About the Editor

Johnny L. Matson, Ph.D. is Professor and Distinguished Research Master in the Department of Psychology at Louisiana State University, Baton Rouge, LA, USA. He has also previously held a professorship in psychiatry and clinical psychology at the University of Pittsburgh. He is the author of more than 800 publications including 41 books. He served as the Founding Editor-in-Chief for the journals *Research in Developmental Disabilities* (Elsevier) and *Research in Autism Spectrum Disorders* (Elsevier) and currently serves as the Editor-in-Chief for the *Review Journal of Autism and Developmental Disorders* (Springer).

Part I

Foundations

History of Intellectual Disabilities

1

Emily A. Roth, Shivali N. Sarawgi,
and Jill C. Fodstad

Introduction

The field of intellectual disability (ID) traces its history back to early Egyptian, Greek, and Roman societies. Civilizations around the world interpret mental illness, specifically ID, in a variety of ways. Beliefs regarding ID are influenced by the current stigmas, society's understanding of mental health, and the conceptualization of the cause of ID. Furthermore, the terminology used to identify individuals with ID has paralleled the societal climate of the era. To understand the current literature and perceptions of ID, it is important to first review the history of conceptualization, terminology, research, treatment, legislation, and beliefs in this area.

On the following pages, we provide a timeline to help outline the following information presented in this chapter; however, this highlights the most important aspects of history and does not exhaust ID in its entirety. As societies across history attempted to conceptualize ID, progress toward modern thinking has been nonlinear and often includes periods of backward regression due to the religious, political, or social beliefs of the time. Advocacy groups helped propel this movement forward as they disseminated information on ID and advocated for the rights of individuals with disabilities (Fig. 1.1).

Ancient Perceptions

For much of history, ID was undifferentiated from mental illness—both are poorly understood constructs and often the target of stereotypes and stigma. As such, individuals with ID often suffered from societal injustices due to beliefs that symptoms were a by-product of a number of causes, including the individual or their families being cursed or punished for wrongful acts. The earliest definition and descriptions of ID can be found in writings as far back as ancient Egypt (Scheerenberger, 1983). During this era, ancient Egyptians were focused on developing religious and medical procedures to treat a variety of disabilities and problems (Richards, Brady, & Taylor, 2014). However, in ancient Greek and Roman civilizations, the community negatively viewed all disabilities; specifically, Sparta is infamous for killing those with disabilities (Richards et al., 2014). Ancient Greek philosophers, such as Plato and Aristotle, wrote negatively about individuals with disabilities. More specifically, Plato suggested selective mating, a foreshadowing of

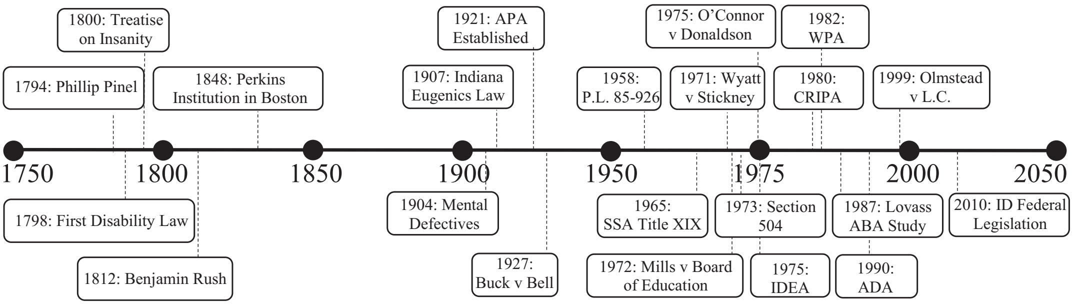

Fig. 1.1 Intellectual disability timeline. This figure illustrates key dates in the history of intellectual disabilities

the eugenics movement (Galton, 1874, 1904; Gillham, 2001a; Richards et al., 2014; Scheerenberger, 1983). Although early Romans pardoned the lives of infants born with disabilities; later Romans returned toward the tendency of infanticide for individuals with disabilities (Richards et al., 2014).

ID during the Middle Ages revolved around religion and superstitions, but Covey (1998) argued that societal response to disabilities varied by the specific disability, its context, and beliefs on etiology. Despite influences of the early Church in eliminating infanticide by providing institutions for individuals unwanted by their families due to disabilities, some argue that Luther's descriptions of the "feebleminded" were excessively negative (Harris, 2006; Richards et al., 2014). However, others argue that Luther's definition of "feebleminded" encompasses spiritual content rather than ID (Andrews, 1998). Nonetheless, during the Restoration period, "idiocy" and general mental illness were associated with immorality resulting in moral punishment (Andrews, 1998).

Philosophy's Influence

History is fraught with many philosophical descriptions and explanations for ID; however, it is important to understand the sociocultural, intellectual, and philosophical foundational contexts did not conceptualize ID as it is now defined (Groce & Scheer, 1990). Historical documentation includes words and phrases asserted to be historical terms for ID (e.g., "fool," "stupidity," and "idiot"), which refer to individuals with a variety of presentations, including mental illness and physical impairments, as opposed to specifically ID (Goodey, 2004). In the late seventeenth century, John Locke was one of the first individuals to differentiate intellectual and mental disabilities from physical disabilities. However, Locke's idea of madness and mental disability truly integrates concepts of intellectual and affective deficits and disorders (Charland, 2010). Furthermore, earlier Renaissance physicians, Paracelsus and Platter, suggested a differentiation between "foolish[ness]," "feebleminded[ness]," and mental illness (Andrews, 1998; Goodey, 2004). In 1664, Willis, another Oxford philosopher and pioneer of brain anatomy, further contributed to the understanding of "stupiditas" and idiocy by describing these states as disease-like and pinpointing various etiologies including heredity, trauma, other diseases, and "animal spirits" (Andrews, 1998; Goodey, 2004).

Asylums

During the seventeenth and eighteenth centuries, despite advances in medical and philosophical understanding (precursors to psychological understanding) of ID, affected individuals still experienced stigma and poor quality of care. They were institutionalized in asylums, hospitals, and prisons during this Age of Enlightenment and Reason. Poor living conditions, neglect, and various forms of abuse were the norm for those who lived in institutions. Furthermore, many believed that basic medical care was not a necessary privilege for individuals with ID. For example, Bethlem Hospital in England rejected individuals deemed "idiots," as they were viewed as outside of the hospital's treatment competence (Andrews, 1998). Toward the end of the seventeenth century, the beliefs of psychiatrist, Philippe Pinel, initiated a paradigm shift in the level and quality of care for individuals with ID and mental illness. Specifically, Pinel advocated for moral treatment of individuals with ID and their release from hospitals and prisons. He was and continues to be renowned for freeing patients from insane asylums in La Bicetre and later La Salpetriere.

By 1794, Pinel published an essay, "Memoir on Madness" that encouraged the study of psychopathology, and by 1798, he published the first edition of his classification of mental disorders (*Nosographie philosophique ou methode de l'analyse appliquee a la medecine*), which served as the first classification of its kind. The *Nosographie* notably differentiated between five disorders, separating ID ("ideotism or obliteration of the intellectual faculties and affections") from dementia, mania, mania without delirium, and melancholia (Pinel, 1806). Pinel's definition of idiotism is not equivalent to modern conceptions of ID. Pinel's student, Jean Marc Gaspard Itard, altered society's perception of how ID was viewed and furthered the potential for treatment and education through an emphasis on humane treatment. The combination of Pinel's work and William Tuke's establishment of humane treatment for patients with mental illness through the founding of the York Retreat for the mentally ill in 1792 served as the foundation of asylums emphasizing moral and humane treatment for patients. Additionally, these institutions began appearing in the early nineteenth century as places of refuge (Dunkel, 1983).

Pioneering the United States

As Pinel and Itard were working in France, a similar movement began in the United States started by Benjamin Rush, a founding father of the country and often considered the father of American psychiatry. Rush also advocated for more humane treatment of mental illness leading to the creation of a separate ward for such patients. In 1812, Rush published *Medical Inquiries and Observations, Upon the Diseases of the Mind*, which served as the first attempt to explain and treat disorders of the mind in the United States. Early nineteenth-century Americans witness the paradigm shift in increased attention to the ideas of mental disabilities and ID. However, at the time, the differentiation of mental disability and ID was not complete; although philosophers attempted to describe it in the past. In the 1930s, James Prichard, another notable psychiatrist, theorized a distinction between ID and mental illness or "intellectual [versus] moral insanity," serving as the foundational definition of this distinction (Carlson & Dain, 1962). Furthermore, advances in awareness of mental illness and general psychiatry significantly relate to advances in understanding and treating ID.

In 1818, the Asylum for the Insane (later the McLean Asylum for the Insane in 1826 and then McLean Hospital in 1892) opened in Massachusetts (Little, 1972) further transforming the quality of care for individuals with ID. Like other asylums of its time, the ideas of "moral treatment" influenced by Pinel and Tuke heavily influenced the model of care for the Asylum (Dunkel, 1983; Pinel, 1806). The McLean Asylum's groundbreaking research and its transition to Belmont, Massachusetts, established the transformation from institutional settings to a more residential environment (Little, 1972). By 1848, Samuel Gridley Howe opened the Experimental School for Teaching and Training Idiotic Children, within the Perkins Institution (a residential institution for the blind), in Massachusetts, serving as the first residential facility for those with developmental disabilities. Now called the Walter E. Fernald Developmental Center, this school became a leader in providing education to individuals with ID. The Experimental School for Teaching and Training Idiotic Children helped change current beliefs to demonstrate that individuals with ID are capable of learning and need to be appropriately challenged. During the mid-nineteenth century, the

Association of Medical Superintendents of American Institutions for the Insane was established, which eventually became the American Psychiatric Association in 1921 (Hirshbein, 2004). This organization was influential in the advancement of science and understanding mental illness and ID.

Eugenics Movement

While the early nineteenth century was marked by the emphasis of humane treatment of those with mental disabilities and ID, the latter part of the century was marked by the eugenics movement, leading to a de-emphasis on ethical treatment and increased stigma against individuals with various disabilities, including ID. The movement was started by Sir Francis Galton who originated the word "eugenics" in 1883. Originally developed from Platonian thought of artificial selection, eugenics occurred as a treatment of individuals with ID and other mental disabilities in early civilizations and medieval times (Richards et al., 2014; Scheerenberger, 1983). However, Galton (1904) conceptualized eugenics as a science focusing on the "improvement" of the species, with emphasis on the influence of nature versus nurture (Galton, 1874). Galton and eugenics were heavily influenced by Charles Darwin's publication, *On the Origin of Species*, in the mid-nineteenth century (Gillham, 2001a). In Galton's distinction between nature and nurture, he indicated that human ability was most strongly influenced by nature. Through this belief, Galton advocated for the heritability of intelligence and cognition (Galton, 1865, 1874; Gillham, 2001a).

As noted above, an era's sociocultural makeup heavily influences conceptualizations of intelligence and ability/disability. Galton's applications of natural selection through the eugenics movement were in opposition to other societal movements of his time during Victorian England (Galton & Galton, 1998). The eugenics movement developed at the same time as societal reforms in England, such as the Anti-slavery Bill, educational acts, protections for the poor, and other social reforms. Galton's work led to the creation of a eugenics register, an arbitrary scale of "worth," and classification of families as gifted, capable, average, or degenerate. However, this measure of intelligence was not available during his time nor proposed by Galton (Galton & Galton, 1998; Gillham, 2001b). Regardless of any scientific merit of Galton's work, it instigated a societal movement that holds significant impact on the treatment of individuals with disability (as well as other socially constructed groups) including sterilization, the restriction of movement, and segregation of individuals with ID.

Twentieth-Century Eugenics and Involuntary Sterilization Laws

Eugenics has existed for centuries, with many influential leaders including Charles Darwin, Cesare Lombroso, Thomas Malthus, Arthur de Gobineau, and Herbert Spencer (Gejman & Weilbaecher, 2002). The eugenics movement gained traction when elected officials focused on ensuring the quality of the population by minimizing and decreasing the number of feebleminded, insane, imbeciles, and idiots (Kendregan, 1966; Stern, 2007). Supporters of eugenics posited that affected individuals were a social burden to the country and should not procreate (Sofair & Kaldjian, 2000). Within the United States, Indiana was the first state to pass a compulsory eugenic sterilization bill in 1907. Thurman Rice piloted sterilization outside of institutions within the state of Indiana. Following Indiana's passing of this legislation, 29 states created their own sterilization laws, including 18 that involved involuntary sterilization (Kendregan, 1966; Sofair & Kaldjian, 2000). Within the first 40 years of these laws, almost 40,000 people underwent sterilization in the United States (Proctor, 1988). Over time, challenges to the constitutionality of these laws occurred. Indiana's sterilization laws were deemed unconstitutional in 1921; however, new legislation (reinstating sterilization) was approved in 1927 (Stern, 2007). The change in beliefs regarding sterilization was not limited to the state of Indiana: consecutive cases on the grounds of constitutionality of sterilization occurred across the United States (Kendregan, 1966; Sofair & Kaldjian, 2000; Stern, 2007).

The Supreme Court case, *Buck* v. *Bell* (1927), served as a monumental shift in the perception of the legality of involuntary sterilization (Berry, 1998; Kendregan, 1966; Siegel, 2005; Sofair & Kaldjian, 2000). The individual who led to *Buck* v. *Bell* (1927) was Carrie Buck, a young woman in Virginia whose mother could no longer care for her (Berry, 1998). Carrie, a teenager, became pregnant as a result of rape. Despite her admission, the courts considered Carrie, her mother, and her infant daughter to be "feebleminded," resulting in Carrie's institutionalization in 1924 when she was 18. The superintendent petitioned to the Board of Virginia Colony that Carrie be sterilized to prevent her from having more children that required further services. The board approved this motion; however, Carrie's lawyer appealed her case to the Virginia trial court, then the Virginia Supreme Court, and finally the US Supreme Court (Berry, 1998). The US Supreme Court ruled in favor of involuntary sterilization. Justice Holmes gave the US Supreme Court's majority's opinion in *Buck* v. *Bell* (1927), claiming that "It is better for all the world, if instead of waiting to execute degenerate offspring for crime, or to let them starve for their imbecility, society can prevent those who are manifestly unfit from continuing their kind" (p. 207). Prior to the court's determination, 23 states already enacted legislation related to involuntary sterilization (Laughlin, 2009); therefore *Buck* v. *Bell* (1927) confirmed these states' stance on sterilization. One of the largest counterarguments and a descending opinion to this case is that forcing an individual to be sterilized is "cruel and unusual punishment" (Siegel, 2005). In the aftermath of this case, upward of 50,000 Americans received involuntarily sterilization over the next few decades (Berry, 1998). In 1978, the Department of Health, Education, and Welfare altered the requirements for sterilization to include informed consent, therefore, abolishing involuntary sterilization (Title 42, 1978).

Earliest Textbook

In 1904, Martin Barr, MD, published the first textbook on ID titled *Mental Defectives: Their History, Treatment, and Training*. Barr (1904) provided professionals unprecedented information on understanding ID based upon the labels of the time: imbeciles, feebleminded, idiots, and mental deficient. Barr (1904) differentiates between an idiot and imbecile by explaining an idiot "see nothing, feels nothing, hears nothing, and knows nothing," whereas imbeciles have the capacity to understand and reason (p. 18). Furthermore, he stated that differentiating between these two is influential in selecting treatment protocols and assigning realistic prognosis. Through his definitions and classifications, Barr paved the way for others to appropriately differentiate causes and prognoses of those presenting as deficient in some way. Tredgold (1908) expands on Barr's concepts by creating a resource for professionals to educate on appropriate diagnosis, treatment, eligibility for services, and long-term placements. Barr (1904) and Tredgold (1908) provide descriptions of biological, physical, and cognitive differences of those with mental defects. Barr (1904) provides hope for those labeled as mentally defective prognosis by differentiating between disease and defect and argues that regression is preventable through appropriate treatment for those who fall within defect. However, through his classification of idiots and imbeciles, Barr postulates idiots are unable to make any gains and treatment will not result in any improvements; therefore, treatment resembled nurseries. However, treatment focused on those termed as imbeciles' emotions, body, and mind through training them in how to complete daily living activities through step-by-step instructions and avoiding any abstract concepts (Barr, 1904). The importance of differentiating and understanding the cause and prognosis of one's mental deficiency continued to inform ongoing research into the treatment of ID for centuries to come (Roberts, 1952; Schalock & Luckasson, 2013).

National Associations

After witnessing firsthand the inadequate services and advocacy for children with disabilities, Edgar Allen made it his life's effort to ensure the other children received proper care (Williams, 1994). In 1919, Mr. Allen founded the Ohio Society for Crippled Children as an organization advocating for the rights of disabled children. The organization began requesting donations to fund children's services and advocating for children's right to live. In 1967, the organization had slowly gained a national presence and officially changed its name to Easter Seals. As the Americans with Disabilities Act (ADA) developed, Easter Seals pioneered the advocacy movement for those with disabilities in Washington, DC. Easter Seals focuses on providing services to families within five categories: live, learn, work, play, and act. Easter Seals served as an example for other advocacy organizations within the United States and worldwide (Williams, 1994).

In 1930s, the National Association of Parents and Friends of Mentally Retarded Children began forming groups to advocate for improving their children's care (Hay, 1952). By 1951, the United States and Canada had over 125 groups with thousands of members. The growing membership resulted from two very important areas: (1) parents and the community's awareness that children were not receiving appropriate treatment and (2) the medical community simultaneously developing new treatments for conditions previously thought to be untreatable. This association, which later became known as the National Association for Retarded Children (ARC), focused on circulating accurate information on mental health and advocating for adequate treatment, education, vocational services, housing, and government policies (Hay, 1952).

Simultaneously, in 1946, the National Mental Health Foundation was founded, which was a civilian-run organization focused on the dissemination of factual information about mental health to legislators, educators, the public, and mental institutions. This foundation advocated for an increased standard of care for mental health treatment, education of the layperson on aiding those with mental health problems, promoting focus on psychiatry programs within already developed universities, and furthering current mental health professionals understanding of the illnesses ("National Mental Health," 1946).

In 1979, the National Alliance on Mental Illness (NAMI) originated as a small grassroots organization. NAMI focuses on educating, advocating, listening, and leading. NAMI develops educational programs to inform families and providers on mental illness and its personal implications. NAMI frequently spearheads public policy ensuring appropriate representation of the rights of individuals with mental illness in legislation. NAMI offers a helpline to assist in connecting families with local providers and supporting individuals with suicidal ideation. NAMI also hosts frequent events to increase the public's awareness of mental illness and work toward destigmatizing the field (NAMI, 2018).

Appropriate Training for Service Providers

President Eisenhower signed the Education of Mentally Retarded Children Act (1958), which allotted funds to provide additional training to universities on educating individuals with mental retardation. When the act, P.L. 85–926, was first signed, it allocated $11 million per year for educators and professionals to gain additional knowledge and understanding of mental retardation. Through this added knowledge, these leaders create programs within already established colleges and within local public school systems aimed at teaching and adapting curriculum for those with mental retardation (Martin, Martin, & Terman, 1996). An addendum was passed in 1963, P.L. 88–164, which expanded on the earlier act to include adaptation for other disabilities (e.g., emotional disability, deaf, crippled, speech impaired, blind, and other health impairments). From the initiation of P.L. 85–926 through the addendums, over 20,000 educators and professionals received training to adapt education to affected individuals. From the initial $one million allotment per year, this amount expanded to $55 million allotted in 1970 ("Programs for the Handicapped," 1969).

Terminology Changes Over Time

The terminology to refer to ID continues to change over time. In the early 1990s, labels for individuals with ID were imbecile, feeble-minded, idiots, and mental deficient in the early 1900s (Barr, 1904). In 1952, the American Psychiatric Association (APA, 1952) published the first *Diagnostic and Statistical Manual* (DSM-I) classifying this disorder as "chronic brain syndrome with mental deficiency" (p. 14) and "mental deficiency" (p. 23). In 1959, the American Association of Mental Deficiency introduced the term "mental retardation" and changed their name to the American Association of Mental Retardation (AAMR) (Fredericks & Williams, 1998). In the 1960s, APA (1968) published their second edition of the DSM-II, which incorporated the new diagnosis of "mental retardation." It was not until the publication of DSM-III in 1980 that APA (1980) addressed that mental retardation does not solely include a deficit in intellectual functioning but also impairment in adaptive skills. From 1980 through the early 2000s, this remained the definition and conceptualization for mental retardation. In 2010, the World Health Organization and the AAMR, now known as the American Association on Intellectual and Developmental Disabilities (AAIDD), formed work groups to prepare for proposed changes in the International Classification of Diseases (ICD-11). In 2010, the ICD-11 implemented the change in terminology to "intellectual disability" following President Obama signing "Rosa's Law" which changed "mental retardation" to "intellectual disability" in federal education laws (Tassé, Luckasson, & Nygren, 2013). Shortly after, DSM-5 was released in 2013 and agreed and incorporated the diagnosis "intellectual disability" (APA, 2013).

