the family caregivers perceive the cognitive capabilities of their child with intellectual disability impacts on the nature and extent of any sexuality education they provide (Pownall et al., 2011). For example, Pownall, Jahoda, and Hastings (2012) in Scotland

and Gürol, Polat, and Oran (2014) in Turkey reported similar findings that although mothers recognised the need to provide sexuality education for their children with intellectual disability, they did not provide that sexuality education. One major issue is the limited access to education support about sexuality for family caregivers of people with intellectual disability, in particular more explicit sexual activities and expression (Gardiner & Braddon, 2009; Rojas, Haya, & Lazaro-Visa, 2016). By limiting access to education and support for aspects such as intimacy, sexual intercourse, sex for pleasure and procreation, does the person with intellectual disability a disservice which may be attributed to the disablist myth of asexuality. That is, the conception by family caregivers of their sons/daughters with intellectual disability as not capable of, or not interested in, the more intimate aspects of sexuality (Dupras & Dionne, 2014; Pownall et al., 2011). Further to this, family caregivers have also been reported as trying not to "wake sleeping dogs" where the fear is held that providing any sexuality education may inadvertently make their children aware of "new" sexual knowledge that may lead to added problems for the caregiver (Kahonde, 2016).

Family caregivers also identified a lack of skills and knowledge as one of the reasons that prohibit them from providing people with intellectual disability with the necessary supports and education for sexuality (Aunos & Feldman, 2002; Isler, Beytut, Tas, & Conk, 2009; O'Neill et al., 2015). This lack of knowledge and information is even common in high-income countries that, arguably, one would assume to have more progressive disability policies and more accessible services (O'Neill et al., 2015; Wilson & Frawley, 2016). Those family caregivers who do provide sexuality education, seem to do it selectively and with a primary focus on protecting their family member with intellectual disability rather than supporting them to develop friendships and to underpin the formation of healthy relationships. Hence, early intervention in supporting the family caregivers and their specific concerns about sexuality and relationship formation is vital.

Supporting People with Intellectual Disability to Form Meaningful Relationships

Having meaningful relationships and finding someone to share life experiences with are important aspects for our perceived quality of life. Additionally, being able to develop meaningful sexual relationships are an important aspect to our sexual health (World Health Organization, 2010). Unfortunately, many people with intellectual disability do not have the opportunities or experience to develop these relationships and get little help from others to form and maintain relationships. Some studies show that people with intellectual disability experience loneliness more so than those without a disability (Fulford & Cobigo, 2016; Gilmore & Cuskelly, 2014). The social networks of people with intellectual disability are also known to be small and consist mostly of family members or professional caregivers (Van Asselt-Goverts, Embregts, & Hendriks, 2013). Where people with intellectual disability do have friends, some report they do not see them very often (McVilly et al. 2006). In research with people with intellectual disability on relationships, to the question, "Why are relationships important?" many people answered that they want somebody to share their life with and don't want to be alone (Schaafsma, Kok, Stoffelen, & Curfs, 2017). Arguably this is the same response you would expect from anyone who has been asked this question; however, for people with intellectual disability the pursuit of such relationships can be difficult, and loneliness can ensue.

Experiences of loneliness can have detrimental effects on one's quality of life. There are two types of loneliness, social and emotional loneliness. Social loneliness arises when a person feels that their social network is inadequate. People have the need to belong to different groups of people, with each group having their own role and function. Friends, for example, fulfil a different role than colleagues. Emotional loneliness is felt when a person lacks intimate relationships, in other words, when a person does not have anyone they can discuss important issues with or when a person has a lack of physical intimacy with other people (De Jong Gierveld, 1998). Having meaningful relationships also helps to improve one's self-esteem and self-confidence with low self-esteem linked to a range of psychopathology, such as depression, anxiety and eating disorders (Bos, Huijding, Muris, Vogel, & Biesheuvel, 2010; Fulford & Cobigo, 2016). Other benefits of having meaningful relationships that were mentioned by people with intellectual disability are having access to practical and emotional support (Fulford & Cobigo, 2016) and having a "normal identity", which for some is associated with a sense of pride (Bates, Terry, & Popple, 2016).

Therefore, in order to counter loneliness, it is important to not only increase the number of people in one's social network and make sure there is diversity, but also improve the quality of these relationships. Although the characteristics of having intellectual disability may mean difficulties with social skills and social communication, they also face added barriers to making contact with friends on their own and getting to know another person through conversation and social contact. Barriers to developing an intimate relationship can include the negative attitudes of caregivers towards these relationships, leading to restrictive rules (e.g. not allowed to have somebody sleep over) and a lack of privacy; especially for those living in supervised residential settings. Further, a lack of money can limit social contact and has associated barriers including access to transport to spend time developing these relationships (Fulford & Cobigo, 2016).

In the quest of finding a partner, studies have shown that *similarity* is important, meaning that relationship success is related to having things in common. For example, enjoying the same activities or having a similar level of intellectual disability (Fulford & Cobigo, 2016). However, this is not always straightforward. For example, some people with intellectual disability have reported not being attracted to people who have a "visible" disability, such as people who use a wheelchair (Bates et al., 2016). Also, dating agencies for people with intellectual disability have reported some challenges with matching people, partly due to the unrealistic expectations of one partner in the relationship regarding who they see themselves having an intimate relationship with. Some people with intellectual disability have also reported not wanting to date another person with intellectual disability or indeed a person who has a greater degree of intellectual disability than themselves (Fulford & Cobigo, 2016; Schaafsma, n.d.). Other issues for people looking for heterosexual relationships includes that more males than females are looking for relationships, and for people whose lives are closely supported by caregivers and family there are issues for getting the right kind of support for dating and developing intimate relationships.

Having meaningful relationships including intimate relationships is good for our well-being, but people with intellectual disability experience many barriers to this. In order for them to succeed, support by family or professional caregivers is vital. They need help in learning how to make contact with other people, practical support such as being driven to a date or meeting, and support when they do manage to find somebody they enjoy spending time with. For many people with intellectual disability, family caregivers can have the primary role in providing support for developing a range of relationships including intimate relationships. Gender and sexual orientation of the person with intellectual disability can play a major part in the issues thy face getting the support they need.

Issues Facing Women and Girls with Intellectual Disability

Research on the lived experiences of women with intellectual disability has repeatedly concluded that gender and disability cannot be separated, emphasising the importance of gender in understanding people's lives and experiences (McCarthy, 2014; Traustadóttir, 2006). For women and girls with intellectual disability, this includes their access to and experience of health, particularly gynaecological health, and their gendered experiences of sexuality and sexual autonomy. In addition, they face the same gendered disparities in health and gendered messages about sexuality as other women, while somehow also being seen as inherently "unlike" other women.

Research in the area of gynaecological health has shown that women with intellectual disability have lower rates of participation in preventative screening such as cervical screening and breast screening, in numbers often markedly below women without intellectual disability (Cobigo et al., 2013). This research documents the often "extremely limited knowledge" of women with intellectual disability, high anxiety about women's health screening including mammography and a general lack of understanding about women's health (Truesdale-Kennedy, Taggart, & McIlfatrick, 2011).

Menstruation is the subject of many myths for women with intellectual disability, including the idea that they will inevitably have problems with menstrual care, including hygiene, increased discomfort during menstruation and premenstrual stress (Gomez, Carlson, & Van Dooren, 2012). Research with young women with intellectual disabilities confirms that menstruation and management of it is a strong focus of sexuality education for them (Frawley & Wilson, 2016) and clearly the management of menstruation has underpinned the management of reproduction. The way that reproductive rights have been managed for women with disability, including sterilisation–often performed involuntarily–is well documented in the research and oral history literature (e.g. Tilley, Walmsley, Earle, & Atkinson, 2012). Initially it was ideas from eugenics that enabled the control and management of women's reproductive rights. The same arguments are now presented as being in the "best interests" of the woman and/or the carers who support her; that involuntary sterilisation continues today demonstrates how the lives and rights of women with intellectual disability remain surrounded by a "roaring silence" (Tilley et al., 2012).

In research with women with intellectual disability they have highlighted: the importance of intimate romantic relationships (e.g. Rushbrooke et al., 2014); experiencing barriers to their sexual autonomy through implementation of service policies by staff and surveillance by family members (e.g. McCarthy, 2014; O'Shea, 2016); issues relating to knowledge of and choice about contraception (McCarthy, 2009, 2010), and a lack of health information and treatment for menopause (McCarthy, 2002). Where sexual autonomy is achieved, it is something that women fear losing as they get older. As Rojas et al. (2016) noted, the attitudes of others about women and girls' sexuality are significant because of the corollary between restrictive views and how they can hinder women and girls achieving their rights. Further, the messages presented to women with intellectual disability by disability service staff are informed by traditional gendered stereotypes and while there may be a focus on factual information there is no attention given to pleasure, desire or intimacy (Bernert, 2011).

There is evidence that gender can present a positive and productive frame for negotiating desired identities and relationships for women with intellectual disabilities (O'Shea, 2016). However most of the research paints an unhappy picture, where women report predominantly "negative perceptions, negative experiences, thwarted ambitions and abuse that dominate the narratives of the women [who spoke about their lives]" (McCarthy, 2014, p. 124). Women with intellectual disability have also echoed traditional gender beliefs, particularly concerning homophobia, limited and exclusively heterosexual sexual experiences (which were viewed with fear both of the act and of negative consequences), and overwhelmingly negative stories of disconnection and dissatisfaction with sexuality (Fitzgerald & Withers, 2013).

Motherhood is one of the strongest gendered roles available to women, in most cultures it defines contemporary ideals of womanhood and femininity. Many women with intellectual disability have reported their desire to become mothers. A review of the history of sterilisation of women with intellectual disabilities found that this is a hope most often thwarted (Tilley et al., 2012). Women with intellectual disability who do become mothers are significantly marginalised with compulsory removal of their children common. Even if children are not immediately removed, the difficulty in accessing effective maternal and child health and support services and the often high levels of surveillance mothers with an intellectual disability experience have resulted in further isolation and disempowerment for them. The effects of removal of their children are felt deeply and have resulted in significant, longstanding grief and turmoil for many women with intellectual disability.

Issues Facing Men and Boys with Intellectual Disability

Men and boys with intellectual disability face unique gendered issues concerning their sexuality. This is not only due to the greater prevalence of intellectual disability in males when compared to females at a ratio of approximately 3:2, but the reality that the majority of caregivers—paid and unpaid—who provide support and care to people with intellectual disability, are female. This specifically gendered dynamic, although a usually tacit and common occurrence across the globe, has received scant attention in the research literature by practitioners and applied researchers. In addition, unlike the area of women's health and intellectual disability, there are very few, if any, well-known international researchers who are leading a male intellectual disability research agenda looking at health and wellbeing. This limited gendered focus means that there is not a wide body of work about men and boys with intellectual disability that can be drawn upon in the pursuit of evidence-based interventions (Merrick, Morad, & Carmeli, 2014).

The most common area of research focus reported in the literature is about problematic male sexual behaviour (Wilson, Parmenter, Stancliffe, Shuttleworth, & Parker, 2010). Specifically, this problematized research covers socially inappropriate sexual behaviour (Wheeler & Jenkins, 2004), public masturbation (Hingsburger, 1994), prescription of anti-libidinal medication (Sajith, Morgan, & Clarke, 2008), and unwanted touching of female paid caregivers (Thompson, Clare, & Brown, 1997). There are also a few smaller areas of focus including the increased prevalence of hypogonadism (McElduff & Beange, 2003), testicular cancer and undescended testes (Sasco et al., 2008), and one paper that reports a much greater incidence of STIs in a sample of Dutch males with intellectual disability (van Schrojenstein Lantman-de valk, 2005). Given the ageing of the population of people with intellectual disability, the lack of any research about prostate screening represents a major gap that, conceivably, will become more prominent in the years ahead.

In an attempt to chart a more meaningful and positive approach to the sexuality of men and boys with intellectual disability—rather than further reifying the dominant problematized discourse—an Australian study reported that the expression of their sexuality is a combination of the individual's developmental stage and the gendered influence of caregivers (Wilson, Parmenter, Stancliffe, & Shuttleworth, 2011). That is, sexuality and sexual expression is a healthy biological imperative that is often and reluctantly regulated by caregivers who are forced to act as interactional gatekeepers in a service delivery context where policy guidance is severely limited. Missing are guidelines and interventions that provide staff with a framework of supports guiding them on what to do in order to better support men with intellectual disability. For example, in this Australian study female caregivers reported not knowing what to do when changing the incontinence pad for a man with intellectual disability or showering a male with an erection. Rather than a common sense guideline in how to respond to such normative sexual expression, the issue becomes a problem for the male with intellectual disability, thus pathologising their sexuality even further. A different example involved a UK study where adult males with intellectual disability who accessed pornography, were stopped from doing so as it upset a female paid caregiver (Yacoub & Hall, 2009).

Research focusing on masculinity in the lives of boys and men with intellectual disability has identified that external control is often applied in relation to the embodiment and expression of gendered identity (Charncok & Standen, 2013; Wilson, Parmenter, Stancliffe, & Shuttleworth, 2013). Together this small body of research stresses the difficulties experienced across the spectrum of intellectual disability in specialist residential and educational settings. Furthermore, the research highlights the similarities and differences for boys and men at different points on the spectrum, emphasising the need for a focused approach to the critical study of men and masculinity for this group.

Wilson et al. (2013) in their ethnographic study, concerned with the lives of both boys and men living in three group home settings staffed predominately by female carers, describe difficulties with the construct of a masculine identity when the individual has a significant intellectual disability. Data from interviews with carers, participant observation and the collection of relevant artefacts created the concept of *Conditionally Masculine*, which suggests both normalised notions of changing masculinity and change that is conditional on the severity of disability and on the position of workers to the performance of masculinity. The researchers identified the concept to help recognise that significant levels of intellectual disability can be associated with acquired disadvantage in relation to a developing gendered identity. In essence, disadvantage was an accepted feature of being a boy or man if an intellectual disability was present. However, Wilson et al. (2013) argued that *Conditionally Masculine* was identified as neither an entirely negative or positive concept, but provides hope that its further investigation will be helpful in establishing a valued construct of masculinity for boys and men with intellectual disability.

In contrast, the study by Charncok and Standen (2013) explored the development of culturally normative ideas of masculinity for teenage boys in a special educational setting. In this study, the voice of the boys themselves gives shape to their lives and offers an insight into their hopes for the future. This revealed a complex tapestry of both restriction and emancipation, as the boys begin to face the prospect of life in a gendered world and a developing understanding of the effect of their impairment on this. The analysis of the data builds a theoretical model for *the ways we do intellectual disability boy to men*, underpinned by the boy's desire to be like other boys. The model asks those working with boys with intellectual disability to adopt a more critical approach to the unquestioning acceptance of normalised constructs of masculinity. In doing so workers are asked to be mindful of: the changes experienced when making the transition from being a teenager to becoming an adult man; the ideals held as exemplars by boys with intellectual disability with regard to masculinity; boys experience of masculinity in the world; and vicarious positions, observing the lives of boys and men without intellectual disability. In parallel to this the findings warn against ignorance of the effect of impairment in the guise of unachievable hope, as this may magnify vulnerability in this population.

LGBTIQ Issues Experienced by People with Intellectual Disability

People with intellectual disability who are lesbian, gay, bisexual, trans∗, intersex, queer, or questioning (LGBTIQ) have the same desire for intimate sexual and romantic relationships as their heterosexual peers (McClelland et al., 2012; Stoffelen, Kok, Hospers, & Curfs, 2013). Nevertheless, LGBTIQ people with intellectual disability face added regulation of their sexuality from others. For example, existing conservative attitudes about sexuality held by paid caregivers and families of people with intellectual disability, are heightened further when it comes to non-normative sexuality or gender expression (McCann, Lee, & Brown, 2016; Stoffelen et al., 2013; Taylor Gomez, 2012; Wilson et al., 2016). The research literature identifies a number of things that LGBTIQ people with intellectual disability have said is important to them including being listened to and having the opportunity to talk with others about sexuality and relationships in a safe and personal way that respects their wishes and their sexuality (Bane, Deely, Donohoe, & Wolfe, 2012; Fitzgerald & Withers, 2013; Kijak, 2013; Stoffelen et al., 2013; Wheeler, 2007). They have also articulated the need for ongoing support to maintain relationships, to understand themselves in their relationships and to overcome the inevitable relationship difficulties that everyone faces (Brown & McCann, 2018). One source of appropriate support may come from accessing mainstream LGBTIQ support services such as advocacy and counselling (Azzopardi-Lane & Callus, 2015; Friedman, Arnold, Owen, & Sandman, 2014).

LGBTIQ people with intellectual disability have also reported barriers in relation to their sexuality, including a lack of privacy and their rights being ignored in their own homes by caregivers, access to transport and the ability to travel independently (Bernert, 2011; Brown & McCann, 2018; Wheeler, 2007). Safety and privacy at home is a particularly important right for everyone, but for many people with intellectual disability, home is also a place where heteronormative attitudinal barriers can be the most significant (Stoffelen et al., 2013). For example, in a Canadian study, LGBTIQ participants with intellectual disability noted how other people—particularly paid caregivers and parents, but also social workers, counsellors, foster parents, and siblings "had control over their personal time and space to explore their sexuality, whether with themselves or others" (McClelland et al., 2012, p. 814). Participants also reported that because sex at home was forbidden, they sought sexual experiences and opportunities outside the home and in a range of public places. Despite their view that home was one of the most comfortable and safe locations for sexual practices (and where, for example, condoms were the more easily and reliably accessible), participants continued to engage in potentially unsafe sexual practices, which then involved more risk-taking, less physical safety and privacy, reduced opportunity for healthy decision making and unprotected sex (McClelland et al., 2012, pp. 816–817). Consequently, caregiver-driven sexual rules intended to increase safety (i.e. disallowing sex at home, with the assumption that extends to sex in all places) can backfire and end up contributing to increased risk particularly for marginalised groups (see also Cambridge, 1996; Johnson, Hillier, Harrison, & Frawley, 2001).

Sexual Abuse and Sterilisation

Rarely is sexuality and intellectual disability discussed without some mention of sexual abuse. It is widely understood that sexual abuse is about power and control intersecting with gender inequality, and in the lives of people with intellectual disability additionally intersecting with myths about asexuality and a damaged identity or personhood. Researchers since the 1990s have urged us to see the sexual abuse of people with intellectual disability more systemically or ecologically, rather than focusing on the behaviours or characteristics of the individual. Sobsey (1994), Brown and Turk (1994) and Fitzsimons (2009) have highlighted that higher risk of sexual abuse for people with intellectual disability is intrinsically linked to the attitudes perpetrators of abuse hold about intellectual disability that diminishes their humanness and thereby devalues them as people and as people with sexual agency. Prevention of abuse starts with establishing equality of humanness and personhood and changing social and institutional structures that oppress, isolate and "other" people. For people with intellectual disability this means dismantling ideas about "other, special, extraordinary and incapable" and replacing them with ideas about value, equality, worth and agency; sexual abuse cannot be prevented by restricting sexual rights including reproductive rights or privacy or restricting sexual expression.

For many women with intellectual disability, their lived experiences reflect that high levels of abuse and negative experiences in relation to their reproductive rights and parenting are too common. It could be argued that there is a need for a more holistic discussion about sexuality for women with intellectual disabilities, one that takes account of gender, sexual identity, sexual agency and rights. However, the seriousness of reproductive decisions being taken out of their hands and the high rates of sexual abuse warrants a continued focus, albeit perhaps with an intersectional lens that can be used to see these two issues within a more holistic frame, in particular looking at the intersection of gender and disability.

It is difficult to quantify the incidence and prevalence of sexual abuse and of reproductive rights violations for women with intellectual disability. Research suggests that these experiences are under-reported by women with intellectual disability and that "official" data are hard to locate. This is due in part to the often "hidden" nature of abuse and sterilisation and relates to the idea of an "extraordinary sexuality" that exists for people with intellectual disability overviewed earlier in this chapter. Canadian research by Desjardins (2012) argued that there is in fact a "new extraordinary sexuality" or an "adapted sexuality". This extraordinary and adapted sexuality sees sexual expression without the "risk of reproduction" and that takes place under the surveillance of others as "safe" for people with intellectual disability. There are significant risks in aligning these ideas with safety when research has shown that a history of sterilisation—to avoid reproduction—has not stopped abuse and that within living environments where people's lives are watched carefully, abuse has still occurred. Although involuntary sterilisation was meant to be a practice from the past, it is evident that many family caregivers globally still support the sterilisation of people with ID, especially girls and women. This is engendered by both fear of the girls and women with ID falling pregnant and avoiding the challenges of managing menstrual periods of the women with ID (Kahonde, 2016; Tilley et al., 2012; World Health Organization, 2011). Also alarming are narratives of males with intellectual disability being sterilised, particularly those who are being chemically sterilised by anti-libidinal medication that can have a devastating long-term impact on the health and wellbeing of the male.

Cultural Considerations

Research about the intersection of sexuality, intellectual disability and culture is scant and any discussion of this intersection needs to take into account the dominance of research from the global North. Although there is a growing body of literature from low and middle income countries (Adnams, 2010; Aldersey, 2012), the preponderance of research still emanates from high income settings (McKenzie, McConkey, & Adnams, 2013). This globally unrepresentative research raises at least three issues:

1. The impact of poverty on achieving desirable outcomes for people with intellectual disability is not well understood.
2. Different cultural understandings of disability, family, community and what it means to have a good life are underexplored.
3. The rich contribution of different cultures to our overall understanding of the phenomenon is not drawn upon.

Each of these aspects has a particular impact upon our understanding of sexuality of people with intellectual disability. As regards to poverty, Emerson (2007) has noted the dual and cumulative effect of a lack of access to health services for people with intellectual disability limits the economic participation of family members. In these circumstances the pressing needs for food, shelter, and freedom from abuse become the focus with sexuality an after-thought (Kahonde, McKenzie, & Wilson, 2018). Although evident globally, responding to the sexuality of people with intellectual disability in a manner that overemphasises their vulnerability, becomes even more intensified when the family lives in poverty and within a community where the risk of abuse is heightened (Kahonde, 2016). Unfortunately, it is often true that poverty and increased risk within the community restricts independent activity, such as going to the shop or meeting with friends, and the fears of risk of abuse take precedence.

In studies with families of people with intellectual disability in several African contexts it is apparent that family caregivers perceive disability in multiple ways (Chataika & McKenzie, 2013). There is a traditional perspective that sees intellectual disability as a consequence of a transgression of societal norms (such as a woman being unfaithful to her husband). Such a perception leads to stigmatization and isolation of both the mother and the disabled child. This often intensifies their bond and makes the mothers fierce protectors and advocates for their children's rights, often in the absence of fathers who bow to family and social pressure and abandon both mother and child. Caregivers in these tightly knit relationships frequently draw on spiritual sources to gain the necessary strength in this often-lonely task. Mothers describe their child as a gift from God, who has entrusted this child to their care as part of their spiritual journey and who will give them the strength to fulfil this destiny (Ingstad, 1995). This has the effect that people with intellectual disability are cloaked in an aura of innocence and being close to God in ways that prohibit their engagement in sexual activity. The gendered nature of care poses particular problems for male children whose sexuality is perceived as threatening and not the domain of mothers who expect fathers to educate their sons in the meaning of masculinity and male sexuality (Kahonde, 2016). This is most evident when mothers face the dilemma of how their male child with intellectual disability will participate (or not) in male rites of passage.

Perhaps the most overlooked contextual consideration is that of cultural practices that provide potential for greater participation and social inclusion of people with intellectual disability. The African context is a collectivist form of conducting social interaction. That is, the individual is not alone in making their decisions and needs to consult and consider the impact of their decisions on the family and community. This is most clearly expressed in the notion of Ubuntu which recognises that we are only human beings in our relation to others (Mabovula, 2011). Interdependence is at the heart of this philosophy and remains gendered with roles clearly demarcated for different members of society. This has the, as yet unrealized, potential of distributing care and support across the community. However, this is hampered by the stigma that is attached to disability. In terms of sexuality there are signs of how this might be seen differently. Protective mothers in a study by Kahonde (2016) spoke about how they would want their son or daughter to get married or to have children so that the care that they provide could be continued by a family member of a different generation. These notions of extending care to another generation is also reflected in research about the forced marriage of people with intellectual disability in some Asian societies (e.g. Clawson & Fyson, 2017).

In some patriarchal societies, males with intellectual disability are given more support in the area of sexuality than females (Gürol et al., 2014; Morales, Lopez, & Mullet, 2011). Research evidence to support this from studies in Turkey and Mexico reported that the mothers were more supportive of sexuality education for boys than for girls (Gürol et al., 2014) or acceptance of sexual relationships by the family was higher for males with ID than for females (Morales et al., 2011). On the other hand, cultural and religious beliefs around issues like masturbation and contraception may be hindrances blocking people with intellectual disability from freely expressing and enjoying their sexuality (Kahonde, 2016; Lafferty, McConkey, & Simpson, 2012). The fear of the person with intellectual disability being ostracised by society may result in them being disallowed from expressing their sexual identity.

Sexual Knowledge

Adequate and accurate sexual knowledge enables people to identify and ask for what is sexually pleasurable for them. It also allows them to be better able to set healthy sexual boundaries which are essential for safer sex (Abraham & Sheeran, 1994). Conversely, low sexual knowledge has been found to be linked to higher rates of sexually transmissible infections, higher numbers of unplanned pregnancy and more negative feelings about sex (Healy, McGuire, Evans, & Carley, 2009; Lafferty et al., 2012). Many people with intellectual disability have fundamental gaps in their sexual knowledge (Jahoda & Pownall, 2014). It is proposed that sexual knowledge assessment tools should be used with people with intellectual disability to identify gaps in sexual knowledge and that these identified gaps should be addressed through individually tailored sexual health educational programs (Bell & Cameron, 2003; Galea, Butler, Iacono, & Leighton, 2004).

Several studies have utilised pre- and post-sexual knowledge assessments to demonstrate an increase in the sexual knowledge of people with intellectual disability following their participation in a sexual health education program (Murphy, Powell, Guzman, & Hays, 2007).

Many people with intellectual disability have difficulties with communication and comprehension that affect their ability to understand and answer questions, including questions about sexual knowledge. For example, when compared to standard assessments designed for the general population, the responsiveness of people with intellectual disability increased more than three-fold when assessment questions with simplified wording designed specifically for people with intellectual disability were used (Stancliffe, Wilson, Bigby, Balandin, & Craig, 2014). Therefore, to aid in the appropriate assessment of the sexual health knowledge, it is critical that assessment tools have been developed specifically for people with intellectual disability. This approach is needed so that gaps in knowledge can be identified accurately, rather than the person being unable to explain what they know simply because they could not understand the question (Thompson, Stancliffe, Wilson, & Broom, 2016a; Thompson, Stancliffe, Wilson, & Broom, 2016b).

There have been several sexual knowledge assessment tools which have been developed specifically for people with intellectual disability including the Sexual Knowledge, Experience and Needs Scale for People with Intellectual Disability (SexKen-ID) (McCabe, 1994), the Human Relations and Sexuality Knowledge and Awareness Assessment (Family Planning Victoria, 1997), the Assessment of Sexual Knowledge (ASK) (Butler, Leighton, & Galea, 2003), the Socio-Sexual Knowledge and Attitudes Assessment Tool-Revised (SSKAAT-R) (Griffiths & Lunsky, 2003) and the General Sexual Knowledge Questionnaire (GSKQ) (Talbot & Langdon, 2006). All of these sexual knowledge assessment tools are similar in content and structure.

In their current form, sexual knowledge assessment tools contribute to the pathologising of sexual health of people with intellectual disability (Thompson et al., 2016b). Positive aspects of sexual health such as pleasure and sexual aides are not covered by the tools. Yet, content on sexual pathology has been systematically included in the tools. Indeed, the GSKQ (Talbot & Langdon, 2006) was specifically developed to test for counter deviance of men who display sexually offending behaviours and the SSKAAT-R (Griffiths & Lunsky, 2003) was used by its developers to assess the sexual knowledge of men with intellectual disability who sexually offend (Lunsky, Frijters, Griffiths, Watson, & Williston, 2007). They concluded that there was a "need to assess sexual knowledge, sexual attitudes, and prior sex education when an individual commits a sexual offence" (Lunsky et al., 2007, p. 80). Yet, the SSKKAAT-R has not been validated to assess risk of recidivism or to plan for the management of people with intellectual disability who sexually offend or display problematic sexual behaviours.

Several studies have focused on the development of sexual knowledge assessment tools (e.g. Galea et al., 2004), but only one study has focused on their use in a clinical setting. A recent study by Thompson et al. (2016b) found that although clinicians stated that such tools are needed to support the work they do in relation to sexual health of people with intellectual disability, that these tools also have several limitations. These included: missing important sexual health topics (such as libido and sexual pleasure), not enough questions to adequately determine level of knowledge in relation to each of the topic areas, complex wording of items, not enough pictures to support the questions, not enough guidance on how to administer the tools, and the tools are outdated (the latest tool is over a decade old). It has also been identified that sexual knowledge assessment tools are not able to be used for people with more severe levels of intellectual disability as they were too difficult for them to comprehend (Bell & Cameron, 2003). The study by Thompson et al. (2016a) reported that if the person with intellectual disability does not have their sexual knowledge assessed then they generally do not receive any sexual health provision at all. They also reported that sexual knowledge is typically only assessed when there has been an incident of problematic sexualised behaviour, typically perceived to be displayed by males with intellectual disability. This reactive approach perpetuates and further reifies a pathological sexual health discourse for people with intellectual disability.

Sex Education

Traditional sex education has been mainly focused on knowledge transfer. Popular topics include reproduction, puberty, contraception and sexually transmitted infections, that is, a focus on bodily changes, how babies are made and what happens if you do not practice safe sex. Nowadays we understand that in order to live a sexually healthy life, sex education should focus on a much broader array of areas to include topics such as sexual diversity, dating and how to have pleasurable sex. Developing a sex education program for people with intellectual disability poses an extra challenge in relation to their problems with learning and generalizing knowledge and skills to real-life situations (Bruder & Kroese, 2005; Schaafsma et al., 2014). Therefore, special attention needs to be given to how to increase knowledge and improve relevant skills in people with intellectual disability and provide them with opportunities to practice these skills in real-life settings. Tailoring sex education to a person's individual needs is thus necessary, but requires some skills from the person who delivers the sex education. In addition, sexuality is still a taboo topic and often professionals do not know how to talk about sexuality in a common-sense manner (Abbott & Burns, 2007), rather it is often in response to a problem (Schaafsma et al., 2014)

So why is it so difficult to talk about sexuality? One explanation could be that talking about sexuality feels too personal and embarrassing. People do not separate private sexuality (e.g. personal sexual experiences and attitudes) and professional sexuality (e.g. general information and support). A second explanation might be that sex education is associated with coitus and condom use. People often do not realize that topics such as relationships and dating are also important. These are usually easier topics to talk about. A third explanation could be that people (unconsciously) fear that talking about sexuality might lead to problems such as negative experiences (including sexual abuse) and (unwanted) pregnancies. Finally, a fourth explanation might be that both family and professional caregivers do not really know what they should and should not talk about. In other words, where their responsibility lies and when they should involve an expert?

People involved in the care of people with intellectual disability should be aware of three types of sex education: the spontaneous conversation, the goal-oriented conversation and the specialist conversation. The first type, the spontaneous conversation about sexuality is instigated by everyday situations. Something might happen on television or something might be mentioned during dinner. One should utilize these kinds of opportunities to educate and normalize the conversation about sexuality-related topics. It can also be a good way to test the knowledge of a person with intellectual disability or inquire about their experiences. It is important that the person providing this type of education realises they do not have to be all knowing when it comes to the topic of sexuality. Being about the level of expertise on the topic should not be a reason not to talk about sexuality.

The second type is the goal-oriented conversation. We know that people with intellectual disability have lower levels of sexual knowledge than peers without intellectual disability, experience sexual abuse at higher rates than people without intellectual disability and experience barriers forming relationships (Fulford & Cobigo, 2016; Murphy & O'Callaghan, 2004). With this in mind, we know that more goal-oriented sex education is needed. This means that, next to spontaneous conversation, we should also provide more systematic education. Two questions should underpin this type of education: what does a person with intellectual disability want to learn and what do they need to learn? What a person needs to learn is linked to what a person needs to know and be able to do in order to experience sexuality in a healthy and pleasurable way.

Examples of areas that need to be included are forming relationships, enjoyable and safe sex and information about respectful relationships and abuse prevention. The third type is specialist sex education. When a person with ID has experienced sexual abuse or expresses concerning sexual behaviour, one should always involve a specialist. These kinds of issues are beyond regular goal-oriented sex education.

There exist a number of sex education materials available for people with intellectual disability, however, their quality differs. Most do not have a theory and/or evidence base such as a description of how the materials are meant to improve the sexual health of people with intellectual disability and nor is evidence provided on why the materials are effective in improving sexual health (Schaafsma, Kok, Stoffelen, & Curfs, 2016; Schaafsma, Stoffelen, Kok, & Curfs, 2013). Nevertheless, an improvement can be seen in this area as more and more programs are starting to provide a detailed description of the goals of the materials, the methods included in the materials and the evidence base (see for example (Frawley et al., 2017, Frawley, Barrett, & Dyson, 2012). Topics that are covered in some more recent and comprehensive program are: rights, respectful relationships, sexual diversity, parenthood, pleasurable and safe sex and abuse prevention. Identifying the right kind of approach and/or resource to support the goals people have for their education is important. For example, some goals could be reached simply by explaining and practicing relevant skills while require a more formal approach.

Future Needs

Sexuality remains a fraught issue for people with intellectual disability. To summarise, people with intellectual disability have had, and continue to have, their sexuality and sexual health needs problematized rather than being viewed as a holistic need about love, pleasure, desire and identity. Both young men and women with intellectual disability view their sexuality within a fear-based paradigm: women are fearful of the risk of unwanted pregnancy and abuse, and men are fearful of being sexually inappropriate (Frawley & Wilson, 2016). Although much of the policy and practice settings have changed over the decades to more of a rights-based framework, the sexuality and sexual health of people with intellectual disability remains regulated and surveilled by others. This is a human rights issue. People with intellectual disability want friends and to develop meaningful relationships—whether intimate or not—and want access to the right to develop their own health sexuality at a pace of their choosing. The reality is that by virtue of having a cognitive impairment, they have been perceived as lacking capacity to develop skills and knowledge or to "have" sexual autonomy or agency. Most caregivers are family caregivers and in the absence of knowing what to do or where to access the appropriate supports and services, they can react conservatively in what they perceive as the "best interests" of their adult child with intellectual disability. Although not exhaustive and notwithstanding the absolute imperative that mainstream services have a major role to play, below is a summary of urgent needs in this area:

1. People with intellectual disability need more opportunities to form and maintain friendships and relationships. Other than descriptive studies, there is little research reporting on approaches to support relationship building and to counter loneliness.
2. Sex education programs that are based on bodies, pregnancy and disease are outdated. New evidence-based programs from a more salutogenic starting point are needed that promote sexual health and wellbeing, respectful relationships and that support ascertainment of sexual rights. These approaches need to focus on access to information and learning that meet people's needs as articulated by them or through appropriate assessments. In the new millennium, sex education also needs to take account of social media.
3. Sexual knowledge assessment tools should be based on the same salutogenic principles of the sex education programs. In addition, more

accessible formats that not only incorporate sexual diversity but also acknowledges and is responsive to different degrees of intellectual disability.