Deinstitutionalization

Many individuals with mental health diagnoses lived in state hospitals, which reached its peak census in 1955 with over 550,000 individuals hospitalized (Bachrach & Lamb, 1989). Over the next decade, the deinstitutionalization movement progressed, with the federal government's formalization of deinstitutionalization beginning in 1965 as the civil rights movement gained traction and advocates fought for the least restrictive environment (Chow & Priebe, 2013). This transition did not occur over night, and it took decades to fully transition individuals from state hospitals to outpatient community mental health centers ("Deinstitutionalization Movement," 2007). To successfully deinstitutionalize and rehabilitate, society needs proper funding to create treatment centers and transitional housing. Additionally, for this process to be effective, individuals need to be compliant with treatment recommendations and have the financial and social supports to meet these goals (Bachrach & Lamb, 1989). Unfortunately, due to limited rehabilitation services in America, many affected individuals become homeless.

Federally Funded Programs

In 1965, the federal government passed Title XIX within the Social Security Act (1965), which instated the federal- and state-level Medicaid programs (Klees, Wolfe, & Cutris, 2009). Title XIX identified individuals with low income, children, pregnant women, blind individuals, and permanently disabled individuals. An individual was considered disabled if their physical or mental diagnosis prevents them from being able to work. This was the first legislation of its type to recognize that individuals with disabilities need additional funding for appropriate services. The Medicaid plan covers a variety of treatments, including inpatient-, outpatient-, residential-, and community-based centers (Social Security Act, 1965).

Special Olympics

Through the late 1950s and early 1960s, Eunice Kennedy Shriver became abundantly aware of the injustices faced by individuals with ID; therefore, she made it her personal mission to create an atmosphere conducive to individuals with ID to thrive and enjoy life (Special Olympics, 2018). In 1962, Ms. Shriver held her first summer camp in Washington, DC, which included sporting events and outdoor activities. In 1967, Chicago proposed an idea to replicate the Olympics track meet for those with ID. The following summer of 1968, Ms. Shriver held the first International Special Olympics Summer Games in Chicago, IL, leading to the formal incorporation of Special Olympics as an organization that fall. Throughout the 1970s, the Special Olympics continued to grow within the United States, and by 1977, the winter Olympics developed. At the 1987 International Special Olympics held in Indiana, athletes from 70 countries competed (Special Olympics, 2018). The Special Olympics continues to be a remarkable organization promoting the enjoyment of life for those with disabilities and advocates for individual's rights in the progression of disability legislation.

Disability Legislation and Right to Treatment

The first legislative recognition in favor of increased funding for individuals with ID came in 1970 with the Developmental Disabilities Services and Facilities Construction Amendments (1970). This act provided states with funding for treating, giving services, and creating new treatment facilities for those with ID. The Developmentally Disabled Assistance and Bill of Rights Act (1975) served as an amendment to the earlier policy and included the advocacy of individuals with developmental disabilities, early screening, and the protection of their rights. The "rights of the developmentally disabled" were described as including individuals' right to treatment, services emphasizing the individual's potential, and appropriate funding for this treatment. An additional amendment, the Developmental Disabilities Act of 1984, addressed treatment goal of establishing services to help the individual with gaining independence, assimilation into the community, and supporting individuals to become employed. This Act and its amendments represent the shift within society in understanding the importance of quality of life of individuals with disabilities and advocating for their right to achieve this.

While legislation occurred on a federal level in the 1970s, states were also similarly grappling with legislation to improve care for individuals with ID. For example, in the state of Alabama, quality of patient care and access to safe-staffing models at Bryce State Hospital became the cornerstone of *Wyatt* v. *Stickney* (1971). The state of Alabama increased taxes on cigarettes, which affected Bryce State Hospital's ability to pay their employees. Therefore, they fired around 100 employees, leaving few professionals to care for the residents and patients. The ratios for patient to provider were outrageous: 1 psychiatrist served over 1500 patients, 1 nurse cared for 250 patients, and 1 doctor tended to over 350 patients (Carr, 2004). The focus and ruling of *Wyatt* v. *Stickney* (1971) laid the foundation for future cases recognizing patients', including those in mental health facilities, right to appropriate treatment and safe environments (Perlin, 2011).

O'Connor v. *Donaldson* (1975) was the first case to reach the US Supreme Court on the basis of right to treatment and constitutionality of confinement. After receiving a diagnosis of paranoid schizophrenia in 1957, Kenneth Donaldson's father civilly committed him. Donaldson petitioned for his release, claiming that he was not receiving treatment. Donaldson asserted that it was his constitutional right to discharge himself or receive treatment (Fields, 1976; Wold, 1975). The appellate court ruled on the presumption that Donaldson's constitutional right was to receive treatment, therefore, ruling against his discharge request. In *O'Connor* v. *Donaldson* (1975), the US Supreme Court ruled in support of Donaldson, declaring that he was involuntary committed, which deprived him of his personal liberties. The court stated that the only justification for involuntary commitment is if an individual is receiving treatment or is dangerous; given that neither of these was true for Donaldson, they ruled that a violation of his constitutional rights occurred. They further indicated that an individual's mental illness, considered independently, is not enough to qualify for involuntary commitment (Fields, 1976; Wold, 1975).

In 1980, the Civil Rights of Institutional Persons Act (CRIPA) further established the rights of individuals in institutions (e.g., prisons, hospitals, mental health facilities, nursing homes). The Attorney General claimed that any setting receiving federal aid much respects individual's rights. CRIPA (1980) specifically protects individuals against sexual abuse, inappropriate mental health treatment, inefficient rehabilitation, inadequate education, and abuse or neglect. CRIPA (1980) does not establish new rights for individuals; rather CRIPA creates a system for the Department of Justice (DOJ) to monitor and prosecute violations.

In the early twenty-first century, the Developmental Disabilities Assistance and Bill of Rights Act set the stage for increasing accessibility of treatment within the field of ID. This act supports ongoing research of developmental disabilities and ID to ensure federal policy conforms to updated research. This act also advocates for the individual's rights and protects them from unlawful abuse. The Developmental Disabilities Assistance and Bill of Rights Act of 2000 created numerous programs and legal counsel to represent those with intellectual and developmental disabilities in policy. There are state counsels which represent their rights and ensure that updated policies adhere to disability laws and remove individuals' barriers to treatment and participating within society. Protection and advocacy groups also appeared to advocate and empower individuals to represent themselves. Also created were University Centers for Excellence in Developmental Disabilities Education, Research, and Service (UCEDDS) to ensure educational organizations represent their rights and provide appropriate accommodations (Developmental Disabilities Assistance and Bill of Rights Act, 2000).

Educational Rights for the Disabled

A class action lawsuit, *Pennsylvania Association for Retarded Citizens (PARC)* v. *Commonwealth of Pennsylvania* (1972), filed petitions against the board of education and specific school districts. This was the foundational case in establishing students' right to education. *PARC* v. *Pennsylvania* (1972) claimed that students with mental retardation did not receive the same, if any, education as their peers. This case argued that the 14th Amendment of the US Constitution specifies that legislation cannot impede on citizen's rights (e.g., right to education). Therefore, school systems were violating this right by denying students with mental retardation the right to their education. The ruling on this case asserted that law requires school districts to offer public education to all children, regardless of mental abilities. Shortly after this case, a similar class action suit, *Mills* v. *Board of Education* (1972), was brought against Washington, DC. Schools excluded upwards of 18,000 children with mental and physical disabilities from receiving public education. The ruling of *Mills* v. *Board of Education* (1972) emphasized students' right to education and required schools to redistribute their financial allocations to provide adequate funding for students with mental and physical disabilities (Yell, Rogers, & Rogers, 1998).

Both cases laid the foundation for federal legislation, Section 504 of the Rehabilitation Act of 1973. This act asserts that discrimination against individuals based on their disability, including mental health diagnoses, is unlawful. This legislation particularly applies to any organization that receives federal funding, which includes educational institutions (Yell et al., 1998). The Education for all Handicapped Children Act of 1975 (EAHCA) offered states federal funding for special education services. As previously discussed, states must offer free education; therefore, EAHCA serves as an incentive and support for states to provide adequate education. EAHCA (1975) posits that students have the following rights: modified education, free education, least restrictive environment, nondiscrimination, and due process. EAHCA also incorporated

Individualized Education Program (IEP) that tailors a student's education to their particular needs (Yell et al., 1998). In 1990, EAHCA changed its name to the Individuals with Disabilities Education Act (IDEA) that altered the wording to represent person-first language (e.g., individual with a disability). IDEA (1997) amended earlier legislation to include specialized category for autism, emphasis on parental involvement, and serving individuals from infancy through the age of 21.

National and International Legislation

In 1982, the United Nations established the World Programme of Action (WPA) Concerning Disabled Persons. The WPA addresses disability advocacy from a human rights perspective, focusing on country's legislation and policies for the equality of the individual. Given the foundation within the UN, the WPA addresses disability rights and advocacy at an international level and aims to empower individuals to become fully integrated into society as active participants. This initiative tackles countries' lack of resources and this role in the perpetuation of disability among future generations. WPA strives to prevent, rehabilitate, and create equal opportunities for those with disabilities across the world (WPA, 2018).

Established within the Department of Education in 1978, the National Council on Disability (NCD) has been monumental in federal advocacy efforts for those with ID. This council briefs the president, congress, local/state governments, and other agencies on issues affecting individuals with disabilities. NCD collects data to present to their counsel, participates in debates related to monumental issues, and prepares solutions to problems related to disabilities (NCD, 2018). NCD was instrumental in the development of the Americans with Disabilities Act (ADA), which expanded upon previous legislation impacting federally funded programs to include private businesses in being responsible for respecting the rights of those with disabilities (Waterstone, 2015). ADA (1990) protects individuals against discrimination at work, at home, in public locations, on transportation, in recreational settings, institutionalizations, and accessing public services. Prior to the passing of ADA (1990), other legislations protected individuals' civil rights, but it lacked protection based on a disability. In addition to protecting individuals with physical disabilities, ADA (1990) also protects against mental impairment.

Olmstead v. *L. C.* (1999) was instrumental in establishing mental health patients' rights to appropriate treatment without confinement and institutionalization against their will. The case involved two women, Lois Curtis and Elaine Wilson, who were both diagnosed with mild ID and treated at a hospital in Georgia. Both women voluntarily committed themselves. However, after reaching treatment goals, the hospital prohibited their discharge to a community treatment facility. Lois Curtis remained hospitalized for 3 additional years after her psychiatrist considered her fit for discharge. The premise of *Olmstead* v. *L. C.* (1999) sits upon an individual's human rights, and unlawful confinement violates these rights as stated in ADA (1990). This case escalated to the US Supreme Court after numerous appeals by the state of Georgia defending their actions of not releasing these women. The US Supreme Court agreed with the previous courts that Georgia was acting in violation of ADA (1990) and the state holds the responsibility of allocating proper funding to ensure patients have access to necessary care (e.g., state hospital versus community-based setting). This case merges previous cases both on an individual's right to treatment, disability law, and adhering to federal legislation (McCants, 1999).

Applied Behavioral Analysis

The Journal of Applied Behavioral Analysis published their first periodical in Spring 1968 and continues to publish four volumes per year (JABA, 2018). O. Ivar Lovaas, often credited with developing applied behavior analysis (ABA), proved its effectiveness with children with autism spectrum disorder (ASD) and

ID. ABA is an intensive behavioral treatment that utilizes positive reinforcement and interventions to solicit positive behaviors and discourage undesirable behaviors. Lovaas pioneered the treatment for these disorders by emphasizing the importance of early intensive intervention or ABA. Lovaas' earlier research focused on understanding antecedents and consequences and functional behavior analysis (Smith & Eikeseth, 2011). Lovaas, Koegel, Simmons, and Long (1973) published a preliminary study assessing the long-term effects of ABA, which demonstrated that if parents were involved in the treatment and trained in behavioral principles, children had longer-lasting benefits and decreases in behaviors. However, when institutionalized, the initial gains from ABA dissipated, and the child returned to baseline functioning. Lovaas (1987) published a comprehensive article discussing the effectiveness of ABA for children with ASD and ID. This study assesses long-term behavior treatment and concluded that almost half the participants reached normal cognitive functioning and at grade level school performance. Additional findings by Lovaas showed that of those 50% of students placed in special education classes, around 40% of students functioned at a delayed level, with the remaining 10% being profoundly intellectually disabled (Lovaas, 1987). McEachin, Smith, and Lovaas (1993) published a longitudinal study documenting the effectiveness of long-term early intervention behavior therapy, demonstrating that by the age of 7, participants were comparable to typically developing peers. In sum, Lovaas and his colleagues' findings emphasized the importance of beginning ABA early: children who participated in extensive treatment prior to beginning school achieved more optimal outcomes. There is extensive research on ABA and its implications within the field of ID.

Disability Culture

Over the past centuries, individual's, society's, and the international community's beliefs on disability have shifted. Chicago held the first Disability Pride Parade in the United States in 2004 (Schmich, 2017). This parade symbolized the drastic shift in perception of disability within the United States and society's move toward acceptance of differences and individuality. As technology improved, national organizations, blogs, and social media outlets now host open conversations about disability and disseminate accurate information that was previously unavailable to the general public (Brown, 2015). Now, more than ever, individuals embrace their differences and disability, and there are many public figures who openly discuss their disabilities and the challenges they face. Disability culture has boomed over the past few decades as information is readily available online (Brown, 2015).

Summary

This chapter attempts to disseminate the long, complicated history of ID while highlighting key points that were influential in the forward trajectory of the perception of mental health, specifically ID. ID's early history is traced back to ancient Roman, Egyptian, and Greek philosophers. Initially, many philosophers and scientists attempted to understand mental health and individuals who did not conform to what was typically expected. Treatment facilities ranged from asylums to institutions, to inpatient hospitals and residential treatment facilities, to now, more commonly, community mental health centers. As the understanding of mental health and ID began establishing within the United States, individuals began to fear those different than themselves, leading to the eugenics movement. Stemming from eugenics and involuntary institutionalization began the legislative history in the United States, which laid the foundation for modern-day civil rights. National organizations were established, which spearheaded the civil rights movement and fought the battle against the stigma of mental illness and ID. As the understanding of ID advanced, individuals and national organizations fought for the rights of those with ID, specifically their right to quality humane treatment and appropriate education. Numerous laws were passed protecting individuals' rights and abolishing ancient treatment methods. As individuals were educated on ID, additional trainings were created for those treating individuals with ID. Newer treatment modalities were discovered that were evidence based for ID. As the cultural perception of ID shifted, the terminology used to discuss individuals with ID adapted to be more sensitive.

Theories of Intelligence

2

Matthew J. Euler and Ty L. McKinney

Introduction

A prominent definition of intelligence describes the construct as follows:

> Intelligence is a very general mental capacity that, among other things, involves the ability to reason, plan, solve problems, think abstractly, comprehend complex ideas, learn quickly, and learn from experience. It is not merely book learning, a narrow academic skill, or test-taking smarts. Rather, it reflects a broader and deeper capability for comprehending our surroundings—"catching on," "making sense" of things, or "figuring out" what to do (Gottfredson, 1997a, p. 13).

This working definition has been broadly endorsed and repeated by numerous scholars in the field (Haier, 2016; Nisbett et al., 2012; Protzko, 2017) and captures many of the traits and capabilities that scientists and lay people alike would consider important parts of intelligence. Notably though, while it does a good job of describing various things that intelligent people tend to do, and distinguishes the construct from others (e.g., book knowledge), it also recapitulates a key tension at the heart of the intelligence literature. Namely, how is it that intelligence is on the one hand a very *general* capacity and yet attempts to define it very often invoke a host of apparently discrete behaviors and tendencies? For intelligence theorists, this question can be translated into the issue of whether intelligence truly represents a singular or *unitary* capacity, as much of the psychometric literature has suggested, or whether the appearance of a unitary structure is merely a statistical or measurement artifact, such that intelligence actually represents an aggregate of many capacities.

As detailed below, the issue of whether intelligence is a unitary capacity arguably represents the most important issue concerning theories of intelligence and can serve as an organizing theme for the models discussed in this chapter. Beyond that, any theory of intelligence can then be grouped according to (1) whether it is better construed as a historical or a contemporary theory; (2) whether its evidence base is primarily *psychometric* (based on statistical modeling of the correlations among various types of mental tasks), *experimental* (derived from analyses of laboratory-based measures, rather than norm-referenced standardized tests), *conceptual* (derived from literature reviews and rational considerations), or even *physiological* (arrived at through correlations of intelligence task performance with EEG or neuroimaging data); and finally (3) whether it emphasizes the importance of more *basic* (i.e., sensory perceptual) or more

complex tasks in measuring and defining intelligence. Upon exhausting those dimensions, each theory of intelligence can ultimately be characterized in terms of its more distinguishing features and contributions to the literature. Given that psychometric research forms the bulk of the evidence base for these theories in general, the next sections outline the history of psychometric models of intelligence (also termed "structural" models), from Charles Spearman's discovery of psychometric *g* up through the development of multifactor and hierarchical models in the middle and later part of the last century.

Early Psychometric Theories of Intelligence

Spearman, the Birth of Factor Analysis, and Psychometric *g*

The most important historical figure in psychometric intelligence research is undoubtedly Charles Spearman, whose key ideas are still relevant today. As reviewed in his 1904 monograph, prior research in early psychology had produced conflicting findings about the nature of intelligence. On the one hand, Francis Galton (discussed below) and others had advocated for a view of intelligence as a single mental capacity that had its basis in relatively primitive functions such as sensory discrimination (e.g., discriminating fine differences between the weights of objects or the pitches of auditory tones). However, other scholars had either failed to find evidence for this claim or had at times contradicted it showing that more complex mental abilities better reflected the nature of intelligence (Spearman, 1904). Having reviewed the literature on both sides and found it wanting, Spearman sought out to more rigorously investigate the relation between sensory discrimination and intelligence, in an effort to improve the theoretical and empirical foundations on which the debate rested.

For that purpose, Spearman collected measures of sensory discrimination in samples of school children and related them to various tentative estimates of intellectual ability, such as class rankings in various subjects (Classics, English, French, Mathematics, and Music) and teachers' and others' general impressions of the students' abilities. Notably, Spearman also included a precursor to the contemporary IQ score in the form of a mental age measure, where he distinguished between a form of intelligence he called "present efficiency" (absolute academic performance) and "native capacity" (a student's performance in a given subject divided by their age). Overall, these studies produced several important contributions.

First, Spearman recognized the need to control for the unreliability of measurements, which, if achieved, would allow one to obtain a better estimate of the true relationship between two variables (Jensen, 1998a, p. 23). Second, Spearman also identified that by examining the variance that is shared across different types of tasks (e.g., visual and auditory discrimination, proficiency in Greek vs. piano-playing; Spearman, 1904, p. 259), one could determine the extent to which they involve one or more underlying dimensions or faculties. This marked the beginning of factor analysis (Bartholomew, 2004, p. 18), wherein Spearman laid the mathematical foundations to be able to ask whether, for example, auditory and visual discrimination reflect wholly distinct capacities, owing to their basis in different sensory modalities, or whether the variance between people on each reflects a more general sensory discrimination ability. That is, factor analysis allows one to assess how many dimensions contribute to variance in performance on a group of psychological tasks. For that reason, it has come to be the primary tool in psychometric intelligence research, including many of the following models discussed in this chapter. It also brings us to Spearman's third and most important contribution, where he showed that, indeed, there was evidence for "general discrimination" and "general intelligence" factors that were common to all of the respective measures and, further, that the two factors were related to such a large degree that they seemed to both draw on a single mental capacity (Spearman, 1904, p. 272).

While contemporary estimates of the correlation between intellectual ability and sensory discrimination suggest that the relationship is considerably smaller than Spearman's initial claim (Acton & Schroeder, 2001), the basic finding has nevertheless proved reliable (Sheppard & Vernon, 2008) and provides meaningful support for the reductive program in intelligence research, as outlined further below. More importantly, however, Spearman's broader suggestion that a single capacity might be common to all cognitive tasks has proved to be even more central.

In particular, it has now been shown that across hundreds of datasets (Carroll, 1993), whenever a sufficiently diverse set of mental tasks is administered to a sufficiently large and representative group of people, the tasks will invariably positively intercorrelate, producing the so-called *positive manifold* phenomenon. Crucially, this is an empirical phenomenon and not a logical necessity, in the sense that there is nothing inherent to the statistical procedures that require that grades in Mathematics, Classics, and French must be positively correlated. Rather, their correlation reflects an empirical truth. Not only did Spearman observe the now-ubiquitous positive manifold among the academic and sensory measures, but he further saw that the correlations between the various subjects exhibited a clear hierarchy, such that grades in English and French related more strongly to grades in Classics than either did to Math. He then showed that upon extracting what he called the common "general intelligence" factor, all of the measures—sensory and academic alike—seemed to derive their variance from only this general factor and a second, idiosyncratic test-specific factor (see Fig. 2.1). This in turn made it possible to determine how "saturated" each task was with the general factor (i.e., its "*g*-loading" in contemporary parlance) and could ultimately allow for identifying which tasks would provide the best of measures of overall intelligence (Spearman, 1904, p. 277).

Altogether, these results provided the basis for Spearman's "two-factor" theory[1] of mental ability, which argues that the variance between people on any given task appears to be a function of only two factors: that which is *specific* to each task (termed "*s*") and that which is *general* or shared, now known as psychometric *g* (Spearman, 1927).

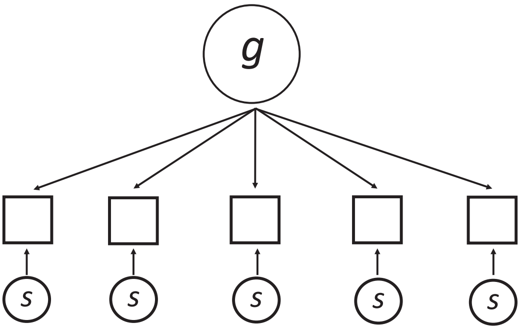

Fig. 2.1 Spearman's two-factor theory. Spearman's two-factor theory of intelligence asserts that the variation between people on all cognitive tasks is a function of two factors: general intelligence (*g*) and test-specific variance (*s*). A hypothetical battery of five tests is shown, where the variance in each test reflects only the contributions of *g* and test-specific variance. Following typical conventions for depicting structural equation models, latent factors are depicted as circles, and manifest variables (obtained test scores) are depicted as squares

In the time since Spearman's initial observations, it has become essentially universally accepted that a general factor can often account for much of the variance among cognitive tests (typically approaching 50%; Deary, 2012). Yet, as will be seen, the status and significance of this factor remain an important area of debate. On that note, it is appropriate to turn to a discussion of Spearman's primary interlocutors and the alternative models they favored.

Thurstone and Multifactor Theories

Spearman's two-factor theory of intelligence is most often and readily distinguished from Louis L. Thurstone's model of Primary Mental Abilities (Thurstone, 1938). The latter exemplifies an alternative class of models that advocated a multifactor rather than unitary structure for mental abilities (Sattler, 2008, p. 224). As the name implies, Thurstone's model emphasized the idea

---

[1] The name "two-factor" theory can be somewhat confusing, in the sense that it strongly emphasizes the importance of the single *g* factor. Nevertheless, the name refers to the assertion that any task involves contributions from two factors: *g*, which is common to all tasks, and *s*, which is unique to particular tests.

that, rather than invoking just a single general factor along with test-specific factors in explaining cognitive performance, a group of independent, lower-order processes, with a clearer psychological meaning (e.g., memory, verbal skills, spatial skills, etc.), might better explain the patterns of correlations among cognitive tests. Indeed, a form of this idea can be seen in Spearman's very own hierarchy, where he observed that grades in certain subjects (e.g., Classics, French, and English—all notably linguistic) correlated more highly with one another than they did with other measures.

Inspired by that premise, Thurstone devised a large set of cognitive tasks that were designed to be maximally pure in their reliance on what were presumed to be independent capacities. Using an alternative factor-analytic technique that forces the extraction of maximally independent factors (Jensen, 1998a, pp. 75–76), he was then able to derive a model that consisted in seven, seemingly independent, primary abilities (see Fig. 2.2). Among these were capacities like memory, perceptual speed, and spatial visualization (Sattler, 2008), which exhibit an intuitive degree of conceptual separation, as well as others like verbal comprehension and word fluency that might be expected to have more variance in common. As it happens, this turns out to be the case, as Thurstone himself later recognized. That is, although it is possible to achieve maximally independent factors by (1) carefully selecting tests on that basis and then (2) mathematically constraining the relations between resulting factors, in truth, when the latter constraints are relaxed, the primary factors will positively intercorrelate. As explained by Jensen (Jensen, 1998a, Chapter 4), this is due to the fact that although some tests may load only on one primary ability, they all will still invariably load on *g*.[2] Moreover, the latter will often account for considerably more variance in performance than do the primary abilities. In turn, the *g* factor can then be modeled at a level above the primary abilities, or even alongside them, to account for their intercorrelations, as in the contemporary hierarchical and bi-factor models described below. As will be seen, these latter models provide something of a compromise position (Deary, 2000, Chapter 1).

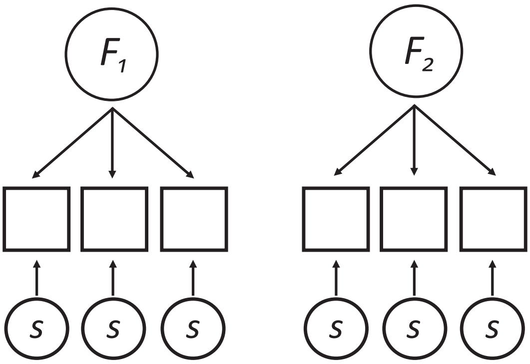

Fig. 2.2 Schematic factor model depicting two orthogonal primary abilities. A simplified version of Thurstone's primary ability model is shown here with only two factors, derived from three tests each. The key distinguishing features of Thurstone's initial model are the presence of uncorrelated (mathematically "orthogonal") primary abilities and the absence of a general factor. F_1 and F_2 designate hypothetical primary abilities (e.g., verbal and spatial skills)

Sampling Theory and Thomson's "Bonds" Model

While it is instructive to distinguish between the extremes represented by Spearman's two-factor theory and Thurstone's initial model based on Primary Mental Abilities, in recent years, a third alternative outlined by their contemporary, Godfrey Thomson, has been rediscovered. As recently described by Bartholomew and colleagues, Thomson's work is unique, in that it does not necessarily dispute the mathematical adequacy of two-factor theory, but somewhat like Thurstone's early model, it objects on conceptual grounds (Bartholomew, Deary, & Lawn, 2009). Specifically, whereas Thurstone emphasized the need for psychological and conceptual coherence in psychometric models of intelligence, Thomson was concerned with biological plausibility in terms of neural organization.

---

[2] It should be noted that Thurstone himself came to recognize these issues and acknowledged the possibility of a high-order *g* (Carroll 1993, p. 56; Major et al. 2012, p. 544).

As an intuitive, if high-level example, consider the well-known neurological findings that specific, higher-order faculties (e.g., language comprehension) can be disrupted by focal lesions, while leaving other cognitive skills intact. This of course suggests that cognitive functions are subserved by at least partly dissociable neural systems and that individual differences therein might not be the result of a single underlying factor. Yet, unlike Thurstone, Thomson did not argue that the underlying neural processes should be wholly independent, in the sense that they would never interact. Rather, just as we now know that language production and comprehension are both largely housed in the dominant hemisphere (Lezak, Howieson, Bigler, & Tranel, 2012) and even interact (Papathanassiou et al., 2000), one might expect these abilities to positively correlate based on their overlapping substrates.

In essence, Thomson extended this basic logic to develop a broader account of how diverse neural processes could give rise to the appearance of a single underlying factor in mental abilities. He reasoned that this could occur any time the items or tests in a given battery each "sampled" the same set of discrete but connected neural processes (which he termed "bonds"). In turn, as the number of bonds shared among tasks increases, so too should the correlation between them. Thus, Thomson argued, and more recent work has confirmed (Bartholomew, Allerhand, & Deary, 2013) that it is possible to develop a statistical model that replicates the *g* factor, despite actually being comprised of numerous underlying processes. Further, although not recognized at the time, Thomson's proposal makes even more sense when one considers the finding that the tasks with the highest *g*-loadings are nearly always the most complex. Given that complexity has been explicitly defined as the number of processes involved in a task (Guttman, 1954; Marshalek, Lohman, & Snow, 1983; Stankov & Raykov, 1995), it is quite suggestive that the most complex (and hence most *g*-loaded) tasks might in fact involve the most overlapping processes. Interestingly, like much of this literature, this idea, presented here in a psychometric context, would come to be echoed later on in more conceptual theories.

Cattell's Legacy: Fluid and Crystallized Intelligence and Investment Theory

Working in the middle and later part of the twentieth century, Raymond B. Cattell made a major contribution to this literature in developing the concepts of fluid and crystallized intelligence (respectively, denoted as Gf and Gc). In a seminal paper, Cattell (1963) described his effort to synthesize factor-analytic methods with developmental considerations as they pertain to the growth of intelligence. One of his key assertions was that "there is not *one* "general ability" second-order factor…but more," with each having a semi-independent basis and developmental trajectory (Cattell, 1963; emphasis in original). Specifically, he argued that it is possible to separate the *g* factor into Gf and Gc, where the former represents the capacity to respond adaptively in novel situations, while the latter is drawn upon by tasks that require learned skills and knowledge. Concretely, Gf would be expected to play more of a role in solving tasks involving unfamiliar relationships or components, such as in the well-known Raven's matrices (Raven & Court, 1998). These tasks are broadly nonlinguistic and require examines to identify the shared features among abstract figures arranged in a matrix. Gc, on the other hand, loads heavily on linguistic, academic, and other skill-based knowledge and should be more important for tasks involving things like verbal reasoning and one's general fund of information.

In line with these distinctions, Gf was hypothesized to more closely reflect one's inborn, momentary cognitive processing capacity, which is then *invested* in developing crystallized skills (thereby forming the crux of "investment theory"; Cattell, 1987). In addition, the trajectory of Gf and Gc should follow a particular developmental course, with Gf increasing as children reach adulthood but declining in middle and older age, whereas Gc would in principle continue expanding as individuals accrue further experience. Indeed, this general trajectory has been roundly confirmed (Salthouse & Davis, 2006) and represents a key consideration in developing norms for cognitive tests. Notably, although the Gc-Gf model may sound very similar to that of Primary Mental Abilities, it is distinguished from this and other "multifactor" models in that its components are allowed to intercorrelate (a so-called oblique model; Kovacs & Conway, 2016). Last, although the original Gf-Gc model contained only two factors (see Fig. 2.3), Cattell and his coworker John Horn later extended it to include ten broad abilities (McGrew, 2009).

Ultimately, while the Gf-Gc distinction has been retained in some more recent psychometric models (notably CHC theory, see below), it is not without its challenges. Most significantly, it is now well-established that although it is possible to separate Gf and Gc statistically, if one allows for a *g* factor at a third level in a higher-order model (see next section), Gf and *g* then correlate at or close to unity (Kan, Kievit, Dolan, & van der Maas, 2011; and Lichtenberger & Kaufman, 2013, p. 32–33). This of course makes them statistically and potentially substantively indistinguishable. Second, as noted by Cattell (1963), the theoretical distinction between Gf and Gc has important implications for determining which sorts of tests would be the most likely to show bias due to educational or cultural factors. Yet, although it is clearly the case that tests which presume certain linguistic and cultural information are not appropriate for some examinees, it unfortunately does not follow that the so-called "nonverbal" measures are in fact culture fair or "culture free." To the contrary, recent work examining age differences in performance on the Raven's progressive matrices suggests that such tasks are in fact highly sensitive to broader cultural knowledge, such as that which changes over successive generations (Fox & Mitchum, 2012).

Other aspects of the Gf-Gc model have received mixed support as well. On the one hand, there is meaningful support for investment theory's claim that investing in developing a certain type of skill may limit the growth of others (e.g., resulting in strong verbal and weaker math skills or vice versa; Coyle, Purcell, Snyder, & Kochunov, 2013; Coyle, Snyder, Richmond, & Little, 2015). However, at the same time, other research has undermined some of its other claims (e.g., Kievit et al., 2017). Thus, while the Gf-Gc distinction still finds support in facets of the literature, the overall challenges faced by the model have given sufficient reason to consider alternatives.

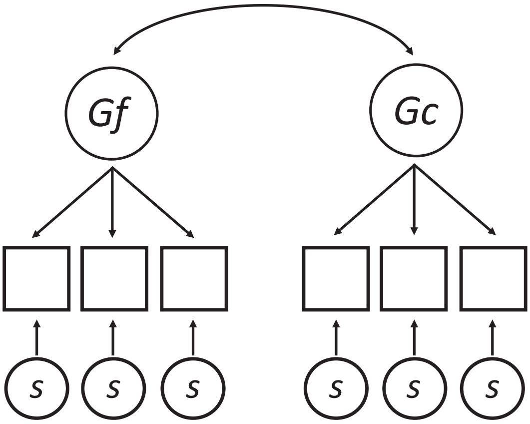

Fig. 2.3 Oblique fluid and crystallized intelligence model. Oblique factor structure depicting a schematic version of the initial Gc-Gf model. Unlike Thurstone's Primary Mental Abilities model, the two factors are allowed to intercorrelate

Carroll and Vernon's Hierarchical Models

The last group of notable historical models is the hierarchical models developed by Phillip Vernon (2014) and John Carroll (1993).[3] Like Spearman, these theorists posited a *g* factor that was common to all cognitive tasks, but like Thurstone and Cattell, they also acknowledged and incorporated other factors that had a clearer psychological meaning. They accomplished this through the process of successive factorization (developed by

---

[3] Although many authors have considered Carroll's model to be a quintessential example of a hierarchical model (Deary 2000; Lubinski 2004), it has also been argued that Carroll's view was in fact closer to the bi-factor model discussed in the next section (Beaujean 2015).

Thurstone, 1947; cited in Carroll, 1993, p. 637), where, after extracting first-order factors that corresponded to broad abilities, the remaining correlations between those factors were then factor analyzed themselves, giving rise to a single higher-order *g* factor and thereby creating a hierarchy.

Vernon's model (depicted schematically in Fig. 2.4) posited two major group factors below the level of *g*. These are v:ed, which refers to verbal or educational skills, and k:m, or kinesthetic and mechanical skills (Johnson & Bouchard, 2005b). Below those two major factors, the model then contained the six minor factors of creative abilities, numerical skills, and verbal fluency, which loaded on v:ed, and spatial, psychomotor, and mechanical ability factors which loaded on k:m (Sattler, 2008, p. 227). Although Vernon's verbal-educational and kinesthetic-mechanical factors share some similarities with Gf and Gc, in contrast to Cattell, he argued that v:ed and k:m were both susceptible to cultural influences (educational and noneducational, respectively). Further, he chose to omit Gf, due to its considerable statistical overlap with *g* (Johnson & Bouchard, 2005b).

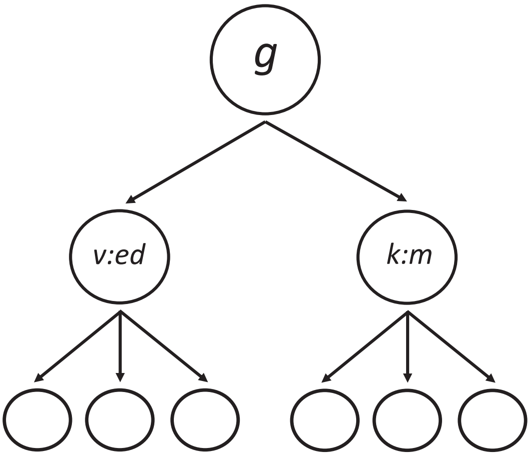

Fig. 2.4 Vernon's hierarchical model. Schematic depiction of Vernon's hierarchical model with a second-order *g* factor that explains the correlations between the verbal-educational and kinesthetic-mechanical group factors. Test-specific factors and manifest variables are omitted for simplicity

As recounted by many authors (Beaujean, 2015), Carroll's work and the resulting model are among the most celebrated achievements in psychometric intelligence research. He arrived at his framework through a meticulous reanalysis of over 450 previous datasets, from which he synthesized the then-extant literature to arrive at his "three-stratum" theory of cognitive ability. In the model, the strata, or level, at which a given ability was placed partly reflected the number of successive factorizations that were performed in deriving it but more directly corresponded to the factor's *generality* in terms of the types of lower-order factors that loaded on it (Carroll, 1993, p. 577). At the lowest level were *narrow* (Stratum I) abilities, or those that are specific to particular tasks (e.g., visualization and sequential reasoning in matrices tasks). Broad (Stratum II) factors then constituted group factors, like those employed by Thurstone and Cattell and Horn, that were common to a given class of tasks. Finally, *g* formed the single Stratum III factor representing general cognitive ability (Carroll, 1993, Chapter 16).

In summarizing his results, Carroll derived four primary conclusions: (1) that there was "abundant" evidence for a general factor of intelligence that would emerge at the highest order of factorization in any given dataset, (2) that eight broad abilities could be distinguished at Stratum II (fluid intelligence, crystallized intelligence, general memory and learning, broad auditory perception, broad retrieval ability, broad cognitive speediness, and processing speed or reaction time decision speed), (3) that additional second-order factors could further be identified in domains such as learning and memory and language (among others), and (4) that the general program of analyzing abilities into strata provided valid insights into the structure of human cognitive ability and could form the basis for such a theory.

Aside from the significance of Carroll's overall achievement, his model was also noteworthy in that, in addition to providing a relatively definitive account of the broad ability factors known at that time, he also arranged them according to their approximate *g*-loadings (Fig. 2.5).

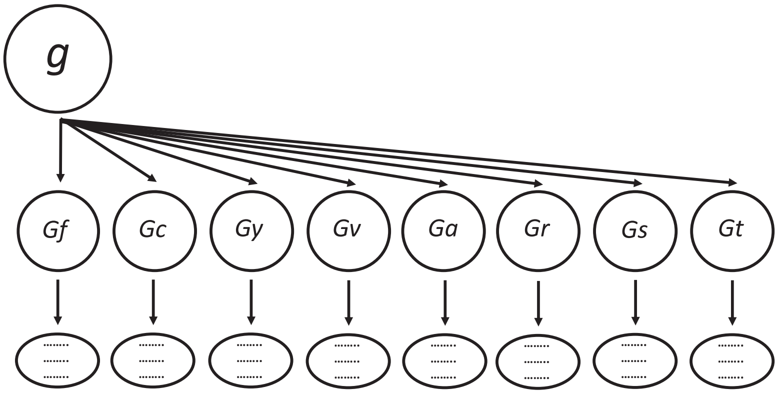

Fig. 2.5 Carroll's three-stratum model of cognitive abilities. Adaptation of Carroll's (1993) hierarchical model, with *g* at Stratum III and broad abilities ordered by their approximate *g*-loadings from left to right. Stratum II factors use contemporary abbreviations, following McGrew (2009). *Gf* fluid intelligence, *Gc* crystallized intelligence, *Gy* general memory and learning, *Gv* broad visual perception, *Ga* broad auditory perception, *Gr* broad retrieval ability, *Gs* broad cognitive speediness, *Gt* reaction time decision speed. Ovals containing ellipses depict narrow Stratum I variables, which varied in number across Stratum II factors

This is useful, because in principle, such an ordering should help to clarify which sorts of measures best predict overall intelligence and hence might inform the "true" nature of construct (e.g., does intelligence have more to do with on-the-spot reasoning or with one's depth and breadth of general knowledge?). Carroll's model is also remarkable for the fact that it truly represented a comprehensive synthesis of the available literature (Johnson & Bouchard, 2005b, p. 395). For example, although he included Gf and Gc in his model, the proximity of the former to *g* also acknowledges the debate (both then and since; Gustafsson, 1984; Colom, Rebollo, Palacios, Juan-Espinosa, & Kyllonen, 2004; Oberauer, Schulze, Wilhelm, & Süß, 2005) about whether Gf or other lower-order factors best define the limits on intelligence. Thus, it is perhaps due to the success of this synthesis that Carroll's model forms one half of the prominent, contemporary Cattell-Horn-Carroll integrated model, or simply CHC (McGrew, 2009).

Contemporary Psychometric Theories of Intelligence

Having incorporated the lessons of the prior century, the current phase of psychometric intelligence research is generally characterized by a clearer acknowledgment of the statistical validity of the *g* factor and a move toward discussing how best to represent it in model structures, what its substantive implications might be, and on determining the number and status of the broad ability factors. At present, there are arguably four major models under discussion.

Cattell-Horn-Carroll (CHC) Theory

The CHC model is likely the most prominent contemporary psychometric theory. Its elements have long been incorporated into the Woodcock-Johnson Cognitive Assessment Battery (initially as Gf-Gc theory; Woodcock, 1990; and later as CHC itself; Woodcock, McGrew, & Mather, 2001), it has received prominent treatments both in the scholarly literature and in practical assessment guides (Lichtenberger & Kaufman, 2013; Newton & McGrew, 2010), and at the time of this writing, a major review of CHC (McGrew, 2009) lists more than 700 citations in the Google Scholar database.