4. Family caregivers have asked to learn from professionals and to have better access to peer support, practical and affordable sexuality support and education services.
5. There are few notable advocates and researchers with a focus on and expertise in the intersection of male health and masculinity. Most importantly, the pathological discourse of male sexuality needs to be challenged with the development of male-specific approaches that give access to and reinforce a distinctly positive and healthy masculinity and male sexuality.
6. LGBTIQ people with intellectual disability are marginalised and a concerted effort to explore inclusive approaches, particularly from the mainstream LGBTIQ community, that can reduce this marginalisation should be prioritised.
7. Policy development must include greater collaboration with people with intellectual disability and their families. Mainstream service providers should be supported to develop inclusive approaches in partnership with disability supports, services and advocacy. This should always take into account the reality of different degrees of intellectual disability and need for support.
8. Continue to grow the research and evidence base in this complex area, including a focus on the lived experience, to identify ways that can better inform policy, education and practice.

An Example of a Promising Approach—Peer Support

Emerging Australian research shows that a peer education approach in partnership with mainstream services is both productive and positive (Frawley et al., 2012). The work undertaken as part of the *Living Safer Sexual Lives* and later *Sexual Lives and Respectful Relationships* (SL&RR) suite of programs have been shown to underpin best practice in the support of people with intellectual disability having access to a rights-based approach that prioritises the expertise and lived experience of people with intellectual disability (Frawley & O'Shea, 2012). The model that underpins this program has four key components; peer education by and for people with intellectual disability, learning support from trusted allies, community partnership with community based sexual health, sexual abuse and other related sexual and relationship services, and systemic change through the development of an evidence base (Frawley & Bigby, 2015). The program at the centre of this model uses the life stories of people with intellectual disability gathered in research (Johnson et al., 2001; O'Shea & Frawley, in press) as the basis for a respectful relationships program. The program was developed and is continually revised by project teams that comprise people with intellectual disability and academics. People with intellectual disability are the primary facilitators of the program as peer educators supported in program facilitation by professionals from community and sexual health. These partnerships form the basis of local networks that promote and run the program locally for adults with intellectual disability and serve as a resource to and conduit for, broader sexuality and relationship rights activities locally like the month of action against violence.

At the time of writing this chapter, there were over 60 trained peer educators and 60 trained program partners in seven local networks across Australia. This represents a large network of mainstream services working in partnership with people with intellectual disability in the provision of a sexuality and respectful relationships program which is both unique in terms of sexuality and sexual health approaches, and as a model of cross sector partnership unmatched in any other area of work with people with intellectual disability. These local networks run on average four programs a year with an average of eight participants per program. The SL&RR national network implements this program with over two hundred adults with intellectual disability each year across Australia. In 2018 the program has added stories and piloted a program for LGBTIQ adults with intellectual disability and is replicating the model with people with an Acquired Brain Injury.

Using peer education in this way with people with cognitive impairments in sexuality education and support is also unique and offers an important opportunity to build on the “nothing about us without us” dictum of the self-advocacy movement to prioritise and acknowledge the liberating power of working from the strength of shared lived experiences in the area of sexuality. Research on this approach has found that people with intellectual disability who have had the experience of being peer educators in this work feel more confident about their own relationships, their capacity to inform and manage their own sexuality and that through this role they can be role models for their peers (Frawley & Bigby, 2015). Further research is being undertaken on this model to better understand the structural and relational factors that underpin the strength of the local networks and partnerships, the outcomes for community organisations that are involved as partners and the learning and other outcomes for the participants with intellectual disability. Further work is also being undertaken with the peer educators to better understand what enables them to be the powerful sexuality educators they are and what this means for the future of sexuality education for and by people with intellectual disability.

Access to Mainstream Services and Supports

People with intellectual disability are often an overlooked cohort in mainstream sexuality research. One example in Australian research is the longitudinal study of sexual health, behaviour and experiences of secondary school age young people which in its fifth iteration in 2013 still did not recruit students with any type of disabilities (Mitchell, Patrick, Heywood, Blackman, & Pitts, 2014). These missed opportunities mean that the experiences of people with intellectual disability are not being identified, counted and understood alongside their non-disabled peers and are not present in the policy and practice outcomes from research. Mainstream education, health, counselling and support services relating to sexuality are not being shaped by knowledge about the disability experience. Further, although there is an increasingly strong focus on engaging mainstream services in understanding and responding to people with intellectual disability and the growth of inclusive and personalised approaches to funding and support worldwide, sexuality related needs of people with intellectual disability are either overlooked or considered to be the remit of “specialists”. While family planning organisations pay significant attention to and in some cases provide specialist services in sexual health for people with intellectual disability these are not broadly accessible. People with intellectual disability report being left out of sexuality education in mainstream schools (Frawley & Wilson, 2016), women with disabilities report that health professionals refuse to believe that they are sexually active and therefore ignore this area of their health (WWDA, 2018) and services like domestic, family and sexual assault services still struggle to provide fully accessible support to women with disabilities (Dyson, Frawley, & Robinson, 2017). Earlier sections of this chapter have suggested that what underpins this exclusion may well be sexual ableism whereby people with intellectual disabilities are not acknowledged as being imbued with the same sexual characteristics as others that afford them the right to be sexual (Gill, 2015).

Little work has been done that focuses on access to and inclusion in mainstream sexuality related services for people with intellectual disability. Williams, Scott & McKechanie (2014) reported that young people with intellectual disability used a range of sources for their information about sexual health including friends, family, their own research and TV, yet they would only go to their doctor if there was something “medical”. Research in Australia by Frawley and Wilson (2016) supported this view, finding that young people had devised many ways to become informed about sexual health often independent of health services, including talking to friends, using the internet and less frequently asking parents. These studies found that young people wanted and needed access to information about sexual health yet their past education experiences and current information finding approaches did not meet their needs and only a small number used mainstream sexual health services.

To address access to mainstream sexuality related services for people with intellectual disability there needs to be a multi-faceted approach that goes beyond questions of physical access. Research undertaken on access to mainstream domestic violence and sexual assault services for women with disabilities calls for an approach to access that includes physical access, information access, attitudinal access and procedural access Lea (2015). Others refer to this as programmatic access (Frohmader et al., 2015) where this means full access equal to what was available for all users of these services. Unpacking what is meant by access in this more holistic way has been found to be useful in addressing barriers to these mainstream services for women with intellectual disability and should be translatable to other services dealing with other sensitive and complex areas of life including sexuality and sexual health.

The multi-faceted approach recommended for full access to mainstream sexuality and other related services must start with a holistic understanding of disability taking an intersectional approach where this means understanding "the relationship between multiple dimensions and modalities of social relations and subject positions" (McCall, 2005 p. 1771). Dyson et al. (2017) outline that this approach must look at the complex lived experiences of disabilities where gender, race, class, culture, sexual and gender identity are considered where they intersect with other experiences including domestic and sexual violence. Here we suggest this is also applicable when addressing sexual health. Building on this approach services then engage in a range of ways of developing a broadly accessible service while also paying attention to specialist information and access needs. In the research on domestic and family violence services Dyson et al. (2017) found the following approaches were promising; making service adaptations underpinned by training of staff in understanding the complex lived experience of disability; cross sector collaboration where disability and specialist services work together from referral through to future planning; and developing and responding to a broad understanding of access where this includes thinking from the perspective of the person with intellectual disability and considering the approachability, appropriateness, affordability and availability of services. This more nuanced understanding of access informed by the work of Levesque, Harris, and Russell (2013) in health services makes a distinction between access where this means being able to "enter or obtain" a service and accessibility, where this means "it is useable to me".

Research cited earlier in this chapter makes it clear that the sexual health status of people with intellectual disability is not improving. While they are employing a range of strategies to become informed about their sexuality they are not accessing services that could provide them with the same access to beneficial information and support their non-disabled peers use. Learning from research about access to health and domestic violence services organisations like Family Planning Associations, women's health services and sexual health services could engage in a multifaceted approach to better understand disability and to better understand access to ensure people with intellectual disability do find these services "useable to them".

Pain

53

Lara M. Genik, Kaytlin Constantin,
Frank J. Symons, and C. Meghan McMurtry

This chapter begins with a short review of pain relevant terms and concepts, as well as a summary of life span/developmental perspectives on pain including prevalence, assessment, and management. This information will provide important context for our subsequent review of what is known about pain assessment and management in people with DD. The complexities of pain assessment and management in populations with DD will be further illustrated through a special section on advancing the field through research and two cases studies. Throughout, we have made reference to "pain in developmental disability ('pain in DD')". There is enormous heterogeneity associated with the DD label which does encompass people with and without intellectual disability (ID); however, for the purposes of readability, we have used the term "DD" interchangeably with ID throughout the chapter.

Introduction to Pain

Pain is a common experience that occurs throughout the life span, and can be defined as an "unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (Merskey & Bogduk, 1994, p. 210). The International Association for the Study of Pain (IASP) further indicates that pain is subjective, and that difficulty communicating verbally does not prevent an individual from experiencing or requiring relief from pain (International Association for the Study of Pain (IASP), 2012, Pain terms, para. 2; Merskey & Bogduk, 1994). The complexity of pain is well captured by the biopsychosocial model, which considers an individual's internal pain experience and external pain expression to be multiply determined by biological (e.g., genetics, hormones), psychological (e.g., emotions), and social factors (e.g., caregiver behaviors; Craig, 2009; Craig, Versloot, Goubert, Vervoort, & Crombez, 2010; Hadjistavropoulos et al., 2011); in turn, pain also influences these factors. For example, if an athlete were injured during a tournament, a number of factors such as adrenaline levels, how the player feels, and the number

of people watching the game could impact his or her subsequent pain experience and expression.

An important distinction can be made between two types of pain: acute and chronic. Acute pain is limited to a short period of time and is generally viewed as adaptive, serving to alert an individual of potential harm and motivate him or her to take appropriate action (American Academy of Pediatrics, 2001). Common sources of acute pain include injury, illness, brief tissue-damaging medical procedures (e.g., finger pricks, lumbar punctures, venipuncture) and non-tissue-damaging medical procedures (e.g., suctioning; American Academy of Pediatrics, 2001; Stevens & Zempsky, 2013). In a typical week, approximately 30–40% of children experience some type of acute pain (McGrath, 1990). Epidemiological data from eight Canadian hospitals revealed that just over 78% of children admitted had undergone at least one painful procedure, and common procedures varied in pain severity from mild (e.g., suctioning) to moderate/severe (e.g., venipuncture; Stevens et al., 2011). In adults, it is estimated that approximately 56% experience some level of pain within a three-month period (Nahin, 2015). Poorly managed acute pain can lead to a number of negative impacts, including an increased risk of developing chronic pain conditions (Sinatra, 2010).

Chronic pain is typically defined as pain lasting longer than three months' duration (Merskey & Bogduk, 1994). It can involve recurrent pain, which includes episodic acute pain (e.g., headaches, stomachaches) or persistent pain, which is more enduring (e.g., backaches; Stevens & Zempsky, 2013). The occurrence of chronic pain in both children and adults increases with age, and once reaching adolescence, females report more frequent and intense experiences (Johannes, Le, Zhou, Johnston, & Dworkin, 2010; King et al., 2011). Pain in children and adolescents has been deemed a public health concern (Haraldstad, Sørum, Eide, Natvig, & Helseth, 2011; Perquin et al., 2000); the prevalence of headaches ranges from 8% to 83%, abdominal pain from 4% to 40%, and back pain from 14% to 24% (King et al., 2011). Approximately one in five adults experience chronic pain (Schopflocher, Taenzer, & Jovey, 2011), with prevalence estimates ranging from 8.7% to 64.4% depending on the population, type of pain and survey method (Johannes et al., 2010; Leadley, Armstrong, Lee, Allen, & Kleijnen, 2012; Nahin, 2015; Steingrímsdóttir, Landmark, Macfarlane, & Nielsen, 2017).

Taken together, existing research on pain across the life span demonstrates the high prevalence of acute and chronic pain in children, youth, and adults. The experience of pain, particularly chronic pain, can interfere significantly with daily functioning and is associated with health and economic consequences. Children and adolescents may miss school, withdraw from social activities, and are at risk of developing internalizing symptoms (Palermo, 2000). Further, children commonly report that their pain has significant impact on their sleep quality and ability to engage in activities and hobbies (Haraldstad et al., 2011; Valrie, Bromberg, Palermo, & Schanberg, 2013). Similarly, adults with chronic pain tend to experience lower health-related quality of life, interference with daily activities, job loss or reduced job responsibilities, higher rates of internalizing symptoms, and strained relationships (Doth, Hansson, Jensen, & Taylor, 2010; Sessle, 2012). There are also financial burdens associated with chronic pain, including the cost for patients, caregivers, the health care system and the economy more generally. Individuals with chronic pain tend to utilize almost twice as many health care resources as the general population, and the management of pain requires access to a wide range of services, including physical therapy, inpatient, pharmaceutical, and primary care (Sessle, 2012). In Canada, the personal financial costs for patients with pain is approximately $1500 per month; the combination of direct and indirect costs to the Canadian economy has been estimated to be greater than $40 billion per year (Lynch, 2011; Sessle, 2012). In the USA, this cost is estimated at more than $500 billion a year (Sessle, 2012).

Pain in People with Developmental Disabilities (DD)

Pain in people with DD is frequently underrecognized and underreported and has received minimal attention in the research literature

(McGuire, Daly, & Smyth, 2010). A number of false beliefs and assumptions may contribute to this dearth of research, such as historical views associated with dehumanization and depersonalization of people with DD (Sobsey, 2006). For example, in the past, people tended to view those with DD as either (a) "less than human," and therefore less deserving of appropriate treatment, or (b) suffering in extreme ways which were ultimately unmanageable (Sobsey, 2006). In either case, these polarized beliefs often led to inadequate care, neglect or abuse of those with DD (Sobsey, 2006). There are many examples of the impact of these beliefs, such as the use of pain to teach people with DD in the 1960s and 1970s (Sobsey, 2006). At that time, it was not uncommon for caregivers and therapists to use painful stimuli such as hitting and shocks for punishment or conditioning stimuli (Sobsey, 2006).

One of the most significant and long-standing beliefs related to pain and people with DD regards their ability to experience or feel pain (Sobsey, 2006; Symons, Shinde, & Gilles, 2008). Specifically, it was believed that people with DD were (a) insensitive or incapable of experiencing pain, or (b) in a constant state of severe and unmanageable pain, inevitably leading to a culture in which pain was disregarded and untreated (Sobsey, 2006). Appropriate pain assessment and management for people with DD continues to be problematic, and there is still a tendency for pain to be missed, discounted, or ignored. For example, following spinal fusion surgery, children with DD were less often assessed for pain and given fewer pain-relieving opioids compared to those without DD (Malviya et al., 2001). Similarly, parents report that their children with DD are treated differently in medical settings, with professionals often seeming to overlook the pain or "pass it off" as someone else's responsibility (Carter, McArthur, & Cunliffe, 2002). Still further, work by McGuire et al. (2010) suggests continued under-recognition of pain in people with DD. This may be particularly true for those with more severe disabilities and limitations (McGuire et al., 2010). Despite accumulation of research to the contrary, false beliefs and related misunderstandings such as these can deeply impact and limit the quality of care provided to people in need.

Prevalence

In reality, true insensitivity to pain is very rare and not commonly associated with DD (Nagasako, Oaklander, & Dworkin, 2003; Sobsey, 2006). Much of the DD literature instead points to increased sensitivity to pain compared to people without DD (e.g., Defrin, Pick, Peretz, & Carmeli, 2004; Nader, Oberlander, Chambers, & Craig, 2004; Symons, Harper, McGrath, Breau, & Bodfish, 2009). It is therefore understood that people with DD do feel pain (Oberlander, O'Donnell, & Montgomery, 1999); however, limitations and challenges associated with their diagnoses may impact or alter their experience and/or expression of pain (e.g., Dubois, Capdevila, Bringuier, & Pry, 2010; Hennequin, Morin, & Feine, 2000; Nader et al., 2004; Valkenburg, Tibboel, & Dijk, 2015). For example, experimental work with both children and adults diagnosed with Down syndrome has demonstrated differences when compared to typically developing samples such as slower reaction times to painful stimuli and decreased ability to accurately demonstrate pain location (Hennequin et al., 2000; Valkenburg et al., 2015).

While the true prevalence of pain in people with DD is unclear, research suggests that pain is not only common for people with DD but may actually occur more frequently than in populations without DD, particularly in children (Breau, Camfield, McGrath, & Finley, 2003; Stallard, Williams, Lenton, & Velleman, 2001). For example, in a study of children with disabilities, 75% of the sample was reported to have experienced pain over a two-week period, 84% of whom had experienced pain on at least 5 days (Stallard et al., 2001). Similarly, in another sample more than one third of children with severe DD experienced pain lasting more than 1 h on a weekly basis (Breau, Camfield, et al., 2003). In both of these studies, the frequency of pain experience increased alongside the severity of the child's disability (Breau, Camfield, et al., 2003; Stallard et al., 2001). Despite small sample sizes, these rates are much higher than those reported in prevalence studies associated with pain in typically developing children (e.g., Perquin et al., 2000). Prevalence studies focusing on adults with DD have also suggested that pain occurs frequently (e.g., Boerlage et al., 2013; McGuire et al., 2010; Walsh, Morrison, & McGuire, 2011). For example, in one study caregivers reported that at least 15.4% of the sample of adults with DD experienced chronic pain (Walsh et al., 2011). Notably, the rates of pain prevalence for adults with DD are somewhat lower than in other studies of adults without DD (e.g., Boerlage et al., 2013). Given the history of misbeliefs and misunderstandings associated with pain in people with DD, these may be under-representations of true prevalence rates, particularly for adults with limited ability to communicate effectively (Boerlage et al., 2013; McGuire et al., 2010).

Pain sources are diverse and include everyday pains (e.g., headaches), unintentional injury (e.g., bumps, fall), and medical procedures (e.g., venipuncture). Most frequently for people with DD, however, pain seems to originate from comorbid medical conditions and related medical procedures (Breau, Camfield, et al., 2003); thus, certain types of pain may be more prevalent for people with specific disabilities. For example, people with Down syndrome may be more susceptible to pain associated with congenital health defects and oral health-related diseases (Bottos & Chambers, 2006), while musculoskeletal and gastrointestinal pain may be more common among people with cerebral palsy, severe DD, and autism spectrum disorder (Walsh et al., 2011).

Impact on Functioning

In many ways, the broad impact of pain on people with DD is similar to that of people without DD described above. For example, in youth with autism spectrum disorder and DD pain is associated with parasomnias, sleep duration, and sleep disordered breathing (Breau & Camfield, 2011; Tudor, Walsh, Mulder, & Lerner, 2015). Breau, Camfield, McGrath, and Finley's (2007) work highlights the deleterious impact that pain has on adaptive functioning skills of youth with DD across four domains: communication (e.g., understanding language), socialization (e.g., interacting with others), daily living skills (e.g., feeding), and motor skills (e.g., moving). Similarly, pain in adults with DD has been associated with limitations in exercising, maintaining relationships, completing self-care activities and/or emotional distress such as depression, anxiety, and self-injury (Walsh et al., 2011).

Importantly, while the functional domains impacted by pain may be similar, the degree of impairment seems to be greater for people with DD compared to those without. For children and youth, this phenomenon is particularly the case as the severity of DD increases (Breau et al., 2007). This is likely due to a number of factors including the cognitive limitations experienced by people with DD, and preexisting limitations in adaptive functioning (Breau et al., 2003). Further, a number of behaviors less commonly seen in people without DD tend to occur in the presence of pain for people with DD. For both children and adults, "problem behavior" such as aggression may increase in both frequency and intensity in tandem with the level of pain experienced and/or pain-related indicators (Carr & Owen-DeSchryver, 2007; Courtemanche, Schroeder, Sheldon, Sherman, & Fowler, 2012). Further, it has been suggested that some of these behaviors such as self-injury may serve a communicative and/or regulatory purpose (Breau, Camfield, et al., 2003).

In recognizing the impact of pain on this population, the pediatric literature (the adult pain in DD literature is extremely limited) most clearly demonstrates that not only will pain lead to a decrease in functioning in the short term, but also in the long term it leads to decreased practice of skills leading to difficulty acquiring skills (e.g., Breau et al., 2007). As shown with children diagnosed with cerebral palsy, corresponding difficulties associated with poor adaptive functioning skills may in turn greatly impact the level of independence and support needed in daily living, participation in desired activities, and overall quality of life (e.g., Houlihan, O'Donnell, Conaway, & Stevenson, 2004). In sum, pain has a number of implications and addressing it to the best of one's ability could improve quality of life and functional ability of people with DD (Breau et al., 2007).

Challenges in Pain Assessment and Management

For people with DD, pain assessment and management are complex and challenging processes (Carter et al., 2002; Chen-Lim et al., 2012). Indeed, many of the challenges unique to this population stem from varied levels of cognitive and physical abilities as well as limited adaptive functioning skills (Breau, McGrath, & Zabalia, 2006; Doody & Bailey, 2017). A number of these challenges are discussed below.

First, self-report has historically been regarded as the "gold standard" in pain assessment, particularly given the subjectivity of the pain experience (Schiavenato & Craig, 2010; Twycross, Voepel-Lewis, Vincent, Franck, & von Baeyer, 2015). A number of limitations to this approach have been indicated in recent years, however, such as oversimplification of the pain experience (Twycross et al., 2015). Further, people with limited ability to effectively communicate through verbal or nonverbal means may be unable to utilize tools developed for self-reporting one's pain (Chen-Lim et al., 2012; Doody & Bailey, 2017; Dubois et al., 2010; Schiavenato & Craig, 2010; Temple et al., 2012). For example, pain assessment scales often rely on a number of cognitive abilities, such as understanding graded responses/seriation, in order to be used as intended (Ely, Chen-Lim, Carpenter, Wallhauser, & Friedlaender, 2016). If people with DD have not developed this understanding or are unable to follow directions to respond in the intended manner, self-report will be inaccurate (Schiavenato & Craig, 2010). As such, adaptations to the type of measures and questions asked when obtaining self-report from people with DD may be necessary to ensure the accuracy of these reports.

Second, although behavioral observations are often considered an important component of a multi-dimensional pain assessment approach, these too can prove difficult for people with DD. Indeed, pain in people with DD can be expressed through verbal and nonverbal pain behaviors, which may be different than those used by people without DD to communicate pain (Carter et al., 2002; Doody & Bailey, 2017; Dubois et al., 2010; Temple et al., 2012). Results from a systematic review have identified 14 types of behavioral pain indicators utilized by people with DD (de Knegt et al., 2013). The four most common types of pain-related expression include motor activity such as pacing, facial activity such as grimacing, social behavior such as one's interaction with others, and vocal expressions such as the production of distressing sounds (de Knegt et al., 2013). Beyond pain intensity, a number of factors may influence the types of behavior used to communicate pain such as verbal ability, mental age, and sex (de Knegt et al., 2013). Additionally, the expression of pain in people with DD can at times be atypical/idiosyncratic, unclear, and inconsistent (de Knegt et al., 2013). For example, a person with DD may become aggressive when they are tired, hungry, overwhelmed by noises/crowds, and when in pain. Further, a person may sometimes become aggressive but other times withdraw when experiencing pain. Behavioral cues may not always be reliable, and it is important to compare observations against what is typical for the person on pain-free days (Carter et al., 2002; Temple et al., 2012).

Third, a number of unique context-dependent barriers to assessing and managing pain may exist. For example, in school settings, maladaptive or problem behavior may be misinterpreted as defiance or work avoidance and may therefore represent missed opportunities for pain assessment (Quinn & Serna, 2017). Similarly, in school contexts it may at times be difficult to understand whose role it is to assess and manage pain, which may result in confusion and a lack of action (Quinn & Serna, 2017; Symons et al., 2008). Finally, pain is a subjective experience and given the difficulties with self-report described above, people with DD may rely on others to make judgments about their pain. It can be difficult for others to assess the pain of another person and this judgement is accompanied, and likely informed, by biases and prior beliefs. Thus, for certain carers such as those in health care, pain-related decision making processes may be highly subjective (Temple et al., 2012).

The Unique Role of Caregivers

Due to the limitations and challenges described above, caregivers of people with DD are often relied upon to ascertain whether pain is present and which interventions are needed (Findlay, Williams, Baum, & Scior, 2015). In this way, the pain assessment and management process is bidirectional (Craig, 2009), and consideration of the caregiver's contribution to these processes is important. For example, primary and secondary caregivers may hold pain and disability-related beliefs and biases (e.g., about pain sensation in people with DD) which have the potential to impact or predict care decisions (Beacroft & Dodd, 2011; Breau, MacLaren, McGrath, Camfield, & Finley, 2003; Findlay et al., 2015; Genik, McMurtry, & Breau, 2017; Shinde & Symons, 2007). Awareness of these is important, as research suggests that in its complexity, caregivers may fall for stereotypes, overlook, or discount pain (Carter et al., 2002; Hunt, Mastroyannopoulou, Goldman, & Seers, 2003). In pediatric DD literature, three knowledge domains have been identified as important for accurate pain assessment and management: "knowing the child," "familiarity with children with the same or similar conditions," and "knowing the science" (Hunt et al., 2003). This breadth of knowledge is likely to be uncommon in any one person (Hunt et al., 2003) and further highlights the need for collaborative and improved communication efforts between those caring for people with DD (Beacroft & Dodd, 2011).

Although often overlooked, parents and primary caregivers are important resources who can assist in the pain assessment and management process (Baldridge & Andrasik, 2010; Carter et al., 2002; Carter, Simons, Bray, & Arnott, 2016). This support from parents and primary caregivers typically continues into adulthood with respect to provision of pain ratings and access to medical and health services (Clarke, Thompson, Buchan, & Combes, 2008; McGuire et al., 2010; Walsh et al., 2011; Weissman-Fogel, Roth, Natan-Raav, & Lotan, 2015). Parents know their children well and have developed skills and competence specific to their child with respect to pain expression and capacity for self-report (Carter et al., 2002). Knowledge of an individual's baseline and history is critical to placing his/her behavior into context (Hunt et al., 2003). Parents of both children and adults with DD describe the development of their knowledge as an active process which involves guesswork, trial and error, and intuition (Carter et al., 2002; Clarke et al., 2008; Hunt et al., 2003). People with DD also report seeking assistance from their caregivers not only for pain assessment but also as much needed support (e.g., verbal children with autism spectrum disorder; Ely, Chen-Lim, Carpenter, Wallhauser, & Friedlaender, 2016). It is therefore critical to gather information from parents and other highly involved caregivers to assist in this regard (Carter et al., 2002; Clarke et al., 2008).

Importantly, primary caregivers are not always available to assist with pain assessment and management, and may seek the support of or rely on others in making pain-related decisions. Unfortunately, parents have expressed concerns that health professionals and other caregivers may treat their children differently due to their special needs, or lack knowledge to adequately assess, treat, and refer their loved ones to appropriate services (Carter et al., 2002). This can lead to parents feeling isolated in their journey and concerned that their children will need to accept and live with pain rather than having these needs met (Carter et al., 2002). Parents emphasize the need for and importance of skilled and knowledgeable professionals who can help them with their children's pain (Carter et al., 2002; Carter et al., 2016; Hunt et al., 2003).

In order for other caregivers to reach a more nuanced level of personal knowledge about those they support, time as well as a commitment to building relationships with and hearing the stories of people with DD and their families are required (Hunt et al., 2003). Unsurprisingly, pain assessment and management are viewed by secondary caregivers such as school nurses and residential support workers as difficult and complex; this is particularly true when they are lacking critical information or resources such as pain assessment tools (Beacroft & Dodd, 2011; Quinn, 2016). Although some research suggests that these caregivers may be able to identify important factors to consider when assessing pain and useful management strategies, their application may be suboptimal. Indeed, an audit of 33 residential services for adults with DD in Surrey, UK found that none of nine researcher-developed pain assessment and management standards were met (Beacroft & Dodd, 2011). These included items such as the recognition that people with DD do not have a higher pain threshold than others without DD, having access to appropriate pain assessment tools and having pain management policies in place (Beacroft & Dodd, 2011). Similarly, work regarding a variety of caregivers supporting children and adults with DD have highlighted deficits of pain-related knowledge, skills, confidence, and resources, and the need for targeted pain-related education (Beacroft & Dodd, 2011; Carter et al., 2016; Genik, McMurtry, Breau, Lewis, & Freedman-Kalchman, 2017; Malviya, Voepel-Lewis, Merkel, & Tait, 2005; Nilsson, Johnson, & Adolfsson, 2016; Quinn, 2016; Quinn & Serna, 2017).

Thus far, provision of pain assessment and management training programs in settings including pediatric respite, school, and adult residential settings have demonstrated positive impacts immediately following training and/or at follow-up. These include increases in pain-related knowledge, changes in perceptions and attitudes, and increased intent to implement/use new strategies in practice (Genik, McMurtry, Breau, Lewis, & Freedman-Kalchman, 2017; Mackey & Dodd, 2010; Quinn & Smolinski, 2017). The broad dissemination of these types of programs and resources is necessary in order to be of their intended use (Findlay et al., 2015).

Pain Assessment

As with people who do not have a DD diagnosis, there are a number of approaches used to assess pain and arrive at management-related decisions, such as self-report and observation. The use of multiple methods is recommended (Solodiuk et al., 2010). An understanding of pain assessment tools and resources is necessary but not sufficient, as "knowing the child" is also critical (Carter et al., 2002). Consultation with primary caregivers regarding the child's pain history and usual pain behavior patterns is always recommended and can improve assessment. While some of this information can be gleaned from informal conversations with caregivers, more formal communication using structured tools between caregivers may be helpful in this regard. For example, one might use the Pediatric Pain Profile (described below; Hunt et al., 2004) across settings to assist with pain assessment. Further, although not specific to pain, resources such as the health passport communication tools developed by the Health Care Access Research and Developmental Disabilities team have been successfully implemented in medical settings (Heifetz & Lunsky, 2018).

Self-Report

Despite the challenges described earlier, literature suggests that people with mild to moderate levels of impairment can generally provide some form of pain self-report; however, the approach used and depth of information provided may vary (Benini et al., 2004; Fanurik et al., 1999). For example, one study found that although 80% of children with Down syndrome were able to indicate when they were in pain, most were unable to describe how severe their pain was or where the pain was located (Valkenburg et al., 2015). In contrast, findings from a study with high functioning youth with autism spectrum disorder suggested they were able to provide self-reports to hypothetical scenarios no different than those reports of "typically developing" peers (Bandstra, Johnson, Filliter, & Chambers, 2012). In a pilot study of adults with Down syndrome, the majority (73%) could complete portions of a self-report measure of pain for people with intellectual disabilities, although only 18% could complete the entire measure without assistance from a trained caregiver (de Knegt, Lobbezoo, Schuengel, Evenhuis, & Scherder, 2016).

Research exploring the ability of people with DD to provide self-report highlights the importance and need for individualized or adapted approaches tailored to a person's developmental level (Benini et al., 2004; Dubois et al., 2010). For example, when asking for self-report, it is important to adapt the language used such as saying "hurt" or "cry" rather than "pain" and using words, pictures, or numbers as needed (Ely et al., 2016). Consideration of the child's preferences, such as type of self-report activity, and other abilities may also be important (Crosta, Ward, Walker, & Peters, 2014; Ely et al., 2016). For example, if someone is unable to respond verbally they may provide self-report by pointing or nodding. In other cases where physical limitations may prohibit the ability to point, people with DD may respond using assistive technology or by looking in the direction of their desired response.

Although psychometrics have generally not been explored in a population of people with DD, a number of self-report tools originally designed for "typically developing" children and/or adults have been successfully utilized in pediatric DD research (see Table 53.1). The use of these tools has largely remained unexplored in adult DD literature. In addition to those listed in Table 1, adaptations of formal self-report tools (e.g., modified Eland Color Scale and Cube Test; Benini et al., 2004) as well as the use of informal assessment approaches (e.g., iPad applications allowing children to draw their pain or indicate its location; Ely et al., 2016) have also been successfully applied in pediatric DD populations. In some cases, provision of a "training session" instructing children how to use the self-report measures prior to a medical procedure has also proven beneficial (Benini et al., 2004).

Recently, a self-report measure of pain specific to adults with DD was developed, called the Self-Reporting Tool on Pain in People with Intellectual Disabilities (STOP-ID!; de Knegt et al., 2016). The STOP-ID is an online tool that aims to capture various qualities of the pain experience, including: intensity, affect, quality, and location of the pain using graphic images and pictograms. The measure can be completed on either a laptop or a tablet device. This computer-based approach has the advantage of providing an efficient way to collect information, thereby reducing the burden on caregivers associated with monitoring and reporting of pain conditions. Although further research is needed, preliminary findings suggest this measure has the potential to enable people with DD to self-report pain and provide a standardized tool to cover multiple aspects of the pain experience (de Knegt et al., 2016).

The wide range of measures discussed here as well as results from preliminary work demonstrate that there is no one self-report measure that can be utilized for people with DD (Ely et al., 2016). Rather, an assortment of tools may be needed to meaningfully assess pain in this population (Ely et al., 2016). Further, it is important to keep in mind that these studies have largely focused on people with mild to moderate DD; thus, the efficacy of these tools in those who are more severely impacted by DD or have other comorbidities is unclear (Bandstra et al., 2012). For example, preliminary research indicates that adults with severe DD have difficulties using self-report tools and comprehending the questions posed (e.g., STOP-ID; de Knegt et al., 2016).

Behavioral Observations

As with self-report, observational tools and approaches used with people who are "typically developing" may lead to inaccurate judgements and underestimations of pain in people with DD given differential expression of pain (Dubois et al., 2010). A number of specialized behavioral observation tools have been developed and involve assessment of agreed upon behaviors commonly exhibited by people with DD when experiencing pain, such as facial expressions and vocalizations (Crosta et al., 2014). The goal of these measures is to improve the ease and accuracy with which observers make judgements about pain for people with DD. These measures have been implemented in various degrees in clinical settings, and differ in aspects such as format, time for completion and degree of primary caregiver input required (Crosta et al., 2014).