According to a recent chapter detailing the tenets of CHC, the theory consists in two primary components. First, it provides a "taxonomy" or classification of human cognitive abilities, and second, it provides "a set of theoretical explanations for how and why people differ" in those respects (Schneider & McGrew, 2012). As the name indicates, CHC represents a synthesis of the Cattell-Horn extended theory and John Carroll's three-stratum model. Although *g* is included, owing to the disagreement between its namesakes regarding its status (McGrew, 2009, p. 4), the substantive emphasis of CHC is decidedly on the broad and narrow factors. Not only is the casual status of *g* left undetermined, but practitioners who adopt CHC are explicitly encouraged to ignore it if they question its theoretical value and particularly for practical aspects of assessment (Schneider & McGrew, 2012, p. 111). A schematic depiction of CHC would thus be similar to Fig. 2.5 above but lacking a causal arrow from *g* to the broad factors or the emphasis on *g*-loadings.

Although the most well-known treatment of CHC lists ten broad (Stratum II) abilities along with six tentative factors, McGrew and colleagues have since reorganized aspects of the framework to clarify the conceptual groupings among the factors at that level (Schneider & McGrew, 2012). The present section draws heavily from their excellent exposition, which interested readers should consult for a deeper treatment, as well as practice guidelines. The first conceptual grouping corresponds to Domain-Free General Capacities and includes Fluid Reasoning (Gf), two memory factors (Short-Term Memory, Gsm, and Long-Term Storage and Retrieval, Glr), and three cognitive speed factors (Processing Speed, Gs; Reaction and Decision Speed, Gt; and Psychomotor Speed, Gps). These factors group together because they all emphasize more process-related aspects of cognition (e.g., how fluently can one perform a task, how readily can one recall information) as opposed to particular content.

Next, CHC emphasizes four broad, content-related factors under the heading of Acquired Knowledge. These are Comprehension-Knowledge (Gc), Domain-Specific Knowledge (Gkn), Reading and Writing (Grw), and Quantitative Knowledge (Gq). Naturally, these factors depend at least in part on educational and cultural exposure, and on that basis Schneider and McGrew (2012) emphasize their conceptual alignment with Cattell's crystallized intelligence factor. While the expression of these skills clearly depends on specific content and hence cultural exposure, it remains the case that many narrow capacities in this domain nevertheless have process aspects as well. For example, while this domain includes the narrow capacities of General Verbal Information and Lexical Knowledge (loading on Gc), it also includes skills such as Reading Comprehension and Writing Speed (including under Grw). As an interesting side note related to this domain, despite its seemingly straightforward character, Gc arguably represents one of the more controversial factors in intelligence research, both in the CHC model and in the field as a whole. For example, in contrast to early theory which predicted stronger genetic influences on fluid rather than crystallized skills (Cattell, 1963), there is now evidence that more culture-loaded factors may actually be the *most* heritable abilities (Kan, Wicherts, Dolan, & van der Maas, 2013). Indeed, even the status of Gc as a true cognitive capacity is currently under debate (for further reading, see Kan et al., 2011).

In the last conceptual grouping, CHC emphasizes a set of more modality-specific capacities, in the form of Sensory-/Motor-Linked Abilities. Each of these factors is tied to its respective sensory modality, where the list includes Visual Processing (Gv), Auditory Processing (Ga), Olfactory Abilities (Go), Tactile Abilities (Gh), Kinesthetic Abilities (Gk), and Psychomotor Abilities (Gp). Note that these factors are not thought to be mere perceptual capacities but more complex mental operations that depend upon a given modality. For example, Gv entails visualization skills such as those required for mental rotation tasks or for imagining obscured portions of objects, while Ga includes phonemic decoding (implicated in some forms of dyslexia; Coslett, 2003) and memory for sound patterns. However, these examples notwithstanding, it remains the case that assessing some of these skills often entails mere acuity tests (e.g., olfaction, tactile skills; Schneider & McGrew, 2012). Overall, while this grouping undoubtedly includes valid dimensions of individual differences, it nevertheless also seems clear that additional research in this area is needed (Stankov, 2017).

Finally, with regard to CHC's theoretical implications, the current framework is perhaps closest to Cattell and Horn's views which emphasized the diversity of abilities, as opposed to the relative primacy of any given factor in defining intelligence. This is perhaps also consistent with CHC's very practical emphasis, in that it aims to bridge the "theory-to-practice gap" in cognitive and educational assessment (McGrew, 2009, p. 4). That is, because CHC emphasizes broad and narrow abilities, it provides a very practical framework from which to guide assessment of individual people, with their unique and diverse needs. Thus, whereas the ambiguous status of *g*, or some of the less-well established Sensory-/Motor-Linked Abilities, is somewhat unsatisfying from a theoretical perspective, CHC nevertheless has the unique virtue of eschewing those sometime esoteric debates in favor of very explicitly seeking to inform practical considerations.

Verbal-Perceptual-Image Rotation (VPR)

An equally valid, but somewhat underappreciated, model is the VPR theory, which was first articulated by Johnson and Bouchard (Johnson & Bouchard, 2005b). Using a dataset comprised of 42 cognitive ability tests that had been administered to 436 adults, those authors set out to examine whether the Cattell-Horn two-factor Gf-Gc model, Vernon's v:ed-k:m model, or Carroll's three-stratum model best fit the data. Although they concluded that each model fit reasonably well, they also noted a number of issues. For example, the Gf-Gc model demonstrated a high correlation between those two factors, suggesting the presence of a *g* at a third stratum. In addition, the same model contained two lower-order abilities below the primary level that reflected fluid and crystallized skills, but these proved to be statistically indistinguishable from their respective higher-order factors. The Vernon model performed well, but did not meet the authors' a priori criteria for model fit, failed to represent memory, and also showed a very high correlation between its lower-order verbal factor and v:ed. In the three-stratum model, the fluid intelligence factor was indistinguishable from *g*.

On that basis, the authors sought to evaluate a new model, using Vernon's model as a guide but adding another factor to better account for the data. Ultimately, they arrived at what they termed the VPR model (Fig. 2.6), which, as the name indicates, identifies three broad factors below the level of *g*: verbal ability, which includes things like linguistic and scholastic skills (e.g., memorization); perceptual ability, which includes skills like the ability and speed with which one detects patterns; and image rotation, which more uniquely captures perceptual tasks that emphasize rotation per se (note that some tests load on multiple factors; Johnson & Bouchard, 2005b).

In discussing the advantages of the VPR model, the authors noted that whereas Gf-Gc includes both verbal and perceptual content as part of crystallized intelligence (e.g., mechanical ability is both learned and spatial), both Vernon's model and the VPR model distinguish these as loading on factors that reflect their respective content. Indeed, such a division of verbal and spatial skills has been repeatedly borne out in replications of VPR, where it has been shown that various tests which should theoretically reflect crystallized intelligence (e.g., naming pictures, identifying tools) have actually had *negative* loadings on the crystallized factor (Johnson & Bouchard, 2005a; Johnson, te Nijenhuis, & Bouchard, 2007). Over the course

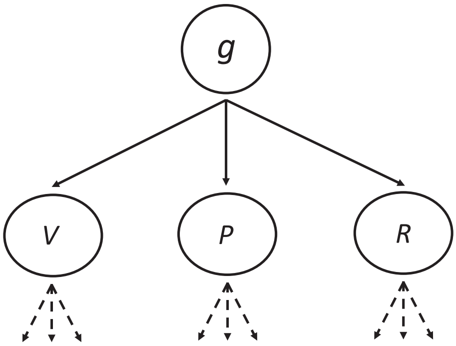

Fig. 2.6 Verbal-perceptual-image rotation model. Schematic depiction of the VPR model. Dashed arrows reflect the fact that first-order factors are unspecified (see text). *V* verbal, *P* perceptual, *R* image rotation

of those and subsequent studies, Johnson and colleagues have now consistently demonstrated the relative superiority Vernon's model over that of Gf-Gc, for both statistical and substantive reasons, as well as the superiority of VPR in turn (Johnson et al., 2007; Johnson & Bouchard, 2005a). VPR has since been shown to fit better than either the extended Gf-Gc model or a three-stratum version of CHC (Major, Johnson, & Deary, 2012).

From a theoretical standpoint, VPR is unique in emphasizing a *dimensional* view of intelligence, such that verbal and rotational skills are thought to represent two poles on a continuum (Major, Johnson, & Deary, 2012). Notably, this may conceptually align it with the well-known (relative) specializations of each cerebral hemisphere (i.e., the left hemisphere is typically dominant for language and sequential processing; the right hemisphere is typically dominant for spatial and configural processing; Lezak et al., 2012), giving it a strong degree of neurological plausibility (Johnson & Bouchard, 2005b). Relatedly, the VPR model also explicitly avoids pre-specifying the number and content of lower-order factors (Major et al., 2012, p. 544), arguing that these instead will depend on the test batteries at hand. Thus, when constructing a model based on a given sample and battery, the obtained perceptual factor may correlate more highly with verbal ability, depending on the exact tests from which it is derived (e.g., if the stimuli tend to induce verbalization), while in another battery with a greater proportion of highly spatial tasks, the perceptual factor might relate more strongly to image rotation.

Overall then, VPR represents a departure from the tradition of precisely specifying models down to all of their constituents. Rather, it aims for a more parsimonious view of intelligence, wherein a *g* factor influences task performance by virtue of its relation to just a few higher-order factors, which are aligned on a single verbal-spatial dimension. While it may be possible to enumerate all of the lower-order capacities in the manner of CHC, VPR instead prioritizes parsimony in its account of intelligence. Although its practical applications are less-developed than that of CHC, its strong base of empirical and substantive support nonetheless makes it a viable alternative to its more prominent counterpart.

Bi-factor Models of Intelligence

Another important class of models to briefly consider is the bi-factor models, which are unique in the way that they represent the relationship between *g* and the group factors. In all of the hierarchical models discussed up to this point, *g* influences individual test scores solely by virtue of its relation to the group factors (Cucina & Byle, 2017). This means that the latter account for all the shared variance among the tests that load on them (e.g., the shared variance among a group of working memory tasks would be fully explained by a working memory factor), with *g* then being modeled at a higher level to account for the correlations between the group factors. Under this scenario, any change in an individual's level of *g* can only impact their test performance through the resulting impact on the relevant group factor(s) (Beaujean, 2015).

In contrast, bi-factor models also allow one to represent *g*, but they instead place it in a nonhierarchical relation. Here, rather than first extracting primary factors and then modeling *g* based on their relations, *g* is extracted first, and primary factors are extracted separately from the remaining shared variance among the tests (Jensen, 1998a, p. 78). This means that the resulting factors are independent of variance due to *g*, with all the latent factors existing at the same level of the model (Gignac, 2016b; Morgan, Hodge, Wells, & Watkins, 2015; and see Fig. 2.7). The result is that variation in test performance across individuals can reflect *either* variance due to *g* or that due to the primary factors, with the two being completely independent (Beaujean, 2015; Morgan et al., 2015).

Following from the previous example, in a bi-factor model, one's score on a given working memory test would be a function of *both* one's level of "general intelligence" and their independent, more specific working memory ability. Setting aside the various technical considerations

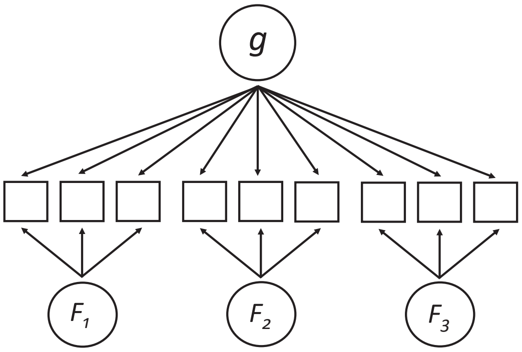

Fig. 2.7 Example bi-factor model. Schematic bi-factor model with three group factors. Boxes represent measured variables (specific tests), and circles represent latent factors as above. Each arrow going from a latent factor to a measured variable reflects the former's unique contribution to variance in the latter

related to the challenges and virtues of the bi-factor model (see Gignac, 2016b; Morgan et al., 2015; Murray & Johnson, 2013), these models are of substantive interest because they provide an alternative way to think about *g*. Namely, because both the general and group factors independently account for test performance in these models, they seem to allow a greater reconciliation between the empirical evidence for *g*, on the one hand, and the notion that more specialized skills might have additional explanatory utility on the other (e.g., Benson, Hulac, & Kranzler, 2010).

The Mutualism Model

The final psychometric model is somewhat akin to Thomson's sampling theory in also offering a very different perspective on psychometric *g*. Specifically, whereas sampling theory argues that the positive manifold arises from a situation where cognitive tests recruit overlapping sets of neural connections, the mutualism model holds that initially uncorrelated processes, such as group factors like memory and perceptual ability, come to be correlated through reciprocal positive interactions that occur during development (van der Maas et al., 2006). In essence, what are initially independent processes come to support the growth of one another, thereby increasing their interrelations. Some related examples from the empirical literature come from the work of Demetriou and colleagues, who have shown that various lower-order factors appear to play different roles in intelligence at different developmental phases (Demetriou et al., 2013; Makris, Tachmatzidis, Demetriou, & Spanoudis, 2017).

Using simulation studies,[4] van der Maas et al. (2006) demonstrated that given a model containing no relationships among limiting resources but with positive correlations between otherwise independent processes, factor analyses of the simulated data are nonetheless consistent with a single major latent factor such as psychometric *g*. As a result, because the model is comprised of multiple, separate but *correlated* processes, the resulting statistical pattern cannot be said to result from a single underlying cause. Thus, although fully hypothetical, the mutualism model suggests an alternative route by which *g* could statistically arise, but without a unitary cognitive or neurological basis. In turn, van der Maas and colleagues further demonstrated that the mutualism model could also explain several other important phenomena in the intelligence literature. These include the more complex cognitive hierarchies like the models described above, as well as patterns of intellectual development, intra-subject variability, and cohort effects on IQ test performance (see discussion and details in van der Maas et al., 2006).

In the time since mutualism was first proposed, the theory has received mixed support. For example, although mutualism suggests that *g* should account for more variance in test performance as children grow older, a study that examined this in a cross-sectional sample ranging from 2 to 90 years old failed to support this (Gignac, 2014). A second study also argued against mutualism when it failed to find expected patterns in factor-analytic results (Gignac, 2016a). However, proponents of mutualism debated the prior

---

[4] Primary simulations were based on 16 hypothetical neurocognitive processes, which were each independently sampled from pre-specified distributions to define 1000 simulated subjects. Different models specified various constraints and relationships among model parameters.

study's premise (van der Maas & Kan, 2016). These issues notwithstanding, in the most recent and direct test of mutualism to date, a longitudinal study did find evidence for reciprocal positive interactions between two broad abilities over the span of almost 2 years (Kievit et al., 2017).

Finally, the mutualism model provides a good venue to raise an additional point related to modern conceptions of psychometric ability models. Specifically, while most of the models considered here are said to be *reflective* in nature, mutualism (along with sampling theory and possibly VPR; Deary, Cox, & Ritchie, 2016; Major et al., 2012, p. 544) instead represents what is known as a *formative* model (van der Maas, Kan, & Borsboom, 2014). In a reflective model, the latent factors are understood to be the cause of the observed variation in the individuals' test scores, in the sense that factors are taken to represent real entities (Borsboom, Mellenbergh, & Van Heerden, 2003; Kievit et al., 2011), without which the observed results would not be obtained. As an example, whenever one attributes a global quality to an individual, e.g., he or she broke the law because they are simply a "bad person," one is implicitly making a reflective explanation—an underlying attribute of the person was the cause of their behavior. Under this scenario, because of the specified causal direction, changing the subtests that are used to measure the variable (intelligence in this case) would change the accuracy of the measurement, but could not logically affect the variable itself (Kievit et al., 2011).

In contrast, although formative models also relate latent factors to observed data, here, the factors are merely understood to be weighted composite scores, such that the data are responsible for the composition of the factor, as opposed to vice versa (van der Maas et al,. 2014). Common examples of formative variables include constructs like socioeconomic status and "overall health," where it can be readily seen that many diverse factors come together to define them. Researchers might disagree about whether cardiovascular efficiency or strength and flexibility are more important aspects of health, but they likely would not argue that an underlying "health factor" was the cause of variation in both. The two are of course often related in healthy people, but it is possible to have one without the other. In turn, to the extent that one chose to measure one dimension at the exclusion of the other, these choices could produce very different pictures of a person's overall health. In this instance, the choice of indicators determines the attributes of the factor, rather than the reverse (see Fig. 2.8). Finally then, returning back to intelligence, it can be seen how the formative/reflective distinction provides a useful way for thinking about *g*. Although reflective models *imply* a unitary cause for variation in intelligence, the mutualism model (along with sampling theory) shows that this is not necessarily the case. Rather, *g* could in fact be legitimately unitary in a statistical sense, while still ultimately resulting from many underlying processes (Deary et al., 2016).

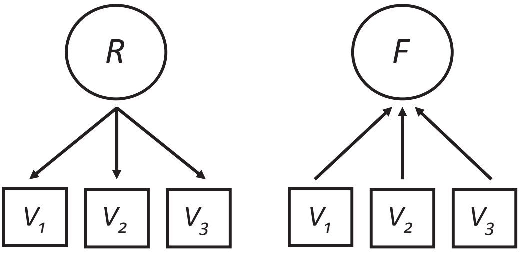

Fig. 2.8 Reflective vs. formative models. In a reflective model (left), including most models of intelligence, the latent factors are to understood as causing the variation in the obtained scores (V_1–V_3). In a formative model (right), the casual direction is reversed such that the composition, and thus the nature, of the latent factor entirely depends on the variables used to measure it. Error and residual terms and other parameters are omitted for simplicity.

Summary of Psychometric Theories

To summarize this section, psychometric theories of intelligence have addressed the "structure" of the construct, considering the role of various specific and broad factors (e.g., Gf and Gc) and of course the role of *g*. While early historical accounts debated whether intelligence is better reflected by a single general factor (*g*) or a series of independent skills, more recent theories have generally endorsed a hybrid of the two. That is, intelligence likely has a hierarchical structure, with *g* at the top, and broad factors operating between *g* and performance on particular types of tests. Practically, this suggests that a single general capacity influences all tasks, regardless of their content, although more specific abilities govern the relation between *g* and specific tasks. More recent theories have also debated the nature of these broad factors, with CHC perhaps being the most comprehensive, though VPR offers a conceptually simpler account centered around a verbal-spatial continuum. These two theories emphasize continuity with different theoretical traditions, but they differ in their emphasis on practical utility vs. theoretical consistency. Still other psychometric theories acknowledge the empirical phenomenon of *g* but propose alternative ways that it might come about, in terms of the interrelations between lower-level cognitive and neural processes. Overall, while psychometric theories are useful for thinking about the structure of intelligence (i.e., is it a single capacity or many?), they say less about its "nature." These latter issues, such as whether intelligence relates to more basic or complex processes, and its more-detailed information processing basis, are better addressed by conceptual theories of intelligence, as reviewed in the next section.

Conceptual Theories of Intelligence

Because psychometric theories involve a high degree of mathematical rigor, they have perhaps justifiably dominated discussions about intelligence. Nevertheless, a number of more conceptually oriented theories still have their place in filling out the scope of these debates. These models run the gamut from being primarily theoretical and rationally derived, to those that are backed by a substantial body of empirical results. In the latter category, some models (especially those that emphasize working memory and processing speed) could also claim substantial psychometric support. Yet, insofar as they advocate for *particular* processes in defining intelligence and also bring experimental methods to bear on their views, they are somewhat more similar to conceptual models than the primarily statistical frameworks outlined above. In every case, though, the models and theorists highlighted below have been selected for review because of the ways in which they exemplify other key or controversial ideas in theories of intelligence.

Francis Galton: The Reductive Tradition in Intelligence Research

Sir Francis Galton is generally regarded as the most important early figure in the modern era of intelligence research.[5] His work took place in the context of Victorian England with evolutionary theory in the intellectual milieu (Jensen, 1998a), including its emphasis on the role of genes in determining the traits of organisms. Whereas many at the time held that intelligence could "act independently of natural laws," Galton held the contrary, evolutionary view that genes and the biological processes they govern should be important determinants of intellectual ability (Galton, 1883). In turn, by examining the implications of just that single assertion, one can derive what are perhaps Galton's three most important intellectual contributions.

First, if mental capacities are akin to physical traits in being subject to biological principles, this means that, like other phenomena in the natural sciences, intellectual capacity should be amenable to objective quantification. Thus, it should be possible to develop reliable measures of intellectual ability that can quantify differences among individuals. Second, if mental ability is largely determined by genetic variation, then more fundamental attributes of individuals (those which are more closely tied to their genes) might place constraints on higher-order mental skills. For Galton, this meant that the basic efficiency of lower-order, sensory-motor capacities (those that should be more directly tied to basic nervous system functions, like nerve conduction

---

[5] Though see Deary's (2000, Chap. 2, and p. 68) account of several authors who espoused similar views but predated Galton

speed) should limit "the field upon which our judgment and intelligence can act" (Galton, 1907; cited in Wasserman, 2012). Thus, while Galton did not necessarily hold that intelligence could be *fully* reduced to lower-order capacities, the primacy he placed on them nevertheless exemplifies the reductive tradition. Third, Galton also made a number of statistical contributions, being the first to develop a measure of the relation between two variables (the forerunner to Pearson's correlation coefficient) and to use the normal distribution to rank individuals on an interval scale (Jensen, 1998a, pp. 10–11). Thus, he provided a foundation not only for differential psychology but also for normative principles that are still used today.

In pursuit of these various ideas, Galton established his "anthropometric laboratory" in London, where, for a small fee, members of the public could be measured on mostly low-level traits and capacities, such as height, grip strength, breathing capacity, and visual and auditory acuity (Sattler, 2008; Wasserman, 2012). Although he amassed data on more than 9000 individuals, likely owing in part to methodological limitations, his measures proved only weakly related to indices of intelligence (e.g., occupational attainment; Jensen, 1998a, Chapter 11). As recounted by Deary (2000, Chapter 2), subsequent prominent but likely overemphasized failures to apply Galton's measures to *practical* assessment may in part account for the waning of interest in Galton's approach and the following stagnation in reductive research. In the time since, the approach has rebounded, and a more balanced view has emerged. On the one hand, many recent studies, including meta-analyses and population-based research, clearly support Galton's contention that lower-order processes should relate to intelligence (e.g., Acton & Schroeder, 2001; Deary, Der, & Ford, 2001; Euler, McKinney, Schryver, & Okabe, 2017; Melnick, Harrison, Park, Bennetto, & Tadin, 2013). Nevertheless, to the extent that effect sizes are modest (typically correlating near $r = -0.30$; Sheppard & Vernon, 2008), their conceptual significance remains open to debate.

Alfred Binet and David Wechsler: Theoretical Insights Gleaned from Practical Assessors

In contrast to Galton's decidedly theoretical aims, the work of Alfred Binet and David Wechsler, who respectively developed the Binet-Simon and Wechsler Intelligence Scales, illustrate a number of insights that were gleaned through more practical endeavors. Specifically, while it would be difficult to discount the predominant role of theory and basic research in advancing this field, the systematic research through which these measures were developed nevertheless yielded important principles that have stood the test of time. Indeed, even if there were no principles guiding their development (untrue in either case; Binet & Simon, 1916; Wechsler & Edwards, 1974), the immense practical success of these instruments (and the tests they inspired) would seem to speak to their construct validity. To wit, if an instrument is near-universally accepted as a valid measure of intelligence, then it stands to reason that the principles that govern it may help elucidate the construct.

In the case of Binet, he and his colleague Theodore Simon developed what is now generally recognized as the first useful test of intelligence in the Binet-Simon scale, with the goal of better identifying children with intellectual disabilities (Sattler, 2008). In the course of their studies, Binet articulated what has proved to be a fundamental principle not only of intelligence testing but of intelligence itself. Specifically, he identified that more complex measures involving multiple dimensions are far superior to simple tasks as measures of intelligence—for the reason that complex tasks elicit more variability across individuals (Wasserman, 2012, p. 14). Here then, is a clear contrast between the lessons suggested by Galton and Binet's work. As Binet acknowledged, simpler measures can be more precisely controlled with respect to stimulus characteristics and the like. Yet, because simple measures elicit little variability across individuals, this mitigates their advantage over less precise but more *sensitive* tasks that involve more complex mental operations (Binet & Henri, 1894; quoted in Wasserman, 2012). Thus, although narrow psychophysical capacities may meaningfully relate to, and even constrain, overall intelligence, the construct itself seems to inherently represent a *higher-order* capacity. In addition, Binet also emphasized the necessity of using multiple tasks to arrive at a composite intelligence measure (Binet & Simon, 1916), and he considered individual tasks to be of questionable value (Boake, 2002). Not only has this become a foundational principle of most intelligence tests, but it also reflects the core theoretical notion that intelligence represents a fundamentally general capacity (Gottfredson, 1997a).

Although David Wechsler was more theoretically inclined than Binet (and produced a number of theoretical papers; Wechsler & Edwards, 1974), he was also largely concerned with practical assessment. Here again though, it can be seen how his practical considerations served to clarify a key feature of intelligence. In particular, while serving in the army, Wechsler was tasked with individually examining unschooled recruits or those with limited English proficiency, who had been deemed intellectually disabled based on their performance on the very verbally dependent Stanford-Binet (Boake, 2002). Yet, in many cases it was evident to Wechsler that these recruits had previously held significant social and professional responsibilities, attesting to their average if not higher intelligence. Based on these experiences, Wechsler came to believe that intelligence could be expressed equally well through verbal and "performance-based" measures (i.e., perceptual and visuospatial tasks) and strove to include diverse measures spanning both dimensions in developing his own scales (Matarazzo, 1972, Chapter 8).

On the one hand, this represents a practical and clinical necessity. For certain examinees, such as those with various neurological syndromes or with limited English proficiency, one might indeed expect their intelligence to be better expressed through a particular route. Yet, like Binet, Wechsler's clinical insight around this reflected a deeper fact about intelligence itself. Namely, that although most healthy individuals will not demonstrate such discrepancies, intelligence itself is broader than any single dimension and thus can be expressed through multiple routes. Not only is this evident in the ubiquity of *g* but also in the somewhat lesser-known phenomenon of the "indifference of the indicator." As discovered by Spearman (1927), this refers to the finding that highly diverse measures with no content in common (e.g., vocabulary vs. visuospatial reasoning) can in some instances predict intelligence equally well (see: Wechsler, 2008; Table 5.1). Thus, as in Binet's case, although practical considerations drove Wechsler's approach, the insights he derived reflected important aspects of intelligence.

Arthur Jensen and Lazar Stankov: Contemporary Debates Around Reductive Approaches

On the spectrum of unitary-non-unitary perspectives of intelligence, Arthur Jensen is a strong supporter of an overall *g* factor. Where Jensen differs from psychometric approaches, however, is in his extensive use of mental chronometry (reaction time-based tasks; RT) as a means to assess information processing accounts of intelligence. As a *g*-theorist, Jensen believed that intelligence could be reduced down to one fundamental process, which he tried to capture through patterns of RT performance (Jensen, 1981). He proposed that speed of information processing (SOP; Jensen, 1993) was this fundamental process and tried to link IQ scores to mathematical models of RT task performance (Hick's Law; Hick, 1952). These studies argue that intelligence is about how long it takes one to process a "bit" of information (Jensen, 1981, 1982, 1998a, 1998b), with variation in other processes (e.g., working memory—one's ability to hold and manipulate information held in mind) being the result of variability in SOP (Jensen, 1993). While a correlation between RT and IQ scores is a well-replicated finding (Sheppard & Vernon, 2008), there is much debate about the nature of this relationship (Stankov & Roberts, 1997) and what it means for understanding intelligence.

In an attempt to resolve these questions about RT-IQ correlations, mental chronometry has explored how discrete processes typically examined in cognitive psychology (working memory, etc.) could be related to intelligence. For example, while overall RT correlates with IQ scores, so does the variability of one's RT within a given task (RT standard deviation; RTSD; Doebler & Scheffler, 2016; Jensen, 1992). Likewise, one's slowest individual RT trial often correlates better with intelligence than their fastest RT (Rammsayer & Troche, 2016; Ratcliff, Schmiedek, & McKoon, 2008). This led to theories that higher-ability people may experience less "neural noise" (Jensen, 1993) or have better "evidence accumulation" during decision-making (Schmiedek, Oberauer, Wilhelm, Süß, & Wittmann, 2007). Finally, since chronometric tasks lend themselves well to neuroscience methods, the two approaches have begun to merge. Indeed, Jensen argued that explanations for chronometric effects would only be valid insofar as they were biologically plausible (Jensen, 1993). In a way, many contemporary neuroscience-based theories of intelligence (such as Process Overlap Theory, discussed below) could be considered intellectual descendants of Jensen's initial linkage of experimental and differential psychology.

An interesting contrast with Arthur Jensen's reductive approach can be found in the work of Lazar Stankov and colleagues. While Jensen tried to link chronometric performance to a unitary *g*, Stankov instead used experimental approaches to consider how the coordination of several processes, as opposed to a particular one, might define intelligence. Specifically, he argues that intelligence reflects the capacity to engage multiple processes simultaneously to accomplish a task. Indeed, Stankov has provided experimental evidence demonstrating that tasks with increasing numbers of components (i.e., more complex tasks) correlate better with intelligence (Stankov & Crawford, 1993; Stankov & ,Raykov 1995). While Stankov acknowledges *g*, he argues that it is generally overemphasized and that second-stratum factors are more important to understanding intelligence (Stankov, 2017). In line with his emphasis on higher-order coordination of discrete processes, Stankov has also advocated for the integration of non-cognitive process into models of cognitive ability (e.g., emotional intelligence and meta-cognition; Stankov, 2017). Thus, in contrast to Jensen who emphasized the primacy of *g*, and speed of processing as its ultimate basis, Stankov's work illustrates an alternative experimental approach that eschews strong reductionism and emphasizes a more holistic perspective.

The Role of Executive Abilities: Working Memory Capacity and Process Overlap Theory

The negative correlation between intraindividual variability in RT and IQ scores (meta-analysis: Doebler & Scheffler, 2016) suggests that attention may be an important component of intelligence, for the reason that higher variability may reflect attentional lapses. The execution of the top-down attention (commonly called executive functioning; EF) is thought to reduce RT variability and promote higher Working Memory Capacity (WMC; Bellgrove, Hester, & Garavan, 2004; Miyake, Friedman, Rettinger, Shah, & Hegarty, 2001). Given these findings, it is perhaps not surprising that structural models often find strong relationships between intelligence and WMC. Research examining the known neurophysiological correlates of these constructs has highlighted the importance of the prefrontal cortex (Kane & Engle, 2002, 2003) as a common neural substrate of both EF and Gf (a robust correlate of *g*). These authors argue that fluid reasoning is achieved through the manipulation of information held in working memory and that WMC (and thus EF as well) acts like a "bottleneck" on reasoning and the expression of intelligence (Kane & Engle, 2002). In the time since, process overlap theory (POT; Kovacs & Conway, 2016) has been developed from this original WMC model. POT integrates experimental (e.g., RT variability, complexity effects) and psychometric (e.g., IQ-WMC correlation) findings to propose frontal-parietal networks as the ultimate neural basis of the aforementioned bottleneck, consistent with the known neuroimaging correlates of intelligence (Basten, Hilger, & Fiebach, 2015; Jung & Haier, 2007). While POT is a relatively new theory, it integrates a number of findings in the intelligence literature and, unlike many theories, proposes fairly concrete neurological correlates. While POT strongly emphasizes WMC, the latter's relation to intelligence is perhaps best thought of as a necessary, but not sufficient explanation (Redick et al., 2013), with intelligence being a broader construct and WMC acting as a limiting factor.

The Planning, Attention, Simultaneous, and Successive Model

The Planning, Attention, Simultaneous, and Successive (PASS) model of intelligence was developed by Naglieri and Das (1990) and was heavily influenced by the work of the esteemed neuropsychologist Alexander Luria. Like POT, PASS also emphasizes the role of EF but also considers lower-level cognitive operations in its conceptualization of intelligence. PASS theory outlines how any complex task involves three different functional units that are differentially involved depending on the task demands. The first unit corresponds to basic attention processes, the second unit corresponds to perceptual processing and multimodal sensory integration, and the third unit corresponds to the planning, maintenance, and correction of behavior. Das and Naglieri argue that these three units are involved in all tasks, whose effective coordination and integration with prior knowledge constitute intelligence. That is, intelligence is the capacity to (1) effectively engage with the environment (2), process information from the environment (3), and plan/execute effective behavior in the environment based on that information. The authors argue that the structured nature of current IQ tests do not adequately capture the first and third functional units (specifically basic attention and planning processes), thus limiting their capacity to make more sophisticated claims about an individual's real-world achievement.

In support of the PASS model, studies have found that neuropsychological tests of executive functioning (corresponding to the third unit) are more predictive of daily functioning (Barkley & Fischer, 2011) and achievement (Clark, Prior, & Kinsella, 2002) than IQ tests alone. A handful of studies suggest that PASS-based measures are at least as sensitive to dysfunction in ADHD and academic achievement as traditional IQ tests (Naglieri & Bornstein, 2003; Naglieri, Goldstein, Delauder, & Schwebach, 2005; Naglieri, Goldstein, Iseman, & Schwebach, 2003), though some argue that PASS is merely a recapitulation of certain CHC factors (Keith, Kranzler, & Flanagan, 2001). While the evidence for PASS is somewhat limited, it highlights the synergistic importance of processes at all levels of the cognitive hierarchy, from basic attention to complex planning and reasoning, when considering real-world success.

Detterman's System Theory of Intelligence

Finally, Detterman's (1987) system theory of intelligence is noteworthy here because in addition to trying to explain the nature of intelligence, it explicitly addresses intellectual disability. As outlined above, a major debate in intelligence research concerns whether intelligence is fundamentally unitary, as at least superficially implied by psychometric *g*, or whether various correlated but ultimately independent factors better represent the construct's true structure. For individuals with cognitive disabilities, this could (hypothetically) translate into either (1) a deficit in overall ability (*g*) or, possibly, (2) a deficit in some but not all cognitive abilities. Detterman's model provides an innovative, partial synthesis of these two ideas, in that it recognizes and explains *g* but in a way that also acknowledges the multiple factors that make up intelligence.

Specifically, Detterman takes a *systems* view, in arguing that intelligence arises through the interactions of "independent but interrelated parts" (Detterman, 1987). In explaining this concept, he likens IQ scores (which aggregate performance over multiple tests) to the ways in which one might rank universities. For example, one might evaluate various different aspects of a university, like the quality of the faculty and the facilities, the size of the endowment, its physical location and layout, etc., and sum them together to derive an overall score. As just described, each aspect could in principle be fully independent, with the resulting score reflecting an aggregate index of the university's overall quality. Note however, that in practice, such factors will likely not only be correlated, but any *central* factors, like the size of the endowment, will set a limit on the level of the others (Detterman, 1987). Thus, in the case of intelligence, various group factors (or still lower-level processes) might seem independent in principle, yet if some are more central than others, they will place limits on the rest. Indeed, the working memory and process overlap theories of intelligence make exactly this case.

Detterman's theory also has specific implications for intellectual disability. He argues that if intelligence reflects the operation of an interconnected neural system, where some parts are more central than others, this implies that inefficiencies in central resources should cause scores among cognitive tests to be more interrelated at lower levels of ability (Detterman, 2002). Conversely, individuals with highly efficient central processing resources will have fewer constraints on the development of their more specific capacities, and hence cognitive test scores should be less highly related at higher ability levels. Indeed, Detterman and Daniel (1989) found evidence for this exact phenomenon (also known as cognitive differentiation), which has been replicated in numerous other studies (Blum & Holling, 2017; Tucker-Drob, 2009). In the case of intellectual disability, Detterman predicted that it "would be shown to be a deficit in one or more basic abilities…with a moderate to high degree of centrality (Detterman, 1987, p. 8)." Notably though, as discussed further on, he was also careful to note that this does not mean that all intellectual disabilities result from a single cause.

Other Prominent Theories

Finally, there are two other prominent theories of intelligence that also deserve brief mention. Both Howard Gardner's theory of multiple intelligences and Robert Sternberg's Triarchic Theory of Successful Intelligence are widely cited accounts, which remain prominent in some fields. Although these theories do not have strong support among most contemporary intelligence researchers (Warne, Astle, & Hill, 2018), their popularity in applied settings warrants a brief review.

Gardner's Theory of Multiple Intelligences

On the spectrum of intelligence theories which include few to many factors, multiple intelligences (MI) is perhaps only less expansive than that of CHC. Published in the book *Frames of Mind* (Gardner, 2006), MI outlines the view that there are eight conceptually distinct intelligences, which are all of equal importance, with no hierarchical structure. Gardner arrived at these ideas through extensive readings in a variety of different fields, but did not generate any data to empirically test his theory. To date, experimental studies trying to validate MI theory have yielded limited empirical support (Almeida et al., 2010; Visser, Ashton, & Vernon, 2006).

Overall, while the notion that there can be multiple distinct forms of intelligence, which are not all cognitive in nature, is appealing in some respects, this idea is better supported by other theories, with a larger empirical base. For example, Stankov (2017) has argued that emotional intelligence should be considered as a second-order factor in CHC, thereby presenting a more empirically grounded alternative to Gardner's interpersonal and intrapersonal intelligences. Likewise, Carroll convincingly argued that capacities such as musical and mathematical ability, which are included in MI in various forms, actually express themselves via different contents at different levels of ability and also involve numerous lower-order skills (e.g., visualization, induction, sequential reasoning, in the case of mathematical ability). Thus, Carroll argued that such constructs should be regarded as "inexact… popular concepts[s]" rather than distinct, scientifically supported cognitive capacities (Carroll, 1993, pp. 626–627). Finally, insofar as there is essentially overwhelming evidence for the *psychometric* reality of *g* (as distinct from its potential neural basis, which remains undetermined), the literature provides little support for the view that all aspects of intelligences are equally influential, with no hierarchical features.

Sternberg's Triarchic Theory of Successful Intelligence

Finally, Robert J. Sternberg's prominent theory of successful intelligence also deserves a mention here. Overall, Sternberg emphasizes the ecological aspects of intelligence, contrasting between intelligence as typically discussed, and *successful intelligence*, which is argued to be a more comprehensive construct that considers one's sociocultural context and idiographic patterns of strengths, weaknesses, and experience (Sternberg, 1999). His conceptualization of intelligence strongly emphasizes the interactive, transactional nature of an individual within their environment (i.e., the adaption, selection, and shaping of one's environment), focusing on how factors like specific goals, prior experience, and contextual information can change the expression of intelligence (Sternberg, 2012). As such, he argues that the measurement of intelligence should depend on the goals and the environmental context of the individual, as opposed to traditional IQ tests. Sternberg's triarchic theory emphasizes the role of not only analytical skills (his term for what most IQ tests measure) but also creative (i.e., idea generation) and practical skills (i.e., implementation of ideas in real-world settings), so that an individual can be successful as they define it within their environment (Sternberg, 2012). Collectively, these skills are referred to as process skills, which together with meta-components (somewhat like executive functions as described by Suchy, 2015) and knowledge acquisition skills (i.e., learning) are argued to better capture the notion of success in a culturally neutral way. Overall, Sternberg's notion of successful intelligence integrates many often-disparate approaches to studying intelligence (i.e., factor-analytic, experimental, culturally relative, application-based approaches, etc.), and has both some strengths and weaknesses.

Perhaps the most controversial aspect of the triarchic theory relates to the distinctiveness of analytical and practical intelligence and to the extent to which the latter is more predictive of real-world success. Psychometric evaluation of an intelligence test designed specifically to assess the triarchic theory found that a modified *g* model was the best fit for the data (Chooi, Long, & Thompson, 2014). A separate study highlighted that many of Sternberg's findings could potentially be explained by measurement error (Brody, 2003). Additionally, Gottfredson (2003) critically reviewed the studies supporting the triarchic theory and concluded that practical intelligence and traditional IQ scores are statistically related (as opposed to distinct entities), especially when methodological aspects of the studies are considered (e.g., size and diversity of the samples). She further asserted that there is no evidence supporting the idea that a "practical *g*" exists as a separate factor apart from the conventional *g* (an argument supplemented by a separate paper; McDaniel & Whetzel, 2005). In summary, although both the triarchic and MI theories have conceptual merits, relative to the other theories discussed in this chapter, they each have more limited empirical support.

Overall Summary

The preceding sections aimed to give an overview of the historical development of theories of intelligence, with an eye toward articulating the key principles and debates and clarifying current thinking in the area. The overall consensus from psychometric approaches suggests that intelligence consists in an individual's general cognitive capacity, which influences every mental task they might undertake, irrespective of its nature. Although lower-order abilities have a clear and legitimate place in the cognitive hierarchy—consisting in more domain-general, content-related, and modality-specific skills (to borrow from CHC)—their unique significance in determining one's overall intelligence remains a matter of debate. Unlike most contemporary models, which are largely hierarchical, sampling theory

(Bartholomew et al., 2009) and mutualism (van der Maas et al., 2006) both highlight how *g* can arise from a non-unitary basis, giving psychometric credence to the idea that intelligence may result from a collection of interacting processes rather than a single fundamental one.