Table 53.1 Summary of self-report assessment measures used in research with children with DD

Self-report measure	Initial age range intended for use	Brief description of task	Link to original measure	Relevant DD-specific citation(s)
Measures of pain intensity				
Faces Pain Scale—Revised (Hicks, von Baeyer, Spafford, van Korlaar, & Goodenough, 2001)	4 to 19	Six drawings of faces representing pain ranging from 0 (*No Pain*) to 10 (*Very Much Pain*). The person providing self-report is asked to indicate which face best represents how he/she is feeling.	www.iasp-pain.org/FPSR	Bandstra et al. (2012) ∗Study using hypothetical scenarios; Faces Pain Scale—Revised converted from a 10-point scale to a 5-point scale to correspond with another measure used in the study
Hester Pieces of Hurt Tool (Hester, Foster, & Kristensen, 1990)	3 to 18	If the person providing self-report indicates that he/she is in pain, four red poker chips are provided to them. The person is told that each piece represents one piece of hurt, and are asked to choose "how many pieces of hurt" he/she has.	Attachment B7: http://www.homesteadschools.com/Nursing/courses/ManagementCancerPain/AttachmentB.html	Ely et al. (2016)
Numeric Rating Scale (von Baeyer, Chambers, Forsyth, Eisen, & Parker, 2013)	8 and above	Most typically, a scale ranging from 0 (*No Pain At All*) to 10 (*Most Pain Possible*). The person providing self-report is asked to indicate on paper or verbally the level of pain he/she is experiencing.	n/a	Bandstra et al., 2012 ∗Study using hypothetical scenarios; used a 0–5 scale for increased simplicity and to correspond with the number of response options from another measure used in the study
Visual Analogue Scale (Scott & Huskisson, 1976)	8 and above	On a 10 cm line (0 = "*No Pain*"; 10 = "*Severe Pain*," the person providing self report is asked to point to or mark a point on the line which represents the amount of pain he/she is experiencing.	n/a	Benini et al. (2004) Ely et al. (2016)
Wong Baker FACES Scale (Wong & Baker, 1988)	3 and above	Six cartoon faces ranging from "*No Hurt*" to "*Worst Hurt*". The person providing self-report is asked to select the face that is most representative of how he/she feels.	http://wongbakerfaces.org/types-of-access/	Ely et al. (2016)
Measures of pain intensity and location				
Eland Colour Scale (Eland & Anderson, 1977)	4 to 10	After assigning colours to four pain categories (No Pain, Mild Pain, Moderate Pain, Severe Pain), the person is asked to colour where he/she hurts using the corresponding colours based on pain severity.	Attachment B6: http://www.homesteadschools.com/Nursing/courses/ManagementCancerPain/AttachmentB.html	Benini et al. (2004)

Table 53.2 Summary of behavioral assessment measures for pain in children and adults with DD freely available online

Measure	Validation	Intended/ Validated age range	Acute pain	Chronic pain	Link to measure
Chronic pain scale for nonverbal adults with intellectual disabilities	∗Pilot study only Burkitt et al. (2009)	18 and above		X	http://pediatric-pain.ca/wp-content/uploads/2013/04/CPSNAID.pdf
Individualized numeric rating scale	Solodiuk et al. (2010)	6 to 18	X		http://www.marthaaqcurley.com/inrs.html
Non-communicating adult pain checklist	Lotan, Ljunggren, et al. (2009); Lotan, Moe-Nilssen, et al. (2009); Meir et al. (2012); Weissmann-Fogel, Roth, Natan-Raav, & Lotan, 2015	15 to 75	X		https://www.painbc.ca/sites/default/files/Non-Communicating%20Adult%20Pain%20Checklist.pdf
Non-communicating children's pain checklist—postoperative version	Breau, Finley, et al. (2002) French: Zabalia et al., 2011	3 to 18	X		http://pediatric-pain.ca/wp-content/uploads/2013/04/NCCPCPV_200901.pdf ∗Also available on pediatric-pain.ca in German and French
Non-communicating children's pain checklist—revised	Breau, McGrath, et al. (2002) German: Kleinknecht (2007) Swedish: Johanssen, Carlberg, & Jylli, 2009	3 to 18	X	X	http://pediatric-pain.ca/wp-content/uploads/2013/04/NCCPCR_200901.pdf ∗Also available on pediatric-pain.ca in German and Swedish
Pediatric pain profile	Hunt et al., 2004	1 to 18	X	X	http://www.ppprofile.org.uk/ppptooldownload.php?s=209 ∗Also available in Portuguese
Revised face, leg, activity, cry, and consolability scale	Malviya et al., 2006	4 to 21	X		http://ilemsc.org/PainMgt/rFLACC.pdf

They can be used on their own or in combination with other assessment modalities.

For the purpose of this chapter, only behavioral measures that are freely available online, have known psychometric properties in English, and are frequently discussed in the literature will be described in detail. A summary of these measures for both children and adults with DD can also be found in Table 53.2. Findings from individual pediatric studies or research groups have been used to make suggestions about which scale may hold the most clinical utility, but unfortunately, recommendations are not consistent (e.g., Chen-Lim et al., 2012; Crosta et al., 2014; Ely et al., 2016; Quinn, Seibold, & Hayman, 2015; Taddio et al., 2015). The variability may reflect the need for varied assessment approaches to meet the unique needs of each setting, observer and person with DD. Importantly, while some of these measures indicate guidelines and interpretations/cut off scores (e.g., r-FLACC; 0–3 represents mild pain; Malviya, Voepel-Lewis, Burke, Merkel, & Tait, 2006), these have only been used in research, and their accuracy may be questionable (Breau, McGrath, Camfield, & Finley, 2002). As such, there is potential for underestimation of pain, and these scores should not be the only method for determining the presence or absence of pain and subsequent treatment (Breau, McGrath, et al., 2002).

With respect to children and youth with DD, two versions of the Non-Communicating Children's Pain Checklist (NCCPC) have been developed: the Revised Version (30 items) and the Postoperative Version (27 items), both of which are designed for use with people with DD ranging from 3 to 18 years of age (Breau, Finley, McGrath, & Camfield, 2002; Breau, McGrath, et al., 2002). These measures ask caregivers to indicate the frequency with which a number of pain-related behaviors are observed over a period of time ranging from 0 (“*Not At All*”) to 3 (“*Very Often*”); the revised version uses a 2 h time frame whereas the postoperative version uses 10 min (Breau, Finley, et al., 2002; Breau, McGrath, et al., 2002). Subscale and total scores can then be derived, and may be compared to cut-off scores used in research as follows: revised version: > 7 = pain; postoperative version: 6–10 = mild pain and = 11 = moderate to severe pain (Breau, Finley, et al., 2002; Breau, McGrath, et al., 2002;). Both of these measures have demonstrated excellent validity and reliability which appear to be maintained when translated into other languages (Breau, Finley, et al., 2002; Breau, McGrath, et al., 2002; Johansson, Carlberg, & Jylli, 2010; Kleinknecht, 2007).

Based on the Face, Leg, Activity, Cry, and Consolability Scale (FLACC) initially designed for young children who have not yet developed verbal abilities, the revised version (r-FLACC) measures pain intensity by rating each of the five titular domains from 0 to 2 (Crosta et al., 2014; Malviya et al., 2006). This revised measure is individualized, allowing parents to add in specific behaviors unique to their child in each section. A total score is calculated by adding the scores from each subcategory; a total score from 0–3 represents mild pain, 4-6 moderate pain, and 7-10 severe pain (Malviya et al., 2006); again, as noted previously, these cut offs have been primarily used for research purposes. Both the English and Danish version of the r-FLACC have demonstrated excellent interrater reliability, construct validity and criterion validity, and can be used for people ranging in age from 4 to 21 (Malviya et al., 2006; Pedersen et al., 2015). This, combined with its advantages (e.g., quick to complete, easy to use) makes the r-FLACC a strong candidate for integration into practice (Quinn et al., 2015).

Adapted from more traditional numeric rating scales, the Individualized Numeric Rating Scale (INRS) ranges from 0 (“*No Pain*”) to 10 (“*Worst Possible Pain*”) and allows parents and other caregivers to provide behavioral descriptions which correspond with each intensity rating (Solodiuk et al., 2010). For example, a caregiver may indicate that a child screams when their pain intensity is at 10, but may withdraw socially when their pain intensity is at a 3. Previous work by Solodiuk and colleagues (2003, Solodiuk et al., 2010) has suggested that the r-FLACC can be used to assist parents in identifying pain behaviors to highlight on the INRS. Research with a sample of nonverbal children with DD ranging in age from 6 to 18 suggested good inter-rater reliability, construct validity, and convergent validity (Solodiuk et al., 2010).

The Pediatric Pain Profile (PPP) developed by Hunt et al. (2004) is an observational measure designed for use with children who have severe disabilities ranging from 1 to 18 years of age. This measure includes 20 items and was designed to simultaneously serve as a record/pain communication tool (Hunt et al., 2004). The PPP is an in-depth document including sections for caregivers to share information about the child’s pain history, baseline, and current pain behavior. It also allows parents and caregivers to complete ongoing pain assessments and track information related to pain assessments, outcomes, and interactions with other professionals (Hunt et al., 2004). With respect to ongoing pain assessments, caregivers are asked to rate the frequency of a series of pain-related behaviors (e.g., disturbed sleep, hard to console, appears withdrawn/depressed) during a specific time period from 0 (“*Never*”) to 3 (“*A Great Deal*”). Ratings can be summed and result in a total score ranging from 0 to 60, with higher scores representing high pain intensity. General interpretation patterns based on previous research are provided; however, it is acknowledged that each child’s range of pain behaviors will be unique. Evidence of construct, concurrent and face validity as well as interrater reliability of the PPP have been demonstrated (Hunt et al., 2004). An initial implementation study of the PPP in an in-patient setting suggested that although aspects of this measure were valued, there are a number of implementation barriers such as completion of pre-admission assessment, length of time it takes to complete, and the requirement for ongoing documentation (Hunt & Franck, 2011).

Observational methods are not as commonly employed with adults. However, a number of assessment tools have been developed from the NCCPC-R (Breau & Burkitt, 2009). The NCCPC-R was piloted in individuals over 18 years of age with ID by having two staff members from an adult residential treatment centre watch residents and rate their behaviors using the NCCPC-R. Items related to "jumping around," "screaming," and "floppy" were removed as they were not sensitive to pain in the adult sample. This resulted in the development of the Chronic Pain Scale for Nonverbal Adults with Intellectual Disabilities (CPS-NAID), a 24-item scale that requires caregivers to indicate the frequency of observed pain-related behaviors, ranging from 0 ("*Not At All*") to 3 ("*Very Often*"). This scale has demonstrated preliminary psychometric properties (Breau & Burkitt, 2009; Burkitt, Breau, Salsman, Sarsfield Turner, & Mullan, 2009). Given that the CPS-NAID includes a subset of items from the NCCPC-R and the NCCPC-PV, scores on the NCCPC as an adolescent can be compared to their scores as a young adult on the CPS-NAID, and thus allowing for monitoring of long-term conditions (Breau & Burkitt, 2009). Nevertheless, this scale has only been evaluated in one study and further research is needed before using this scale in clinical situations (Breau & Burkitt, 2009). The Non-Communicating Adult Pain Checklist (NCAPC) is an 18-item scale that was developed from the NCCPC-R to be used for adults with DD (Lotan et al., 2009). Similar to the NCCPC-R, caregivers rate the frequency of observed pain behaviors on a four point scale (Lotan, Ljunggren, et al., 2009). The behaviors are divided into six subcategories: vocal expression, emotional reaction, facial expression, body language, protective reactions, and physiological signs (Lotan, Ljunggren, et al., 2009). Scores can range from 0 (no pain behavior observed) to 54 (maximal duration of all pain behaviors observed). Research supports the validity and reliability of the NCAPC in the context of acute procedural pain and chronic pain, and this measure demonstrates high sensitivity to pain in adults at all levels of DD (Lotan, Ljunggren, et al., 2009; Lotan, Moe-Nilssen, Ljunggren, & Strand, 2009; Meir, Strand, & Alice, 2012; Weissman-Fogel et al., 2015).

Other measures developed for use with children and/or adults are not as widely used, may not be freely available in English, and psychometric properties may require further exploration for intended target audiences. Examples of these include the Checklist Pain Behavior Scale (original: Terstegen, Koot, de Boer, & Tibboel, 2003; reduced: Duivenvoorden, Tibboel, Koot, van Dijk, & Peters, 2006), Pain Behavior Checklist (van der Putten & Vlaskamp, 2011), Pain Evaluation Scale for Clients with Cerebral Palsy (Collignon & Giusiano, 2001), Pediatric Indicator for Communication Impaired Children (Stallard et al., 2002), and the Disability Distress Assessment Tool (DisDAT; Regnard et al., 2007).

Combining Subject and Objective Assessment Approaches

Given the above described inherent difficulties in measuring pain among individuals with motor, communicative, and/or intellectual impairment associated with DD, yet another approach is to pair observational ratings with an exam-based procedure with or without additional reports from others such as caregivers. The Pain and Discomfort Scale (PADS) is a pain assessment tool which has been used to characterize nonverbal behavioral pain reactivity/expression of people with DD during a standardized physical exam known as the Pain Examination Procedure (PEP; Bodfish, Harper, Deacon, & Symons, 2001). PADS is composed of 18 items across five domains such as vocal and facial expressions; all items were derived directly from the NCCPC (Breau, Finley, et al., 2002; Breau, McGrath, et al., 2002). Preliminary work with the PADS has demonstrated excellent reliability for clinical screening, content validity, and sensitivity to painful procedures (Bodfish et al., 2001; Phan, Edwards, & Robinson, 2005). A benefit of pairing the PADS with a standard examination procedure such as the PEP is the ability to ensure that all body areas are examined and observed for possible pain signs. The pain examination procedure (PEP) consists of 5 assessment steps (head, arms, hands, torso, legs/feet), with a 3-part observation at each step (pain sign present/absent, intermittent, continuous). During the PEP, the PADS take approximately 5 min to complete by a trained nurse, direct care staff, or other provider, including parents.

Special Illustration of Advancing the Field: Research Application of Combined Assessment Approach for People Who Are Nonverbal with Severe DD

In addition to pain assessment, combined approaches such as the PADS/PEP may also be used to explore and illustrate the associated challenges and complexities of understanding pain in people with DD who have complex health problems and communication needs. For example, Rett syndrome (RTT) is a rare X-linked developmental disability causing severe cognitive, motor and language/communication problems, occurring almost exclusively in girls (Neul et al., 2010). From a clinical care perspective, there are frequent health issues that when combined with communication impairments lead to an increased risk that pain may be overlooked or discounted. This is also complicated by the inclusion of pain insensitivity as part of the diagnostic criteria for the syndrome.

The initial support for pain insensitivity was derived from several case study reports in which the apparent absence of pain sensitivity/reactivity associated with nociceptive events (e.g., falls, exposure to fire/flame) was documented (Hagberg, 2002). In a large survey study, the majority of parents reported their daughters had apparent reduced pain sensitivity, although some did report increased sensitivity (Down et al., 2010). Importantly, however, in a subsequent survey where parents were asked more specific questions about their daughter's pain based on items from a validated nonverbal pain scale (NCCPC-R described above; Breau, McGrath, et al., 2002), the majority reported that their daughters experienced a great deal of chronic pain (Symons, Byiers, Tervo, & Beisang, 2013). Indeed, almost a quarter of the sample reported their daughters experiencing pain for greater than 1 week in the prior month. It was also found that the frequency of pain episodes significantly correlated with the number of pain sources and the number of chronic health conditions.

Thus, it seems as though parents will report on pain insensitivity as well as problems with chronic pain about the same population. Part of the issue may be in how pain is assessed (as we suggested above—both in how it is "asked" about and in the "sampling frame"—in what sort of time window) as well as "what kind of pain is it" (nociceptive acute, chronic, etc.). To this point, in a further investigation examining the relation between parent proxy report of pain symptoms and directly observed pain behaviors using the PADS/PEP combination as described above, Barney, Feyma, Beisang, and Symons (2015) documented that the majority of parents (89%) reported their daughter as having experienced pain in the previous week. Moreover, based on direct observation, pain expression appeared intact and frequent when coded observationally during the PEP consistent with behavioral pain expression in other nonverbal populations with severe DD.

Overall, the detailed subjective reports of pain experience provided by parents and objective coding of pain expression during a physical-based standardized exam in RTT suggests the issue surrounding pain in RTT may be a detection issue rather than a sensitivity issue. This specific finding may be part of a more general issue associated with complex cases associated with severe or profound DD. Severe motor and communicative impairments limit the ability to self-report subjective pain experiences in conventional ways. Because of this, there is the possibility that pain may be overlooked and undertreated; indeed, despite parental concerns about health, almost half (43%) of parents reported they were unsure how to reliably determine when their daughter was in pain (Symons et al., 2013). One can clearly understand through this example the complexities and bidirectional nature of the challenges in assessing and understanding pain in people with DD.

Pain Management

Unsurprisingly, research related to pain management in people with DD has also lagged behind that regarding those who are considered "typically developing." The following section will therefore highlight pain management more broadly, while also citing work which has investigated these strategies with people with DD. As with pain assessment, consideration of a person's abilities, preferences, and needs in addition to the completed pain assessment will help guide pain treatment; adaptations to certain approaches may be warranted. Strategies for pain management are often organized into categories known as the "three P's": pharmacological, psychological, and physical. Arguably, a fourth "P" also exists. Process interventions can be thought of as alterations of the environment surrounding the painful incident or painful procedure itself that could exacerbate one's pain experience (Riddell et al., 2015). For example, if a person is bothered by loud noises or crowds, their pain may be better managed in a quiet environment with limited carers present.

Importantly, preliminary work in medical settings has suggested a number of barriers which may interfere with the implementation of adequate management strategies including difficulty with pain assessment and related tools, reliable documentation, and inadequate pain-related knowledge specific to people with DD (Baldridge & Andrasik, 2010; Malviya et al., 2005). Despite the lack of research regarding the efficacy of pain management strategies for people with DD, these are still applied by caregivers in an attempt to relieve pain of those they support. For example, carers of children and adults with DD report having implemented a wide range of strategies including pharmacological (e.g., acetaminophen), psychological (e.g., distraction), and physical (e.g., massage; Carter, Arnott, Simons, & Bray, 2017; McGuire et al., 2010; Walsh et al., 2011).

Pharmacological

Analgesic pharmacological strategies are widely used and recommended for children and adults alike (e.g., Berde & Sethna, 2002; Walsh et al., 2011). Children and youth with high-functioning autism spectrum disorder have indicated that medication can help them to feel better when in pain (Ely et al., 2016). Unfortunately, however, little is known about the use and implications of pharmacological strategies for people with DD. Challenges with pain assessment as well as ethical considerations (e.g., consent) may be partially to blame for this dearth of research (e.g., Valkenburg et al., 2015). Valkenburg, van Dijk, de Klein, van den Anker, and Tibboel (2010); Valkenburg et al. (2015) have shared a "plea" for more research to be conducted in this area, and have spoken about the need to shift foci from mainly pain assessment to pain management. To date, only a handful of pharmacology-related studies have been conducted, and they have focused largely on surgical procedures (e.g., Koh, Fanurik, Harrison, Schmitz, & Norvell, 2004; Malviya et al., 2001). Importantly, when people with DD report high levels of pain and are considered to be in pain by observers, they still may not receive pharmacological treatment or they may receive fewer analgesics than the general population (Boerlage et al., 2013; Hodgkinson et al., 2001).

Medication management of medical comorbidities in people with DD can complicate pharmacological management of pain (Taddio & Oberlander, 2006). Careful consideration of potential side effects is crucial when prescribing medication for pain in people with DD (Taddio & Oberlander, 2006). For example, when prescribing medications of a certain analgesic drug class (e.g., opioids, nonsteroidal anti-inflammatories, acetaminophen), it is important to think about the person's underlying condition, relevant contraindications and potential drug interactions prior to prescribing (Taddio & Oberlander, 2006). Ensuring that communication is open and ongoing across caregivers will be helpful in ensuring that people with DD do not experience unnecessary side effects and instead the desired effects of decreased pain (Taddio & Oberlander, 2006). Resources in relation to pharmacological management of pain are limited for people with DD; readers are encouraged to consult Taddio and Oberlander (2006) for further information regarding pharmacological interventions for pain in children with DD.

Psychological

Psychological management strategies have been broadly studied and found effective for both acute and chronic pain (e.g., Birnie et al., 2015; Eccleston et al., 2014; McManus, Treacy, & McGuire, 2014; Palermo, Eccleston, Lewandowski, Williams, & Morley, 2010; Uman et al., 2013; Williams, Eccleston, & Morley, 2012). Examples of these strategies are provided in Table 53.3. Critically, however, the majority of these strategies have not been formally examined in DD literature, and none of these strategies have substantive research support for their use with this population.

Based on various individual factors (e.g., developmental level, preferences), adaptations to these management strategies may be made. For example, some people may require the assistance of caregivers to utilize distraction, while others may be able to engage in this independently. Similarly, some people may require breathing props such as bubbles to help them engage in and successfully apply deep breathing. Finally, more concrete approaches may be important to help people with DD master these skills such as using a stress ball to teach how to squeeze and release in progressive muscle relaxation.

These strategies are often used across settings. In some cases, people less severely impacted by DD may be able to discuss and implement these approaches. For example, youth in a study by Ely et al. (2016) spoke about the helpful use of distraction such as engaging in preferred activities. Notably, psychological strategies have also been successfully used in combination with others such as topical anesthetics and positive reinforcement (Slifer et al., 2011).

A widely used and commonly researched class of psychological interventions for both acute and chronic pain fall under the umbrella of cognitive behavioral therapy (CBT), which aim to foster an individual's self-management (Logan et al., 2014; McManus et al., 2014). The goal is to enhance an individual's adaptive coping in order to resume their daily life, despite the pain (Turk, 2003). Preliminary research has incorporated modified

Table 53.3 Brief descriptions and examples of commonly used psychological strategies for pain management

Strategy	Description	Examples
Distraction	Activities aimed at shifting an individual's attention away from pain through presentation of other stimuli (Cohen, Cousins, & Martin, 2014).	Interactive toys, video games, virtual reality; auditory distraction (music); audiovisual distraction (television, online videos), Slifer et al. (2011) Koller and Goldman (2012).
Imagery	Involves having the individual imagine a safe and comfortable situation.	Guided imagery: encouraged to let their minds wander, imagine, and focus on a scene/environment that is pleasurable, peaceful, or relaxing. Can be facilitated using audio prompts. Logan, Coakley, and Barber Garcia (2014)
Progressive muscle relaxation	Systematically relaxing body parts, at times following brief periods of tensing the muscle.	See Cautela and Groden (1978) for progressive muscle relaxation for individuals with special needs.
Hypnosis	Dissociation from painful experience and distress via hypnotic induction, suggestions, and imagined fantasy, similar to but more involved than imagery; requires specialized training.	Koller and Goldman (2012)
Deep breathing	Breathing with long breaths, deliberately pacing the breath.	Bubble blowing, blowing exercises.

CBT in the treatment of chronic pain in adults with DD (McManus et al., 2014). An eight-session manualized intervention program called Feeling Better was included, which aimed to increase pain management knowledge and coping skills (e.g., increase wellness-focused coping and reduce illness-focused coping). Following the intervention, participants had higher ratings of pain management knowledge and wellness-focused coping; however, gains were not maintained at one-month follow-up. Additional research examining a prolonged and intensive intervention incorporating caregivers is required (McManus et al., 2014). A group-based CBT treatment for menstrual pain management has been developed from the Feeling Better program for young women with DD, although results from this clinical trial have not yet been released (Kennedy, O'Higgins, Sarma, Willig, & McGuire, 2014).

Physical

Similar to psychological management strategies, a number of physical strategies may be effective in managing both acute and chronic pain (Rakel & Barr, 2003; Taddio et al., 2015). Examples of physical strategies include positioning, stretches, hot/cold compresses, hugs, and exercise. Physical therapy is an integral part of chronic pain treatment (Tupper, Swiggum, O'Rourke, & Sangster, 2013). Particular physical techniques have been recommended to reduce vaccination related pain in all populations (Taddio et al., 2015). Many complementary and alternative medicine approaches such as massage therapy and acupuncture may be helpful in mitigating experiences of pain (Breau, Lotan, & Koh, 2011). In this way, involvement of other professionals may be beneficial when considering interventions such as massage or stretching. However, techniques such as massage, vibration and acupuncture may inflict sensations similar to procedural pain; thus, the ability to understand and tolerate these types of strategies should be considered for individuals with DD (Doody & Bailey, 2017).

Conclusions and Future Directions

Pain in people with DD is prevalent and can greatly impact all areas of adaptive functioning and quality of life. There has been some increasing research interest in particular topics regarding pain assessment for people with DD. Yet as a whole, this is a very understudied research area and pain continues to be under-recognized and mismanaged among this group of people. A number of intra and interpersonal challenges play a role in some of these difficulties. For example, people with DD often struggle to communicate their pain effectively through self-report, and may express pain in idiosyncratic, atypical, and/or inconsistent ways leading to difficulties associated with behavioral observation. Caregivers play an important role in assisting with pain assessment and management, yet may hold inaccurate pain-related beliefs that could negatively impact care. Further, limited pain-specific education is available for caregivers despite their unique role and the risks associated with under-recognized and mismanaged pain. Future work is needed in all areas related to pain in people with developmental disabilities, and it will be important to include not only caregivers of those with DD but also people with DD themselves.

First, while some basic information can be gleaned from prevalence studies previously conducted, there are no larger scale studies examining pain prevalence, for example. Further, little is truly known or understood about pain sensitivity and expression. Developing a better understanding of pain sensitivity, for example, will be helpful in informing pain assessment, management, and related care for people with DD.

Notably, not only is assessment important to better understand a person's difficulties, but it is also critical to inform treatment approaches. With respect to self-report, emerging research continues to suggest that people with DD may be able to provide self-reports of their pain when measures are adapted and explicitly taught. Pain is subjective; providing people with DD a fair opportunity to share their pain experiences is important. To date, there are no validated measures or approaches for gathering self-report in this population. Further work in this area to develop a better understanding of which measures may be useful for people with DD and how they can be adapted will therefore be useful. Although a number of behavioral observation scales have been developed and validated specific to people with DD, these are largely intended for use in medical settings. Focusing on pain assessment beyond that which occurs when primary caregivers are present or in health care settings could be helpful in improving other caregivers' abilities to ensure that these children's needs in this regard are adequately met.

Intervention strategies have not been systematically evaluated. This area has lagged well behind even that of pain assessment for people with DD. Specifically, understanding which strategies are most helpful to people with DD and how to best adapt/apply them in clinical settings will be critical to ensuring pain is managed adequately. This is the case for both pharmacological and nonpharmacological strategies.

Finally, there has been a growing body of literature associated with development of education and resources to improve caregivers' abilities across settings to effectively assess and manage pain in people with DD (e.g., Genik, McMurtry, Breau, Lewis, & Freedman-Kalchman, 2017; Mackey & Dodd, 2010; Quinn & Smolinski, 2017). These efforts have been positively endorsed by study participants (e.g., Genik, McMurtry, Breau, Lewis, & Freedman-Kalchman, 2017). Continued efforts in this domain will be helpful to ensure that all caregivers of people with DD have adequate training and baseline pain assessment and management skills. Given the tendency to under-recognize pain, more information could help lessen the likelihood that pain is missed among people with DD. Additional efforts in ensuring that new knowledge continues to be shared with and translated to a lay audience will also be critical in ensuring that people with DD receive the best possible support and care.

Case Study 1

Ellory is a 13-year-old girl diagnosed with autism spectrum disorder and a mild intellectual disability. She is in good health and has started menstruation last month. Although Ellory is able to communicate her needs relatively well and understands simple instructions, she tends to be slow to process information and becomes overwhelmed if it is provided too quickly. Further, she struggles with abstract concepts and often requires problems to be described in concrete terms or accompanied by aids, such as images or manipulatives. Ellory responds best when her environment and the responses of others are predictable and consistent.

Ellory attends school full time, spending the first part of her day in a mainstream Grade Eight class, and the remainder of the day in a class specifically for children with mild intellectual disabilities. Her favorite subject is art and her least favorite is math. Ellory has an educational assistant, Mrs. Smith, who supports her on an as-needed basis in both classrooms. Ellory has known Mrs. Smith since Grade Three, and they have a strong relationship. Ellory's parents have worked closely with Mrs. Smith to facilitate communication (e.g., advocating for her needs, communicating how she feels) and employ consistent behavioral strategies at home and at school. Each morning and afternoon, Ellory colors a picture of a person to show how she feels. Ellory's parents use a structured document outlining how to recognize when she is in pain and help her feel better. This document outlines pain behaviors that Ellory may exhibit when in pain, self-report approaches, and strategies that tend to help Ellory feel better (see Fig. 53.1, as developed by Genik, Millett, & McMurtry, 2016[1]). Ellory's parents have also developed a 'pain management menu' at home

---

[1] Currently under review with a peer reviewed journal, this resource as developed by Genik this resource as developed by Genik, Millett, and McMurtry (2016) addresses initial feasibility and usability of the resource in respite care settings. Future work will also include implementation of this resource in secondary care settings.

How to Tell if My Child is in Pain

(Please circle all answers that apply for each question)

When in pain...

1) What facial expression does your child show?

Changes in mouth Furrowed brow
[✓ Changes in eyes] Grimace Stone face
Grinding teeth None
Other/Describe: Squinches her eyes sometimes

2) Does your child's sleeping patterns change?

Sleeps more Sleeps regularly Sleeps Less
Sleeps on and off Restless [✓ No]
Other/Describe:

3) Does your child avoid eating?

Yes Sometimes [✓ No]

4) Does your child's breathing change?

Holds breath Gasps [✓ No]
Other/Describe :

5) Does your child tense his/her muscles or become rigid?

Tenses muscles Becomes rigid [✓ No]
Other/Describe:

6) Does your child show you the area of the body where the pain is located?

[✓ Touch/ grasp area] Gesture at area Guard/Protect Area
Favour area Move a certain way No
Other/Describe: Only sometimes

7) Does your child become sweaty or clammy ?

Sweaty / Clammy [✓ No]
Other/Describe:

8) Does your child's comfort seeking behaviour change?

Seeks emotional comfort Seeks physical comfort
Withdraws from comfort [✓ No]
Other/Describe:

9) Does your child's behaviour change?

Irritable Agitated Uncooperative
Distracted [✓ Aggressive]
Fidgety/ cannot sit still No
Other/Describe: Verbally and physically - will say 'shut up', hit or bite

10) Does your child's activity level change?

Loses interest Less active
More active [✓ No]
Other/Describe:

11) Does your child make vocal sounds?

Whimpering Screaming Crying
Grunting Groaning No
Other/Describe: If asked directly, can tell you if she is in pain; non-verbal response options are best

12) Does your child engage in any atypical behaviour ?

Self-injury Smiling
Laughing [✓ No]
Other/Describe :

Ways to Help My Child Feel Better

(Please circle all answers that apply for each question)

When in pain…

1) Does physical comfort help soothe your child ?

No Rubbing area Hugging
[✓ Other/Describe]: Hot/Cold Compress

2) Does your child self– soothe?

No Yes [✓ Sometimes]

3) Are distractions helpful in managing the pain?

No [✓ Yes] Sometimes

If yes, what are your child's favourite distractions?

Favourite toy(s): Art/colouring, puzzles

Favourite comfort(s): Bean bag chair; stuffies and other soft items

Favourite movie/ T.V show(s): No specific show; loves music

Favourite Snack(s): Fish crackers

Other/Describe: Blowing bubbles
*Can have ibuprofen for headaches and stomach aches

4) Has your child had experience with another secondary caregiver who would be available for further consultation?

If yes, what is the caregiver's:

Name: Mrs. Smith at school

Number: (   )   -   -

Parents: Please make sure to fill out the back of the pamphlet →

Fig. 53.1 Snapshot of communication document between Ellory's parents and school staff outlining ways to help Ellory feel better when she is experiencing pain

which allows Ellory to choose from a variety of pain management options (see Fig. 53.2).

This week, Ellory's parents indicated that she may be nearing her time of menstruation and may be prone to stomach cramps. During math class, Mrs. Smith began to notice Ellory becoming more irritable (e.g., skipping over questions that were difficult rather than persevering as she normally would, mumbling angrily to herself). As this is common for Ellory given her difficulty with and dislike of math, Mrs. Smith provided some additional support, and also tried moving Ellory to the resource room where she could work in a more quiet setting. When this additional support did not appear to alleviate Ellory's frustration and upset, Mrs. Smith continued to monitor closely for other shifts in behavior. She noticed that Ellory was holding her stomach with one hand while working, which can be a sign that she may be experiencing pain. Mrs. Smith then used simple language consistent with that used at home, to ask if she had any hurt. Mrs. Smith allowed Ellory to respond nonverbally by pointing to her response (yes/no) on a piece of paper. She then provided Ellory with the picture of the person she colors each morning, and asked Ellory to show where her pain was. Ellory pointed to the person's stomach, and colored the stomach "red" to represent "a lot" of pain.