While psychometric approaches clarify the relationships between cognitive abilities in a detailed way, they are somewhat agnostic as to what *g* and various broad factors reflect in a more functional sense. This is where conceptual theories can help fill in the gap. This latter work has clarified that while lower-order processes play a role in intelligence, it is clearly best characterized as a higher-order capacity and one that is particularly implicated in managing cognitive complexity (Gottfredson, 1997b). Thus, intelligence appears to relate not only to the level of one or more discrete abilities but also to their efficient coordination in support of adaptive behavior. Finally, insofar as the most recent era of experimental and theoretical studies has supported the centrality of particular processes, it appears likely that capacities like WMC and other executive skills (Kovacs & Conway, 2016) or possibly speed of processing (Jensen, 1993; Schubert, Hagemann, & Frischkorn, 2017) may constrain overall intelligence. These constraints are apt to be strongest at lower levels of ability, whereas at higher ability levels, profiles should be more differentiated (Detterman, Petersen, & Frey, 2016). Tables 2.1 and 2.2 summarize the major features of the models discussed in this chapter.

Table 2.1 Overview of historical theories of intelligence

Theory	Major theme	Status of *g*	Emphasizes basic vs. complex processes	Evidence base
Galton	Reductionism	Unitary	Basic	Psychometric, experimental
Spearman	Discoverer of *g*	Unitary	Complex	Psychometric, experimental
Binet	Complex tasks, practical assessment	Ambiguous	Complex	Psychometric
Thurstone	Primary abilities	Non-unitary	Complex	Psychometric
Thomson	Sampling mental bonds	Non-unitary	Basic	Simulation, psychometric
Cattell	Fluid vs. crystallized intelligence	Non-unitary	Complex	Psychometric
Carroll	Hierarchical factor structure	Hierarchical	Complex	Psychometric
Wechsler	Performance-based, practical assessment	Non-unitary	Complex	Psychometric

Table 2.2 Overview of contemporary theories of intelligence

Theory	Major theme	Status of *g*	Emphasizes basic vs. complex processes	Evidence base
Jensen	Speed of processing	Hierarchical	Basic	Psychometric, experimental
Gardner	Multiple intelligences	Non-unitary	N/A	Conceptual
Sternberg	Triarchic/successful intelligence	De-emphasized	Complex	Conceptual, experimental
PASS	Planning, attention, simultaneously, successive	Non-unitary	Complex	Conceptual, psychometric
Detterman	Systems	Non-unitary	Basic	Psychometric, experimental, simulation
Stankov	Role of complexity and group factors	De-emphasized	Complex	Psychometric, experimental

(continued)

Table 2.2 (continued)

Theory	Major theme	Status of *g*	Emphasizes basic vs. complex processes	Evidence base
VPR	Verbal, perceptual, spatial rotation	Hierarchical	Complex	Psychometric
CHC	≥10 broad factors	De-emphasized	Complex	Psychometric
Bi-factor	Simultaneously models *g* and group factors	Unitary	Complex	Psychometric
Mutualism	Developmental, *g* as epiphenomenal	Non-unitary	Basic	Simulation, psychometric
Working memory/process overlap theory	Executive attention	Hierarchical/hybrid	Complex	Psychometric, experimental, physiological

Implications for Intellectual Disability

In applying these concepts to intellectual disability (ID), perhaps the biggest implication is that intelligence, as it manifests empirically through *g* and in turn through IQ scores, is indeed a very general capacity (and note that IQ scores share >80% of their variance with *g*; Kranzler, Benson, & Floyd, 2015). This is all the more so in ID, given that narrow abilities are more strongly interrelated at lower levels of IQ. In turn, since intellectual functioning is of course one of the two central features in the diagnosis of ID (the other being adaptive functioning; American Psychiatric Association, 2013), the effect and hence the goal of the diagnosis should be to identify individuals whose cognitive challenges span diverse content and situations. Thus, unlike other cognitive disorders which are characterized by some degree of specificity (e.g., specific-learning disorders, ADHD), a diagnosis of ID indicates more pervasive cognitive difficulties.

Notably, the ID diagnosis also helps to clarify what intelligence is not. Because ID also requires adaptive impairments, which further establish diagnostic severity, it highlights the fact that cognitive functioning does not wholly determine one's functional capabilities. This same distinction holds within much of intelligence research, where although earlier theories did emphasize the role of non-cognitive factors (e.g., motivation; Wechsler, 1943), current theories (and particularly psychometric models) tend to restrict themselves to purer cognitive measures. Importantly, this is not to deny the role of such variables in adaptive behavior (e.g., Duckworth, Quinn, Lynam, Loeber, & Stouthamer-Loeber, 2011) but merely to distinguish between cognition and intelligence strictly construed and the other traits and capacities that people bring to bear on life's challenges.

A second implication relevant to the concept of ID is the fact that while psychometric theories seem to make implicit claims about *neural* organization (i.e., they address the relatedness of one cognitive function to another), ID is of course a *behavioral* diagnosis the reflects a diverse group of underlying causes (Lee & Harris, 2006, Chapter 5). Thus, while the ID diagnosis clearly depends upon cognitive capacities that are mediated by the brain, it encompasses a wide group of ultimate neural etiologies. This means that although the diagnosis should correctly identify persons who face broad cognitive challenges, because it does emphasize intelligence, it will tend to obscure more subtle, individual needs. Given that many of the syndromes responsible for ID are now known to be associated with more specific cognitive profiles (Edgin, 2013; Grigsby, 2016), this calls for bringing the neuropsychological approach into individual assessment of ID (see Chap. 27, this volume).

On a final more conceptual note, as Detterman observed (Detterman, 1987), different potential causes for psychometric *g* have different implications for the ways in which ID might arise. In the case of hierarchical theories or those that emphasize one or more central factors in intelligence (e.g., POT, system theory), one might expect the functioning of various core networks to strongly determine one's level of intelligence. Physiologically, this is perhaps most akin to parieto-frontal integration theory (P-FIT; Jung & Haier, 2007) and similar accounts (Duncan, 2010) that emphasize the centrality of those specific regions to overall intelligence. In contrast, mutualism makes a developmental case that initially independent factors become increasingly integrated through time. Finally, as recently pointed out by Deary, Cox, and Ritchie (Deary et al., 2016; citing Burt, 1940), *g* might also arise though a shared adaptive *property* of the brain, as opposed to the features of one or more major structures. That is, while a single neuroanatomical network might account for the appearance of a unitary *g*, individual, lower-level modules (or even single neurons) could also give rise to *g* if they are all homogenous in terms of their lower-level attributes (e.g., dendritic arborization, neural membrane properties; Jensen, 1998a, p. 121). This too could give rise to a *g* factor but for a very different reason. Thus, although there is strong evidence for the *effective* unity of intelligence as it manifests through testing, the ultimate causes of that cohesion could be numerous and multifaceted.

Definition and Diagnosis

Intellectual disability (ID) has been an evolving construct beginning early in history and has been generally defined by significant, lifelong impairments in cognition and daily functioning. While intellectual and adaptive behavior deficits are essential in the diagnosis of ID, the presentation of ID can vary widely between individuals in relation to the degree of impairment and in distinct strengths and weaknesses. Further, the ID population, across severity levels, has an increased prevalence of a range of comorbid medical and psychiatric disorders. Therefore, ID is a highly heterogeneous condition that requires thoughtful, comprehensive, and individualized assessment across the life course. Providing appropriate diagnostic and evaluation services is essential for informing treatment planning and ensuring individuals with ID can optimize their prognosis and reach their potential.

This chapter will briefly review the evolution of the definition and conceptualization of ID. In addition, a detailed discussion will be presented regarding the current definition and how to interpret this definition in the context of the diagnostic process. A brief review of specific measurement techniques and how they are used in concert will also be provided. Further, a developmental perspective will be used to explain the differences in the diagnostic process across age groups based on severity level of the disability.

The Evolving Definition of Intellectual Disability

Since antiquity, people have conceptualized and labeled ID in many different ways. The field has made many important advances in policy and research over the course of decades that have led to our current understanding of the definition of ID and to support needs related to ID. However, this attitude of inclusion and intervention has not always been the norm. Individuals with ID have historically been subjected to significant discrimination and injustices (Witwer, Lawton, & Aman, 2014). For example, during ancient times, ID was thought to result from possession by a supernatural being, and those with ID were mistreated and subjected to exorcism and even death. Other early theorists believed that ID was the product of sin and evil or divine visitation (Cardona, 1994), and again treatment of ID fell in line with this conceptualization. Fortunately, in the eighteenth century, Jean Marie Gaspar

Itard showed that people with ID were able to learn and many improvements in the field followed. For instance, in the nineteenth century, Samuel Howe followed up on this critical discovery by founding the first school for children with ID in 1848 (Cardona, 1994).

Improvements in our knowledge regarding etiology of ID have also contributed to advances in the provision of services. Historically, the definition of ID focused on inadequate social behavior (Doll, 1941). However, medical advancements in the twentieth century most notably resulted in the scientific discovery that ID is hereditary. Following this discovery, ID came to be seen as a medical construct (Devlieger, 2003). The conceptualization of ID changed once more as the intelligence testing movement took hold: with the advent of valid and reliable intelligence measures, the emphasis shifted to an individual's IQ score, which was compared to a normative sample (Devlieger, 2003; Schalock, Luckasson, & Shogren, 2007).

The nomenclature has also evolved. In the late 1800s and early 1900s, people with ID were labeled feebleminded, imbeciles, and idiots (Cardona, 1994). These terms had technical definitions; however, they quickly took on derogatory meanings. In the mid- and late 1900s, the terms mental deficiency and then mental retardation were used to classify individuals with ID (Cardona, 1994; Greenspan & Switzky, 2003). It was not until the introduction of the *DSM-5* that the term mental retardation was formally changed to intellectual disability (Schalock et al., 2007, 2010). ID was chosen to replace mental retardation for several reasons. The term ID better aligned with the new construct of disability from the World Health Organization (WHO) and the American Association on Intellectual and Developmental Disabilities (AAIDD). This new conceptualization emphasized a move away from a person-centered definition of innate deficit to defining functional limitations based on a person-environment interaction. Relatedly, the term ID matched up with current clinical practice that focuses on functional behaviors and individualized, environmental supports necessary to improve a person's functioning. Finally, in addition to addressing the negative connotation associated with the term mental retardation, the new terminology improved consistency with terminology used internationally (Schalock et al., 2007).

Despite the evolving vocabulary used to classify ID and the associated advancements in research, policy, and clinical practice in recent decades, the construct of ID has remained largely the same. Three essential elements have been retained and include (1) deficits in cognitive functioning, (2) limitations in adaptive behavior, and (3) an early onset of symptoms (Schalock et al., 2007).

Diagnostic and Statistical Manual (DSM)

ID was termed mental deficiency in the first edition of the *Diagnostic and Statistical Manual* (*DSM-I;* American Psychiatric Association [APA], 1952) and was used to classify individuals who presented with "a defect of intelligence existing since birth, without demonstrated organic brain disease or known prenatal cause." Chronic brain syndrome with mental deficiency was diagnosed when the etiology of intellectual deficits was known. In the *DSM-I*, IQ estimates were provided to correspond with severity levels ranging from mild to severe; however, an emphasis was placed on functional behaviors as well, noting that severity level should be informed by both cultural, physical, and emotional factors as well as occupational, educational, and social success (APA, 1952).

In the *DSM-II*, ID was called mental retardation and was defined as "subnormal general intellectual functioning, which originates during the developmental period" (APA, 1968). Severity levels within the *DSM-II* included borderline, mild, moderate, severe, and profound mental retardation. As in the *DSM-I*, discrete IQ cutoffs were provided for determining severity level, but the need to evaluate adaptive behavior in conjunction with IQ was stated as well. Clinical subcategories were also offered to detail any known etiological information related to an individual's intellectual deficits. Unspecified mental retardation became available in the *DSM-II* to diagnose individuals who could not participate in a formal assessment of IQ but were clinically "subnormal" (APA, 1968).

The *DSM-III* (APA, 1980) emphasized the dual-criterion approach to a greater degree than in previous editions; the *DSM-III* definition hinged upon significantly "subaverage" intellectual functioning in addition to deficits or impairments in adaptive behavior. IQ estimates corresponding to severity levels continued to be present; however, the authors of the *DSM-III* highlighted the error of measurement and encouraged clinicians to treat IQ scores with "some flexibility." Adaptive behavior in the *DSM-III* was defined as the "effectiveness with which an individual meets the standards of personal independence and social responsibility expected for his or her age and cultural group." As tools for standardized measurement were limited at this time, the authors encouraged the use of clinical judgment in evaluating adaptive functioning. Further, symptom onset had to occur prior to 18 years old. Of note, borderline mental retardation was removed, and "borderline intellectual functioning" was added as a "V" code within the *DSM-III*. The definition of ID remained largely the same in the 1987 *DSM-III-Revision* (APA, 1987).

The criteria for diagnosis in the *DSM-IV* (APA, 1994) and *DSM-IV-Text Revision* (APA, 2000) were also similar (APA, 1994). Again, discrete IQ cutoffs were provided to determine an individual's severity level (i.e., mild, moderate, severe, and profound). Though, criteria for adaptive functioning was clarified to specify limitations in at least two of the following areas: communication, self-care, home living, social/interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety (APA, 1994, 2000). Notably, while mentioned in previous editions, a greater emphasis was placed on psychiatric comorbidity within the *DSM-IV* and *DSM-IV-TR* conceptualization. The increased vulnerability for mental health disorders and the complexity in assessing for these disorders were clearly stated (APA, 2000).

The DSM-5 Definition of ID

The *DSM-5* (APA, 2013) presented several changes to the previous conceptualization of ID, including but not limited to the change in terminology from mental retardation, and provided comprehensive guidance for diagnosing ID. Following revisions to the *DSM-IV-TR* definition, the *DSM-5* classification is also more equivalent to the *International Classification of Disease*, *11th Revision*'s (*ICD-11*) diagnosis of intellectual developmental disorder (APA, 2013). Within the *DSM-5*, ID is presented alongside other neurodevelopmental disorders, emphasizing its enduring nature and association with early brain dysfunction. The core diagnostic features of ID remained the same and include deficits in two domains—intellectual functions and adaptive skills—relative to age, gender, and sociocultural expectations, which are based on clinical judgment and standardized assessment results.

In the *DSM-5*, the term intellectual functions refers to reasoning abilities, problem-solving skills, planning, abstract thinking, judgment, practical understanding, and learning. Deficits in adaptive functioning are characterized by difficulties performing skills of daily living in a variety of conceptual (academic), social, and practical areas, across multiple contexts (i.e., home, school, vocational, and community settings). Impairments in intellectual and adaptive functioning must manifest during the developmental period; this is a change from previous editions of the *DSM* where an age of onset prior to 18 years old was explicitly required (APA, 2013).

One of the most notable changes in the *DSM-5* was the removal of IQ scores from the diagnostic criteria. Individuals are instead diagnosed with mild, moderate, severe, or profound ID based upon adaptive functioning (APA, 2013). Since severity classifications are used to communicate the level of support an individual requires, and adaptive functioning refers to skills in practical contexts, the *DSM-5* approach better identifies treatment needs and therefore has greater clinical utility. This paradigm shift also reduces an over-reliance on IQ scores, which is critical in light of research that suggests IQ measures are less valid in the lower end of the IQ range (Hessl et al., 2009). The APA also notes that an IQ score alone may not reflect skills for reasoning in real-life situations nor is a single IQ score useful in understanding intellectual abilities compared to comprehensive neuropsychological profiles (APA, 2013). However, the APA is clear that IQ tests should continue to be administered in the assessment of intellectual functioning. Further, the upper limit of an IQ of approximately 70 remains (APA, 2013).

According to current estimates, ID occurs in 1% of the population (Witwer et al., 2014). However, prevalence differs as a function of severity level. Mild ID is the most prevalent, encompassing approximately 85% of the ID population (van Bokhoven, 2011). Further, ID occurs in both males and females across sociodemographic backgrounds. However, the numbers are higher in males and in lower-income populations (Maulik, Mascarenhas, Mathers, Dua, & Saxena, 2011; Witwer et al., 2014). Gender differences are likely a result of sex-linked genetic factors (Harris, 2006), and the increased prevalence in low-income populations may be due to several factors, including heightened risk for poor prenatal care, malnutrition, and exposure to illness, injury, toxins, or environments with reduced stimulation (Matson & Cervantes, 2019; Maulik et al., 2011).

While etiology of mild ID is often unclear, individuals with more severe impairments (e.g., moderate to profound ID) are more likely to have an identifiable, organic cause, like a genetic disorder or significant pre-, peri-, or postnatal complications (Witwer et al., 2014). Prenatal screening can be done to identify if a genetic disorder associated with ID is present (de Jong, Dondorp, Frints, de Die-Smulders, & de Wert, 2011; Genetic Alliance, 2009). Examples of genetic disorders associated with ID include Down syndrome, Prader-Willi syndrome, Angelman syndrome, Williams syndrome, and Fragile X syndrome. When a genetic disorder is responsible for intellectual impairment, the individual may also present with dysmorphic features at birth. For example, newborns with Down syndrome present with brachycephaly, which is characterized by shortened, anteroposterior dimension of the head (Wechsler & McDonald, 2018). Other genetic disorders may become evident during infancy and early childhood. For instance, Lesch-Nyhan syndrome is associated with a distinct behavioral phenotype, including delayed motor development evident at 3–6 months of age and persistent self-injurious behavior during toddlerhood (Harris, 2010; Nyhan, O'Neill, Jinnah, & Harris, 2014). ID can be acquired prenatally through factors such as inadequate prenatal care, maternal infections during pregnancy, and maternal alcohol or substance use during pregnancy. Perinatal causes can include infections, intracranial hemorrhage, and hypoglycemia, and ID may be acquired postnatally through events like meningitis and encephalitis from bacterial or viral infections, significant psychosocial trauma (e.g., abuse, neglect, and malnutrition), exposure to environmental toxins (e.g., lead), and head injury (Harris, 2006; Shevell, 2008).

In terms of age of onset, diagnosis often occurs at different times based upon severity level. Children with mild ID may not be recognized until school years when increased academic and social demands make symptoms more evident, whereas children with moderate ID are typically diagnosed in the preschool years, and children with severe and profound ID are typically identified before or shortly after birth (Witwer et al., 2014). Often though, individuals with ID experience some degree of apparent developmental delays in infancy and early childhood. Generally, one or more of the following early symptoms are present: motor delays (e.g., sitting, crawling, or walking later than same-age peers), language delays (e.g., talking later than expected or having trouble speaking), memory deficiencies, problem-solving weaknesses, and difficulties understanding the results of their actions (Centers for Disease Control and Prevention [CDC], 2017).

For these young children who present with clear developmental difficulties but are too young to participate in structured testing, a diagnosis of global developmental delay (GDD) may be warranted. GDD is diagnosed in children under

5 years old when significant deficits are present across two or more developmental domains (e.g., motor skills, speech/language, social skills, activities of daily living, cognition; APA, 2013; Moeschler, Shevell,, & Committee on Genetics, 2014). As IQ is not considered stable in early childhood (Ozonoff, Goodlin-Jones, & Solomon, 2005), GDD is an appropriate label for young children until valid and reliable IQ testing can be conducted and a diagnosis of ID, or a different neurodevelopmental disorder, can be confirmed (Moeschler et al., 2014). A diagnosis of GDD highlights the need for reassessment after a period of time (APA, 2013) and predicts later diagnosis of ID (Shevell, 2008). When an individual is over the age of 5 but cannot participate in structured testing due to sensory or physical impairments, severe problem behaviors, or comorbid psychopathology, a diagnosis of unspecified ID should be provided until data from a reassessment can confirm a more specific diagnosis (APA, 2013).

The Diagnosis of DSM-5 ID

Assessment for ID focuses on measurement in the two primary domains discussed above: intellectual functioning and adaptive behavior. It is imperative to measure both intellectual and adaptive domains in a systematic and objective manner in order to generate a complete picture of an individual's strengths and weaknesses. Further, obtaining information regarding how impairments manifested across the life span is necessary for the diagnosis of ID.

As with all diagnostic evaluations, a multimodal assessment process incorporating clinical interviews, behavioral observations, and standardized measures should be used. It may also be helpful to obtain educational and medical records, especially if a diagnosis of ID is being made in adolescence or adulthood. The evaluation should begin with a comprehensive interview of developmental history and current functioning. Such an interview should be conducted with an individual's primary caregiver(s) and inquire about medical, psychiatric, developmental, behavioral, and educational realms. Within the medical history, given the known etiological bases for ID, history of prenatal, perinatal, and postnatal complications should be obtained. Specifically, it is necessary to assess for possible maternal substance use and exposure to alcohol, smoke, and illicit drugs in utero, as well as exposure to toxins. Information should be collected regarding the pregnancy and birth, including gestational age, birth weight, and APGAR scores if available, any history of head trauma, injuries, and illnesses, and timing of early developmental milestones. It is also necessary to obtain a family history of developmental disorders (DDs), ID, and other medical and psychiatric conditions (McDonald, 2006; Shevell, 2008; Tirosh & Jaffe, 2011). After attaining a comprehensive history, current behaviors, including cognitive, communication, social, adaptive, and academic functioning, should also be evaluated through interview, behavioral observations, and standardized measures.