Based on parent requests, Mrs. Smith allowed Ellory to remain in the quieter resource room setting and provided Ellory with a physician approved amount of ibuprofen to help alleviate her stomach cramps. Mrs. Smith obtained the "pain management menu" that was co-created with Ellory and allowed her to select what she needed to help her feel better. Mrs. Smith provided Ellory with a hot compress for her stomach, and she went to lay down in the sensory break room. Ellory listened to music while laying

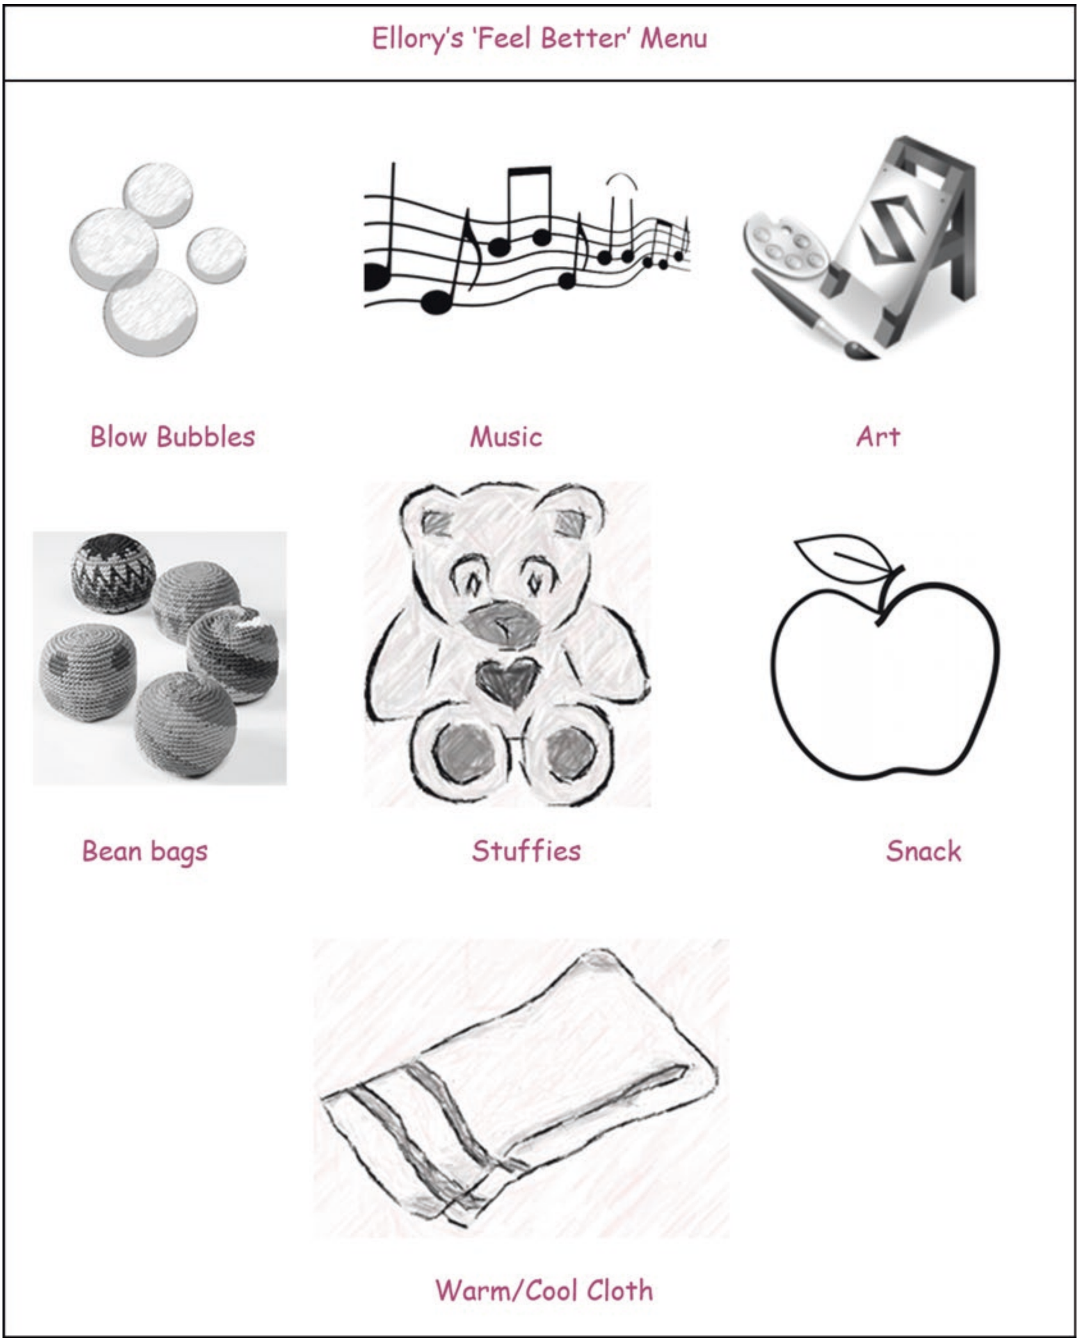

Fig. 53.2 Ellory's "pain management menu"

in the bean bag chair. Mrs. Smith continued to check in with Ellory to determine when the medication began to take effect and when she was feeling better. After about 30 min, Ellory colored another picture of a person with a yellow crayon, indicating that she only had "a little" pain in her stomach. Mrs. Smith helped Ellory return to her classroom to participate in the remaining activities. Mrs. Smith continued to monitor and assess Ellory's pain through observation and self-report for the remainder of the day. When Ellory's parents picked her up from school. Mrs. Smith provided them with a brief report of what occurred, actions that were taken, and the time Ellory took the initial dose of ibuprofen.

Case Study 2

Colton is a 40-year-old man diagnosed with a severe intellectual disability. He is generally in good health, but is lactose intolerant and experiences severe stomach aches after ingesting products containing lactose. Colton is able to understand very basic language but has extremely limited abilities to express himself through verbal means. For example, he generally speaks only with single words and simple sentences. Further, while he is able to respond to questions with "yes" or "no" these responses are at times acquiescent in nature or inconsistent. He uses a tablet to communicate many of his needs, such as when he is feeling hungry, through pictures.

Colton lives in a residential setting with three other people who have varying levels of DD. Supports are provided 24/7 by a core group of full time staff. He looks forward to weekly visits with his parents. Colton is generally a happy-go-lucky and easy going gentleman who enjoys taking walks, swimming, and helping with food preparation before meals. Although not validated for adults with DD, Colton's support workers use adapted documents derived from the Pediatric Pain Profile (Hunt et al., 2004) to maintain updated, relevant and organized information about Colton's pain history and his behavior "on a good day" versus "when in pain" (see Fig. 53.3 for example of Colton's behavior when in pain). They use an individualized document adapted from the Non-Communicating Adult Pain Checklist (NCAPC; Lotan, Ljunggren, et al., 2009) to assess his pain based on his individualized behaviors. As Colton spends at least one full day per week visiting his parents, Colton's support workers and parents maintain open communication about any pain he experiences and how he communicates it to others.

Colton's ability to understand and use verbal language to communicate often decreases when pain is present, making it more challenging to communicate with him. He does have pain-related pictures that he can select on his tablet, but uses these inconsistently. Knowing this, caregivers often ask for self-report but also rely on the use of structured behavioral observation measures to make judgments about the presence or absence of pain. Colton's physician has provided approval for him to take acetaminophen when in pain, and he responds well to the use of distraction. Often, Colton wishes to stay in his room when in pain, so support staff respect this and support him there as needed. As he does not respond positively to touch when in pain, staff generally do not use physical pain management strategies.

On a morning when Colton was to spend the day with his parents, Colton woke up 2 h earlier than usual (5 a.m.). When Sarah, the overnight support worker tried to support him in beginning his morning routine, Colton refused to get off of the living room couch. He refused breakfast as well as the opportunity to prepare breakfast for his housemates. Around 7 a.m., he began to grind his teeth. As Sarah's shift was ending, she consulted with the replacement staff member Celeste and they decided to document their observations by completing an ongoing pain assessment sheet. Although Colton often protects the area in pain, he seemed to be holding his face and continued to open and close his mouth. When Celeste showed Colton a picture he usually associates with headaches, he responded "NO" on his tablet. Nevertheless, Celeste decided that Colton was experiencing some form of pain and to try and help to alleviate it.

Based on documentation of pain management strategies that are most helpful for Colton, he was given a physician approved dose of an over-the-counter pain-relieving medication (acetaminophen) and his tablet to watch his favorite show. Celeste then contacted Colton's parents to provide them with an update and share her observations. Given the unclear and unusual nature of Colton's pain expression (i.e., opening and closing his mouth), his parents offered to take him to a walk-in clinic. Upon their return, they shared with Celeste that Colton had a toothache. They provided Colton with prescription medication provided by the

When in pain Colton&	Not at all	A little	Quite a lot	A great deal
• Withdraws from social situations			X	
• Becomes uncooperative in daily routines				X
• Sleeps less		X		
• Eats less		X		
• Grinds his teeth			X	
• Protects/guards areas in pain			X	

Fig. 53.3 Sample of baseline document used to communicate Colton's pain behaviors adapted from the Pediatric Pain Profile (Hunt et al., 2004)

doctor at the walk-in clinic, and made an appointment with his dentist for the following day. Celeste continued to check on Colton throughout the afternoon and assisted with the use of distraction as needed. Finally, Celeste recorded relevant information in Colton's adapted NCAPC and shared this information with the support worker covering the overnight shift.

Nutrition

Regina M. Subach and Lori Klein

> **Food can be the greatest form of medicine, or the slowest form of poison.—Ann Wigmore**

Despite the ancient wisdom that the food we eat determines the robustness of our health, we continue to struggle with adequate nutrition at a global level. When humans eat healthful, fresh, whole foods in the amounts needed to maintain a healthy body weight, the potential result is a vibrant, longer life with lower risk of chronic diseases. The number of people classified as overweight or obese remains disastrously high across the population, and individuals with intellectual disabilities (ID or IDD) suffer from overweight and obesity at equal or greater rates in comparison (Ptomey, Goetz, Lee, Donnelly, & Sullivan, 2013). An unhealthy body weight is one of the strongest risk factors for the development of other chronic diseases including diabetes and cardiovascular disease.

There is limited research on the prevalence of overweight/obesity, chronic disease, and nutritional risk for individuals with ID, but the available information paints a gloomy picture for these vulnerable citizens (Ptomey et al., 2013). Current data indicates obesity rates double that of the general population which translates into increased chronic disease risk (Ptomey & Wittenbrook, 2015).

The Academy of Nutrition and Dietetics (AND) is the leading authority on evidence-based nutrition information and publishes “Position Papers” on critical areas of nutrition research with guidelines for special populations. These articles summarize nutrition policy and guide the 100,000 credentialed nutrition professionals who are members of AND. The 2016 Position Paper on Nutrition Services for Individuals with Intellectual and Developmental Disabilities and Special Health Care Needs details a multitude of nutritional risk factors for this underserved group, including altered growth patterns, difficulty with self-feeding, metabolic disturbances, and medication interactions (Ptomey & Wittenbrook, 2015). As noted previously, individuals with ID also have a higher risk of developing comorbid conditions such as obesity and metabolic syndrome that further heighten the need for programs that address nutritional needs (Ptomey et al., 2013). Intellectual disabilities complicate an already challenging problem with additional barriers related to nutrition knowledge, limited resources, and perceptual differences.

This chapter discusses the Dietary Guidelines for Americans, the additional barriers faced by individuals with ID in meeting these recommendations, and practical applications to improve the

nutrition status of this population. Specific disabilities and case studies are included to demonstrate nutrition risk and interventions.

Nutrition Basics

Before reviewing the Dietary Guidelines for Americans, it can be helpful to understand basic nutrition terms and the components of the foods we eat and how they support overall health. Nutrition has been defined as the "science of food, the nutrients and other substances therein, their action, interaction and balance in relation to health and disease, and the process by which the organism ingests, absorbs, transports, utilizes and excretes food substances" (Lagua & Claudio, 1995). For a more simplified definition, nutrition is the process of consuming food to meet the dietary needs of the human body.

The food we eat every day comprises macronutrients (protein, carbohydrates, and fat), micronutrients (vitamins and minerals), and dietary fiber. Macronutrients provide energy needed for physical activity, growth, and structure for basic body functions. Micronutrients have important roles aiding in immune function, neurological function, cell growth, and cell repair.

Macronutrients

Carbohydrate broken down into glucose is the main energy nutrient and preferred source of energy for the brain and nervous system. Dietary recommendations for carbohydrates come primarily from plant foods: cereals, grains, fruits, vegetables, as well as dairy products. Whole grains are the preferred choice over processed grains due to their higher fiber and nutrient content. Consuming plant sources is an added bonus because they also contribute as the primary source for dietary fiber.

Dietary fibers are the nondigestible part of plants is found in all foods derived from plants. Whole grains and non-processed plant foods provide good amounts of dietary fiber. Dietary fiber found in legumes, oat, barley, and citrus fruits are classified as soluble fibers. Soluble fibers form gels when dissolved in water and are digested by bacteria in the intestinal tract. They reduce the risk of cardiovascular disease and diabetes by lowering blood cholesterol and stabilizing blood sugars. Dietary fiber found in whole grains and vegetables and some fruits such as apples, raspberries, and strawberries are classified as insoluble fiber. This type of fiber aids in elimination and helps reduce constipation. Fiber recommendations are 25 g for women and 38 g per day for men. The average fiber intake of Americans is ~15 g. Following recommendations of MyPlate and Dietary Guidelines for Americans will aid in meeting daily fiber recommendations.

Proteins are amino acids which make up most tissues in the major part of the human body. Amino acids have both functional and structural roles which aid in the building and repairing muscle, bone, and skin; act as enzymes for metabolic reactions; are hormones, regulate fluid balance; act as antibodies; and aid in glucose production when needed. Dietary recommendations for protein include both animal- and plant-based protein sources. Animal proteins include meat, poultry, fish, eggs, and dairy products. Plant-based proteins are found in beans, legumes, nuts, soy, vegetables, and grains.

Fat is the most concentrated source of energy. It serves as the structure and insulation of cell membranes and also aids in the absorption of fat-soluble vitamins A, D, E, and K. Dietary intake of fat comes from both animal and plant sources. Animal sources of fat from meat, eggs, poultry skin, and dairy contribute the highest amount of saturated fat and cholesterol in the diet. Saturated fat plays a role in increasing blood cholesterol and should be limited to no more than 10% of calorie intake. The most recent DGA has no specific recommendation for cholesterol intake, but adherence to a diet that limits saturated fat to less than 10% will limit cholesterol intake to 100–300 mg across the calories levels (U.S. Dept., 2015). Plant foods, poultry, and fish provide polyunsaturated and monounsaturated fatty acids to the diet. These types of fatty acids aid in heart health through maintenance of healthy blood cholesterol level.

Micronutrients

Vitamins and minerals are essential nutrients needed in small amounts to prevent deficiency and promote health. They are classified as "micro" or "transfer nutrients." They aid in the transformation of energy nutrients into fuel and are critically important for supporting heart function, immune response, cell repair, and numerous other vital functions. Food selectivity, limited intake of fruits and vegetables, and omission of foods or entire food groups puts individuals at risk for micronutrient deficiencies. This reduced diet quality has been seen to lead to deficiencies of vitamin A, vitamin D, vitamin E, vitamin K, folate, potassium, fiber, and calcium among a group of persons with intellectual disabilities (Ptomey et al., 2013). The Academy of Nutrition and Dietetics also notes several vitamins and minerals of concern for this group overall as well as for specific disabilities that occur in conjunction with intellectual disabilities. See Table 54.1.

Nutrient deficiencies may be more likely to go undetected in individuals with ID, because of difficulty communicating fatigue, pain, and illness. If there are not enough food sources of vitamin A in the diet, the end result can be a permanent visual impairment. Vitamin D insufficiency can occur when there is not enough exposure to sunlight and a lack of fortified foods, and this can impair bone density and lead to osteoporosis. Vitamin E deficiency is rarely seen because it is prominent in oils (as well as nuts and seeds) but can occur with metabolic disorders related to fat absorption, and could lead to neurological disturbances, muscle fatigue, and visual impairment. Vitamin K from leafy greens is important for proper blood clotting, and a dietary deficiency can result in bruising and uncontrolled bleeding. Folate is responsible for proper nervous system function. Many subtle signs can signal inadequate intake, which could eventually lead to anemia in adults; children may suffer additional neurological effects including seizures. Calcium works in conjunction with vitamin D for bone health and deficiency symptoms are well documented through osteoporosis. On a larger scale the imbalance of higher sodium intake with lower potassium intake is a contributor to high blood pressure and increased risk of cardiovascular disease.

Vitamin D and vitamin B-12 are two critical micronutrients for this population due to potential food limitations, malabsorption conditions, and issues that limit sun exposure.

Vitamin D

Vitamin D is a fat-soluble vitamin that is also classified as a hormone that can be produced endogenously by the body through exposure to ultraviolet rays from the sun. With the exception of cod liver oil and fatty fishes vitamin D is not found abundantly in foods. Milk and dairy products are often fortified with vitamin D, serving as the most common dietary source of vitamin D; beef liver, egg yolks, and cheese contain smaller amounts. Vitamin D from sun exposure and food is biologically inert and must be activated in the body.

Vitamin D is associated primarily with bone health in conjunction with calcium and phosphorus, both necessary for adequate bone mineralization. In addition to its role in bone health vitamin D aids in cell growth, neuromuscular and immune functions, and reduction of inflammation (NIH, 2010). Research continues on other possible health effects of vitamin D, including reduced risk of chronic disease and depression.

The Recommended Dietary Allowances (RDA) for vitamin D vary based on age and stages of the life cycle ranging from 400 to 600 International units (IU). Average American Intake of vitamin D solely from foods has been estimated to be lower than the RDA. More research must be conducted on vitamin D supplementation (Tripkovic et al., 2012).

Persons at risk for vitamin D deficiencies include breastfed infants, the elderly, persons with dark skin, and individuals with limited sun exposure, inflammatory bowel disease, malabsorption, and/or who have undergone gastric bypass surgery. Individuals with disabilities,

Table 54.1 Key vitamins and minerals of concern for individuals with intellectual disabilities

Vitamin/mineral	Primary function	Food sources	Deficiency signs and symptoms	At-risk groups
Vitamin A	Vision	Green leafy, orange, and yellow vegetables, cantaloupe, and dairy	Vision impairment or loss	Restricted diets that avoid fruits, vegetables, and dairy
Vitamin D ∗produced in the skin with sunlight exposure	Bone Strength	Fatty fish such as salmon, tuna, mackerel and fortified foods milk	Rickets Osteomalacia	Restricted diets that avoid dairy Residence in inpatient facilities, low mobility, reduced times outdoors
Vitamin E	Nerve Function	Vegetable oils, nuts, seeds, green vegetables such as spinach and broccoli	Anemia Neurological impairment Seizures	Individuals with disabilities have lower intake, but clinical deficiency is rare
Vitamin K	Blood Clotting	Leafy green vegetables, broccoli, and canola oils	Bruising Excessive bleeding	Individuals with disabilities have lower intake, but clinical deficiency is rare
Vitamin B-6	Protein metabolism	Fish, beans, beef, poultry, Fortified cereals/foods, potatoes, starchy vegetables	Microcytic anemia Dermatitis with scaling near mouth and swollen tongue Depression	Restricted diets Malabsorption disorders (celiac, Crohn's)
Vitamin B-12	Nerve Function Red Blood Cell Formation DNA synthesis	Fish, meat, poultry, eggs, milk, and other dairy products Fortified foods	Megaloblastic Anemia Neuropathy Depression/ Confusion	Elderly Vegetarians/Vegans Malabsorption disorders (celiac, Crohn's) Resection of stomach/ small intestine
Folate	Neural tube formation Nerve function Blood Cells	Leafy greens, citrus, beans and legumes Fortified foods	Neural tube defects in fetus Weakness/fatigue Headache Behavior disorders Megaloblastic anemia	Medication interference Malabsorption disorders (celiac, Crohn's) Inadequate intake of food sources
Calcium	Bone Strength	Milk, cheese, and yogurt; vegetables like kale, broccoli, cabbage, and canned sardines and salmon with soft bones	Limited stature in children Osteopenia Osteoporosis	Medication interference Inadequate intake of food sources Lactose intolerance Thyroid disorders
Potassium	Electrolyte balance Blood pressure regulation Muscle and nerve function	A variety of leafy greens and root vegetables, fruits like grapes, apricots, and citrus.	Weakness/fatigue Gastrointestinal upset High blood pressure Heart palpitations	Inadequate intake of food sources

especially those residing in group home or disability rehabilitation centers, have higher incidences of vitamin D deficiencies (Wimalawansa, 2016). Diets of individuals who are lactose intolerant have a milk allergy or follow an ovo-vegetarian (a vegetarian diet that excludes dairy products but includes eggs) or vegan diet are often vitamin D deficient (IOM, 2010). Food selectivity and "fad diets" that limit or eliminate vitamin D fortified foods increase the risk of insufficient intake. Vitamin D deficiency results in rickets in children and osteomalacia in adults, and these conditions are characterized by softening of the bones and may lead to an inability to bear weight on the legs.

Individuals with medically complex developmental disabilities (MCDD) may have an even higher risk of vitamin D deficiency due to use of medications such as steroids, phenobarbital, and phenytoin known to interfere with vitamin D metabolism (NIH, 2010; Wimalawansa, 2016). Increased exposure to sunlight, ultraviolet therapy, and/or supplementation may be necessary for at-risk individuals (Wimalawansa, 2016). Supplementation should be done under the supervision of a professional.

Vitamin B-12

Vitamin B-12 is a water-soluble vitamin that is responsible for red blood cell maturation, nerve function, and DNA synthesis (ODS, 2018). This vitamin is prevalent in animal products including beef, fish, poultry, milk, and eggs. Additionally, many plant-based foods such as cereal and tofu are fortified with vitamin B-12 (ODS, 2018). The recommended intake varies throughout the life span ranging from 0.4–0.5 micrograms (mcg) in infancy, 0.9–1.2 mcg during childhood, 1.8 mcg adolescence, to 2.4 mcg in adults (pregnancy-2.6 mcg, lactation-2.8 mcg) (ODS, 2018). For comparison, fortified cereal contains 6.0 mcg per serving of active B-12 that is readily absorbed. A serving of beef contains 1.4 mcg of vitamin B-12 (ODS, 2018).

Although vitamin B-12 deficiency is generally uncommon due to its abundance in animal products, there are some groups known to be at higher risk (ODS, 2018). Regular consumption of fortified foods or oral supplementation is highly recommended for individuals who follow a vegetarian or vegan diet and therefore do not consume animal products, especially for women who are pregnant or breastfeeding to ensure adequacy for the fetus/infant (ODS, 2018). Hydrochloric acid and intrinsic factor present in the stomach are both needed for the breakdown and intestinal absorption of vitamin B-12 and factors that can impair these processes include the aging process with decreased HCL production and increased rates of pernicious anemia, the use of medications for acid reflux, malabsorption disorders like Crohn's disease and celiac disease, and surgical resection of the stomach and/or small intestine (ODS, 2018). Individuals in these high-risk groups should have regular blood samples checked for B-12 adequacy. A medical professional must recommend appropriate supplementation in these cases, because intramuscular injection may be necessary when processing and absorption are impaired or when the deficiency is severe (ODS, 2018).

When vitamin B-12 deficiency does occur, it is critical to address to avoid permanent damage. Three separate physiological symptom categories may be present when there is a lack of B-12—hematological, psychiatric, and neurological—and this spectrum of symptoms can lead to misdiagnosis (ODS, 2018). Megaloblastic anemia presents with large, immature red blood cells that may cause fatigue and weakness. Neuropathy, tingling in hands and feet, and loss of balance are signs and symptoms of neurological impacts that can be permanent and may occur without anemia. Confusion, depression, and memory loss are psychiatric components of vitamin B-12 deficiency that could be mistaken for Alzheimer's disease or dementia. It is also important to note that when folic acid intake is excessive, particularly through supplementation, it can hide the B-12 deficiency and increase the chances of permanent nerve damage (ODS, 2018). Routine screening should be done for high-risk groups, and blood work is warranted for anyone who exhibits potential signs of this deficiency.

The Dietary Guidelines for Americans

The current dietary guidelines for 2015–2020 focus on 5 overarching guidelines designed for disease prevention and health promotion. This section serves as an outline of each guideline followed by barriers and "practical strategies" for improving nutritional health of persons with ID.

The Dietary Guidelines for Americans (DGA), released every 5 years since their introduction in 1980, provide evidence-based food and beverage recommendations for Americans ages 2 and older. The DGA serve as a resource for policy makers, public health agencies, educational institutions, and health professionals in the development and implementation of nutrition policies and programs designed to improve the overall health of all Americans. They are the basis for federal nutrition programs like The Federal School Lunch Program and Child and Adult Care Feeding program. The DGA 2015–2020 are based on the latest scientific evidence that reinforces the innate ancient wisdom connecting nourishing food intake and positive health outcomes.

Guideline One: Follow a Healthy Eating Pattern Across the Life Span

> *All food and beverage choices consumed matter. Choose a healthy eating pattern at an appropriate calorie level to help achieve and maintain a healthy body weight, support nutrient adequacy, and reduce the risk of chronic disease*—(U.S. Dept., 2015).

The typical eating pattern of many Americans does not align with the recommendations of the DGA. The primary emphasis is on "Healthy Eating Patterns as a Whole" rather than attention to specific nutrients like calcium, vitamin D, saturated fats, or "superfoods" such as nuts, berries, or dairy to improve overall heath. An eating pattern, often referred to as a "diet," is defined as a combination of foods and or beverages that constitute an individual's complex intake of food over time (U.S. Dept., 2015). There is a strong emphasis on the synergistic effect of food and beverage on health and wellness.

Healthy eating patterns have been associated with positive health outcomes. There is strong evidence between healthy patterns and reduced risk of cardiovascular disease. Moderate evidence shows an association between healthy eating patterns and reduced risks of type 2 diabetes and certain types of cancer, overweight, and obesity (U.S. Dept., 2015**).** Emerging research is indicating a relationship between eating patterns and neurocognitive disorders and congenital abnormalities (U.S. Dept., 2015).

Healthy eating patterns are adaptable and include a variety of food sources including proteins from plant and/or animal sources, whole fruits, whole grains, dairy, vegetables, and oils. Half of all grains consumed should be "whole grain" such as brown rice, oats, and popcorn; rather than processed grains in white rice, white bread, and sugary baked goods. Vegetable intake should include subgroups of dark green, red and orange, beans and peas, starchy and other vegetables. Dairy should be from low-fat sources. Fat should come in the form of healthy oils such as olive or canola instead of solid fats. Healthy eating patterns limit added sugars, saturated fats, trans fats, and processed foods. Recommended eating patterns highlighted in the guidelines include the Healthy US Style meal pattern, the Mediterranean diet, the Dash Diet, and vegetarian and vegan diets. Links to additional information on these eating patterns can be found on the My Plate website.

MyPlate

The recommendations in the Dietary Guidelines for Americans are communicated to the public through the MyPlate message. MyPlate translates the macronutrients (carbohydrates, fat, and protein) into a more easily understood depiction of food groups and how foods fit into a healthy eating pattern. The image of MyPlate (Fig. 54.1)

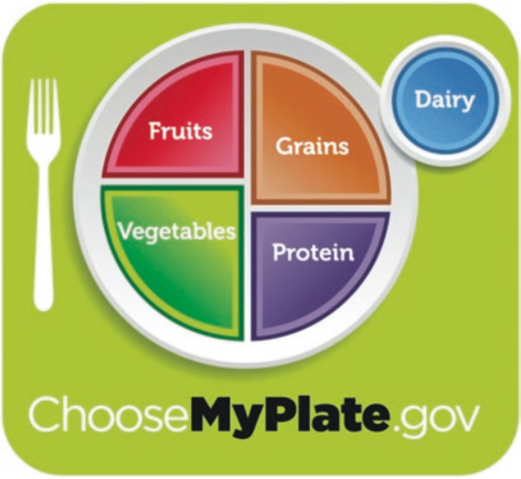

Fig. 54.1 MyPlate

was introduced to transform the previous Pyramid depiction of the Dietary Guidelines into a more concrete visual of how the food groups fit into a meal pattern. This symbol outlines a plate with 1/2 fruits and vegetables that conveys to support the “5 a day” motto for intake of these nutrient rich foods, and the other half of the plate is taken up by grains and a smaller protein portion. Dairy is highlighted on the side in the common cup form for serving milk products. There are many choices with additional recommendations within each group, but this simple image conveys the most important pieces of dietary advice for Americans by encouraging increased fruit and vegetable intake.

Guideline Two

Focus on Variety, Nutrient Density, and Amount

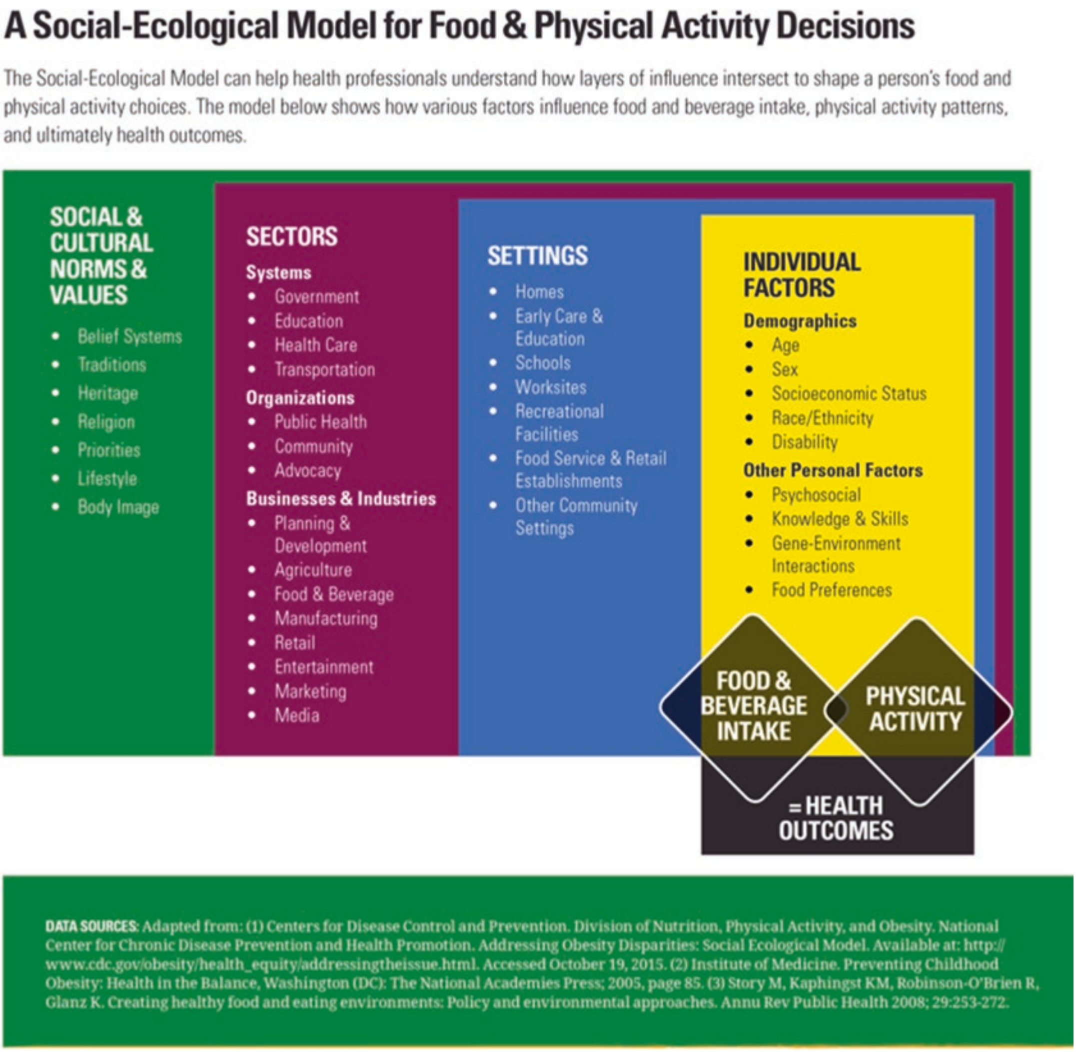
> *To meet nutrient needs within calorie limits, choose a variety of nutrient-dense foods across and within all food groups in recommended amounts.*—(U.S. Dept., 2015)

Most Americans do not follow the healthy eating pattern described in Guideline One as seen in lower intake in fruits, vegetables, and dairy categories and excess intake of sugars, sodium, and saturated fat as compared to the recommendations (U.S. Dept., 2015). In a dietary pattern where fruit and vegetable intake is low and refined grains are chosen over whole grains, the protective effects of fiber are reduced and subsequently overall diet quality is greatly diminished (McGill, Birkett, & Fulgonii, 2016). Guideline Two breaks down the Healthy Eating Pattern into more specific dietary advice within each food group and also addresses appropriate portion sizes. In addition to lower than recommended overall fruit and vegetable intake, the American diet low is specifically lacking in variety that provides the full array of micronutrients. Variety of intake refers to the selection of foods from an assortment of the food groups: fruits, vegetable, grains, proteins, and dairy and their subgroups.

Nutrient needs should be met primarily from food with a focus on nutrient-dense foods. Nutrient-dense foods are foods that are not diluted with calories from added fats, sugars, refined starches, or solid fats not naturally present in foods (U.S. Dept., 2015). Examples of nutrient-dense foods are fruits, vegetables, and whole grains that typically contain a variety of vitamins, minerals, phytonutrients, and fiber. A meal pattern that includes large amounts of juice drinks and processed grains is less nutrient dense than a diet that includes a variety of whole fruits and whole grains.

The majority of vegetables consumed by Americans are in the form of potatoes (French fries) and tomatoes (sauces and condiments), and the 2015 DGA now include recommendations for vegetable subgroups as a result (U.S. Dept., 2015). Recommended servings are based on a 2000 calorie diet (that will vary based on age, sex, and energy needs) as seen in the printable checklist, Fig. 54.2. The daily 2 1/2 cup-equivalent (c-eq) of vegetables in a 2000 calorie diet is broken down into subgroups for maximum nutrient density and fiber intake. Subgroups have weekly intake suggestions and include dark green (1 1/2 c-eq), red and orange (5 1/2 c-eq), legumes (beans and peas—1 1/2c-eq), starchy (5 c-eq), and other vegetables (4 c-eq) to supply maximum nutrient density with a wide array of vitamins, minerals, phytonutrients, and fiber (U.S. Dept., 2015). The fruit recommendation suggests the whole food form over fruit juices for improved fiber and potential for excess calories in juice. When juice is chosen within the fruit category, it should be 100% fruit juice (U.S. Dept., 2015).

Although over half of Americans meet the total protein and grain recommendations, they do not choose the healthful options recommended in these food subgroups (U.S. Dept., 2015). There has been a continuing shift in the DGA to include plant-based protein sources such as beans and legumes which also contain fiber and a multitude of vitamins and minerals. Animal protein sources are still favored in the typical American Diet but contain higher saturated fat and cholesterol without the beneficial fiber (U.S. Dept., 2015).



A Social-Ecological Model for Food & Physical Activity Decisions

The Social-Ecological Model can help health professionals understand how layers of influence intersect to shape a person's food and physical activity choices. The model below shows how various factors influence food and beverage intake, physical activity patterns, and ultimately health outcomes.

SOCIAL & CULTURAL NORMS & VALUES
- Belief Systems
- Traditions
- Heritage
- Religion
- Priorities
- Lifestyle
- Body Image

SECTORS

Systems
- Government
- Education
- Health Care
- Transportation

Organizations

Fig. 54.2 The social ecological model (U.S. Dept., 2015)

Grains may be avoided because of the high-carbohydrate content in the refined, processed grains that are heavily consumed, and the DGA recommend that at least half of grain intake come from whole grains for increased dietary fiber and key nutrients including zinc, iron, folate, magnesium, and a variety of B vitamins (U. S. Dept., 2015). The nutrient content varies between grains and many refined grains have nutrients added back during processing. Whole grains contain the entire kernel and are single foods like oats, popcorn, and rice, but also present in breads, crackers, and other products that are labeled as 100% whole grain.

Although there is little research comparing eating patterns for individuals with intellectual disabilities to the DGA recommendations, a 2013 study compared the diet quality of the general population to a group of 70 overweight/obese adults with IDD (Ptomey et al., 2013). This comparison showed lower overall diet quality and even lower intake of fruits, whole grains, vegetables (dark green and orange) with higher amounts of dietary oils and sodium (Ptomey et al., 2013). Additionally, many nutrient deficiencies were noted in vitamin A, vitamin D, vitamin E, vitamin K, folate, potassium, fiber, and calcium (Ptomey et al., 2013).

MyPlate Daily Checklist

Find your Healthy Eating Style

Everything you eat and drink matters. Find your healthy eating style that reflects your preferences, culture, traditions, and budget—and maintain it for a lifetime! The right mix can help you be healthier now and into the future. The key is choosing a variety of foods and beverages from each food group—*and making sure that each choice is limited in saturated fat, sodium, and added sugars.* Start with small changes—**"MyWins"**—to make healthier choices you can enjoy.

Food Group Amounts for 2,000 Calories a Day

Fruits	Vegetables	Grains	Protein	Dairy
2 cups	**2 1/2 cups**	**6 ounces**	**5 1/2 ounces**	**3 cups**
Focus on whole fruits	Vary your veggies	Make half your grains whole grains	Vary your protein routine	Move to low-fat or fat-free milk or yogurt
Focus on whole fruits that are fresh, frozen, canned, or dried.	Choose a variety of colorful fresh, frozen, and canned vegetables—make sure to include dark green, red, and orange choices.	Find whole-grain foods by reading the Nutrition Facts label and ingredients list.	Mix up your protein foods to include seafood, beans and peas, unsalted nuts and seeds, soy products, eggs, and lean meats and poultry.	Choose fat-free milk, yogurt, and soy beverages (soy milk) to cut back on your saturated fat.

Limit

Drink and eat less sodium, saturated fat, and added sugars. Limit:
- Sodium to **2,300 milligrams** a day.
- Saturated fat to **22 grams** a day.
- Added sugars to **50 grams** a day.

Be active your way: Children 6 to 17 years old should move **60 minutes** every day. Adults should be physically active at least **2 1/2 hours** per week.

Use SuperTracker to create a personal plan based on your age, sex, height, weight, and physical activity level.

SuperTracker.usda.gov

Guideline Three: Limit Calories from Added Sugars and Saturated Fats and Reduce Sodium Intake

> *Consume an eating pattern low in added sugars, saturated fats, and sodium. Cut back on foods and beverages higher in these components to amounts that fit within healthy eating patterns.*—(U.S. Dept., 2015)

While Guideline Two focuses on the nutrients that Americans need to increase and improve, Guideline Three clarifies the need to limit foods containing harmful components that are in excess in the diet. Recommendations suggest limiting both added sugars and saturated fat to less than 10% of daily calorie and limiting sodium intake to less than 2300 mg/day.

The consumption of sugar-sweetened beverages (SSBs) is the leading source of added sugar in the American diet (Park et al., 2016). Beverages classified as SSB include, but are not limited to, fruit drinks and beverages (100% fruit juice is excluded), regular soda, energy and sports drinks, sweetened flavored waters, and coffee and tea beverages with added sugars (Park et al., 2016).

Consumption of SSBs which provide little or no nutritional value is correlated to an increase in risks of overweight and obesity, cardiovascular disease, type 2 diabetes, kidney disease, and asthma (Rosinger, Herrick, Gahche, & Park, 2017).

Regular consumption of SSB by adults with disabilities contributes excess sugar and calories to the diet. Increased caloric intake can add to weight gain when physical activity is limited as is often the case in persons with disabilities. Excessive weight gain leads to an increase in the risk of chronic disease states such as diabetes and cardiovascular disease (Kim, Park, Carroll, & Okoro, 2017). Statistics comparing consumption of SSBs by persons with disabilities to the overall population show a slightly higher intake for persons with disabilities and a need for increased education and strategies to decrease this source of added sugars (Kim et al., 2017).

Other primary sources of added sugar in the American diet come from refined, processed treats like cookies, cakes, and ice cream (U. S. Dept., 2015). On a daily basis Americans consumed 270 calories (over 13%) of daily intake from added sugar (U. S. Dept., 2015). Another chunk of added calories that are disease promoting comes from saturated fat.

The largest contributor to saturated fat in the American diet comes from animal products that are part of menu items with cheese and meat including pizza, burgers, and tacos (U. S. Dept., 2015). Dessert items (that also contain high added sugars), full fat dairy products, and animal proteins account for most of the remaining saturated fat intake. Most Americans exceed the 10% of daily calories limit for saturated fat with average intake at 11% of caloric intake (U. S. Dept., 2015). Many of these foods also contain high levels of sodium which is another nutrient of concern.

Although sodium does not provide unnecessary calories, excessive intake can lead to hypertension and increased risk of cardiovascular disease. American sodium intake greatly exceeds the recommended maximum of 2300 mg/day (U. S. Dept., 2015). Mixed menu items containing meat and cheese (like the pizza, burgers, and tacos with high saturated fat) also represent the highest proportion of sodium in the United States diet (U. S. Dept., 2015). All commercially processed and prepared foods are potentially high in sodium.

Alcohol is included in the category of other items to limit as part of a healthy eating pattern because it is a source of extra calories that do not provide nutrients. Moderate consumption of alcohol is often misinterpreted and 2 out of 3 drinkers exceed the recommendations (U.S. Dept., 2015). If alcohol is consumed it should be limited to one drink per day for women and two drinks per day for men, and only by adults of the legal drinking age.

Guideline Four: Shift to Healthier Food and Beverage Choices

> *Choose nutrient-dense foods and beverages across and within all food groups in place of less healthy choices. Consider cultural and personal preferences to make these shifts easier to accomplish and maintain.* (U.S. Dept., 2015)

Guideline Two discusses the rational for consuming a variety of foods, focusing on nutrient density and amounts needed to stay within energy requirements. Guideline Four expands on guideline two discussing the need of making gradual shifts to healthier food choices to reach the goal of a health promoting eating pattern. It is estimated that almost half of Americans suffer from at least one chronic disease state that are related to poor dietary intake (U.S. Dept., 2015). Americans are consuming excessive calories as reflected in the high percentage of Americans that are overweight or obese. To stay within energy requirements and meet nutritional needs, nutrient-dense food should be consumed. Nutrient-dense foods are classified as foods that are high in nutrients but low in calories. Foods typically consumed by Americans are not nutrient dense due to the added calories from fat and sugar. Recommended shifts towards a healthier eating pattern include switching from processed foods with added fats and sugars to more nutrient-dense foods. Simple recommendations can be seen in Table 54.2.

The new Nutrition Fact Label can guide consumers in choosing foods that are lower in saturated fats, sodium, and added sugars. The new label lists serving sizes that reflect the amount of food consumers customarily eat and has a new section identifying added sugars. Vitamin D and potassium are now listed on the label as these nutrients are often deficient in the American diet. More information on the nutrition fact label can be found at https://www.fda.gov/downloads/Food/LabelingNutrition/UCM511646.pdf.

Table 54.2 Simple food swaps to increase nutrient density

Instead of…	Try this…
White bread	100% Whole Wheat Bread
Soda, juice “drinks”	100% Fruit Juice or water
Fruit, fruit products with added sugar	Whole fruit
Salty processed snacks	Unsalted nuts or popcorn
Whole fat dairy	Low-fat dairy
Butter or solid fats	Healthy Oils

Guideline Five: Support Healthy Eating Patterns for All

> *Everyone has a role in helping to create and support healthy eating patterns in multiple settings nationwide, from home to school to work to communities (DGA, 2015).*

The Social-Ecological Model seen in Fig. 54.2 is a tool designed for health professionals to better understand the factors that contributes to an individual’s health outcome. The model examines the impact of social and cultural norms and values, sectors providing programs, the settings in which food and beverages are offered, and individual factors have on health outcomes. Knowledge of factors within the model can help the health professional and/or caregivers tailor an eating pattern that best fits an individual’s profile and personal preferences. Individual eating patterns based profile and preferences are more likely to be adapted and maintained over time. Incorporating the recommendations in a personalized fashion may result in meaningful shifts in food consumption resulting in improved health outcomes. Evidence supports improved eating behaviors when changes are made at various levels of the Social-Ecological Model (U.S. Dept., 2015).

Barriers and Strategies: Following a Healthy Eating Pattern Across the Life Span

There are many barriers to a healthy eating pattern noted among the general population including psychological beliefs, environmental factors, cultural conditions, and nutrition knowledge. Lack of nutrition knowledge with confusion over current research and a preference for fad diets and busy schedules that limit time for food preparation and increase reliance on convenience foods and fast/casual dining, and higher cost of fresh foods over processed foods are the barriers still present for individuals with intellectual disabilities and their families but are greatly exacerbated by the increased difficulties of daily life and disability specific nutritional needs and conditions.

Barrier: *Competing High Urgency Needs.*

When children are diagnosed with an intellectual disability at a young age, parents are often devastated and overwhelmed. Many families spend their days rushing between evaluation and intake appointments, therapy sessions, and meetings with a variety of agencies involved in their child's treatment and care. This loaded schedule is in addition to the requirements of daily life—working, managing a household, and caring for other family members. Nutrition and food often end up at the bottom on the priority list and contributes to greater reliance on fast food and convenience foods. This barrier continues to be problematic across the life span when there is a poor nutritional foundation in early childhood.

Strategies: *Encourage nutrition as a priority*

- Educate parents and caregivers on the impact of food choices to overall health and wellness. The connection between nutrition and brain health is complex, but there is sufficient evidence to support the importance of food choices and healthy body weight. See Research Highlight 1.
- Parents and caregivers can be supported with easily implemented nutrition tips and resources as offered throughout this chapter and available at http://choosemyplate.gov.

Research Highlight 1: Education on the Impact of Nutrition on Learning

A 2014 review of the literature on the impact of obesity on learning notes that obese children (without ID) have lower task performance than normal weight peers, and that excess abdominal weight and insulin resistance as found in Type 2 Diabetes also reduces cognitive control (Hillman, Khan, & Kao, 2015). These impacts would likely have an even greater impact on children with ID. Parents of 22 children with ID and autism participating in a 10-week school-based nutrition and physical activity program reported decreased hospital visits and illness related school absences (Hinckson, Dickinson, Water, Sands, & Penman, 2013). Parents and caregivers can be motivated by the understanding that nutrition is not a lower priority item, and supported with resources and tools to make food part of the therapeutic experience to improve quality of life for individuals with intellectual disabilities. This education is ongoing for all direct care staff throughout the life span. Size was relatively small and included younger students, this study offers several workable options for creating healthful food environments for all ages. In order to undertake these changes, residential and direct care staff will need a basic food and nutrition knowledge base and support system.

Barrier: *Sensory Perception Difficulties.*

Most people can recall a time when they were coerced into trying a food that was unappealing due to visual sight, smell, or imagined taste. Many adults have vivid memories of sitting at the dinner table for hours in refusal of detested foods like slimy Brussels Sprouts, spicy chili, or funky fish. At the other end, there are foods that tasted bland and pasty and had to be choked down. Recalling traumatic sensory experiences of food can lead to refusal to try the same of similar foods for decades, or even a lifetime. Many children with ID are hypo-sensitive (have reduced sensation) or hyper-sensitive (are more sensitive), and may experience combined perceptual differences related to food stimuli. For individuals with intellectual disabilities, this heightened level of sensation impacts every meal and continues past childhood through adulthood.

Feeding programs that use the techniques of Applied Behavior Analysis have been used to reduce the sensory sensitivity of children with autism. Although this can be critical for proper nourishment, the ethics of these programs may be questionable. Individuals are "offered" a small bite of non-desirable food that must be eaten in order to receive a highly preferred food. Some parents of children who complete the programs cite their success as their child will eat anything after completion of the program. However, there are many other cases where individuals are traumatized and further restrict eating after being force-fed foods and then vomiting repeatedly during desensitization.

Individuals with disabilities may also restrict foods because of how they feel after eating a certain food and this can be mistaken for a sensory intolerance. Innate awareness of digestion difficulties due to undetected food allergies or intolerances is often overlooked by caregivers. Again, the communication challenges of individual with intellectual disabilities can inhibit expression of pain and discomfort. What might be perceived as an unprovoked aggression or irrational meltdown may be a result of eating aggravating foods. When individuals with intellectual disabilities severely restrict food choices, parents and professionals alike may be at a complete loss when it comes to deciphering an individual's food rules and nutrition suffers.

Strategies: *Shape sensory tolerances systematically*

- Assess food preferences and encourage new choices by presenting a variety of options in a "grazing bar." Small bite sized portions of fruits, vegetables, whole grains, and nuts/seeds can be placed in an ice cube or other divided tray. Note which types of foods are selected while paying close attention to the accompanying color, texture, flavor, and smell. Collect data and offer similar choices in future sessions.
- Once food preferences have been assessed and types of preferred tastes or textures identified, slowly shape choices into more nutrient-dense choices.
- When sensory perception is related to texture and before shaping is successful, change the texture of the food itself. Crunchy carrots can be cooked and pureed for a smooth texture. If a crunchy texture is preferred, offer crisp fruits, vegetables, and whole grain crackers.
- Serve food from a bowl or plate instead of a package or a box. In addition to controlling portion size this also disconnects the visual identification of food by the brand logo. This can decrease resistance to trying new foods.

Barrier*: Confusion of "fad" diets and cures.*

Additionally, families may receive restrictive dietary advice from other parents or professionals. One of the first pieces of nutrition related input for young children with autism is a regime eliminating all gluten (a protein found in wheat products) and casein (a protein in dairy products). The hypothesis is that children with autism symptoms may actually have a "leaky gut" that cannot absorb nutrients and that gluten and casein are not processed, turning into morphine-like chemicals that result in the repetitive and stereotypical behaviors seen in this disorder. There is little evidence to support this theory, although many families report anecdotal success (Piwowarczyk, Horvath, Łukasik, Pisula, & Szajewska, 2018). When gluten and/or casein are eliminated from the diet, dairy and whole grains must be removed and can further restrict healthy eating patterns unnecessarily.

Strategies*: Promote a healthy eating pattern to ensure adequate nutrient intake.*

- Professionals should educate parents and caregivers on the research and explain the difficulties with anecdotal support for dietary changes and advocate for a healthy eating pattern that includes all food groups.
- Professionals should share the MyPlate resources to encourage a healthy eating pattern.
- If parents or caregivers would still like to trial a specialized diet, they should be encouraged to work with a Registered Dietitian to ensure nutrient adequacy and avoid malnourishment and vitamin/mineral deficiencies.
- Professionals can also support diet trials through data collection that would provide information on successful outcomes.

Barrier: *Use of food rewards.*

Another common nutrition interference for young children with IDD who are followed any type of Applied Behavioral Analysis (ABA) program is the use of food rewards. This is also seen more commonly in children with a coexisting autism spectrum disorder, but food-based reinforcement is seen across the general population and likely more common in children with IDD. The use of favorite food rewards is successful for increasing skills, and it can be more difficult to find other motivators for individuals with intellectual disabilities. When children become adapted to grazing on their favorite treats all day during instruction/therapy sessions, it interferes with current intake of more healthful fruits and vegetables and also conditions the palate to prefer sweet/salty/high fat food choices.

Strategies: *Create a healthy food environment*

- Encourage non-food rewards by utilizing positive social interactions and games.
- Create a healthy food environment by making fruits and vegetables easily accessible and storing sweet/salty/high fat food choices out of sight. See Research Highlight 2.
- Assess for healthy food preferences using “grazing bar” method.
- Use of stoplight (slow, whoa, and go system) using “go” foods (fruits and vegetables) for rewards.

Research Highlight 2: Creating a Healthy Food Environment

In addition to educating caregivers and staff, changes to the food environment have also been shown to have a positive impact on adolescents and young adults ($n = 43$) with intellectual disabilities living in a residential school setting (Hubbard et al., 2015). This quasi-experimental study used digital photography to assess food selection and plate waste before and after a lunchroom intervention (Hubbard et al., 2015). The Smarter Lunchroom strategy encourages more healthful choices by moving energy-dense choices (i.e., desserts, peanut butter and jelly sandwiches) out of sight or later in the line and placing fruits and vegetables within easy reach and earlier in the line. While this intervention has been found successful in typical school settings, this study also adapted the intervention to the students’ needs by providing social stories and visual supports for communication.

The results showed statistically significant increases in whole grain selection and consumption with reduced refined grain selection and consumption, and increased fruit consumption (Hubbard et al., 2015). Another notable positive of this study is that autonomy was encouraged by providing free choice of side dishes instead of bundling sides into the main entrée without alternatives (Hubbard et al., 2015). Participants also had some say in menu planning through taste testing activities in the classroom (Hubbard et al., 2015). Although the sample size was relatively small and included younger students, this study offers several workable options for creating healthful food environments for all ages. In order to undertake these changes, residential and direct care staff will need a basic food and nutrition knowledge base and support system.

Barrier: *Lack of nutrition knowledge for individuals with disabilities and parents/caregivers.*

The plethora of nutrition information in the media is confusing for the general population, and even more so for individuals with intellectual disabilities. Our food environment offers a multitude of choices that are high in sugar and fat and low in nutrients, and these choices are promoted heavily with colorful and attractive packaging and commercials. Additionally, claims made on packaged foods such “high fiber,” “low fat,” or “less sugar” can make these products sound healthier than they are in reality. There is an abundance of inaccurate information on “quick fixes” for our dietary problem that do not work in the long term. The importance of a healthy eating pattern with shifts to increase nutrient density and decrease nutrients of concern is an evidence-based solution that should be clearly communicated to individuals and caregivers.

Strategies: *Educate and support with evidence-based resources*

- Adapt nutrition education for individual needs through interactive, hands-on lessons (see Research Highlight 3).
- Educate using MyPlate model with divided plate system (Research Highlight 4).
- Offer resources similar to MENU-AIDDS.
- http://www.goodnutritionideas.com/products/menu.html
- MyPlate10TipsSeries https://www.choosemyplate.gov/myplate-tip-sheets

Research Highlight 3: Interactive, Adapted Nutrition Education for Individuals with ID

A 2013 study to investigate if implementation of an appropriately planned nutrition education program for young adults with ID would result in changes in food choices to improve the nutrient adequacy of the diet revealed positive outcomes (Subach, 2017). The program design included active participatory lessons incorporating observation and modeling of healthy eating from both the researcher and the program peers. Food logs were used to record all food and drink consumed for a 3-day period at the start and end of the study. Averages of the 3 days were calculated, extracting total calories, fat, saturated fat, cholesterol, sodium, sugar, fiber, and vitamins A, C, and D.

Five nutrition lessons were developed utilizing the U.S. Department of Agriculture's (USDA) MyPlate, designed to meet the participants' needs, based on relevant literature review and on parental input. Nutrition instruction was added to the weekly exercise sessions. Participants were given their own plastic MyPlate for use at home as a visual aid and motivator. Each week featured a lesson and activity on a specific food group. Participants were given take-home food boxes, a corresponding activity, and standardized homework to be returned the following session. Analysis of the pre and post study food logs revealed a reduction of negative nutrients (fat, saturated fat, and sugar) and an increase in positive nutrients (vitamin A, C), although values were not statistically significant. Program reception was positive from parents and participants, as measured by the active participation in group activities, discussions and end of program surveys. There was an overwhelming request for expansion of the program to include shopping and cooking instruction.

Research Highlight 4: Nutrition Education for Direct Care Staff—Divided Plate System

A 2012 study focused on improving weight status for youth with developmental disabilities living in group homes that targeted staff knowledge of dietary guidelines and nutrition knowledge demonstrates the importance of the staff/client relationship (Gephart, 2012). The 4-month study included education on weight status and goal setting procedures and showed significant improvement in mean body mass index (Gephart, 2012). Improving the health literacy of direct care staff and caregivers is a necessary first step to shaping the food choices of individuals with disabilities.

A community-based nutrition intervention program sought to increase the nutrition knowledge of group home staff and subsequent meal adequacy for the 21 residents in four group homes (Edwards, Holder, Baum, & Brown, 2014). All staff attended two nutrition education sessions conducted by a registered dietitian on meal planning, grocery shopping, food preparation, and guidelines for food groups and serving sizes (Edwards et al., 2014). Additionally, portion divided plates were

(continued)

Research Highlight 4 (continued)

used in the homes with daily photographs to record the application of knowledge surrounding food groups and serving sizes before, during, and after the staff training (Edwards et al., 2014). The changes in meal adequacy were significantly positive based on the photographs, and demonstrate that the nutrition education program enhanced staff knowledge and also overcame perceived barriers of increased workload and negative behavior changes (Edwards et al., 2014).

Barrier: *Physical health issues.*

Physical health issues can complicate following a healthy eating pattern for many individuals with ID. These added health impairments may be part of the disability itself, such as feeding issues that occur with cerebral palsy and Down syndrome. Another possibility is that physical health declines due to aspects of the disability such as poor oral health, sensory dysfunction, or food intolerances. The physical health may result from the poor nutritional outcomes as a result of disability in the case of constipation, gastroesophageal reflux disease, nutrient deficiencies, and chronic disease. Detailed information on physical health needs for specific disabilities that may occur in conjunction with ID will be discussed at the end of this chapter.

Poor oral health care is a known nutrition risk factor for individuals with ID due to oral hypersensitivity limiting brushing/flossing/dental visits, reliance on caregivers for oral hygiene, food consistency aversions restricting food textures, and medication side effects impacting taste and saliva production. Access to routine dental visits due to limited transportation, competent providers, and insurance restrictions further exacerbates poor oral health (Ptomey & Wittenbrook, 2015).

Strategies*: Assess and treat underlying medical complications*

- Determine if there are underlying medical issues that need to be resolved to improve nutrition status and refer out to appropriate professional.
- Maintain education on disability specific strategies to ensure appropriate intervention.
- Consult with Registered Dietitian for nutrition assessment and development of care plan.

Barrier: *Communication Deficits.*

Communication difficulties impact following a healthy eating pattern in several ways. Children with ID may not be able to communicate the reason for refusing foods and caregivers must make assumptions on why food is uneaten. These may be incorrect. A food might be refused based on any number of reasons and it could be that the reason is not even related to the disability. Young children often react to new foods with disgust the first several times and the resistance to try new tastes may be heightened for kids with ID. Parents are in a difficult position and may be more inclined to placate their children with ID by offering preferred tastes of salty, sweet, and fatty foods when fruits, vegetables, whole grains, and lean proteins are initially refused.

Strategies*: Support communication and choice*

- Make sure that individual with ID has easy access to adaptive communication as needed to request food appropriately. While teaching communication, reduce access to foods so that they cannot be obtained without asking.
- Food preference assessments as described above can help ensure that individuals have correct vocabulary in any augmentative communication system (Picture exchange, sign language, technology-based apps and devices) to request food choices.
- Offer foods on numerous occasions to determine if they are truly not preferred.
- Collaborate with speech therapist and educate on importance of texture variety of foods for development of muscles for speech when appropriate.

Barriers*: Financial limitations.*

Financial resources and limited access to healthy foods can be a significant barrier to eating a healthy meal pattern in the general population but financial stressors associated with disabilities greatly increase this barrier for families affected by ID. Families often pay more out-of-pocket expenses and higher premiums for health insurance, reduce work hours due to caregiving demands, and have lower household income due to divorce from psychological stress (Goudie, Hall, Narcisse, & Kuo, 2014). Financial limitations continue across the life span for individuals moving into shared or independent living arrangements due to lower compensation, limited employment rates, and reliance on government funding. These excessive burdens are another factor that decreases the budget for nourishing, fresh foods.

Strategies: *Refer to External Resources*

- Refer to Nutrition Assistance Programs as Appropriate: Individuals with ID and their caregivers may not realize that they qualify for Supplemental Nutrition Assistance Programs (SNAP) https://www.fns.usda.gov/snap/supplemental-nutrition-assistance-program-snap . SNAP-Ed is another resource available to individuals and families utilizing Supplemental Nutrition Assistance that provides information on healthy eating with a limited food budget. Additional information on the program and eligibility can be found at https://www.fns.usda.gov/snap/supplemental-nutrition-assistance-program-education-snap-ed. SNAP also offers Farmer's Markets programs: www.fns.usda.gov/snap/supplemental-nutrition-assistance-program-education-snap-ed
- Offer additional resources from the Thrifty Meal Plan, MyPlate on a Budget, and Steps to Healthy Economical Meals: https://whatscooking.fns.usda.gov/sites/default/files/featuredlinks/MeetingYourMyPlateGoalsOnABudget.pdf, https://choosemyplate-prod.azureedge.net/sites/default/files/budget/StepsToHealthyEconomicalMeals.pdf
- Encourage the use of food in all forms according to seasonal availability and pricing. In the summer, fresh foods are often the more cost-effective choice, while frozen, canned, and dried foods can be inexpensive options for out-of-season produce. https://www.fruitsandveggiesmorematters.org/fresh-frozen-canned-dried-and-100-juice

Barriers: *Medication.*

Many individuals with ID require medication(s) that inhibit the ability to follow a healthy eating pattern or block nutrient absorption. Weight is altered through medications through increased or decreased appetite, carbohydrate cravings, changes in hormone production, metabolism, and thyroid function (Grondhuis & Aman, 2014). Common medications include atypical antipsychotics, antidepressants, anticonvulsants, and psychostimulants (Grondhuis & Aman, 2014). Many of these drugs can also interact negatively with the absorption of nutrients and increase the risk of other diseases (Ptomey & Wittenbrook, 2015). This is seen with prolonged use of anticonvulsants for epilepsy negatively affecting bone metabolism and heightening risk of fractures as well as acid reflux medications causing B12 deficiencies due to reduced stomach acid (Ptomey & Wittenbrook, 2015). Specific disabilities may also require additional individual medication for comorbidities increasing the likelihood of multiple medication impacts and interactions.

Strategies: *Cross-collaborate to reduce medication-related nutrition interference*

- Collaborate with health professionals and prescribing physician to understand interactions between medications and potential side effects related to appetite, weight, and nutrient interference.
- Consult with a Registered Dietitian to prevent nutrient deficiencies and determine appropriate nutrient and calorie intake.
- Create a healthy food environment by making fruits and vegetables easily accessible and storing sweet/salty/high fat food choices out of sight.

Barrier: *Environmental Systems.*

Environmental systems like schools, day programs, churches, work sites, and residential homes face competing priorities with limited funds, and nutrition is often the lowest priority need.

Organizations that provide support services to individuals are typically reliant on government funding sources that are continually cut and barely meet the minimum of service needs. Direct care staff are underpaid which results in a high turnover rate of under-qualified and often unmotivated support staff. It can be challenging to develop consistent nutrition education protocols with constantly changing faces among workers. As life expectancy increases due to medical interventions, it is even more critical that environmental systems reduce the healthcare burden through preventive efforts including improvement of nutritional health.

Strategies: *Implement Integrated Wellness Programs*

- Educate on importance of nutrition for reducing negative behaviors, chronic disease, and improving learning and skills acquisition.
- Develop training and systems that promote wellness adapted to the needs of individuals.
- Ongoing nutrition assessment protocols in schools, adult programs, etc.
- Develop a "Train-the-Trainer" for easy implementation of system wide wellness programs (Research Highlight 4).

.

Barrier: *Self-determination and Independent Living.*

Research Highlight 5: Health Matters: Train the Trainer

The "Train-the-Trainer" Model to improve health status of individuals with intellectual disabilities ($n = 67$) was investigated in a 12-week randomized intervention with a specific program, Healthmatters, to determine the efficacy of this approach for providers ($n = 34$) in Community Based Organizations (CBOs) (Marks, Sisirak, & Chang, 2013). The study sought to determine if training the direct care staff impacted the health of adults with intellectual disabilities as demonstrated by improved physiological and psychosocial health status, improved nutrition and exercise knowledge and skills, and improved fitness status (Marks et al., 2013). A coin flip method was used for the 6 CBOs to randomize staff into either and intervention group receiving immediate training or a control group that was "wait-listed" for training after 6 months (Marks et al., 2013). The Health Matters: The Exercise, Nutrition, and Health Education Curriculum for People with Developmental Disabilities, based on the Transtheoretical Model of Behavior Change and Bandura's Social Cognitive Theory, was used in the protocol to train direct care staff to develop a structured program for the adults they support (Marks et al., 2013). After an 8-h, small group staff training, the direct card staff participants initiated the 5 modules of the Health Matters curriculum within the intervention groups (Marks et al., 2013).

The Health Matters: Train the Trainer approach showed promising results as seen in the outcome categories (Marks et al., 2013). Significant improvements for the intervention group were seen in psychosocial measures including Social/Environmental Supports for Exercise and Nutrition and health behaviors, which was a primary target (Marks et al., 2013). This study provides a methodology for expanding the knowledge and skills of direct care staff to support improved health status of the individuals with intellectual disabilities that they support in community settings (Marks et al., 2013)

As individuals with disabilities enter adolescence, new challenges emerge. Throughout adulthood and aging, the quest for independence and self-determination continues and further impacts healthy eating patterns among adults with ID. When individuals with intellectual disabilities reach adulthood, supportive caregivers confront a dilemma between supporting self-determination and ensuring health and wellness. In this situation, "self-determination" refers to the right of individuals with disabilities to make their own choices regarding their budgets, services, and overall direction of life (Nonnemacher & Bambara, 2011). This essential freedom is necessary for all adults to have a high quality of life (Nonnemacher & Bambara, 2011). Staff and caregivers may compromise responsibilities for health to ensure that the individual has the right to choose unhealthy eating patterns and sedentary behavior or vice versa (Gill & Fazil, 2013).

Adults can and should have independence to make their own food choices, but those with disabilities may need extra support and education on healthy eating and cooking. Those who live in group homes or congregate living facilities are at even greater nutritional risk because nutritionally inadequate meals may be provided for them as a result of staff lacking food and nutrition relation knowledge and reduced food budgets (Edwards et al., 2014). The lifestyle, socioeconomic status, and personal preferences of staff influence how they support healthy eating guidelines and are potential barriers to nutritional health of residents (Gill & Fazil, 2013). There is also confusion for residential staff directed to follow a person-centered approach and still find balance between supporting an individual's right to choose their own food and ensuring the presence of healthful choices (Gill & Fazil, 2013).

Strategies: *Active Participation and Skills Instruction for Individuals with ID*

- Incorporate a nutrition assessment as part of the intake process to determine all preferred food choices for all day and residential programs.
- Utilize resources on MyPlate Website: The consumer website for MyPlate helps guide food choices at a more accessible level and offers many colorful resources with graphics that can support a variety of learning styles.
- Residents/consumers should actively participate in menu planning and grocery shopping.
- Use cooking instruction as a social activity to promote healthier eating at home and in the community. See Research Highlight 6.

Research Highlight 6: Cooking Instruction

Numerous research studies on improving food choices in young adults with disabilities have indicated a need for cooking instruction and socialization of persons with ID. In continuation of the adapted nutrition education program seen in Research Highlight 2, twenty participants took part in a pilot 6-week cooking series designed to increase their fruit, vegetable and whole grain intake. Participants were first educated on food safety using the "Clean, Separate, Cook, Chill" program by the USDA (U.S. Dept., 2015). Adherence to food safety guidelines is crucial to decease incidences of food borne illness which is addressed in Guideline Five.

Weekly sessions were held in the University's foods laboratory where participants were given basic food preparation instruction. Equipment modification and one-on-one recipe coaches were used to accommodate recipe execution. Participants followed pictorial recipes using pre-portioned, pre-cut, and frozen food items to ease in recipe completion. Participants took home food items to be used as part of their meal pattern for the following week. Foods prepared included oatmeal bowls, vegetable soup, fruit smoothies, baked potatoes and broccoli, rice bowls and chicken tenders. Program reception was positive with participants verbalizing confidence in their cooking ability and enjoyment of cooking with their peers. This led to the creation of a "coffee house" program that allowed participants to gather and prepare a meal at a local coffee roaster who donated space for the event. Feedback was positive from participants and their families, but lack of funding prohibited the continuation of the program. Outcomes from both programs indicate a need for further research and funding to support program that support healthy eating patterns in social situations.

Specific Disabilities and Case Studies

Specific disabilities that may have a comorbid intellectual disability also have individual physical health issues. Individuals with cerebral palsy (CP) have difficulty with muscle control and/or coordination affecting different parts of the day and are also often diagnosed with ID (Ptomey & Wittenbrook, 2015). The physical limitations of CP can result in over- or undernutrition due to feeding difficulties. Individuals who use a wheelchair for ambulation will have a reduced need for calories and may struggle with weight gain and higher body fat percentage (Ptomey & Wittenbrook, 2015). Individuals with CP may have trouble swallowing (dysphagia) and need enteral nutrition (tube feeding) that can result in inadequate fluid and fiber intake or over/undernutrition (Ptomey & Wittenbrook, 2015). When motor function is limited, the ability to independently eat and drink can result in a myriad of additional physical problems including gastroesophageal reflux disease, constipation, mouth and dental disease, and malnutrition (Ptomey & Wittenbrook, 2015).

AV Case Study

AV, a 25-year-old female, has a deletion on the fifth chromosome (-5q) and mild cerebral palsy. The chromosomal break left her genetically preprogrammed to a disease known as FAP (familial adenomatous polyposis). She was full-term, with a birth weight of 7lbs. 6 oz. She had no feeding challenges as an infant but was failure-to-thrive at 3 months, due to excessive sleeping. AV was diagnosed with low muscle-tone and mild cerebral palsy by age 1. AV consulted with a speech therapist for strategies to increase muscle strength in her mouth as a strategy to promote adequate nutrition intake. She was nonverbal until the age of six. At age 3 she was diagnosed with a B-12 deficiency which subsided after a 6-month regiment of B-12 injections. AV currently has a BMI 21.5 putting her within the normal weight classification. She had an ileostomy at age 12 and wears a stoma to collect the waste 24 h/day. Amy is an avid exerciser and swims competitively. Adequate hydration is a constant challenge due to the constant drainage of her GI system. Hot weather and exercise lasting over 1 h presents a challenge of maintaining hydration and electrolyte balance. She frequently suffers from dehydration and electrolyte imbalance during sporting events occurring in the absence of her parents. Dietary intervention for electrolyte imbalance includes Gatorade, bananas, and potato chips. AV's parents try to educate her on proper hydration practice, but due to the ID she often fails to consume adequate amounts of fluid. Gatorade is used on a regular basis to aid in hydration, but parents try to limit intake due to the sugar content. Food intake is monitored, excluding beans, nuts, and seeds and limiting fiber. Excessive fiber causes extreme pain and has resulted in a blockage and hospitalization. Citrus fruits cause skin irritation and are excluded. Dairy, carbonated beverages, and high sugar intake causes excessive bloating and pain. AV's current diet is based on trial and error, never receiving a nutrition consultation post ileostomy. AV faces challenges when in social settings where excessive food consumption is encouraged. Special attention is paid to the quantity and types of food consumed prior to limit odor from and bloating of the stoma.