As previously stated, the diagnosis of GDD is typically considered for children under 5 years old instead of a diagnosis of ID. The diagnostic process for GDD should not be dissimilar to that described above for ID. However, the tools used for the assessment of GDD differ from those used in the evaluation for ID and will be addressed below. Notably, in more severe cases of intellectual and adaptive impairment, a diagnosis of ID may be warranted prior to age of 5 years old. This may be particularly true for young children with genetic disorders associated with ID.

Evaluation of Intellectual Abilities

Intellectual ability is measured using standardized cognitive assessments, resulting in an IQ score. IQ was originally defined as a ratio of one's mental age to their chronological age, but the ratio IQ has since been replaced by a more complicated deviation IQ (Brue & Wilmshurst, 2016). Previous recommendations encouraged the use of a composite or total test score to be compared to a cutoff score (two standard deviations below the mean, i.e., an IQ of 70) in examining symptom threshold (National Research Council [NRC], 2002); however, the *DSM-5* conceptualization warns against overreliance on an IQ score. Instead, an individual's complete cognitive profile, as measured by a reliable and valid IQ test, should be used as one piece of evidence in the diagnosis of ID.

Cognitive measures typically assess a variety of areas including verbal knowledge, spatial skills, processing/psychomotor speed, memory, and verbal and nonverbal reasoning abilities (Sattler, 2008). Several cognitive assessments are available, and important considerations should be made in choosing the optimal tool for the individual being assessed. These include patient age, developmental level, culture, language, communication abilities, and environment (Schalock & Luckasson, 2004). In addition, clinicians assessing for ID should be experienced in working with children with DDs, as the application of strategies to improve patient motivation and on-task behavior may be necessary to achieve an accurate estimation of ability (Ozonoff et al., 2005).

Assessment tools

Measurement techniques vary as a function of one's age and severity of symptoms. Therefore, examples of assessment tools will be presented based upon their utility across different developmental periods.

Early childhood assessment

In young children, clinicians may choose to obtain a developmental quotient (DQ) instead of an IQ score. A DQ score is a ratio of one's developmental age to chronological age. As IQ is unstable in early childhood, using a DQ to quantify strengths and weaknesses related to developmental milestones may be more precise and clinically useful in young childhood (Matson, Mahan, Hess, & Fodstad, 2010). Therefore, assessment of cognitive abilities should occur in relation to developmental milestones using developmental inventories. The *Bayley Scales of Infant and Toddler Development-Third Edition* (*Bayley-3*; Bayley, 2006) is one example of a developmental measure. The *Bayley-3* is designed for use with children 1–42 months of age and examines developmental functioning across five domains. The cognitive, language, and motor skill domains are administered to the child and are directly assessed by the clinician; social-emotional and adaptive skill domains are obtained through informant-report. Other developmental measures include the *Mullen Scales of Early Learning* (*Mullen*; Mullen, 1995) and the *Battelle Developmental Inventory-Second Edition* (*BDI-2*; Newborg, 2005).

Measures of IQ designed to assess young children are also available. These are typically reserved for use with young children who are closer to 5 years old and less impaired. In these cases, the *Differential Abilities Scale, Second Edition-Early Years Battery* (*DAS-2*; Elliott, 2007) or the *Wechsler Preschool and Primary Scale of Intelligence-Fourth Edition* (*WPPSI-IV*; Wechsler, 2012) can be administered to obtain an estimate of intellectual functioning.

School-aged to adulthood

There are many cognitive tools available for children and adults with verbal language. The Wechsler scales are one of the most widely used. The *Wechsler Intelligence Scale for Children-Fifth Edition* (*WISC-V*; Wechsler, 2014) is designed for use with children aged 6–16 years old, and the *Wechsler Adult Intelligence Scale-Fourth Edition* (*WAIS-IV;* Wechsler, 2008) is used for individuals 16 years of age and older. The Wechsler scales, however, have a high verbal requirement and therefore are generally administered in the assessment of individuals with a high degree of spoken language (Matson & Cervantes, 2019; Ozonoff et al., 2005).

In addition, the *Stanford-Binet Intelligence Scales-Fifth Edition* (*SB5*; Roid, 2003) is routinely used to assess cognitive abilities within evaluations for ID. The *SB5* is designed for use with individuals 2 years of age and older and results in a Full Scale IQ (FSIQ), nonverbal and verbal IQ scores, and five index scores. Based on assessment needs, the clinician can administer solely the verbal or nonverbal IQ domain. If available assessment time is short, an Abbreviated Battery IQ (ABIQ) can also be obtained from the *SB5* in approximately 15 min with the use of two subtests (Roid, 2003). General consensus indicates that the *SB5* is able to assess a wide range of abilities, allowing one to obtain a greater differential at the lower ends of the cognitive spectrum (Silverman et al., 2010). Therefore, the *SB5* may be preferred in the assessment for ID in individuals across severity levels.

The *DAS-II School-Age Battery* (Elliott, 2007) offers another option for the assessment of children with greater impairments, including language difficulties. This measure is designed for use with children 7–17 years old and assesses verbal, spatial, and nonverbal reasoning abilities. Because there is a degree of fluidity across the early years and school-age batteries, the *DAS-II* offers clinicians the flexibility to administer subtests originally designed for younger children if a child is unable to complete a subtest that is meant for their chronological age range. While no data were found comparing the *DAS-II* with the *SB5*, researchers have shown that the *DAS-II* resulted in higher scores when compared to the *Wechsler Intelligence Scale for Children-Fourth Edition* (*WISC-IV*) in a population of children with autism spectrum disorder (ASD). This difference was hypothesized to be due to the inclusion of processing speed on the *WISC-IV* (Kuriakose, 2014).

Measures with minimal verbal requirement

Due to substantial impairments in communication, more traditional tools may not be effective in the assessment of individuals with severe to profound ID. In these cases, the *Leiter International Performance Scale-Third Edition* (*Leiter-3*; Roid, Miller, Pomplun, & Koch, 2013), the *Test of Nonverbal Intelligence-Fourth Edition* (*TONI-4;* Brown, Sherbenou, & Johnsen, 2010), or the *Comprehensive Test of Nonverbal Intelligence-Second Edition* (*CTONI-2*; Hammill, Pearson, & Weiderholt, 2009) may be utilized. These nonverbal assessments are administered without verbal instructions and do not require verbal responses, which allows clinicians to assess nonverbal cognitive abilities in individuals with minimal to no language. Further, developmental measures, such as the *Mullen*, may also be utilized to evaluate the abilities of individuals with severe impairments. When administering developmental measures out of the age range of the standardized administration, age equivalents may be more informative than the resulting IQ score (Bishop, Guthrie, Coffing, & Lord, 2011).

Evaluation of Adaptive Skills

Adaptive behavior deficits across conceptual, social, and practical domains should also be measured using standardized, norm-referenced assessments. Standardized measures provide the age-referenced results necessary for evaluating an individual's degree of impairment against what is expected (Cervantes & Jang, 2016; Schalock & Luckasson, 2004). In regard to evaluating whether an individual meets the adaptive behavior criteria for diagnosis, the *DSM-5* stipulates that an individual must demonstrate difficulties in at least one of the three domains, to the extent that ongoing support is required in at least one setting (APA, 2013).

Assessment tools

Typically, reports of adaptive skills are given by caregivers. However, it can be helpful to obtain information regarding adaptive functioning from multiple sources, including employers, job coaches, teachers, and, in some cases, the individual being assessed, in order to generate a wide-ranging assessment of strengths and weaknesses.

Vineland Adaptive Behavior Scales, Third Edition (Vineland-3)

The *Vineland Adaptive Behavior Scales-Third Edition* (*Vineland – 3;* Sparrow, Cicchetti, & Saulnier, 2016) is one of the most popular and well-known assessments of adaptive functioning. The *Vineland-3* is available in several formats, including interviews and rating scales to be completed by caregivers and teachers. The measure is intended for use with individuals across the life-span. The instrument assesses an individual's adaptive skills across five domains (i.e., communication, daily living skills, socialization, motor skills, maladaptive behavior) depending on the individual's age and evaluation needs. Subdomains exist within each of the larger domains to better define an individual's strengths and weaknesses. The *Vineland-3* also results in an adaptive behavior composite score, as well as standard scores for each domain and subdomain, allowing for comparison of scores across a population.

Adaptive Behavior Assessment System, Third Edition (ABAS-3)

The *Adaptive Behavior Assessment System-Third Edition* (*ABAS-3*; Harrison & Oakland, 2015) is another widely used assessment of adaptive functioning. The *ABAS-3* has five rating forms available to be used across the life-span and to be completed by caregivers, by teachers, or by the individual being assessed. Parent and teacher forms are available for the assessment of individuals 0–21 years old. The Adult form can be administered as self-report for individuals over 16 years old. This self-assessment provides adults with ID autonomy in influencing treatment goals and allows caregivers and service providers to support individuals in generating and implementing self-directed plans. The *ABAS-3* results in scores across conceptual, social, and practical domains, through the assessment of nine or ten adaptive skill areas based upon the individual's age.

Additional Considerations

Because symptoms of ID affect multiple domains of functioning, multidisciplinary assessment is essential in developing appropriate interventions. If an interdisciplinary approach is unavailable during the initial assessment and based upon the results of the evaluation, individuals with ID should be referred to professionals within the speech and language, medical, and occupational and physical therapy fields for further evaluation and support.

Additionally, once a diagnosis is made, medical and genetic testing is often recommended to determine if there is a known etiology of the ID, such as a genetic disorder. Further investigation into the presence of a genetic disorder is especially indicated in the case that there is a family history of genetic disorders and/or a physical examination identifies signs related to genetic disorders (e.g., dysmorphic features, aberrant motor development). This is important because identification of a known etiology offers an individual and their family more detailed prognostic information and more specific supports and services. However, the etiology of many cases of ID, particularly more mild cases, cannot be discerned, and genetic testing is both financially and labor intensive. Therefore, practitioners should be mindful of this when referring families for follow-up evaluation (de Jong et al., 2011; Genetic Alliance, 2009; Matson & Cervantes, 2019).

In addition, even when a diagnosis of ID is made early in life, re-evaluations throughout the life span are necessary for the determination of educational classification and support services, program planning, eligibility for benefits and legal protections, and reimbursement/funding. As limitations related to ID are defined by person-environment interactions, an individual's support needs will change across the life course and as the context in which they are functioning changes.

Dual Diagnosis

In addition to intellectual and adaptive skill deficits and although not necessary for diagnosis, many individuals with ID experience comorbid health and psychiatric conditions as well as a variety of challenging behaviors (e.g., tantrums, aggression, self-injury). Prognosis is typically poorer when comorbidities are present (Matson & Shoemaker, 2011); therefore, comprehensive assessment and targeted treatment of an individual's complete clinical picture is imperative. However, several challenges are present when addressing medical and psychiatric symptoms within the ID population (Tonge, Torr, & Trollor, 2017).

Comorbid Medical Disorders

Individuals with ID commonly present with a range of medical conditions (van Schrojenstein Lantman-de Valk et al., 1997; van Schrojenstein

Lantman-de Valk, Metsemakers, Haveman, & Crebolder, 2000). For instance, hearing and visual impairments, motor and seizure disorders, congenital abnormalities related to areas like cardiac and gastrointestinal functioning, and metabolic, endocrine, and immune system disorders occur more often in individuals with ID (Tonge et al., 2017; van Schrojenstein Lantman-de Valk et al., 1997). Of note, medical comorbidities frequently relate to the etiology of ID. As previously mentioned, ID is often associated with various genetic disorders, and each disorder has related medical problems. For example, individuals with Down syndrome often experience hypothyroidism, hearing loss, and early-onset dementia, and cleft palate, congenital heart disease, and immune system disorders are prevalent in individuals with DiGeorge syndrome (Tonge et al., 2017). The presence of medical conditions is also associated with severity of ID and age; individuals with more severe ID and who are older adults (i.e., 50 years or older) are at higher risk for medical difficulties (van Schrojenstein Lantman-de Valk et al., 1997).

Individuals with ID also experience general health problems more often than typically developing peers, such as obesity, sleep problems, pneumonia, seizures, and gastroesophageal reflux (Didden, Korzilius, van Aperlo, van Overloop, & de Vries, 2002; Tonge et al., 2017; van Schrojenstein Lantman-de Valk et al., 2000). Age-related conditions also occur more frequently in adults with ID; for example, dementia has a higher incidence and an earlier onset for adults with ID than for the general population (Tonge et al., 2017). Though these conditions occur commonly in the general population, their identification and treatment in individuals with ID is complex, thus contributing to the high rates of unmet service needs experienced by the ID population (Peterson-Besse et al., 2014; Tonge et al., 2017).

Assessment of physical symptoms in individuals with ID is particularly difficult due to the communication impairments inherent to ID. Medical professionals often have to rely on behavioral indices of pain rather than verbal report of symptoms. Pain may be communicated through an increase in challenging behaviors (e.g., self-injury, repetitive behavior, noncompliance) or other indirect cues. For instance, behavioral markers for abdominal pain in individuals with ASD and communication impairments include crying with no clear cause, frequent swallowing, facial grimacing, gritting teeth, wincing, unusual posturing, and sleep problems (Buie et al., 2010; Tonge et al., 2017). Symptom presentation may also be complicated by the presence of medication side effects. The ID population is a highly medicated group; many individuals with ID are on multiple psychotropic medications from the same or different classes (Tonge et al., 2017). This can lead to side effects that are difficult to discern from organic medical problems. Further complicating the evaluation process, administering standard examination procedures (e.g., blood draws, neuroimaging) is not always possible given the individual's level of cooperation and challenging behaviors. However, medical conditions that are not recognized and therefore are not treated can lead to more serious conditions later in life as well as greatly reduce an individual's quality of life (Matson & Cervantes, 2019; van Schrojenstein Lantman-de Valk et al., 1997).

To improve our care for the ID population, emphasis should be placed on continued advancements in our understanding of the health risks and preventative service needs of the ID population. It is essential that individuals with ID receive routine checkups on physical health, including dental health, to monitor symptoms, as medical conditions often present as an increase in challenging behavior (Tonge et al., 2017). Regular assessment of medication effectiveness and side effects should also be conducted; the use of tools like the *Matson Evaluation of Drug Side effects* (*MEDS*), which was developed for use with the ID population, would be helpful in this process (Matson & Cervantes, 2013). Medical professionals should be trained in frequently occurring medical problems within the ID population as well as necessary adaptations for medical service provision of people with communication and behavioral difficulties. Improving these assessment procedures should be at the forefront of ID research. Current best practice involves a multidisciplinary approach in which professionals from a variety of disciplines (e.g., speech and language therapy, psychology, medicine) work together in the evaluation and treatment of medical comorbidities within the ID population.

Comorbid Neurodevelopmental and Psychiatric Disorders

In addition to medical conditions, the ID population presents with increased vulnerability for co-occurring neurodevelopmental and psychiatric disorders (Emerson, 2003; Matson & Shoemaker, 2011; Tonge et al., 2017; Wallander, Dekker, & Koot, 2006). Historically, researchers and clinicians did not believe that individuals with ID could have comorbid psychiatric diagnoses (Matson & Shoemaker, 2011). However, it is now clear that ID and mental health conditions are distinct and can and often do present together (Tonge et al., 2017). Of note, prevalence estimates of mental health problems range widely in the ID research literature due to difficulties in assessing for symptoms (Costello & Bouras, 2006). With regard to specific comorbid conditions, attention-deficit/hyperactivity disorder (ADHD) is most common and occurs within the ID population at rates four times higher than in the general population (Neece, Baker, Crnic, & Blacher, 2013). ASD is also highly prevalent within the ID population, with up to 40% of the population meeting ASD diagnostic criteria (La Malfa, Lassi, Bertelli, Salvini, & Placidi, 2004). Further, individuals with ID are at higher risk for psychiatric diagnoses like anxiety and depression (Tonge et al., 2017).

As in medical comorbidities, mental health conditions are also associated with the etiologies of ID. For example, individuals with Prader-Willi syndrome often experience obsessive-compulsive disorder, individuals with Williams syndrome are at increased risk for specific phobias and generalized anxiety, and individuals with DiGeorge syndrome have higher rates of bipolar disorder and psychosis (Tonge et al., 2017). Further, several genetic disorders associated with ID are implicated in ASD, such as Fragile X syndrome and tuberous sclerosis (Muhle, Trentacoste, & Rapin, 2004). While mental health problems in individuals with ID tend to be more stable across the life course (Wallander et al., 2006), emotional and behavioral symptoms are most prevalent in children and adolescence (Tonge et al., 2017). As is the case in the general population, gender differences in psychopathology exist in the ID population. ASD and ADHD are more common in males, whereas females with moderate to severe ID are at heightened risk for anxiety (Tonge et al., 2017). Other risk factors for psychiatric comorbidity in ID include socioeconomic deprivation, living in settings with limited social and occupational opportunities, experiencing co-occurring physical health symptoms, and increased parental and familial distress (Tonge et al., 2017; Wallander et al., 2006).

Despite the high prevalence of mental health problems in the ID population, it is not uncommon for individuals with ID to go without receiving a comorbid diagnosis or to be misdiagnosed, as psychiatric evaluation is complex due to intellectual, language, and social difficulties. First, diagnostic overshadowing may occur where clinicians inaccurately attribute symptoms of concurrent disorders to ID. Further, while psychopathology in individuals with mild-to-moderate ID may be similar to that of the general population, symptoms of psychiatric disorders may present atypically in individuals with more severe ID (Costello & Bouras, 2006; Matson & Shoemaker, 2011).

Given these difficulties, current diagnostic systems are limited in their utility with the ID population, and a range of adaptations must be made for appropriate assessment (Matson & Shoemaker, 2011; Tonge et al., 2017). Psychiatric evaluation should include extensive interview of individuals with ID (to the extent possible) and their caregivers about symptom presentation, the contexts in which symptoms are occurring, and how current functioning differs from premorbid functioning. Accommodations to improve the interviewing of individuals with ID may include visual supports like mood scales and increased session time to allow time for anxiety reduction and rapport development. Ensuring that self- and informant-report measures are valid for use with the ID population prior to administration is also integral. Finally, behavioral observations are paramount to assess for nonverbal signs of psychopathology (Matson & Cervantes, 2019; Matson & Shoemaker, 2011; Tonge et al., 2017).

Following identification of a comorbid psychiatric condition, evidence-based interventions used within the general population (e.g., cognitive behavior therapy) can be applied to individuals with ID. Nevertheless, psychological treatments typically require thoughtful adaptations. These include simplifying concepts by the use of visuals, repetition of concepts and behavioral rehearsal of skills to encourage learning, a heavier focus on behavior than on cognitions, and reinforcement-based behavioral strategies (Matson & Shoemaker, 2011; Tonge et al., 2017). Medication management is also often provided in the treatment of comorbidity. The range of participants with ID being prescribed at least one psychotropic medication is 40–89%, with higher rates associated with comorbid psychiatric concerns and the presence of challenging behavior (Bowring, Totsika, Hastings, Toogood, & McMahon, 2017). However, research into medication efficacy and side effect profiles is limited for the ID population specifically, and adverse effects may occur more frequently in individuals with ID (Tonge et al., 2017). Therefore, close monitoring of symptoms and adverse effects by caregivers and within periodic reassessments is imperative in optimizing care for individuals with ID.

Associated Symptomology

Individuals with ID, with and without comorbidity, also present with a range of associated symptoms. Among these are challenging behaviors including but not limited to tantrums, aggression, noncompliance, property destruction, self-injury, repetitive behaviors, and feeding challenges. While these behaviors are not necessary for a diagnosis of ID, systematic assessment of commonly associated difficulties is important for informing treatment and monitoring an individual's progress across time. Evaluation and treatment of associated symptomology is particularly important given the significant impact challenging behaviors have on the inclusion of individuals with ID in educational, social, and vocational settings and on the quality of life of individuals with ID and their caregivers (Crocker et al., 2006).

Researchers have found that more than half of the ID population demonstrates some degree of challenging behavior, with a minority engaging in severe behavior causing significant bodily injury (Matson & Cervantes, 2019; Crocker et al., 2006). Challenging behavior is also the most common reason for referral for services in children with ID (Costello & Bouras, 2006). Of note, nearly 40% of individuals with ID receiving antipsychotic medication treatment did not have a psychiatric diagnosis, suggesting prescription related to the presence of challenging behavior. Psychotropic medication use is significantly associated with aggression and self-injurious behavior, older age, and male sex. These trends are concerning given the limited research evidence indicating effectiveness for treatment of challenging behavior as well as the large adverse effect profile of long-term use of many psychotropic medications (Bowring et al., 2017).