Strategies for the Health Professionals

- Early intervention of nutrition consultations with a Registered Dietitian, providing the family with nutrition guidelines may prevent flare-ups and hospitalization.
- Education on hydration strategies, providing alternate beverage choice to decrease Gatorade use, however the RD should reinforce that occasional use does not have a significant negative impact on the overall quality of AV's relatively healthy diet.
- Education for AV on safe foods, appropriate portions and culinary instruction may increase her independence in making food choices.
- Education to caregivers and peers on AV's food restrictions.

Down Syndrome

Down syndrome is a common chromosomal disorder affecting 1 in 700–1000 live births. Individuals with Down syndrome typically have congenital heart disease, intellectual delays, shorter height, gastrointestinal problems, and low muscle tone that can negatively affect the ability to follow a healthy eating pattern. Feeding problems often begin during infancy with a weak ability to suck and poor weight gain. Constipation is common in persons with Down syndrome due to decreased gastric motility. A diet rich in fruits, vegetables, and whole grains can aid in improving gastric motility (Ptomey & Wittenbrook, 2015). Celiac disease or gluten sensitivity, which prohibits ingestion of gluten, a protein found in wheat is common and warrants adherence to a gluten-free diet. Persons with Down syndrome often have a high rate of overweight and obesity, with over half of this population being classified as overweight and up to 31% as obese (Ptomey & Wittenbrook, 2015).

Being overweight or obese is a risk factor in the development of cardiovascular disease and diabetes. Persons with Down syndrome have an increased risk of developing cardiovascular disease. Adelekan, Magge, Shults, Stallings, & Stettler (2012) compared lipid levels of 27 children with Down syndrome and their non-affected siblings with a hypothesis that children with Down syndrome would have higher levels of total cholesterol, low-density lipoprotein, triglycerides, and lower high-density lipoprotein levels than their non-affected siblings. Analysis concluded that the children with Down syndrome had a less desirable lipid profile than their non-affected siblings, independent of weight. Due to the increased risk of heart disease in the Down syndrome population, the results provide a significant contribution to the development of screening and intervention within this group.

Leptin Levels and Down Syndrome

Leptin, a satiety-regulating hormone that promotes energy homeostasis through energy expenditure, controls food intake. In the general population, high leptin levels have been associated with obesity and are now being linked to obesity levels in children with Down syndrome. Excessive amounts of leptin cause desensitization to the hormone, making satiety harder to achieve. Decreased satiety increases appetite, leading to overeating, which is a causal factor to weight gain. A clinical study comparing the leptin levels of 25 children with Down syndrome and 25 normal children found that the children with Down syndrome had higher levels of serum leptin levels for their percent body fat compared to normal children. Serum leptin levels were reported higher in females with Down syndrome than males (Sridevi et al., 2016)

Combating Obesity in Persons with Down Syndrome

A nutrient-dense diet consisting of low-energy-density foods such as fruits and vegetables is one strategy used to overcome the negative effect of the medical conditions faced by persons with Down syndrome. Nutrition education with an emphasis on proper portion sizes, healthy food choices, and meal planning is a suggested practice in controlling or combating overweight and obesity (National Down Syndrome Society, 2013). It is recommended to include persons with Down syndrome in menu planning, shopping, and meal preparation as a way of improving their nutritional status through self-determination.

SB Case Study

SB is a 28-year-old young woman who has Down syndrome (DS), autistic spectrum disorder (ASD), a bilateral sensorineural hearing loss, celiac disease, and an allergy to natural rubber latex. Her current BMI is 22.2 putting her within the normal weight classification. She was diagnosed with pituitary dwarfism and tested positive for celiac disease at age 12. She currently supplements with 250 mg calcium and 1000 IU vitamin D3.

SB consulted with a Registered Dietitian at the onset of diagnosis of celiac disease. Initial nutrition education was limited to routine medical visits and was not extensive. SB faces many challenges in meeting her nutritional needs while complying with a gluten-free diet. When she does not comply with her diet, she experiences the natural consequences of an upset stomach, nausea, and fatigue.

SB had been educated on the gluten-free diet, but due to her intellectual developmental disabilities (IDD) it is difficult for her to remember the variety of possibilities. The family focuses on eating naturally gluten-free foods, such as fruits, protein and vegetables and gluten-free grains such as rice and quinoa.

SB has difficulties in social situations communicating her need for food that is gluten free and also free from cross-contamination. Her hearing loss also complicates her ability to adequately communicate in social situations. She cannot eat foods that have been handled by someone wearing latex gloves, nor eat in a restaurant where latex gloves are routinely used for food preparation and handling. SB's participation in social events is often limited by these needs. Although SB has learned about the various food groups and examples of foods in each, she is not able to independently plan a diet that meets her nutritional needs. She requires prompting and assistance to plan, shop for, and prepare many foods, as well as communicate her various medical needs in other environments.

Strategies for Health Professionals

- Provide resources for health professionals and caregivers on the gluten-free diet can be found at the Celiac Foundation's website: https://celiac.org/marketplace/gf-products/ and at the National Celiac Association's website: https://www.nationalceliac.org
- Education of foods to avoid for individuals with a latex allergy. Foods commonly associated with allergic reaction to latex include apples, avocado, bananas, carrots, celery, chestnuts, kiwi, melons, papaya, raw potatoes, and tomatoes. Additional information on latex allergies can be found at The American College of Allergy and Asthma & Immunology website: https://acaai.org/allergies/types/skin-allergies/latex-allergy.
- Education for SB on safe foods and appropriate portions may increase her independence in making food choices. Use of APPs for smartphone to improve communication for SB when in restaurant and social settings. Professional and consumer resources on celiac disease can be found at https://www.eatrightstore.org/product-subject/celiac-disease
- Connect families with practitioners who specialize in celiac disease using the CDF Healthcare Practitioner Directory. The directory of a free listing of physicians, dietitians, mental health professionals and allied health providers who specialize in the treatment of celiac disease and other gluten-related disorders can be found at: https://celiac.org/celiac-disease/resources/provider-directory/#bTsbcyjhKEEvCPy
- Recommend caregivers complete the National Restaurant Association's Servsafe Allergen Training program. The program educates laymen and professional on safely providing food to populations sensitive to allergens. Information on this certification can be found at: https://www.servsafe.com/ServSafe-Allergens/The-Course

Autism

Individuals with autism commonly also have an intellectual disability and face additional nutrition risk factors related to social isolation, sensory-based food selectivity, increased sedentary activities, and common regimens of appetite increasing medications (Presmanes Hill et al., 2015). Additional health-related problems coinciding with autism include mood disorders, attention deficit disorders, and gastrointestinal conditions and these may exacerbate weight gain and chronic disease (Presmanes Hill et al., 2015).

Selective eating patterns seen in autism are a likely contributor to poor nutrition status. A 2015 study found higher rates of nutritional deficiencies despite higher body mass index (BMI) values in a group of young children with autism as compared to an age matched control group of typically developing peers (Shmaya et al., 2015). This pattern of overnutrition and undernourishment is connected to higher rates of chronic disease in the general population.

Aging Population

As the number of individuals diagnosed with autism increases, the aging population with the disorder also expands and with it, the potential for nutrition and weight related disease. Although there is limited data on the health status of adults with autism, a 2015 case-control study found significantly higher rates of almost all medical conditions among adults with autism ($N = 1507$) as compared to the control group including diet and lifestyle related conditions of obesity, dyslipidemia, hypertension, and diabetes (Croen et al.). Additional medical and psychiatric conditions were also found at significantly higher rates in the adult autism population. There are many potential reasons for the increased prevalence of secondary health issues in this group including restricted eating patterns due to sensory issues, medications that promote weight gain, lack of access to recreation and physical activity, and communication and social impairments (Croen et al., 2015).

Case Study: Autism and Vitamin B-12 Deficiency

MK, an active 16-year-old male with autism, consumed a self-restricted diet that contained no meat, dairy, eggs, or other animal products. After an uncomplicated appendectomy with pathology positive for a small tumor, MK also required resection of part of the small and large intestines. The surgeon did not refer to a dietitian and said to continue with "normal" diet. MK recovered well, but continued with a selective and limited diet. He did begin eating additional fruits and vegetables when his mother explained that these would help him not get any more tumors and stay healthy.

His parents sought a neurology consult after a suspected seizure when they found him lying on the ground. Seizure activity was not evident, but lab work to rule out other conditions determined that he had a severe B-12 deficiency with a serum level in the blood of 50 pg/mL. Values of less than 200 pg/mL are a sign of deficiency and will often be symptomatic (ADAM, 2018). Symptoms of B-12 deficiency can be psychiatric, hematological, and neurological and are often misdiagnosed. Due to the inability to communicate bodily sensations that may have been abnormal, the extent to which the B-12 deficiency enhanced other medical issues is unknown. It is possible that the increased weight loss, anxiety, and depression that MK had been experiencing were partially due to the B-12 deficiency. It is incredibly fortunate that blood work was checked before any additional neurological damage occurred. Intramuscular injections of B-12 were initiated and continued for 6 months with quarterly monitoring to ensure that serum B-12 increased. Oral supplementation continues to address this dietary deficiency with regular monitoring. B-12 supplementation is recommended for anyone who does not consume animal products.

Strategies for Health Professionals

- Suggest that a comprehensive panel of blood work be completed to check for nutrient deficiencies when there is a sudden change in behavior.
- Recommend consultation with a Registered Dietitian for any chronic digestion issues, and especially after gastrointestinal surgery.
- Understand that a "normal diet" may be a severely limited diet in individuals with autism and intellectual disabilities.
- Recognize the potential need for some supplementation under guidance of a medical professional when diet or surgical resection reduces nutrients to a level that can cause health complications.

Chapter Summary

It is evident that individuals with ID face extraordinary barriers on all fronts and nutritional health is no exception. Best practice recommendations include a comprehensive approach across home, school, and community environments, and one that involves individuals with ID as well as their caregivers and service providers in order to improve diet quality and nutritional outcomes across the life span (Steenbergen, Van der Schans, Van Wijck, De Jong, & Waninge, 2017) (Table 54.3).

Table 54.3 Lists a summary of barriers and potential strategies to be used to help individuals with ID meet the recommendations of the Dietary Guidelines for Americans to promote health and reduce risk of chronic diseases

Barriers and strategies: Following a healthy eating pattern across the life span	
Barriers	Strategies
Competing high urgency needs	Education on potential impact of nutrition on behavior, learning, and overall health Support with easy to implement tips and resources
Sensory perception difficulties	Continuous assessment of food preferences Slow, systematic shaping of food choices for nutrient density Use of texture modified foods Disconnection of link between food and brand
Fad diet/“cure” confusion	Education on lack of evidence Education on healthful eating patterns Professional support and data collection for trials of “special” diets
Use of food rewards	Assessment and use of non-food rewards Creation of healthy food environment Assessment of healthy food preferences Use of stoplight systems
Lack of nutrition knowledge	Education using MyPlate Model, MENU-AIDDS approach, MyPlate 10 Tips series Use of divided plate system Education on healthy choices for eating out
Physical health issues	Collaboration with health professionals on underlying medical issues Professional continuing education on disability specific needs Consultation with Registered Dietitian for nutrition assessment
Communication deficits	Adaptive communication Food preference assessments Repeated food trials Collaboration with speech therapist Education on importance of texture variety for speech development
Financial limitations	Education on Resources: SNAP and SNAP-Ed: https://www.fns.usda.gov/snap/supplemental-nutrition-assistance-program-snap https://www.fns.usda.gov/ebt/snap-and-farmers-markets www.fns.usda.gov/snap/supplemental-nutrition-assistance-program-education-snap-ed Thrifty Meal Plan Resource and MyPlate on a Budget: https://whatscooking.fns.usda.gov/sites/default/files/featuredlinks/MeetingYourMyPlateGoalsOnABudget.pdf Utilization of food in all forms: fresh, frozen, canned, and dried: https://www.fruitsandveggiesmorematters.org/fresh-frozen-canned-dried-and-100-juice Steps to Healthy Economical Meals. https://choosemyplate-prod.azureedge.net/sites/default/files/budget/StepsToHealthyEconomicalMeals.pdf
Medication	Collaboration with health professionals to ensure proper dosage Consultation with Registered Dietitian to adapt for any related nutrient deficits Creation of Healthy Food Environment

(continued)

Table 54.3 (continued)

Barriers and strategies: Following a healthy eating pattern across the life span	
Barriers	Strategies
Environmental systems	Education on potential impact of nutrition on behavior, learning, and overall health Development of training systems that promote wellness adapted for ID Use of ongoing environmental nutrition assessment protocols Implementation of cooking instruction for improved self-efficacy and social connectedness
Self-determination and independent living	Education and training for direct care staff Consideration of food-related vocational opportunities Implementation of cooking instruction

Acknowledgments A special note of thanks to Mary Kay Martin for her contribution to the section on macronutrients.

Diabetes

Lisa C. Whitehead and Henrietta T. Trip

Diabetes in the General Population

Diabetes is a global issue with 8.5% of the population estimated to be living with diabetes (World Health Organization [WHO], 2016) with increasing prevalence in low-middle income countries. Three-quarters of those living with diabetes are living in low and middle income countries (International Diabetes Federation [IDF], 2017a, 2017b, 2017c). An estimated 1.6 million deaths were directly attributable to diabetes in 2015 (WHO, 2017) and range from 6% in Africa, 9% in Europe, 11% Western Pacific, South and Central America, 13% Middle East and North Africa, 14% South East Asia, North America and Caribbean of all mortality in the 20–79-year-old age group (IDF, 2017a, 2017b, 2017c): Type 1 diabetes (T1D) accounts for between 5% and 10% of total cases of diabetes worldwide (American Diabetes Association, 2008) and therefore type 2 (T2D) makes up to 90% (IDF, 2017a, 2017b, 2017c) .

Diabetes in People with Intellectual Disability

The epidemiology and prevalence of diabetes in people with intellectual disabilities (ID) is emerging. Genetic predisposition is linked to a higher risk of developing T1D. Type 1 diabetes has been reported to be more prevalent in individuals with Down syndrome at 10.6% compared with the general population (Anwar, Walker, & Frier, 2004). Turner syndrome, Klinefelter syndrome, Prader–Willi syndrome, Noonan syndrome and Williams syndrome have also been associated with an increased risk of endocrine conditions such as T1D (Hoybye, 2004; Botero & Fleischman, 2006). The prevalence of T2D in people with intellectual disabilities (ID) compared to the wider population is unclear. However, the most recent review of diabetes prevalence rates in people with ID (MacRae et al. (2015) identified 22 studies and a mean prevalence rate of 8.3%. Prevalence rates varied widely across studies, ranging from 0.4% to 25%. The variance likely reflects diagnostic as well as reporting issues; however, overall, the evidence suggests that prevalence rates may be higher for people with ID than for the wider population.

The prevalence of obesity in adults with ID is greater than that found in the general population (Hsieh, Rimmer, & Heller, 2014; Melville et al., 2008; Rimmer & Yamaki, 2006; Stedman & Leland Jr, 2010). Obesity is strongly linked to the

development of T2D. Using body mass index (BMI) as a measure, obesity has been linked to gender in adults with ID (Emerson, 2005; Hsieh et al., 2014; Yamaki, 2005), the severity of ID (Emerson, 2005), place of residence (Bhaumik, Watson, Thorp, Tyrer, & McGrother, 2008; Hsieh et al., 2014), use of psychotropic medication (Hellings, Zarcone, Crandall, Wallace, & Schroeder, 2013; Hsieh et al., 2014) and cause of ID (Bhaumik et al., 2008; Hsieh et al., 2014). It is likely that the development of obesity-induced insulin resistance involves a complex interplay of genetic and environmental factors (Samuel & Shulman, 2012). Obesity in turn is related to a more sedentary lifestyle and poorer diet (Taggart, Brown, & Karatzias, 2014) As a population, people with ID have been found to have higher rates of cardiovascular disease, hypertension and obesity; risk factors for developing diabetes (Havercamp, Scandlin, & Roth, 2004; Merrick et al., 2004; Shireman, Reichard, Nazir, Backes, & Greiner, 2010; Taggart et al., 2014).

It is clear that, as with the general population, the number of people with ID affected by diabetes is likely to increase (Sohler, Lubetkin, Levy, Soghomonian, & Rimmerman, 2009).

What Is Diabetes?

Diabetes is a condition that develops over many years and the aetiology is a combination of ineffective insulin and not enough insulin. The body becomes resistant to the normal effects of insulin and gradually loses the capacity to produce enough insulin in the pancreas. Insulin is vital in converting glucose into energy and in T2D, the result is commonly hyperglycaemia (too much glucose in the blood). As a result of insulin resistance, the pancreas responds by producing greater amounts of insulin in an attempt to regulate blood glucose levels; over time, these cells become dysfunctional. At diagnosis, it is estimated that an individual will have “lost” 50–70% of their insulin producing cells (Diabetes Australia, 2015).

A healthy lifestyle with daily routines is essential in controlling blood glucose; however, many people living with diabetes in the general population are unable to maintain glycaemic control within the recommended levels (4–7%; 20–53 mmol/mol) (Peyrot et al., 2013). Diet, exercise, stress reduction and medication management are the key mediators of glycaemic control (National Institute for Health and Care Education [NICE], 2015) and are strongly influenced by self-management through individual behaviour and action (Whitehead, Trip, Hale, & Conder, 2016; Wilkinson, Whitehead, & Ritchie, 2011). The short and long-term effects of hyperglycemia are multiple and include microvascular changes (e.g. retinopathy, nephropathy, and neuropathy) and macrovascular changes (e.g. heart disease) (D’Elia, Barba, Cappuccio, & Strazzullo, 2011; World Health Organization [WHO], 2016). Neurovascular changes linked to diabetes include peripheral arterial disease and peripheral neuropathy. Symptoms may include a person not registering the lack of sensation in the feet resulting in decreased recognition of pain, pedal deformities and/or injury, impaired circulation, ulcer formation and possibly gangrene (IDF, 2017b).

Experience of Living with Diabetes-Perspectives from People with ID, Carers and Families and Service Providers

Nine papers have explored the experience of managing diabetes from the viewpoint of people living with ID and/or carers or service providers. These studies provide important insight into living with diabetes, current support and service provision. Two of the eight studies were conducted in the Netherlands: Cardol, Rijken, and van Schrojenstein Lantman-de Valk (2012a, 2012b); three in the UK: Brown et al. (2017); Dysch, Chung, and Fox (2012) and Rouse and Finlay (2016); three in New Zealand: Hale, Trip, Whitehead, and Conder (2011), Trip, Conder, Hale, and Whitehead (2016), and Whitehead et al. (2016) and one in Australia: Rey-Conde, Lennox, and McPhee (2005). Three of the studies were drawn from the same sample of people with ID (Hale et al., 2011; Trip et al., 2016; Whitehead et al., 2016); however, all three of the studies had a different focus with the analyses yielding different results.

The majority of participants were diagnosed with T2D, a mild or moderate level of ID, resided in residential or community housing settings and Down syndrome was the most commonly reported co-existing condition. The main themes identified were participants' understanding of diabetes, challenges to managing diabetes and factors that supported the experience of managing diabetes.

Across the studies people with ID reported a basic understanding of their condition, notably its cause and complications (Dysch et al., 2012; Hale et al., 2011), awareness of changes in their blood glucose level (Dysch et al., 2012; Hale et al., 2011), familiarity with blood tests and of the need to take medication (Cardol et al., 2012a), the role of diet and physical activity (Hale et al., 2011) and the importance of attending medical appointments for review (Cardol et al., 2012a).

Areas identified by participants as challenging were; diabetes was only viewed as "serious" when insulin was required (Cardol et al., 2012a), difficulty differentiating between diabetes symptoms and symptoms arising from other comorbid health conditions (Cardol et al., 2012a) and the complexity of managing a number of conditions at the same time (Dysch et al., 2012; Hale et al., 2011). A difficult relationship with diabetes was described where participants reported feeling frustrated with the restrictions and inconveniences of diabetes (Dysch et al., 2012; Hale et al., 2011), a sense of loss in relation to food choices (Cardol et al., 2012a) and at times feeling fear, insecurity, and being overwhelmed (Rey-Conde et al., 2005). Diabetes was described as sometimes socially stigmatising (Dysch et al., 2012). Hale et al. (2011) also reported that the majority of participants could not recall receiving information about diabetes when they were first diagnosed and expressed a desire to learn more about their condition.

Support from family and caregivers was described as both facilitatory and as creating dependence. People living with ID and diabetes described getting more out of health review appointments when supported by family members or professional carers (Cardol et al., 2012a). Three studies described the action of family and caregivers as supportive and promoting independence and autonomy (Hillege, Gallagher, & Evans, 2013; Rey-Conde et al., 2005; Whitehead et al., 2016) with an increase in support only when assessed as necessary to maintain glycaemic control, such as illness or a change in medication regime (Whitehead et al., 2016). Cardol et al. (2012b) described a more prohibitive approach by carers through the restriction of dietary choices and provision of healthy alternatives on special occasions such as birthday parties.

Other findings indicated that where educational resources were available, they were not appropriate for people with ID due to being in formats that were not accessible (Hale et al., 2011). Rey-Conde et al. (2005) also reported that information on diet was insufficient leading to confusion. It is therefore important that educational resources are appropriately tailored for people with ID.

Limited training and knowledge of diabetes was described by families and carers involved in supporting people with ID. Both Rey-Conde et al. (2005) and Brown et al. (2017) reported staff training to be a barrier to effective self-management support with some issues related to high levels of staff turnover. Levels of knowledge varied according to professional background where nurses had either general or specialised training diabetes but social workers and care workers reported variable levels of training and for some, this was only as a consequence of them seeking out opportunities to improve their knowledge themselves (Cardol et al., 2012b). Trip et al. (2016) reported that some carers were unaware of diabetes management plans and Cardol et al. (2012b), Hillege et al. (2013) and Trip et al. (2016) reported an overall inconsistency in staff knowledge and training. Caregiver dilemmas also reflected a potential need for further training of caregivers. These dilemmas were between enabling autonomy and reducing risk, and were described in four studies (Cardol et al., 2012b; Rouse & Finlay, 2016; Trip et al., 2016; Whitehead et al., 2016).

Guidelines

A global guideline on diabetes management exists (IDF, 2012), along with specific country based guidelines. All have a consistent focus on patient education, dietary advice, managing cardiovascular risk, managing blood glucose levels and managing the risk of long-term complications (e.g. Diabetes Australia, 2018; Diabetes Canada Clinical Practice Guidelines Expert Committee, 2018; Harkins, 2008; IDF, 2017a; New Zealand Guidelines Group [NZGG], 2011; The National Institute for Health and Care Excellence [NICE], 2015; The Society of Endocrinology, Metabolism and Diabetes of South Africa [SEMDSA], 2017; UNITE for Diabetes Philippines, 2014). Support to achieve optimal management, however, is thought to only be reaching the minority (IDF, 2012) due to the size and complexity of the evidence-base, the complexity of diabetes care itself, a lack of proven cost-effective resources for diabetes care and the diversity in standards of clinical practice driving disparities in clinical care.

The guidelines, regardless of country of origin reflect the same key concepts. Diabetes UK (2017a) recently released guidelines setting out 15 essential indicators, also referred to as the 15 Healthcare Essentials which, if achieved by adults with T2D, underpin good quality care. The 15 Healthcare Essentials are the minimum level of healthcare everyone with T2D require to have in place and in Western countries, expect from their healthcare team. These are:

1. Getting your blood glucose levels measured.
2. Have your blood pressure measured.
3. Have blood fats (cholesterol and triglycerides) measured.
4. Ensure eyes are screened.
5. Having your feet and legs checked.
6. Have your kidney function monitored.
7. Get individual dietary ongoing advice.
8. Getting emotional psychological support.
9. Being offered a group education course.
10. See specialist diabetes healthcare professionals.
11. Receive good care if admitted to hospital.
12. Get a free flu vaccine.
13. Have the opportunity to talk about any sexual problems.
14. If you smoke, get support.
15. Get information and specialist care if you are planning to have a baby.

Little guidance exists on diabetes assessment and management for people with ID. Of note, national or international guidelines for T2D vary in regard to whether people with ID are included and/or how they are represented. There may be similarities in reference to other vulnerable populations with cognitive impairment and communication difficulties such as people with acquired-brain injury, stroke, severe mental illness, and dementia for example. Whilst the concept of *Reasonable Adjustments* within employment legislation is not new, the Convention on the Rights of Persons with Disabilities (United Nations, 2006) requires this to be readily implemented across life domains for people with a disability—including healthcare. Diabetes UK (2017b) recently released a *Guideline on How to Make Reasonable Adjustments to Diabetes Care for Adults with Learning Disability* and advocates the following service considerations:

1. Make information accessible and user friendly.
2. Provide training for all staff.
3. Address social barriers.
4. Involve supporters.
5. Plan for and make reasonable adjustments.

There is no evidence, however, that people with ID should attend reviews, be screened or assessed any more or less frequently than the general population. In this respect all of the general guidelines around frequency of assessment apply: What does differ, however, is the need for health and social service providers to frame the encounter to ensure equity of access, maximum benefit and impact on health outcomes for the person with ID. The following suggestions are reasonable adjustments to improve communication and support:

- Ongoing education and training for the self-monitoring of blood glucose.

- Attend annual health checks for HbA1c blood glucose levels, blood pressure, eye checks and flu vaccination.
- Having the support of a family/paid carer with the person with ID at an annual health check and when blood is taken, blood pressure is measured, eyes are checked and the flu-vaccination is given.
- Use of a easy read book with accessible visuals to help explain what is involved in taking blood, taking blood pressure, having eyes checked, receiving a vaccination, how to cook healthy meals, reading food labels and making healthy choices.
- Referral to a dietician and a cooking program to demonstrate how to plan meals, how to cook basic healthy meals and how to manage barriers such as feeling hungry.

A number of plain language resources exist that can be freely accessed and cover a range of topics related to self-management including diet, exercise, blood tests, eye tests, and foot care. These can be downloaded from www.easyhealth.org.uk, www.diabetes.org, www.diabetesaustralia.com.au, www.diabetes.org.uk, and www.safefood.eu.

Self-Management and Self-Management Interventions

Diabetes is a condition in which lifestyle can impact insulin and other medication requirements and glucose concentrations. The self-management of diet, exercise, and, for many, medication are important in managing both type 1 and type 2 diabetes (Reddy, Rilstone, Cooper, & Oliver, 2016; Whitehead et al., 2017). The principles of diabetes management are relevant to all populations. However, where people with ID are screened less often than recommended in national guidelines (Shireman et al., 2010; Taggart, Coates, and Truesdale-Kennedy, 2012), and structured education programmes have not recognised or addressed the specific challenges faced by people with ID, potential opportunities for health promotion are likely being missed (Taggart et al., 2014). Autonomy, the individual's capacity to govern him or herself and decision-making underpin self-management.

Internationally, it is recommended that education is ongoing both in terms of diabetes itself as well as concepts and the practice of self-management for the people themselves and those in their network of support (American Diabetes Association, 2018; SEMDSA, 2017; UNITE for Diabetes Philippines, 2014). Undertaking such education in groups can be beneficial (Diabetes Australia, 2015) as well as identifying peer-led opportunities to encourage those with diabetes to engage with education (Diabetes Canada Practice Guidelines, 2018; Hale et al., 2011), and in the practicalities of peer-led shopping, exercise and growing a garden for example (Hale et al., 2011). In supporting people diagnosed with T2D, a number of countries have developed structured self-management education programs. For example, developed and implemented in the UK, Western Australia and in New Zealand, DESMOND (Diabetes Education and Self Management for Ongoing and Newly diagnosed Diabetes) is a funded self-management diabetes education programme for the general population. This program is theoretically underpinned and has clearly been shown to improve biomedical and psychosocial benefits, as well as the increase in self-management strategies for those people who attend (Khunti et al., 2008; Khunti et al., 2012; Skinner et al., 2006). There may be other structured self-management diabetes education programs in other jurisdictions.

People with intellectual disability rarely access structured self-management education programs for diabetes that are routinely offered to the general population (MacRae et al., 2015; Taggart et al., 2014). The specific challenges related to cognitive limitations, communication difficulties, low levels of literacy skills and learning styles have been neither recognised nor addressed in the mainstream programs. In addition, little consideration of the support and information needs of paid carers has been given to understand and employ self-management concepts (Trip et al., 2016). Self-management of diabetes is recommended by health services across the world for people without disabilities (WHO, 2016). People with diabetes are encouraged, where possible, to attend structured self-management education programmes, such as Dose Adjustment for Normal Eating (DAFNE) for adults with T1D (www.dafne.uk.com) or DESMOND for adults with T2D (www.desmond-project.org.uk). Until recently, no intervention program developed or adapted for people with ID and diabetes was available. There is now some evidence of an initiative to actively screen for prediabetes and diabetes, the STOP program and the adaptation of a major program, DESMOND.

The STOP program, developed in the UK (Dunkley et al., 2017) involved a diabetes screening programme to determine the prevalence of previously undiagnosed T2D and impaired glucose regulation in people with ID. Screening was conducted in a variety of community settings (general practices, ID psychiatric services) and through publicity about the study. Screening involved the collection of anthropometric, biomedical and questionnaire data. Type 2 diabetes and impaired glucose regulation were defined according to (venous) fasting plasma glucose or HbA1c, following WHO criteria. Of the 930 adults (29% of those approached) participated. Mean age was 43 years, 58% were male and 16% of South Asian ethnicity. Most participants were either overweight or obese (68%). Diabetes status was successfully assessed for 675 (73%) participants: Nine (1.3%, 95% confidence interval 0.6 to 2.5) were found to have undiagnosed T2D, and 35 (5.2%, 95% confidence interval 3.6 to 7.1) had impaired glucose regulation. Key factors associated with abnormal glucose regulation included the following; non-white ethnicity and a first degree family history of diabetes. The results from this large multi-ethnic cohort suggest a low prevalence of screen-detected (previously undiagnosed) T2D and impaired glucose regulation in adults with ID. However, the high levels of overweight and obesity detected emphasised the need for targeted lifestyle prevention strategies, specifically tailored for the needs of people with ID.

The DESMOND program is an established diabetes self-management program that has recently been adapted for people with ID, the DESMOND-ID (Taggart et al., 2018). A pilot feasibility study of a structured self-management diabetes education program targeting HbA1c for adults with ID and Type 2 diabetes mellitus was conducted using a two-arm, individually randomised design. A total of 66 adults with disabilities across the UK met the eligibility criteria. Of these, 39 agreed to participate and were randomly assigned to either the DESMOND-ID programme ($n = 19$) or a control group ($n = 20$). The program consisted of seven weekly educational sessions. The primary outcome was HbA1c level, and secondary outcomes included BMI, diabetes illness perceptions, diabetes severity, quality of life, and attendance rates.

The DESMOND-ID program was reported as feasible to deliver and, with reasonable adjustments, participants could provide consent, complete the outcome measures, be randomised to the groups and attend most of the sessions, with minimal loss to follow-up. Using the fixed-effects model, the interaction between occasion (time) and condition resulted in a statistically significant decrease in HbA1c ($p < 0.05$); however, the CI was large. This is the first published study to adapt and pilot a national structured self-management diabetes education program for adults with intellectual disability. This study demonstrates that it is possible to identify, recruit, consent and randomise adults with intellectual disabilities to an intervention or control group and further studies involving adequately powered trials are recommended.

A newly developed intervention for adults with obesity, T2D and an intellectual disability based on standardised supported self-management delivered by diabetes specialist nurses plus treatment as usual was piloted by (House et al., 2018). This feasibility randomised controlled trial included adults aged >18 years with a mild or moderate intellectual disability, living in the community with T2D, on any therapy other than insulin. Most participants were recruited through referral by a primary care physician. Participants were assessed on their mental capacity to consent to research and the intervention. Inclusion criteria included

HbA1c > 48 mmol/mol (6.5%), BMI >25 kg/m^2, or self-reported physical activity below national guideline levels. In this study, the intervention was based on modifying existing approaches to supported self-management, with adjustments made to respond to barriers to self-care in people with an intellectual disability. It emphasised realistic goal setting, identifying resources and barriers likely to influence success in reaching goals, and regular self-monitoring of goal attainment. For the "supported" element the authors chose to use face-to-face contact and employed two diabetes specialist nurses from the local diabetes service, with no prior experience in learning disability or involvement in research concerning trials of complex interventions.

The experimental intervention was compared with treatment as usual alone. Feasibility outcomes included: recruitment and retention; intervention acceptability and feasibility; data collection and completeness for physiological state and values for candidate primary outcomes (HbA1c and BMI). A total of 82 participants (89% of those contacted and eligible) were randomised. All supported self-management sessions were completed by 35/41 participants (85%); only four of whom completed no sessions. Data on the follow-up candidate primary outcomes HbA1c and BMI were obtained for 75/82 (91%) and 77/82 participants (94%), respectively. Primary outcomes were similar across trial arms at baseline and follow-up; however, when comparing within-participant reduction in HbA1c and BMI in individuals with measures at baseline and follow-up, an effect size in the supported self-management arm of 0.33 (0.5/1.5) was observed for BMI, and for HbA1c it was 0.30 (0.17/0.57), whilst minimal effects were observed in the group receiving treatment as usual. Adherence to a supported self-management program and willingness to have blood taken for outcome measurement was high and the authors conclude that a definitive randomised controlled trial is feasible in this population.

These are the first two studies to adapt an intervention for people with ID and diabetes. Differences existed in the delivery, such that for one group the intervention run in a public space (Taggart et al., 2018) and the other was a one-to-one intervention often delivered in the person's own home (Dunkley et al., 2017). Both studies described making reasonable adjustments. Detail on the adjustments made to the DESMOND-ID program were not clear; however, participants reported that the content and the delivery of the program were user-friendly, and the educators advised that the adapted programme content, structure, curriculum, length of sessions, resources, health action plans and interactive sessions were at the appropriate level for those with a range of cognitive impairments and communication difficulties. The opportunity to provide booster sessions was described as a potential to further reinforce the messages of the program. The educators also found that the first session, for the carers only, was a useful means of creating a relationship with the carers, and was supportive of them working through the programme together with the adults with intellectual disabilities. Only one issue was raised by the educators in relation to the increased preparation time needed prior to delivery of the program (Taggart et al., 2018).

The intervention by Dunkley et al., (2017) was described as starting with three principles: that the intervention should respond to known barriers to self-management reported by people with a disability, including practical problems such as transport, likely attrition through drop-out when multiple attendances are expected, and an inability to accommodate the presence of a supporter. The format of the intervention should encourage self-maintained change beyond an early supported element and in this study a focus on involving supporters linked to any aspect of lifestyle relevant to diabetes; and the intervention should be designed to be readily integrated into usual healthcare provision, to ensure sustainability. The intervention was planned to focus on practical aspects of self-care; use of simple (accessible) written materials and charts; supportive contact both with a professional and with a supporter if one could be identified; use of practical goal setting and self-monitoring. The intervention sought to avoid theoretical content on the nature of diabetes and food values, using booklets to cover factual information. Interestingly, in contrast to the Taggart et al. (2018) study Dunkley et al. (2017) decided against group-based interventions predicting that attendance would be low and the ability to meet the specific individual needs of a heterogeneous population harder in such settings.

Conclusion

The challenges of self-management of glycaemic control apply to those with ID in even greater measure when ID can impact on capacity and capability to follow a healthy diet, take physical activity, monitor blood sugar levels, and take medication as prescribed (Whitehead et al., 2016). This means people with intellectual disabilities may be more reliant on family, paid carers and others to support them in making healthy lifestyle choices and in glycaemic control (Cardol et al., 2012a; Hale et al., 2011; Rouse & Finlay, 2016).

For effective diabetes self-management, people with ID require structured education about diabetes in which the language and approach is tailored and adapted to the individual (Bell, 2005; Taggart et al., 2015, 2018), as well as feedback on what has been mastered (Maine, Dickson, Truesdale, & Brown, 2017). Such approaches develop the autonomy and confidence of a person with an intellectual disability and those who support them (Cardol et al., 2012b; MacRae et al., 2015).

Key considerations for future research include further development of interventions specifically for people with ID and diabetes and establishing the core elements of the intervention, for example the value of one to one engagement versus group intervention, and the role that carers provide in promoting self-management.

Key considerations for clinical practice include the provision of joint clinics between primary care, diabetes services and intellectual disability healthcare staff to inform service delivery, accessibility and the continuity of care (Brown et al., 2017). Furthermore, education about diabetes to healthcare staff and people with intellectual disability alike should include the promotion of practice translation the principles of self-management, thereby enabling the inherent and developing autonomy of individuals with diabetes (Trip et al., 2016; Whitehead et al., 2016).

Factors in Weight Management: A Research Story

56

Richard R. Saunders, Muriel D. Saunders,
Joseph E. Donnelly, and Lauren T. Ptomey

Prologue

Concurrent with the movement towards community integration, personal freedom and choice have become the hallmarks of community-based services for adults with intellectual and developmental disabilities (IDD). The more these adults have exercised their rights to freedom and choice, the more they are making the same lifestyle choices as those without IDD and, as such, have become overweight or obese. Designing ways to address issues of weight with these individuals is neither less nor more complex than similar issues with individuals without IDD. With both populations, understanding the causal factors and, therefore, understanding how to intervene is like peeling an onion: the removal of each layer leads to another. Moreover, every person and every onion is different.

As an example, let us begin with a success story from a year-long pilot project that will be described below in detail. We recruited about 35 participants from a day-service/employment facility and introduced them to a reduced-calorie diet. As might be expected, the participants showed varying degrees of weight loss over the 6-month intervention and, some, over the 6-month maintenance phase. Among these, a subset of 10 individuals showed more consistent weight loss than many others. Near the end of the 12-months we noticed cheering, high-fiving, and other forms of satisfaction outside the meeting room as individual weights dropped below 200 lbs. At that point, we learned that the local equestrian program for adults with IDD had a 200 lb. maximum weight for mounting a horse, and the facility was about to open for the spring. Clearly, choosing or not choosing to follow the diet had explicit, tangible consequences.

Briefly, this pilot encouraged a reduced calorie diet with small cash incentives for tracking foods and beverages consumed, included small cash incentives for walking and tracking steps taken, and monthly meetings with project staff to discuss problems and successes. Our experiences with these and additional participants revealed that there were just about as many motivating factors as there were participants. Some worked hard at weight loss motivated by a partner, relative, or friend. Some wanted to alleviate pain in limbs and joints that they attributed to excess weight. Some had been diagnosed as prediabetic or with gout. Some were motivated by seeing friends lose weight. Some enjoyed the small cash

incentives, although these were provided for reporting their food and beverage intake and not specifically for weight loss. It is perhaps noteworthy that with many participants, having cash in hand was a relatively rare event. Most received payment from their employers as direct deposit to their checking accounts or to a guardian of their finances. Others seemed to be motivated by the praise they received from the research staff. Some saw their role in our pilot as a "job" of sorts, as if they were working for the University, and took pride in it. Thus, as these individuals were similar to persons without disabilities in their problems managing weight, they were also similar in what motivated them to change.

In addition to motivational differences, we also learned of the many differences in their living environments, including their residences, social situations and the broader environments around their residences. Among the most influential of these was the rate of staff turnover in their homes. Only a few lived entirely independently and we observed the support staff for those not living independently often changed once or more across the research period. Turnover was potentially significant when staff attitudes about weight management or weight loss changed dramatically: some staff supported the participants efforts because they too were dealing with similar issues, but others did not, as they did not see the need. Others brought attitudes about the IDD population that conflicted with the goals of weight loss. A not uncommon refrain was, "You know, eating is one of the few things these people can enjoy." The potential for participants to move from a diagnosis of prediabetic to a Type 2 diabetic seemed to have little impact on this point of view—this despite the fact that diabetes would significantly alter the participants food and beverage choices, and perhaps a host of other medical, residential, and monetary issues as well.

Both staff and relatives often brought concerns about the components of the diet. Some felt that the sugar substitutes in diet beverages would likely be far more harmful than excess weight. Similar misgivings were voiced regarding the sodium content of many of the prepackaged entrees that formed a core diet component. Staff also voiced concerns about the difficulties in shopping for the entire home, when the needs of the participant differed from others. Purchasing entrees conflicted with the food budgeting process in the homes. How does one purchase bulk meats, for example, for 2 people and entrees for one person. This produced a real and complex cost dilemma. Similarly, staff felt uncomfortable serving different foods to different residents. Many individuals we encountered enjoyed raw vegetables served with generous portions of ranch dressing—a real "no no" on a weight loss diet. Many staff felt uncomfortable serving generous portions (including second helpings) to some residents, but not the participant. Desserts posed a similar problem.

Differences in various skills among the participants posed additional challenges. Some demonstrated good money skills and others struggled, in the grocery store, for example. Consider the complexities of shopping for a week on a limited budget. For all of us, it can be a difficult task to fill a grocery basket up to but not beyond our budget limit. As with us without IDD, it can be embarrassing to get nearly done with check out and realize we must return one or more items to the shelves; it can be particularly so for the person with IDD. Cooking and food preparation skills also came into play. Some of our participants who did cook often worked from a few basic recipes. To be successful at weight management, some of these had to be changed. One of the most essential changes was the need to reduce how much one cooked or prepared at each meal. We also observed that when participants opened a can or box of food, they often consumed its entire contents immediately, rather than reshelving the remainder for a later meal. The difficulties in changing food preparation and cooking were not limited to the participants. In many residences, the approaches and recipes derived from the staff's personal histories. Given any particular meal menu, provided by supervisory staff or dietary consultants, there is room for much individualization and improvisation and many such improvisations were counter to weight loss.

The foregoing suggests why this chapter will not reveal a single formula for successful weight management. It will, however, describe an approach which was successful with many participants despite the factors just described.

Literature Review of Research Findings

Intellectual and developmental disabilities (IDD), are characterized by significant limitations in both intellectual functioning (IQ <75) and in adaptive behavior including conceptual skills (e.g., language and literacy, self-direction), social skills (e.g., interpersonal skills, ability to follow rules) and practical skills (e.g., personal care, use of money/phone) which originate before the age of 18 (American Association on Intellectual and Developmental Disabilities, 2012). These limitations are likely to impact food choice, calorie counting, and so forth. Lack of regular physical activity, increased sedentary behavior (Bartlo & Klein, 2011; Sundahl, Zetterberg, Wester, Rehn, & Blomqvist, 2015), and unhealthy dietary choices (Adolfsson, Sydner, Fjellstrom, Lewin, & Andersson, 2008; Draheim, Stanish, Williams, & McCubbin, 2007; Robertson, Emerson, Baines, & Hatton, 2014; Stancliffe et al., 2011) are associated with weight gain in the general population, as well as in adults with IDD. In addition, genetic predisposition (Farooqi & O'Rahilly, 2005), the use of weight-inducing medications (De Winter, Bastiaanse, Hilgenkamp, Evenhuis, & Echteld, 2012; Hsieh, Rimmer, & Heller, 2013; Stancliffe et al., 2011), and living arrangement (e.g., institution, group home, family home) (de Winter et al., 2012; Melville, Hamiltom, Hankey, Miller, & Boyle, 2007; Stancliffe et al., 2011) all contribute to weight gain in this group. Individuals with IDD represent ~1% to 3% of the US population (American Association on Intellectual and Developmental Disabilities, 2012) with a prevalence of obesity (BMI ≥ 30 kg/m^2) equal to (Stancliffe et al., 2011) or greater than the general population (Hsieh et al., 2013; Melville et al., 2007; Robertson et al., 2014). Adults with IDD have a higher prevalence of obesity-associated health conditions including cardiovascular disease, risk factors for cardiovascular disease, cardiovascular disease mortality (Draheim, 2006; Lauer & McCallion, 2015; Reichard, Stolzle, & Fox, 2011), type 2 diabetes (Balogh, Lake, Lin, Wilton, & Lunsky, 2015; Shireman, Reichard, Nazir, Backes, & Greiner, 2010) and rates of hospitalization related to type 2 diabetes (Balogh et al., 2015) compared with their non-IDD peers.

Several reports from government agencies (2005) and professional organizations (Ptomey & Wittenbrook, 2015) have recommended efforts to reduce the prevalence of overweight and obesity in adults with IDD. However, the lack of evidence regarding the effectiveness of weight management, particularly evidence relative to weight maintenance following weight loss, limits the ability to make sound weight management recommendations for this group. Spanos, Melville, and Hankey (2013), in the most recent systematic review, identified a limited number of trials (n = 22) on weight management in adults with IDD. These trials were conducted over relatively short time frames (8–12 weeks) using nonrandomized designs, in small (n < 25), nonpowered, heterogeneous samples. The majority of trials (21/22, 95%) were not conducted in accordance with current weight management guidelines which recommend "≥ 6 months in a comprehensive lifestyle program that assists participants in adhering to a lower-calorie diet and in increasing physical activity through the use of behavioral strategies" (Jensen et al., 2014). Weight loss observed in these trials was minimal (<3%). In contrast, clinically significant weight loss (≥3%) was observed in 24 and 16 week nonrandomized, multicomponent trials that included energy reduced diets, increased physical activity, and behavioral interventions (e.g., Melville et al., 2011). None of the trials described in the Spanos review included a long-term (≥1 year) comprehensive weight maintenance program as recommended by current clinical guidelines (Jensen et al., 2014). Publications subsequent to the Spanos review (Spanos et al., 2013) have demonstrated the effectiveness of a 1-year weight maintenance intervention in a small sample (n = 28) of adults with IDD who achieved ≥3% weight loss over 16 weeks (Spanos et al., 2013) and clinically significant weight loss (~8 kg) in a sample of 33 adults with IDD attending a community occupational therapy day center, in response to a 17-week intervention consisting of reduced energy intake, physical activity and a token economy motivational system (Martinez-Zaragoza, Campillo-Martinez, & Ato-Garcia, 2015). Pett et al. (2013)

reported modest weight loss (~3 kg) in a small sample (*n* = 30) of young adults (~25 years) in response to a 12-week recreation center-based healthy lifestyle intervention that focused on nutrition and physical activity. However, Bergstrom, Hagstromer, Hagberg, and Elinder (2013) reported no change in BMI or waist circumference in 129 adults with IDD in community residences who completed a 12–16-month intervention designed to improve both diet and physical activity. In summary, prior research on weight management with individuals with IDD has not produced particularly remarkable results.

The majority of weight management trials in adults with IDD have focused on compliance with healthy eating recommendations or energy reductions using a conventional meal plan diet (Bergstrom et al., 2013; Martinez-Zaragoza et al., 2015; Pett et al., 2013; Spanos et al., 2013). Conventional diets (CD) are effective in the general population (Jensen et al., 2014); however, understanding, planning and complying with a CD may be difficult in adults with IDD, and may, at least in part, be associated with the general lack of success of weight management interventions in this group. The Stop Light Diet (SLD) (Epstein & Squires, 1988) which categorizes foods by energy content: green (low energy, consume freely), yellow (moderate energy; consume in moderation), and red (high energy, consume sparingly) has been shown to provide effective weight management for children (Collins, Warren, Neve, McCoy, & Stokes, 2006) and for adults with physical disabilities (Damschroder et al., 2014; Reichard et al., 2015), and may be appropriate for use in adults with IDD.

Our Research Story in Three Phases

Phase 1

In preliminary discussions among a number of researchers in the Life Span Institute at the University of Kansas, the problem of weight management in adults with IDD became a shared topic of interest between a team of behavior analysts with extensive experience in settings where these adults are supported and a team of experienced diet and exercise researchers. In thinking about research to address the problem, this group recognized that as a team, we knew relatively little about the dietary habits of these individuals. Thus, we set about to learn more and several phases of research unfolded.

First, we enrolled residents of several group homes of 3–5 individuals in an observation and data collection project. They consented to our recording their daily dietary intake with digital photo "plate-waste" methods (e.g., Ptomey et al., 2015). We began visiting each home prior to the serving of each breakfast and evening meal. We recorded the sizes and capacities of their meal utensils: plates, bowls, glasses, cups, and so forth. When the meal was served, we photographed each place setting before they ate. When finished, we photographed each place setting again. Notes were taken to clarify any possible confusion as to the food and beverage items, such as the types of bread, margarine, salad dressings, and so forth. We also photographed the contents of their lunch boxes (taken to work, for example) and photographed the contents when they returned in the evening. We also were permitted to follow them to those away settings and to record any additions or changes that occurred. For example, some made purchases from agency vending machines and others swapped food items with friends.

The photos and notes were analyzed by staff trained in evaluating the foods according to nutritional content and kilo-calories (kcal). The average daily consumption exceeded 2200 kcal and often ranged between 2500 and 3000 (typical needs range from 1800 to 2000). These levels were clearly not consistent with weight reduction.

Our time in these homes revealed some other circumstances with potential impact both on why intake was relatively high and how one might begin an intervention. For examples, the plates and bowls were often filled to capacity, second servings were offered when there were leftovers, and typically everyone received the same portions regardless of their height and weight. We also observed that meals followed diet plans (from supervisors and consulting professionals) that sometimes led to unintended consequences. For example, where one glass of orange juice was a recommended breakfast component, the only glasses in the home were actually tumblers with 12–16 oz. capacities. Staff served the glasses full or nearly so. Another observation was that our post-meal photos were superfluous as participants usually had empty plates and lunchboxes. (In our subsequent research, we observed that these circumstances were not unique to the particular homes in that first project; they were seen in many other settings as well.)

Seeking to design a weight loss intervention for evaluation with IDD individuals, the team shared an approach that was having some success in persons in the general population. That approach was referred to as the "packaged meal" approach. Specifically, individuals were encouraged to eat prepackaged entrees of 300 kcal or less at lunch and dinner, to eat five servings of fruits and vegetables daily, and to supplement those with low calorie shakes. The fruits and vegetables could be fresh, frozen or canned. The entrees could be those ordered online from weight management companies or could be frozen entrees from the local grocer. Shake mixes that could be "expanded" by adding water, fruit, and ice in a blender to make filling meals, were the supplements of choice. Such shake mixes are also available online and in local stores. The goal of the packaged meal approach was to limit intake to about 1200–1500 kcal per day, while providing feelings of "fullness." Moderate to vigorous exercise was also encouraged, but not scheduled or supervised by the team. This approach had several characteristics that seemed promising for individuals with IDD—simplified food purchasing, no calorie counting, and no extreme constraints on what foods to eat. Incorporation of pictorial charts of foods organized according to the Stop Light Diet, to allow more choices in meals, appeared useful, as well.

To have some confidence in the diet we were about to share with individuals with IDD, the behavior analysts (who could benefit from some weight loss themselves) began following the diet. With relatively close compliance for several months, the behavior analysts lost 8% and 12% of their baseline weights and suffered no ill affects. In short, the diet seemed safe to share.

Phase II[1]

We enrolled 73 participants, with mild or moderate intellectual disabilities (BMI = 37.0 ± 8.4, age = 31.6 ± 9.6 years, 56% female) (Saunders et al., 2011). Approximately 30% of participants lived at home, while others were in supported living consisting of 1–4 residents. We provided them with shake mixes that were donated by HMR Weight Management Resources, Corp. There are other makers of such mixes, and a few chose to purchase those. Most of our participants purchased their frozen entrees (e.g., Smart Ones, Lean Cuisine, Lean Gourmet, Healthy Choice) in local grocery stores and a few ordered entrees from HMR, WeightWatchers, NutriSystem, Jenny Craig and so forth. There are many, many entrees to choose from and frequently one brand or another is on sale at very affordable prices. Our participants were also encouraged to drink lots of water and to look for other beverages, such as diet sodas, with low or 0 calories. For those who wanted snacks, we encouraged lower-calorie snacks or snacks in smaller amounts. The 100-calorie packages of popular cookies and crackers became a common purchase for many participants. Others, with help from caregivers, purchased large volume packages and repackaged the contents into servings of approximately 100 calories. Of course, this tactic failed without close supervision.

This diet is also referred to as one based on "volumetrics." In such a diet, one tries to eat lower-calorie foods in high volume and eat higher-calorie foods in low volume. In keeping with that principle, we encouraged participants to eat extra servings of fruits or vegetables for a

---

[1] The weight charts, stop light guides, intake self-recording forms and so forth, described in Phases II and III may be found at, and downloaded from www.diet.ku.edu.

snack, rather than cookies, crackers, and candy. For example, we shared that it takes a lot of carrot sticks to get the same amount of calories as a very small serving of cookies; thus, the carrots would more likely provide the feeling of fullness with fewer total calories.

We recommended to our participants that they bring an "advocate" (parent, caregiver, case manager) to our initial teaching sessions and to monthly follow-up visits. We felt it was a good idea to have someone who could discuss our recommendations and help remember the dieting steps to follow.

An advocate also can act as a cheerleader. He or she can also help solve problems, like making sure that other people in the dieter's life know that the individual is trying to lose weight and what their diet consists of. An advocate might also help the dieter with using the materials we distributed. Among these materials was a food-tracking chart that the team designed. The chart could be used to keep a record of what foods and beverages were consumed each day. The chart was intended as a way to see how closely the dieter was following the diet.

We also conducted a food preference assessment that identified what foods and beverages were preferred by the dieter. The preference assessment formed the basis for individualizing the pictorial stoplight (SLD) materials. We taught our participants to eat and drink a lot of green light items, to use moderation with yellow light items, and avoid red light items unless they were part of a low-calorie entrée. We also suggested that our participants weigh frequently and to record their weight on a personal weight chart. We provided a weight-progress chart that became a graph when the participant circled his or her weight for each day or each time the participant weighed. We color coded weight ranges on the chart such that each color band encompassed the individual's weights by BMI. When our participants met their first weight-loss goal, as indicated by weights circled in the next lower BMI band, we offered a certificate of achievement. Some participants enjoyed adding additional Jayhawk (University of Kansas) stickers to their certificates as they met additional goals. We purchased the stickers at campus stores, but stickers of another kind could work as well.

In addition to the certificates and stickers, we provided bragging cards at our monthly meetings. Participants often asked for something in writing to show a parent, friend, caregiver or advocate who could not attend the meeting. We entered their current progress on the cards for them to take with them. We also offered the participants small amounts of cash or other prizes as incentives for keeping records of their diet and of their progress, but not specifically for weight loss. That is, record keeping was the focus of the cash rewards and not weight loss, per se.

Because exercise can be an important contribution to efforts to be healthy, we encouraged our participants to continue whatever form of regular exercise that they were already engaged in. We also offered a walking game board. If they wanted to try and increase their activity levels by walking more, the game board gave them a way to track how many steps they were walking. We provided a step counter (inexpensive pedometer) to each participant who wanted to use the game board.

As a partial guide when dining out, we also provided our participants with lists of menu items from area restaurants that were approximately 500 calories or less, as provided by the restaurants' websites.

At these meetings (held monthly) we learned many important facts about what the individuals and their caregivers knew and did not know about weight management. We also recorded many personal characteristics and lifestyle circumstances that became important in supporting them in their weight loss efforts and in informing us how to expand and alter how and what information to share with future participants.

We learned for example, that prior to our meetings, many participants and caregivers would not have been able to correctly label a number of food and beverage items as green, yellow or red. Orange juice (and other fruit juices) was a common example. Having been taught that orange juice was healthier, compared to sodas for example, its high calorie content was unknown or ignored. Bananas, potatoes, bread, cheese, and beans are other examples that participants did not identify has having higher calorie contents.

This phase covered 12 months. Results for the 66 participants who completed the study (10% loss to follow-up) demonstrated weight loss of 6.4%, and 8.7% from baseline at 6 and 12 months, respectively. These levels of weight loss are similar to the results from the successful Diabetes Prevention Program (Knowler et al., 2002) and exceed the 3% minimum weight loss suggested as clinically relevant in the American College of Sports Medicine Position Stand "Appropriate physical activity intervention strategies for weight loss and prevention of weight regain for adults," (Donnelly et al., 2009). These encouraging results led to the development of the third phase of our research—a trial designed to compare both weight loss and weight maintenance between the eSLD and a recommended care or conventional diet (CD) meal plan diet in adults with IDD.

Phase III

Briefly, 150 overweight/obese adults with mild to moderate IDD, living either in the community with parents/guardians, or in a supported living environment with a paid caregiver, who served as a "study partner," were randomized to either an eSLD or a conventional diet (CD) as part of a multicomponent weight management intervention (6 months weight loss, 12 months maintenance) (Ptomey et al., 2018). In addition to the energy reduced diet, participants were asked to increase physical activity (150 min/wk), self-monitor diet and physical activity, and attend behavioral strategy/educational sessions conducted by a health educator during monthly home visits.

Participants. IDD diagnoses were verified by the Community Service Provider operating in Kansas under the auspices of a Community Developmental Disability Organization (CDDO). Additionally, participants were required to be able to walk, and to communicate preferences (e.g., foods liked/disliked), wants (e.g., more to eat/drink), and needs (e.g., assistance with food preparation) through spoken or sign language, or via alterative communication systems such as voice output communication aids. To enhance the generalizability of our findings, individuals who used medications for prevalent conditions associated with obesity (e.g., hypertension, lipid abnormalities, type 2 diabetes) or other medications commonly prescribed for individuals with IDD, which may impact body weight, including medications to treat depression or other psychological/behavioral problems, were allowed to participate. Clearance from their primary care physician was required for all participants.

Informational brochures describing the project and containing study contact information were mailed/e-mailed to case managers, service providers and CDDOs in the recruitment area of 50 miles. Study staff also made in-person visits to these organizations to describe the trial and to solicit participation. A member of the investigative team, who was familiar with the sensitive issues regarding recruitment of individuals with IDD, contacted potential participants and/or caregivers to describe the trial in detail and determine initial eligibility. Written informed consent, approved by the Human Subjects Committee was obtained from either the participant (self as guardian) or a legal guardian, as well as the study partner. Participants were computer randomized, stratified by the number of adults with IDD in a residence (alone, 1–2, or 3–5), with equal allocation to the eSLD and CD groups. Multiple adults in a single residence volunteering to participate were assigned to the same intervention group. There were 24 residences with 2 participants and 9 residences with 3 participants.

Caregiver role. We recruited a parent/guardian, residential support staff, or an individual who assists with food shopping/meal preparation to serve as a study partner for each participant. Study partners were asked to attend all meetings between study staff and participants and to support, encourage, and assist participants in complying with the study protocol, including selection and preparation of foods consistent with the assigned diet, providing opportunities for increased physical activity, and assisting with self-monitoring of diet and physical activity.

Study partners received $50 gift cards at 6, 12 and 18-months as compensation for the additional burden associated with participation in this trial. Study partners who were unable to complete the trial were replaced.

Weight Loss: eSLD Components

- 2 portion-controlled entrées/day
- 2 portion-controlled shakes/day
- 5 one-cup servings of fruits and vegetables/day
- Ad libitum non-caloric beverages.
- Additional meals and snacks selected using the Stop Light diet guide.

A chart which included lists and pictures of common food items, color coded to the SLD system, was provided to assist with meal planning, food shopping and selection of appropriate snacks. As in Phase II (Saunders et al., 2011), the SLD was enhanced (eSLD) by encouraging consumption of high volume, low energy, portion-controlled meals (PCMs; entrées/shakes) and fruits and vegetables (Academy of Nutrition and Dietetics, 2011). PCMs are effective in controlling portion size and reducing both energy and fat intake and simplify meal planning, food shopping and meal preparation for individuals with IDD and their study partners. PCMs include nutritional information on the label (calories, fat, protein, etc.) making it easier to adhere to specific energy and nutrient recommendations. The simplicity of using PCMs may be especially relevant as caregivers (study partners) frequently have limited formal education specific to nutrition, and the turnover rate among paid caregivers is high (Humphries, Traci, & Seekins, 2008). Participants and study partners were provided with a list of entrées available from several manufacturers (Healthy Choice™, Smart Ones ™, Michelina's ™, etc.) which met our caloric, fat, and sodium requirements. They were asked to purchase entrées of their choice which are available at most grocery stores at a cost of $2.00–$4.00 each. Two low-energy, high-volume shakes/day (HMR Weight Management Services Corp) were provided at no cost to participants in the eSLD group during the 6-month weight loss phase. These shakes could be consumed as a snack or as a drink with a portion-controlled entrée. Participants desiring foods in addition to these recommendations were encouraged to select additional low energy (green) foods from the SLD chart.

Weight Loss: CD Components

- 500–700 kcal/day energy deficit
- Recommended servings of fruits, vegetables, grains, dairy, and protein.
- Instructions regarding serving sizes and food measurement.

Participants randomized to the CD group were taught to consume a nutritionally balanced, low-calorie, high-volume, lower fat (20–30% energy intake) diet following the MyPlate approach as recommended by the US Department of Agriculture (2013). Participants and study partners were taught to select, purchase and prepare appropriate foods, as well as to serve a portion of appropriate size to achieve the desired reduction in energy intake. During weight loss energy intake was reduced to ~500 to 700 kcal below daily estimated resting energy expenditure as estimated using the equation of Mifflin-St Jeor (Mifflin et al., 1990) multiplied by 1.4–1.6 to account for energy expenditure associated with physical activity. As this equation was not developed with individuals with IDD, the estimated energy intake was used as a starting point, which was adjusted in response to weight loss or gain as assessed during monthly home visits. Participants and study partners were provided with examples of meal plans, which suggested the number of servings of grains, proteins, fruits and vegetables, dairy, and fats to achieve the desire energy intake for weight loss, and were counseled on appropriate portion sizes using three-dimensional food models and taught to measure foods to facilitate compliance with serving size recommendations. Participants in the CD group received the monetary equivalent of the cost of the shakes provided to the eSLD group ($30.00/mo.) for the purchase of foods appropriate for CD only during the active weight loss intervention (0–6 months).

Weight Loss: Physical Activity

Participants in both groups were encouraged to accumulate a minimum of 30 min./day of moderate intensity physical activity 5 days/week (150 min/week). We are aware that this level of physical activity is less than recommended by current guidelines for weight management (Donnelly et al., 2009; Jensen et al., 2014). However, based on experience from our pilot trial in adults with IDD, and other reports in the literature demonstrating the low levels of physical activity in this group (Barnes et al., 2013), accumulating 150 min/week of moderate intensity physical activity represents a reasonable recommendation. Brisk walking was recommended as it is inexpensive, safe, fits easily into the daily routine, and can be performed alone or with others. Pedometers (Omron HJ-320, Lake Forest, IL) were provided to all participants as both a motivational tool and to self-monitor physical activity.

Education/Behavioral Sessions

All education/behavioral sessions were conducted during home visits with both participants and their study partner. The frequency and duration of these sessions was equal for both the eSLD and CD groups across the intervention. All sessions were led by health educators trained to deliver the intervention by shadowing a co-investigator experienced with weight management for adults with IDD. This co-investigator also supervised health educators during their initial session with participants and study partners, and attended a minimum of 4 monthly sessions, at random, to insure the intervention was delivered as intended using a checklist. Health educators were assigned to participant/study partners at baseline and delivered both the weight loss (0–6 months) and maintenance interventions (7–18 months) to those individuals.

Intervention

Orientation. Prior to initiating the intervention, participants and study partners completed a 60–90 min. Orientation session with their health educator designed to teach the basic principles of the diet and physical activity intervention, as well as describe the procedures and requirements for self-monitoring. A shorter follow-up home visit (~30 min) was completed ~2 weeks following the initial orientation to answer questions and address any issues that may have arisen as participants. During the home visit, medication information (name, frequency, and amount) was obtained and classified (yes/no) based on the association with weight gain (Domecq et al., 2015).

Diet. Both the eSLD and CD groups were taught basic principles regarding meal planning, food shopping, meal preparation and how to incorporate high volume/low energy foods in their diets, which have been shown to improve weight loss and maintenance (Rolls, 2005). Participants/study partners in the eSLD group were provided with a list of PCMs appropriate for this diet, a month's supply of low calorie shakes, and a color-coded chart (green, yellow, red) which categorized foods based on the Stop Light diet. Participants/study partners in the eSLD group were trained to use the chart to assist in meal planning, grocery shopping, decisions regarding snack foods, and compliance with the diet in special situations such as eating away from home (restaurants, parties, etc.). Participants/study partners in the CD group were taught how to select, prepare, and portion foods to achieve the required level of energy reduction.

Physical activity. The physical activity recommendations were explained to both intervention groups and instructions on how to wear and use the pedometer were provided. Participants were taught how to accumulate physical activity by incorporating activity into their daily routine (work breaks, lunchtime, etc.) and were provided with basic information regarding exercising in hot or cold weather, local sites for indoor walking, appropriate footwear, etc.

Self-monitoring. Participants, with assistance from their study partner, were trained to self-monitor their diet and physical activity across the intervention (0–18 months) using colorful pictorial 7-day tracking sheets specific to their group assignment (eSLD or CD). Participants in the eSLD group were asked to check the pictorial representations of the number of PCMs, shakes, fruits and vegetables, and other green, yellow or red foods consumed each day. Similarly, participants in the CD group were asked to check the number of daily servings of vegetables, fruits, dairy, meat and grains. The tracking sheets for both groups contained space for recording daily pedometer steps and minutes of non-walking physical activity. Participants in both groups were also provided with a pictorial game board to track their progress towards a goal of accumulating 100,000 steps that was associated with a monetary incentive ($5.00). Self-monitoring tracking sheets were collected and summarized by the health educator during monthly meetings and used to provide feedback to participants and study partners regarding compliance with the intervention.

Monthly meetings. Health educators conducted monthly 45–60 min. Home visit meetings with participants and their study partner across the 18-month trial. Participant's body weight was assessed wearing a t-shirt, shorts and without shoes, and weekly self-monitoring tracking sheets were reviewed to provide feedback regarding progress with weight loss and compliance with the study protocol. Health educators answered questions and taught problem solving/relapse prevention strategies to assist participants in maintaining compliance with the intervention. Twenty-four hour dietary recalls were also conducted by the health educator and used to provide feedback relative to compliance with the dietary recommendations. The 24-hour recalls followed the USA Department of Agriculture multiple pass protocol which includes five steps: (*1*) the quick list, where participants provide an uninterrupted listing of foods and beverages consumed; (*2*) the forgotten foods list, where participants are queried on categories of foods that have been documented to be frequently forgotten; (*3*) a time and occasion at which foods were consumed; (*4*) the detail cycle, which elicits descriptions of the specific foods and portions consumed aided by items designed to provide reference and improve recall accuracy such as three-dimensional food models, standard size glasses, mugs, bowls, chip bags, drink bottles, thickness sticks, measuring cups and spoons, and standardized geometric shapes (Wright et al., 2007), and (5) a final probe review (Blanton, Moshfegh, Baer, & Kretsch, 2006, Conway, Ingwersen, & Moshfegh, 2004, Conway et al., 2003). In addition, participants were provided with a simple chart for recording their weight on a frequent basis.

Incentives. In addition to the small monetary incentive for accumulating steps previously described, we gave participants small monetary incentives for recording consumption of foods consistent with the study diets (≤ $16.00/mo.), and for reducing their BMI by 1 kg/m^2 ($10.00). We gave incentives for steps walked, dietary compliance, and decreased BMI were provided during weight loss (0–6 months) but not during weight maintenance (7–18 months). However, during weight maintenance we provided $20.00 was for attendance at monthly health educator meetings. Participants had the potential to receive ~$560.00 in incentives across the 18-month intervention.

Weight maintenance. During weight maintenance (7–18 months) participants in the eSLD group were counseled to continue consumption of PCMs (2 entrées/shakes/day) and increase consumption of foods in the green and yellow categories of the Stop Light diet. Participants in the CD group were provided with energy intake recommendations for weight maintenance based on estimated resting energy expenditure (Mifflin et al., 1990) multiplied by 1.6–1.8 to account for physical activity, and provided with examples of meal plans consisting of suggested servings of grains, proteins, fruits and vegetables, dairy, and fats based on their maintenance energy requirements. Participants in both groups were asked to continue the 150 min/wk recommendation for physical activity. Participants who gained weight, based on weight measured during monthly home visits, were provided with suggestions for improving compliance with both dietary and physical activity recommendations for weight maintenance.

Results

Outcomes Analysis. This phase was powered to detect a difference of 2.6 kg in mean weight loss between the eSDL and CD groups at 6 months (a difference based on prior published data on results with the eSLD and CD diets). Height, weight and waist circumference were measured using generally used techniques in weight loss research. Dietary intake was measured with repeated administration of 3-day food records and analyses. Physical activity was measured not only from the records of steps walked produced by the participants, but also through 7-day accelerometer data. The analysis plan for data may be found in (Ptomey et al., 2018).

Participants. One hundred fifty adults with IDD were randomized to the eSLD (n = 78) or CD groups (n = 72). Body weight assessments were obtained on 67 (87%) and 57 (76%) participants following weight loss (6 months) and 54 (70%) and 47 (65%) participants following weight maintenance (18 months) for the eSLD and CD groups, respectively.

Baseline participant characteristics are presented. Participants were obese (BMI ~37 kg/m^2), middle-age (~36 years) adults with IDD; ~17% were diagnosed with Down Syndrome, while 57% were female. Approximately 16% of the sample was non-Caucasian, and ~82% had at least a high school education (as provided in Kansas special education programs). The majority of participants (~67%) lived in a group situation and received support from paid staff (~74%). Demographic characteristics and baseline measures were similar between the treatment groups.

Body Weight/BMI/Waist Circumference

Weight loss (0–6 months). Weight loss at 6 months was significantly greater in the eSLD (−6.8 ± 5.5 kg; −7.0%) compared with the CD group (−3.6 ± 5.3 kg; −3.8%). The proportion of participants achieving weight loss of >5% among participants completing the 6-month weight loss intervention was greater in the eSLD (62.3%) compared with the CD group (40.4%). None of the covariates of interest (sex, use of obesogenic medications, Down Syndrome, number of study partners, or their relationship with the participant) impacted change in weight at 6 months. Similar to the results for body weight, the decreases in both BMI and waist circumference were significantly greater in the eSLD compared with the CD group.

Weight maintenance (7–18 months). Weight increased from 7–18 months in the eSLD group (+0.3 ± 5.1 kg; 0.3%) and decreased in the CD group (−2.5 ± 8.4 kg; 2.2%); however, the between group difference was not statistically significant ($p = 0.052$).

Weight loss + maintenance (0–18 months). Weight loss at 18 months did not differ significantly between the eSLD (−6.4 ± 7.9 kg; 6.7%) and CD groups (−6.6 ± 9.2 kg; 6.4%, $p = 0.94$). The proportion of participants achieving ≥5% weight loss among participants completing the 18-month intervention was 57.4% and 49.0% in the eSLD and CD groups, respectively. None of the covariates of interest (sex, use of weight-inducing medications, Down Syndrome, number of study partners, or their relationship with the participant) impacted change in weight at 18 months. Similar to the results for body weight, there were no significant differences between groups for change in BMI ($p = 0.98$) or waist circumference ($p = 0.64$) across 18 months.

Intervention Compliance

Dietary recommendations. Participants randomized to the eSLD group were asked to consume 2 portion controlled entrées, 2 low-calorie shakes and 5 servings of fruits and vegetables each day. Self-reported compliance with these recommendations was poor. For example, 9% and 10% of participants complied with the entrée, and 17% and 0% complied with the shake recommendations at 6 and 18 months, respectively. Self-reported compliance with the fruit and vegetable recommendation was observed in 28% and 31% participants at 6 and 18 months. Participants randomized to the CD group were asked to consume a lower fat (<30% total energy intake), reduced energy (~500 kcal/day) diet which included 5 servings of fruits and vegetables per day. Self-reports indicated approximately 29% and 38% of participants in the CD group complied with the recommendation for lower fat intake at 6 and 18 months. Energy intake was reduced by 500 or more calories per day in approximately 29% and 26% of participants in the CD group at 6 and 18 months, as assessed by self-report. Self-reported compliance with the fruit and vegetable recommendation was achieved by 40% and 35% of participants at 6 and 18 months. There were no differences between the groups for changes in energy intake, % fat at intake, or servings of fruits or vegetable at 6 or 18 months.

Self-monitoring. Across the 18-month trial randomized participants completed 54% and 61% of requested monthly self-monitoring reports in the eSLD and CD groups, respectively. Completion of monthly reports was significantly higher in the CD (83%) compared with the eSLD group (70%, $p = 0.01$) among those actively participating in the trial.

Physical activity. Approximately 66%, 62% and 36% of the study sample provided valid accelerometer data at baseline, 6 months, and 18 months, respectively. Moderate-to-vigorous physical activity (MVPA) was generally low, ranging from ~ 15 min/day at baseline, to ~12 min/day at 18 months. There were no significant differences in MVPA between the eSLD and CD groups at baseline, 6 or 18 months. The proportion of participants meeting the MVPA goal of ≥150 min/wk across the 18-month trial was low (~8%) and did not differ significantly between the eSLD and CD groups at baseline, 6, or 18 months.

Discussion

Our results show that adults with IDD can lose significant amounts of weight and maintain that reduction over 18 months. Among the interesting aspects of our findings are that self-reported compliance with the diet and self-recorded data on physical activity did not predict the weight loss and maintenance observed outcomes. Apparently, our participants complied with sufficient components of the intervention to be successful dieters, but were poor at documentation. Another interesting result was that, while the eSLD diet produced the most weight loss initially, those on the CD plan eventually showed similar weight loss, with both diets leading to positive maintenance results. Overall, the results are encouraging for further efforts to design weight loss interventions that can be effective, and perhaps more effective, with adults with IDD than those without IDD.

Our participants received their diet and exercise training, and their monthly follow up meeting with the health educator, in their own homes or in their places of employment/day service. These visits were costly to the project, particularly when participants lived or worked 40–50 miles from the research offices. Many will question whether “taking the intervention to the participant” across the study duration was a major contributing factor in participant success. Certainly, the technical and practical details of each diet can be conveyed by phone, or possibly with some, by email.

Two practical considerations in choosing some form of remote communication and data collection may not be immediately obvious to the researcher. First, almost none of our participants across the pilot and the controlled clinical trial owned a scale. Prior to our work with them, they did not weigh at home, only at the office of a physician or other health care provider. Thus, reporting their monthly weight by telephone will require the provision of a scale. Second, many adults with IDD, and particularly those living alone, do not answer telephone calls from persons not on their cell-phone approved list. Many parents and staff provide an app that blocks non-identified callers. Initial monthly communications will in many cases need to be routed through the advocate.

There is more to this issue than the logistics of communication. Much of our planning for the single-arm pilot and the controlled clinical trial were based on direct observations of participants and their advocates and of their living and working conditions. While data can be acquired remotely, much may be missed that would be just as important in designing the next phase, and the one after that, and so forth. Health educators who visit the participants are able to see the particulars of the conditions in which each participant lives and works, which include the characteristics of their support staff, their home furnishings, their food storage capacities, and their recreation interests (e.g., TV, video games, sports). A specific and relevant example is observation of whether the participant owns a food blender—a device essential for making smoothies.

Another very important example is oral hygiene. Individuals who are endentulous or who are missing numerous teeth or who have pain-producing conditions, will likely have food texture preferences that will impact compliance with aspects of the diet. Certainly, in a practical application of our methods, without the restrictions on participant-to-participant consistency imposed by a research protocol, results of these observations would be important in gradually tailoring the intervention to individual differences.

Related questions arise from the differences in data collection in an in-home versus remote comparison. When our health educators met with participants, they collected the intake tracking forms, reviewed the data recorded by the participant with the participant and their advocate, and distributed new blank forms. With remote administration, it is unclear how the forms would be collected and replaced and it is unclear what would be lost in not reviewing the self-recorded data with the participant and advocate. Those reviews, in many cases, served to improve the understanding by the participant and advocate of what was to be recorded and how to record it. An example is that our tracking forms displayed pictures of carrots to represent "any vegetable" and pictures of apples to represent "any fruit." We learned early on that some participants were not markings these icons because they ate no carrots or apples. Self-recording of steps on the pedometers sometimes suffered in the following way: if the participant recorded 6321 steps yesterday, but forgot to reset the counter to zero, they simply recorded a new total the next day that reflected 6321 plus whatever was accumulated in the ensuing 24-hours. A more significant example of a discussion at monthly meetings, was that participants frequently needed reminders (despite our pictorial handouts) of what foods were red, yellow or green—particularly red items that they were hoping were green!

Other benefits of in-home or in-workplace meetings are that the health educator is able to get some sense of how the participant handles money. Some pocketed the money, some gave it to the advocate for safekeeping, and others seemed to "surrender" the money, less for safekeeping, than more as if it was required. Comments by participants regarding how they were going to spend their money were revealing as well. Some shared very realistic savings goals, such as a new purse, new hat, or new DVD. Others had surprisingly long-term goals, but goals confirmed by advocates, such a taking a cruise or other vacation. The in-person monthly interactions also provide insight on whether the small monetary incentives played much of a motivating role at all. The discovery of the rules at the riding stable is an example. One other observation regarding money deserves mention. Some of our participants lost 50–60 lbs., or upwards of 25% of their body weight. Consequently, their clothes no longer fit. Participants with families with the wherewithal to respond were delighted to purchase new clothes. Those in poverty needed and will need special attention.

When a health educator is visiting in the home, he or she is more likely to hear or be part of conversations about current and upcoming events in the home or at the workplace. Adults with IDD are like everyone else in their desire to have interesting, entertaining, and fun things to do. For many of our participants, Friday was bowling night, Saturday was dinner-out night, Sunday was lunch with mom and dad, Wednesday evening was the social at their church, and anyone's birthday, anniversary, or award was reason to party. In almost every case we encountered (not unexpectedly), these events involve food—usually, high-calorie food—pizza; cookies, cake, and ice cream; and all-you-can-eat buffets. It is a tough sell on the part of the health educator to discourage the all-you-can-eat pizza buffet for $3.99 per person or to ask the advocate to assist the participant in declining the snacks at the church social.

The health educator visiting the home also becomes aware of the effects of poverty on adults with IDD. As with nondisabled adults, the monthly food budget can be exhausted before the month ends. Typical of persons in this predicament is to survive off the most filling, but least costly foods and beverages available (e.g., sugary sodas) and, in response to receipt of the next government check, overeat. In any practical application of the diet methods we described, consideration of how to assist the participants to avoid this type of nutritional rollercoaster will be important.

Conclusion

When our team undertook to write this chapter, we assumed that some who read it, will do so to inform or guide further research. Others, we assumed, would do so to learn of practical supports for individuals with IDD needing to deal with weight problems. Our research projects were guided not just by scientific hypotheses, but also by the observations that preceded the pilot research and occurred in the pilot. Thus, we elected to share our overall experiences as a story, thru which we could share both data and anecdotes, and hopefully have satisfied both audiences.

Incontinence

Johnny L. Matson and Abigail Issarraras

Introduction

Incontinence is a debilitating and common problem among persons with intellectual disability (ID). Typically, this larger problem is broken into four subtypes: diurnal and nocturnal enuresis, and diurnal and nocturnal encopresis. Not only are those problems frequent, but they are more common among persons with ID than they are in the general population (von Gontard, 2013). If not treated, these problems may persist into adulthood. They restrict access to activities, increase the likelihood of infections, and are associated with comorbid psychological problems such as attention deficit hyperactivity disorder (ADHD), anxiety, and depression (von Gontard, 2013).

Several factors put the person at greater risk for problems of incontinence. Hellström, Hanson, Hansson, Hjälmås, and Jodal (1990), for example, studied the toileting habits of 3556 7-year-old children in Sweden. They found that daytime incontinence was more common in girls while nocturnal incontinence was more common in boys. Other factors that appear to be established risk factors include parental history of toileting problems, recent emotional stress, urinary infections, and a history of bedwetting among male siblings (Sureshkumar, Craig, Roy, & Knight, 2000).

The notion that establishing risk factors is important is not new, although early studies tended to be case studies versus more methodologically controlled reports. A case in point is a paper by Bert Beverly published in 1933. He reports on approximately 250 cases of mostly nocturnal enuresis. It is noted that 64% of the cases were boys. He posits that mental health concerns may contribute to incontinence. For example, Beverly (1933) observed that the children in his study were often nervous, fearful, experiencing "infantile habits" such as thumbsucking, nail biting, and frequent crying. He also speculated that jealousy of a new sibling may also contribute to incontinence. The author also states that incontinence can stop as soon as incentives are introduced. Many of these assumptions have proven to be incorrect over time, but not all of them. Certainly, incentives (read reinforcement) have proven effective, but more structure and various learning theory based strategies above and beyond reinforcement are also required in most cases.

The intensity of the intervention in general, increases as the level of cognitive disability increases. As Böhmer, Taminiau, Klinkenberg-Knol, and Meuwissen (2001) point out, for a sample of 215 people with ID who were hospitalized,

laxatives for constipation were frequently prescribed with poor results. Developing effective psychological interventions for constipation is quite important, as a result, since they found that 69% of their sample evinced this problem.

Interventions based on operant conditioning dates to at least the early 1960s. Ellis (1963) employed a stimulus-response model. Bladder extension and approach to a toilet were reinforced in a person with ID living in a developmental center in Louisiana (USA). The shaping of this response eventually led to reinforcement of voiding in the toilet. Ellis (1963) also attempted to establish times when the child was likely to void. He prompted toileting at these times. This approach has been referred to as a "timing method."

Dayan (1964) who was the Director of Psychology at the Sunland Training Center in Mariana, Florida, described the implementation of Ellis' toilet training model at the Florida center. The residents treated were 6–12 years of age with IQs of 30 and below. He identified 25 children as "soilers" or "wetters" or both. Children were placed on the toilet every 2 h. If the child voided while on the toilet they were reinforced, but they were ignored if they did not void. Dayan (1964) reported success as measured by a marked decrease in clothing that needed to be washed.

Several early treatment studies of incontinence for people with ID used Ellis' model. One of these studies was published by Waye and Melnyr (1973). They treated a 15-year-old male who was blind and who had profound ID. According to the authors, he only had one or two words. He was placed on the toilet for 5 min from every 15 min while he was actively mobile and walking around the institutional ward. Time was taken off his training for meals. Reinforcement for voiding included rubbing his head and ears and saying the child's name. Marked improvements were noted as measured by fewer dirtied clothes and less time sitting on the stool before voiding. Improvements were still evident at a 1-year follow-up. These early successes spurred additional study and development.

Assessment

Assessment generally falls into two broad categories. One involves frequency counts of voiding, time on the toilet before voiding (i.e., less time is better), and counting soiled clothes. Fluid intake and volume of voiding have also been used as outcome measures (Hoebeke, Bower, Combs, De Jong, & Yang, 2010). A second type of assessment used less frequently is norm-based scales. These measures are used to survey populations or individuals to determine the particular toileting problems that they experience. An example of this type of measure is the Profile of Toileting Issues (POTI; Matson, Neal, Hess, & Kozlowski, 2011). The scale was specifically developed to assess/screen for toileting problems in persons with ID. Their sample consisted of 108 people with ID who were 16–89 years of age. Participants ranged from mild to profound ID. The scale is a paper and pencil informant test with 56 items. Items are scored as either No Problem or Problem Present or Does Not Apply. Typical items include lost toileting skills, has daytime toileting accidents, hides soiled clothes, has blood in stool, and has hard stools. The test has good reliability and validity.

In another study using the POTI, Matson, Horovitz, and Sipes (2011) found that there were several very frequently endorsed items. These problems included has toileting accidents during the day, has toileting accidents at night, has had wet underwear in the past month, and is on a medication with a known side effect of constipation. One major advantage of a scale like this is to educate staff on a standardized set of problems that need to be addressed. Also, a screener of this sort helps identify problems of incontinence that require treatment.

General Treatment Issues

One of the first issues that need to be addressed is medical concerns. In some cases, particularly where severe physical and/or cognitive disabilities are present, voiding may be difficult to train (e.g., spina bifida). Also, cognitive and/or sensory limitations may make it difficult to teach the requisite skills. Secondary to these concerns are medical problems caused by the toileting problems. Impactions can cause distress or severe damage to the bowel and may necessitate the use of medications that may have side effects and which can become habit forming. Urinary tract infections also occur in approximately 10% of children with urinary incontinence (Loening-Baucke, 1997). These problems are more common in girls than boys.

Psychological Treatment

A number of psychological based issues have been noted as well. Effective treatments typically involve operant and classical conditioning. As a result, these methods are often labor-intensive. Levine and Elliot (1970) address the issue of toilet training persons with profound ID, where limited staff are available. They worked with 103 people ranging in age from 4–48 years old. Their focus was on providing general guidance on the principles of applied behavioral analysis (ABA) during a 10-hour workshop. Based on this introduction to the principles of learning, the authors reported a marked decrease in accidents and in the amount of soiled linen.

Baumeister and Klosowski (1965) took a somewhat different approach. They focused on a group approach to toilet training for persons with severe ID who lived in a developmental center. The individuals treated could not feed themselves, could not speak, and in general, were very limited with respect to their adaptive behavior. The clients who were treated were 10–25 years of age, and all of them could walk. The methods of treatment described previously were used and again proved to be effective.

Equipment

The most famous and enduring technical advance for incontinence is the bell and pad program devised by Mowrer and Mowrer (1938). Sensors are connected when the person wets the bed, causing a buzzer to sound. Over time the person is conditioned to awake before voiding. This method has been used extensively, primarily for persons with typical cognitive development. However, Azrin, Bugle, and O'Brien (1971) developed a daytime variant for persons with ID. The device was named the "pants alarm." These authors trained four persons with profound ID. Two snaps are attached to the crotch of the underwear and to a circuit box that is worn at the waist on a belt. A toilet with a sensor affixed to it that sounded when urinating in the toilet was also used. Drinks were provided every 30 min, and each child was placed on the toilet at 30 min intervals. Voiding in the toilet resulted in praise, hugs, and candy. Urinating in the underpants resulted in one spank to the buttocks, followed by a 10 min time-out. The authors report success with the method.

Chang, Lee, Chou, Chen, and Chen (2011) also describe a mobile system to detect voiding. In their paper, a 9-year-old boy with multiple disabilities was trained. They also used a wetness sensor. This technology was paired with reinforcement for appropriate voiding in the toilet versus his pants.

Client Characteristics

A series of studies have also been published looking at factors associated with client risk-factors. Smith, Britton, Johnson, and Thomas (1975) specifically address the issue of adults with profound ID. As they rightly point out, most research and clinical focus is and has been on children, a factor which is still largely existent in current practice. They suggest that these problems with incontinence may also be very common in adults, particularly among persons who have severe deficits in cognitive functioning. Ambulation can also be an issue, especially for persons diagnosed with severe or profound ID. Additionally, these persons may have difficulty following instructions. Therefore, considerable structure and routine are necessary.

Lancioni (1980) also underscores that point in toilet training persons with profound ID. He notes that physical handicaps are also common in this population, and the focus of treatment therefore is often on prevention rather than the promotion of independent toileting. In his study, nine children and adolescents between 8–16 years of age who had profound ID, and were deaf and blind were trained. They used potty-alert and pants alarm devices to help staff detect accidents. He defined toileting behaviors as independent toileting, partially independent toileting, incomplete toileting, attempted voiding, assisted voiding, and accidents. Water and soft drinks were provided frequently to increase voiding trials. Participants were seated close to the bathroom door so they could touch it. Urination attempts were prompted every 20 min. Edible reinforcers were provided for self-initiations. Over time and with increased success, the chairs participants sat in were moved further from the bathroom. Accidents were followed by cleaning up the chair and floor right around it. The author reported good success using this method. The take away with respect to persons with ID is that modifications to assessment and treatment are likely, and the therapist must be prepared to work with adults as well as children. This point is underscored by Smith and Smith (1977). They trained 13 institutionalized persons with ID over a range of ages. They concluded that children in their sample could be trained much faster than adults over the age of 25 years. Smith and Smith (1977) note that younger children had an 80% decrease in toileting accidents in 5–6 weeks while older more cognitively impaired persons required 8–9 weeks of training to acquire similar improvements. Along these same lines, Dalrymple and Ruble (1992) noted that lower cognitive and by extension verbal skills correlated with the achievement of continence at later ages. These factors point to Bettison's (1986) hypotheses that incontinence is largely due to difficulty learning.

Training Issues

The bulk of toilet training with persons with ID has involved professional staff, primarily in the field of psychology. However, for efficiency and to promote generalization, parents have also been included as trainers in some cases. Ozcan and Cavkaytar (2009) describe one such attempt. They note that the parent may play several roles including a parenting role, but also they can serve as an advocate and as a teacher. They also point out that parents may be particularly helpful in eliminating incontinence since they spend more time with their children than any other adult. These authors also suggest that including parents in training can be very valuable in promoting generalization, and ensuring the lasting effects of treatment.

Feldman, Ducharme, and Case (1999) also note that for families who have children with ID are more likely to be neglected. These authors state that researchers show that parents are particularly responsive to training packages. Feldman et al. (1999) report that common characteristics of these training models include reinforcement, feedback, modeling, pictures used as prompts, and standardized instructions. In their study, a picture-based training manual was used to train basic skills in changing diapers, treating diaper rash, how to give their child a bath, and personal safety tips. They note that skills were largely maintained at a 3-year follow-up.

Treatment for Enuresis

Parent involvement in training has also been emphasized by Rinald and Mirenda (2012). In their paper they describe a training workshop for six parents of developmentally disabled children. A PowerPoint presentation was followed by role play practice with a mannequin and supervised by the workshop leader. Parents then implemented the behaviorally based treatment at home for 5–8 days with phone support from professionals. Reinforcement of appropriate voiding, increased fluid intake, scheduled voiding attempts, redirecting the child when accidents occurred, and specific strategies to increase generalization and maintenance proved to be effective.

Dalrymple and Ruble (1992) also addressed parents in their survey of toileting habits of children with autism. As the reader is likely aware, upwards of 70% of persons with autism also experience ID, thus making this population in large part, compatible with a general ID population with respect to issues in toilet training. Delays in training were commonly reported. For example, 20% of parents needed more than 3 months to establish successful training, despite the fact that training was started later than is the case for typically developing children. The parents also reported a regression in skills for 30% of the 100 children who were trained. Most parents used positive reinforcement while about 1/3 resorted to punishments such as scolding. Risk factors for establishing appropriate toileting included ID and lack of verbal skills. Sensory impairments are also a major risk factor. Luiselli (1994) notes that few studies have focused on ID and sensory impairments. In his paper using a toileting schedule, reinforcement and prompting were employed with children in a residential setting who had these deficits.

Mahoney, Wagenen, and Meyerson (1971) in another early toilet training study taught three typically developing children and five children with ID. Children in this experiment had to be ambulatory, transportation was required, and the families had to agree to participate for 8 weeks. Only one of the children with ID had speech despite the fact that they ranged in age from 4 to 9 years old. These authors used a pants alarm which buzzed when a toileting accident occurred. Parents were asked to not feed or provide drink for an hour before training since food and praise were primary reinforcers in the treatment. Using verbal and physical prompts plus reinforcement, the children were taught to walk to the toilet when the pants alarm went off. Other target behaviors in the sequence included lowering their pants, sitting (or in the case of boys, standing) near the toilet, voiding, and then replacing clothing. Gradually fading out prompts including the pants alarm occurred as success in toileting skills increased. These methods proved to be successful.

Many of these studies aimed at curbing incontinence in persons with ID use a similar set of psychologically based principles. Sells-Love, Rinaldi, and McLaughlin (2002) describe a treatment study with a 19-year-old female carried out in a special education classroom. The program was teacher implemented and resulted in a decrease in the frequency of wet pants. Hyams, McCoull, Smith, and Tyrer (1992) did a 10 year follow-up of 14 persons with severe or profound ID who were trained using operant methods. They note that complete independent training was not maintained. However, they report that maintenance was better for persons who received intensive individual training versus group training.

Taylor, Cipani, and Clardy (1994) describe the training of an incontinent 10-year-old with autism and severe ID. In their study a modified version of the very popular Azrin and Foxx rapid toileting procedure was used (Azrin & Foxx, 1971). The method involved massed practice using operant conditioning and modeling. A time schedule for prompting attempts to void in the stool was followed by edible reinforcers and praised for successful voiding. In their initial study, nine adult males with profound ID were trained. In addition to the methods of applied behavior analysis first described, a pants alarm was employed. When accidents occurred, the clients were to have the alarm deactivated by the trainer. Next, the resident walked to the laundry room to get clean clothes. Then they changed their clothes. A one-hour time out then followed. No fluids were ingested within 30 min, and the toilet schedule of sitting on the stool every 30 min continued.

For the present study, the primary modification to the Azrin and Foxx (1971) method was the removal of the child's pants 5 min after being given liquids. Pants remained off until a correct voiding episode occurred. Each successful elimination resulted in the addition of 1 min to the pants-on period. A modified Azrin and Foxx treatment was also described by Chung (2007). This author treated a 12-year-old male with ID. The main changes included shortened training from eight to three hours daily. Secondly, the overcorrection procedure where the child was required to clean up after accidents was dropped.

Didden, Sikkema, Bosman, Duker, and Curfs (2001) also used a modified Azrin and Foxx procedure. They trained six children with a specific genetic form of ID, Angelman syndrome. Not only did they obtain good effects, the effects also were largely still maintained 2½ years later.

Continuing the theme of successfully using operant methods to train continence in children with ID, Smith, Smith, and Kwok Yi Lee (2000) describe three cases where training including shaping by getting closer and closer to the toilet and reinforcing appropriate responses. The kids had ID and were between the ages of 8–12 years old. Two children had mild ID (one person had fragile X syndrome) and one child had moderate ID. These children were described as having been treatment resistant. To reach the criteria for continence, the time required was 51 days, 54 weeks, and 130 weeks respectively; this is much longer than what has been reported in most toilet training studies employing persons with ID.

Luiselli (1996) used a stimulus control procedure to teach toileting skills to a 7-year-old girl with pervasive developmental disorder-not otherwise specified (PDD-NOS). She was prompted to sit on the toilet and was reinforced. The program took about 2 weeks and proved to be successful.

A somewhat different approach was described by Hagopian, Fisher, Piazza, and Wierzbicki (1993). They treated a 9-year-old boy with profound ID. Major components of treatment included social praise and edibles for appropriate voiding and limited attention while changing clothes after an accident. The latter procedure includes no verbal interaction and minimal physical interaction. An addition twist to the intervention was described as water prompting. This method involved gradually pouring about five ounces of lukewarm water over the child's private areas while seated on the toilet. Also, the child engaged in self-injurious behavior (SIB) during the day long training (most likely with an escape function). Blocking SIB attempts and reinforcing intervals where SIB was absent was the treatment for this challenging behavior. This treatment proved to be effective.

Kroeger and Sorensen-Burnworth (2009) underscore the popularity of the Azrin and Foxx (1971) toileting method. In this review, the authors note that this approach is the most commonly studied procedure among persons with ID, autism, and other developmental disabilities.

Bettison, Davidson, Taylor, and Fox (1976) describe a procedure involving changing and mild punishment to produce an effective intervention for daytime enuresis training. Training components such as praise for voiding in the toilet are described for persons with ID who ranged in age from 7 to 50 years of age. Before the advent of the Azrin and Foxx (1971) approach, behavioral methods used fewer components and more punishment. Even within the original Azrin and Foxx (1971) method, the mild punishment in the form of overcorrection was dropped in later studies. Also, as the field has advanced, guidelines regarding what procedures are best at various stages of development have been addressed.

Some aspects of early training methods have continued to be popular. For example, auditory signals as a discriminative stimulus, practicing steps of the voiding process, prompting to the toilet, and developing skills regarding pants down and pants up (Van Wagenen, Meyerson, Kerr, & Mahoney, 1969). Another of these skills which has been commonly stressed for decades is the focus on adequate fluid intake, which of course is linked to successful trials of voiding (Van Laecke, Raes, Vande Walle, & Hoebeke, 2009).

More recent efforts at toilet training have focused on modeling, and video modeling in particular (Keen, Brannigan, & Cuskelly, 2007). In their study, five boys with autism were trained on daytime urinating. Video modeling was paired with shaping and reinforcement strategies. Children who received modeling had more significant gains versus those children who did not.

Nocturnal enuresis has also been a source of attention in the experimental literature. Smith (1981) describes the training of five adolescents and young adults between 15–21 years of age. All of the participants were diagnosed with severe or profound ID. Three of these people had extreme hyperactivity, verbal and physical aggression, and temper tantrums, which of course complicated the learning process. Trainers were two nurses who worked the night shift. After a 2 week baseline, bedding was checked hourly to determine if it was wet. If wet, the sleeper was awakened and clothing was changed before going back to sleep. During the intervention and alarm system was used to alert the client and staff to a voiding episode. When the alarm sounded, the nurse would wake up the trainee, if the alarm had not been sufficient. The nurse then encourages the client to sit on the toilet by the bed and try to urinate. The trainee was asked to feel the dry sheets as a means of differentiating wet from dry. The wet items were then placed in the dirty laundry. Being dry for the entire evening was followed by a range of reinforcers including extended bedtime, tea, biscuits, access to a juke box, tokens, and trendy clothes. These rewards were not available if the trainee had wet the bed. Length of training ranged from 20 to 93 weeks before continence was achieved. Gains were maintained at a 2-year follow-up.

Medical Treatments for Encopresis

Encopresis has also been treated, in this instance with a general population of children (over 100) at the University of Oklahoma School of Medicine (Wright & Walker, 1978). The main point here is the psychologically based treatments for this problem have been available for some time. Also, many of the methods and procedures are similar to what has been described for the treatment of enuresis. The steps of their procedure began with a physical exam. We would note that this step is certainly warranted given the physical issues such as impactions, that can results and which can cause damage to the intestinal tract. However, for enuresis medical complications are far less likely. Thus, this step may not be necessary unless infection, pain in urinating, or other complications are present.

The second step of the procedure described by Wright and Walker (1978) involved an interview with the parents. The main goal here was to rule out potential psychological disturbance, ID, or behavior problems that may supersede toileting issues. Also, these issues would of course complicate the training process. Step three involved explaining the training process to the parents, and, where applicable, to the child. Step four involved emptying the colon, usually with an enema the night before the program was initiated. Of course, for enuresis this would not be done. The child was then to go to the restroom first thing in the morning. The child sits on the stool, and if they are able to void feces, social and tangible reinforcers are given.

If voiding does not occur, the parent inserts a glycerin suppository and then dresses the child. Here we would note that current thinking would most likely delete enemas and suppositories unless an impaction was present or the child had not passed feces for two or three days with the other training components in place. Additionally, close supervision by the pediatrician would be in order.

These authors note that by the completion of breakfast the suppository should have taken effect. At that point, the child could be taken back to the bathroom for a second voiding attempt. Successful voiding would be followed by verbal and tangible reinforcers. However, the quantity would be less than in instances where successful voiding occurred on the first attempt. If a third attempt was needed before school, a second enema would be used to prompt toileting. As a personal observation, if a procedure like this were to be used, it would be advisable to start the treatment on a Saturday when practical, so that the two days of training would be possible without school issues.

The authors suggest that successful voiding should be possible with only occasional enemas after the first few days. After school the child is checked to determine if any soiling had occurred. When the child was clean, they earned a reward. If the child was soiled, a mild punisher was used. Prompting to the toilet and the use of reinforcement and punishment are of course hallmarks for the bulk of the enuresis programs. Common reinforcers these authors endorse include money, candy, periods of attention from the parents, small toys, and extra privileges. Commonly used punishers they endorse are restricted TV viewing (or possible phone/computer use), monetary fines, extra chores around the house, and loss of privileges.

Lowery, Srour, Whitehead, and Schuster (1985) in another larger study of encopresis treated 58 children for encopresis. After meals, children were prompted to void in the toilet. If defecation did not occur during a 2-day period, enemas were used to prompt defecation. This intervention obviously had a more medical focus than many of the treatments described previously. However, the authors did note considerable gains for most children with respect to continence.

Psychological Treatments for Encopresis

A brief review of psychologically based treatment for encopresis follows next. Most of these interventions pair applied behavior analysis with timed/routine scheduled toileting attempts. In one study that diverged from this model reported by Carpenter (1989), a 22-year-old man with Prader–Willi syndrome was treated. In this case study, the author reported using group therapy, play therapy, family therapy, and medication. This approach cannot be endorsed here due to the lack of controlled data. However, it is worth mentioning to demonstrate the therapeutic approach to encopresis is not a monolith.

A more commonly used approach incorporating applied behavior analysis is described by Doleys and Arnold (1975). They treated an 8-year-old boy using the full cleanliness training model, where the child cleaned up all aspects of the soiling accident. This procedure was paired with social and tangible reinforcement for appropriate toileting. The authors report good success, although inconsistencies by the parents resulted in some regression at the follow-up.

As noted, most of the treatments that have been described in the literature on encopresis have focused on various aspects of learning theory. Piazza, Fisher, Chinn, and Bowman (1991), for example, describe a two-step procedure consisting of increasing bowel movements and discrimination training. This study used observations of possible signs of defecation and pant checks. If bowel movements occurred in the stool and when the person was clean at pant checks, social praise and preferred objects were used as reinforcers. The two trainees were a 5-year-old girl and 15-year-old male, both of whom were diagnosed with profound ID. They were taken to the toilet at regular intervals and prompted to void. After 7 weeks, 100% continence had been achieved for both clients.

Another learning based treatment involved prompting to sit on the stool after meals, which was described by Smith, Franchetti, McCoull, Pattison, and Pickstock (1994). The four participants diagnosed with severe ID trained were also given an increase of fiber in their diet when treatment began. These authors report that the trainees all closely approach the goal of normal toileting.

Encopresis is a problem of considerable magnitude in the ID population. Huntley and Smith (1999) make this point and go on to describe a study they did on the topic. They describe follow-up on 9 people with severe ID who had received behavioral treatment, similar to what has already been described for encopresis. These authors report marked improvement in 8 of the 9 cases with 6 people being relatively accident free.

Conclusions

After more than five decades of development, both clinicians and researchers have together arrived at several fundamentals regarding treatment of incontinence among persons with ID. First, the problem is common in this population and may extend into adulthood if not properly addressed through intensive treatment. Second, this set of problems can produce a great deal of stress and can be a major impediment to independent living (Matson & LoVullo, 2009). Third, comorbid behavior problems such as noncompliance, aggression, and temper tantrums are common. Problems of this type result in the need to modify how toileting issues are assessed, and inevitably impact the treatment planning to address such toileting issues. Fourth, people who have the most serious cognitive deficits are likely to require more intensive interventions over larger periods of time to produce meaningful effects.

The fifth point, and perhaps the most important, is that treatments are generally effective for both enuresis (diurnal and nocturnal) and encopresis (Lancioni, O'Reilly, & Basili, 2001). A host of different treatment elements have been described in the literature including psychotherapy. Having said that, most studies employ several common elements, including whether the enuresis or encopresis occurs during the day or at night. Scheduled times for toileting attempts are common and are often paired with prompts to the toilet by a caregiver be it a professional staff member or a family member. Next, prompts are also used to get the persons to undress and sit on the toilet. When voiding occurs, social and tangible reinforcers are given, at least during initial successful attempts. Also, what we will call dry/clean awareness is a frequent aspect of the treatment. This has been accomplished with a bell and pad alarm at night or pants alarm during the daytime. Another method, which avoids these devices, is to simply have the trainee feel clothing or sheets to determine whether or not they are clean and dry. Modeling is another component which has been incorporated in this model. This can be done with a doll or via videotape. Other components frequently used include gradually fading (i.e., decreasing) the number of prompts, scheduled visits to the toilet, and reinforcement as the trainee becomes more proficient in independent toileting. Early studies used some mild forms of punishment; punishment procedures have included the trainee being involved in cleaning up when accidents occur, a brief (e.g., 5 min) loss of attention, or a designated period without receiving preferred tangible reinforcers. More recently, most researchers have dropped aversive aspects of treatment. Without these punishment procedures, treatments still appear to be very effective.

Moving forward, an important aspect of treatment should be doing as much as possible to avoid “reinventing the flat tire.” Cost-effective, positively reviewed interventions that can be implemented in days or a few weeks are available. However, with each new generation, the potential for at least some of this information being lost is always possible. One method to counter this has been the large number of “How-To” books that have been written and which have largely targeted parents. Incorporating this information into college and high school classes on psychology and education would seem to be another potential means of disseminating this information. No doubt, technology for treating incontinence in persons with ID has been one of the bigger success stories in the field over the last century.