Behavioral interventions are currently the best practice for the treatment of challenging behaviors in ID; therefore, functional assessment of presenting challenging behaviors should be a priority within the evaluation process. Functional assessment is designed to identify maintaining variables to challenging behavior or behavioral functions. Functions assessed include social positive reinforcement (e.g., access to preferred items, access to attention), social negative reinforcement (e.g., escape from demands, avoidance), and automatic reinforcement (Lloyd & Kennedy, 2014). Functional assessments can be conducted indirectly through caregiver interview or informant-report measures (e.g., *Questions About Behavioral Function* [*QABF*]; Matson & Vollmer, 1995), descriptively through direct observation and measurement of challenging behavior or through an experimental functional analysis involving direct manipulation of environmental conditions to determine maintaining variables. Indirect functional assessment can be done rapidly but is subject to bias, and the challenging behavior is never observed. Descriptive functional assessment includes direct observation across many environments to describe behavior-environment patterns but can be time intensive and only yields hypotheses of functional relations. Experimental functional analyses is most accurate in determining the behavioral function but is time and cost intensive, requires expertise, and exposes individuals to conditions that likely induce challenging behavior. Because of this, experimental methods are rarely used within clinical settings (Lloyd & Kennedy, 2014).

After the completion of a functional assessment, an informed function-based intervention can be developed and implemented utilizing evidence-based strategies like extinction and differential reinforcement. Although these practices are empirically supported, an individual with ID should not be treated in isolation. Given the interaction between caregiver stress and behavior problems in the ID population, where parent behavior contributes to challenging behavior and challenging behavior then influences parenting, a family-focused approach is imperative. Treatment should not only incorporate behavioral parent training to improve parent-child interactions and parent effectiveness in managing challenging behaviors but also include strategies to reduce parent stress, like mindfulness. This addition would help improve caregiver ability to access parent training instruction and implement strategies with fidelity (Crnic, Neece, McIntyre, Blacher, & Baker, 2017).

Conclusion

Comprehensive and individualized assessment and reassessment across the life course is integral in developing adequate supports for individuals with ID and their families. Within these assessments, clinicians should use a developmental perspective when building a testing battery, interpreting results, and providing recommendations. For example, when evaluating a young child with cognitive and adaptive delays, an understanding of relative strengths and weaknesses within the context of developmental milestones would inform appropriate early intervention referral. Further, providing recommendations encouraging the development of skills required for learning (e.g., attending behavior, understanding contingencies) would be imperative at this young age. In contrast, when evaluating an older adult with ID, assessment should be directed toward informing vocational opportunities and appropriate residential settings.

As mentioned, ID increases an individual's vulnerability for medical and psychiatric comorbidity and behavioral difficulties. Therefore, an evaluation at any age that is not inclusive of screening for commonly co-occurring but distinct conditions would be inadequate. A multidisciplinary team approach is essential in ensuring the assessment is as wide-ranging as the symptom clusters associated with ID. As mentioned, when a team approach is unavailable, clinicians should acknowledge that individuals with ID are at increased vulnerability for a variety of difficulties, some of which may be outside the clinician's realm of specialty. Therefore, increasing competence in screening for these difficulties and then making appropriate referrals is necessary to improve access to care and address the significant proportion of the population experiencing unmet service needs.

Finally, caregivers of individuals with ID experience heightened rates of stress (Patton, Ware, McPherson, Emerson, & Lennox, 2016). These caregivers undertake tremendous responsibilities throughout the developmental course, from navigating federal agencies and insurance companies to access care and supports to making decisions regarding appropriate school placements and intervention services and researching employment options and residential settings preparing for the transition to adulthood. Importantly, researchers have found that increased social supports is associated with reduced caregiver stress

(Patton et al., 2016). Therefore, professionals should screen for caregiver stress within evaluations, make appropriate recommendations for support and advocacy groups, and be available to help caregivers make well-informed decisions for their child (Matson & Cervantes, 2019).

Problem-Solving and Working Memory in People with Intellectual Disabilities: An Historical Perspective

Ralph P. Ferretti

The experimental study of human memory was marked by the publication of *Memory: A Contribution to Experimental Psychology* (Ebbinghaus, 1964). In this seminal work, Ebbinghaus (1964) described the rigorous application of carefully controlled experimental methods to study fundamental aspects of human memory. Using himself as a subject, he investigated the rapidity with which he learned nonsense syllables, forgot them over time, and retained them as a function of the number of repetitions and repeated relearning. Among his many discoveries include the learning curve, the forgetting curve, and the serial-position effect. While Ebbinghaus self-consciously sought to control the effects of meaningful material on learning and memory, he noted, almost as an aside and somewhat presciently, that his "occasional tests" with Byron's *Don Juan* revealed "…an extraordinary advantage which the combined ties of meaning, rhythm, rhyme, and a common language give to material to be memorized."

The work of Norman Ellis (1963, 1970, 1978) occupies a similarly important place in the history of research about intelligence-related differences in memory and problem-solving. He was among the first scholars to experimentally investigate the possibility of structural constraints on the learning and memory of people with intellectual disabilities (Ellis, 1963). His later studies (Ellis, 1970) provided evidence for intelligence-related differences in strategic and controllable aspects of memory. It is not hyperbole to say that this work inaugurated decades of research about the memory and problem-solving of people with intellectual disabilities. Professor Ellis, who was my dissertation advisor, passed away as I was writing this paper. It is to his memory that this chapter is dedicated.

This report is a selective review of the literature focusing on the problem-solving and working memory[1] of people with intellectual disabilities. Any effort to undertake a comprehensive review of the literature about the cognition of people with intellectual disabilities would require at least a book-length manuscript. My purpose here is to highlight the influence of Norman Ellis's work on the development of theory and research about problem-solving and working memory of people with intellectual disabilities. I begin by describing a theory of

R. P. Ferretti (✉)

Newark, DE, USA
e-mail: ferretti@udel.edu

---

[1] Short-term memory (STM) and working memory (WM) have been used interchangeably to refer to a cognitive system responsible for the temporary storage of information. A theoretical distinction between STM and WM is based on whether the system is simply responsible for maintaining information (STM) or maintaining and manipulating information (WM). However, the concepts have not been consistently distinguished in behavioral data (Aben, Stapret, & Blokland 2012). In this paper, these terms will be cited as they were used by the scholars cited in this manuscript.

J. L. Matson (ed.), *Handbook of Intellectual Disabilities*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-030-20843-1_4

problem-solving (Ferretti & Belmont, 1983; Ferretti & Cavalier, 1991) to provide an interpretative framework for Ellis's pioneering work about intelligence-related differences in memory processes. I then discuss scholarship that was given impetus by his research, including studies focusing on strategic and self-regulatory determinants of intelligence-related differences in memory and problem-solving (e.g., Belmont & Butterfield, 1969; Belmont, Butterfield, & Ferretti, 1982; Borkowski & Cavanaugh, 1979; Borkowski, Reid, & Kurtz, 1984; Bray, 1987; Bray, Fletcher, & Turner, 1997; Brown, 1974; Butterfield & Ferretti, 1984; Butterfield, Siladi, & Belmont, 1980; Campione & Brown, 1977; Ferretti & Cavalier, 1991). I conclude the chapter with a discussion of scholarship about the self-determination of students with intellectual disabilities (Wehmeyer, 2001, 2007). As the reader will see, the historical research about self-regulation, adaptation, and problem-solving informs current efforts to ensure that people with intellectual disabilities are empowered to determine their lives.

Problem-Solving and Adaptation

I take it as axiomatic that people with intellectual disabilities experience deficits in intellectual skills and adaptive functioning (American Association on Intellectual and Developmental Disabilities, 2010). Intelligent adaptation depends upon the ability to solve problems (Ferretti & Belmont, 1983) that arise when a discrepancy exists between a person's current state and a desired goal. A major challenge for the problem-solver is to construct an internal representation of possible solution paths that may reduce this discrepancy (Ferretti & Belmont, 1983). In short, problem-solving involves the strategic deployment of cognitive resources to achieve one's goals (Newell & Simon, 1972). Research about problem-solving focuses on the processes by which people adapt to problematic conditions, as well as the conditions that require adaptation. Viewed this way, the study of problem-solving is a natural extension of the pioneering psychometric work about individual differences in intelligence and the adaptive consequences that result from those differences (Ferretti & Belmont, 1983; Ferretti & Butterfield, 1989; Ferretti & Cavalier, 1991).

Problem-solvers use subordinate and superordinate processes to achieve their goals. Subordinate processes involve the use of step-by-step computational procedures for eliminating the discrepancy between the current state and the goal, i.e., *strategies* (Ferretti & Cavalier, 1991). Of course, strategies differ in their likelihood of success. If a strategy is unsuccessful, it will need to be revised or abandoned in favor of a different strategy. It should be clear that problem-solvers must judiciously choose strategies, monitor their implementation, and attend to feedback about their efficacy. Problem-solving, reasoning, and decision-making are interdependent and affected by individual differences in the psychological processes upon which they depend (Ferretti & Cavalier, 1991).

Superordinate processes are thought to be responsible for overseeing and managing subordinate computational strategies. These *executive or self-management processes* (Atkinson & Shiffrin, 1968; Belmont, Butterfield, & Ferretti, 1982; Butterfield & Belmont, 1977) have been imbued with powerful responsibilities, including goal-setting, problem identification, strategic planning, implementation, monitoring, and revision (Ferretti & Cavalier, 1991). There has been considerable debate in the literature about the necessity of an omniscient homunculus with nearly magical powers of self-regulation (see Baddeley, 1998). However, there can be no doubt that the concept of an executive has been a powerful heuristic for a set of interrelated and potentially malleable processes that can be taught and have been shown to positively impact learning and memory (Belmont, Butterfield, & Ferretti, 1982; Hacker, Dunlosky, & Graesser, 2009).

Problem-solving operates within an information-processing system that has limited capacity (Atkinson & Shiffrin, 1968; Newell & Simon, 1972). Information-processing theories recognize that goal-directed problem-solving requires the temporary storage and manipulation of information in memory and that problem-solving may make demands that exceed the system's working memory capacity (Ferretti & Cavalier, 1991). It should be noted, however, that the functional capacity of working memory can be affected by the organization of information, the use of strategies for maintaining and recoding that information, and the automatization of processes that would otherwise place demands on the system's limited capacity (Anderson, 1981, 1983; Ellis, 1970; Schneider & Shiffrin, 1977; Shiffrin & Schneider, 1977). In short, individual differences in knowledge, strategies, and automaticity interact in any given situation to influence problem-solving and the system's functional working memory capacity (Ferretti & Cavalier, 1991).

Stimulus Trace Theory

Since the ancients, people with intellectual disabilities have been distinguished from and accorded different treatment than people with typically developing intellectual and adaptive skills (Wehmeyer, 2013). One of the earliest definitions of intellectual disabilities (Esquirol, 1838) recognized that "idiocy… is a condition in which the intellectual faculties are never manifested or have never developed sufficiently… to acquire such amount of knowledge as persons of his own aged reared in similar circumstances are capable of receiving." Esquirol's focus on the adverse effects on learning of limited intellectual skills is especially relevant in this context. Much of the empirical research conducted since the mid-twentieth century about the memory and problem-solving of people with intellectual disabilities was designed to identify the psychological and contextual factors that are responsible for these learning difficulties.

Since the earliest psychometric studies of intelligence (e.g., Galton, 1887), memory span has been taken as a diagnostic sign of intellectual disabilities. However, the mechanisms that gave rise to these memory deficiencies and associated behavioral difficulties of people with intellectual disabilities were largely unexplored until Ellis's (1963) pioneering research. He hypothesized that intelligence-related behavioral differences were attributable to a central nervous system (CNS) deficiency that resulted in an impoverished stimulus trace. A very simple memory model based on Hull's (1952) theory of associationism and other neurophysiological theories that were current at the time was used to represent the hypothesized memory deficiency. In brief, an environmental stimulus elicited a transitory stimulus trace that mediated a behavioral response. The amplitude and duration of the stimulus trace were thought to be dependent upon the integrity of the person's CNS. People with intellectual disabilities, whose poor performance on intelligence tests was taken as prima facie evidence of CNS dysfunction, were hypothesized to have a stimulus trace deficit, that is, a trace that was less stable and decayed more quickly than that of people of typical ability. As a result, the duration of stimulus control would be less for people with intellectual disabilities compared to people of average intellectual ability. This theory was intended to account for unlearned behavior. However, Ellis recognized that prior learning was involved, especially when the person's response was delayed, and, furthermore, that future learning was affected by the duration of the stimulus trace.

Ellis (1963) predicted that behaviors that were dependent upon short-term memory would be differentially impacted by intelligence-related differences in the stimulus trace. For example, he reported data about intelligence-related differences in performance on tasks that required a delayed response as compared to those that required an immediate response. He also described findings that suggested that, compared to people without intellectual disabilities, the reaction time of people with intellectual disabilities was more negatively affected by the imposition of a delay between a warning signal and the signal to respond. Furthermore, he reported data that suggested that the paired associates learning of people with intellectual disabilities were differentially and adversely affected by the imposition of a delay between the presentations of the paired stimuli compared to people without intellectual disabilities. He also expected intelligence-related differences in serial-position errors during verbal learning, but the data were equivocal, so he called for further research. Data such as these were generally consistent with the hypothesized stimulus trace deficit in people with intellectual disabilities.

Serious questions about the evidence for the stimulus trace theory were raised by Belmont and Butterfield's (1969) critical review of research about the relations of short-term memory to age and intelligence. Because memory is determined by how much information is initially acquired, the rate with which it is forgotten, and the accuracy with which it is retrieved, Belmont and Butterfield focused their review on empirical studies that varied intelligence and age while controlling for differences in acquisition, retrieval, and other methodological confounds and measurement issues. They found no evidence for the hypothesis that short-term memory varied with age and virtually no credible evidence that it varied with intelligence. The few studies that appeared to show intelligence-related differences in short-term memory employed stimuli for which verbal labels could be used to mediate a delay. At that time, there was little research about the effects of intelligence-related differences in verbal mediation on short-term memory. However, Belmont and Butterfield's analysis raised the possibility that intelligence-related differences in short-term memory could be due to strategic factors influencing the acquisition, maintenance, and retrieval of information from short-term memory.

The Rehearsal Deficit Hypothesis

As I mentioned earlier, the stimulus trace theory of short-term memory was rooted in a simple model of associationism (Ellis, 1970). Subsequent to the publication of the stimulus trace theory (Ellis, 1963), more sophisticated models of human memory were proposed that represented memory processes in terms of stages of information processing involving the sequential storage, retrieval, and transformation of information. These models (e.g., Atkinson & Shiffrin, 1968; Waugh & Norman, 1965) included memory structures that stored information for specific durations (e.g., very short-term memory, short-term memory), had strategic processes that operated on that information (e.g., rehearsal and the articulatory loop), and transferred it to more permanent storage (long-term memory), where the information was represented in the form of abstract knowledge structures (i.e., schemata). These processes were thought to be initiated by sensory input that evoked a sequence of information processes and, as we discussed earlier, were under the control of executive functions that managed the person's limited information-processing resources.

Influenced by these models, Ellis (1970) undertook a series of experiments that focused on intelligence-related differences in short-term and long-term memory. Participants first viewed a sequence of numbers after which they were presented a probe that required the identification of the position in which the probe was last seen. This task allowed Ellis to study differences in memory across each of the positions in the sequence, i.e., Ebbinghaus's serial-position effect. This effect refers to the observation that items presented first and last in a list are remembered best, i.e., the primacy and recency portions of the memory curve. In the information-processing models current at that time (e.g., Atkinson & Shiffrin, 1968), the primacy effect was thought to reflect the transfer of information from short-term to long-term memory by the use of rehearsal strategies. In contrast, the recency effect was thought to reflect the capacity of short-term memory without rehearsal. The information in short-term memory was immediately retrievable but was lost quickly unless it was rehearsed.

The serial probe task also allowed Ellis (1970) to experimentally manipulate a number of factors that had been shown to influence rehearsal processes and memory performance, including item exposure duration, inter-item interval, and the interval between the last item and the probe. In a series of studies, Ellis showed that experimental manipulations that increased the amount of rehearsal time (e.g., a slower presentation rate of the to-be-remembered information) differentially benefitted the memory performance of college students as compared to their peers with intellectual disabilities but only in the primacy portion of the serial-position curve. Similarly, permitting participants to control the amount of time spent between the presentations of each item differentially benefited college students in the primary but not the recency portion of the curve. These findings are consistent with the conclusion that a rehearsal deficit was responsible for the short-term memory deficits of people with intellectual disabilities.

In addition, Ellis (1970) conducted studies that were designed to assess the rate of forgetting from short-term memory under conditions that were intended to preclude rehearsal. This was done by interpolating a variable delay between the presentation of the last item and the memory probe that was either unfilled or filled with a task designed to preclude rehearsal. If rehearsal was responsible for maintaining information in short-term memory, then the filled delay should have more adversely affected the performance of people without intellectual disabilities. Furthermore, if the stimulus trace was responsible for short-term memory, conditions designed to preclude rehearsal should have resulted in comparable decay rates for people with intellectual disabilities and their peers without disabilities.

Ellis (1970) reported that the imposition of a delay appeared to result in more rapid decay for people with intellectual disabilities compared to their peers without disabilities in both the unfilled and filled conditions. While the filled delay resulted in poorer short-term memory performance in both groups, it did not appear to have a differential effect related to intelligence. Given the latter findings and other apparent anomalies in these data, Ellis (1970) was reluctant to draw a strong conclusion about intelligence-related differences in decay rates in short-term memory. He called for a more definitive study that carefully controlled rehearsal strategies. Nevertheless, his data provided tentative support for a rehearsal deficit explanation of the poor memory performance of people with intellectual disabilities.

Ferretti's (1982) study of intelligence-related differences in decay rates from short-term memory was designed to answer Ellis's (1970) call for research that carefully controlled the use of rehearsal strategies. People with intellectual disabilities and their peers without disabilities recalled sequences of consonants after retention intervals of varying durations. In contrast to previous studies of intelligence-related differences in short-term memory, Ferretti (1982) controlled participants' acquisition levels by equating the amount of information they were required to recall with no delay. In addition, participants performed a tonal detection task that was designed to preclude the use memory strategies during the retention interval. Differences in the accuracy and latency of tonal detection with and without memory loads were used to identify people who rehearsed. Ferretti found that the decay rates from short-term memory for people who did not rehearse were unrelated to intelligence. By controlling the level of acquisition and the use of rehearsal strategies, he was able to demonstrate comparable forgetting rates for people with intellectual disabilities and their nondisabled peers. These findings provided empirical support for Belmont and Butterfield's (1969) conclusion about the status of the stimulus trace theory and indirect evidence for the importance of strategic processes in intelligence-related differences in memory performance.

Ellis's (1970) studies provided indirect evidence for the rehearsal deficit hypothesis because inferences about intelligence-related differences in rehearsal were drawn from participants' recall data under conditions that were designed to support or discourage its use. Direct evidence about intelligence-related differences in rehearsal was obtained by Belmont and Butterfield (1969), who designed a variant of the serial learning task that allowed for the explicit measurement of rehearsal strategies. Participants paced themselves through a list of consonants for the purpose of identifying the position of a probe that appeared at the end of the list. In addition to collecting information about their response accuracy, they also collected information about the distribution of participants' pauses across serial positions as they prepared to respond to the probe.

Belmont and Butterfield (1969) found that college students showed distinctive pause patterns that were indicative of different rehearsal strategies. For example, some students used a building strategy during acquisition that was associated with pauses that grew increasingly long for the first few items and then rapid pausing for the final items. This building pause pattern suggested that participants were cumulatively rehearsing information that was distal from the probe and capitalizing on the availability of information in short-term memory that was proximal to it, i.e., cumulative rehearsal fast-finish strategy (Pinkus & Laughery, 1970). In contrast, the pause patterns of many children without disabilities and children and adults with intellectual disabilities were flat and marked by rapid responding throughout the list. In short, the participants' pause patterns were used to infer the use of rehearsal strategies. Furthermore, pause patterns that were indicative of the use of rehearsal strategies were associated with better recall accuracy.

Belmont and Butterfield's (1969) findings about the relationship between intelligence-related strategic behavior and memory performance were confirmed and extended in future studies. For example, Belmont and Butterfield (1971) had people with intellectual disabilities and their normally achieving peers pace themselves through the serial-position task without any instruction. Under self-paced conditions, the abovementioned intelligence-related differences in strategy use and memory performance were observed. Participants then performed the task under two different conditions. In the active rehearsal condition, people with intellectual disabilities and their normally achieving peers were given an instruction to rehearse the earliest presented letters and then proceed quickly through the last few letters. In the passive strategy condition, participants were told to label each item as it appeared and then proceed immediately to the next letter. They found that compared to the self-paced condition, the active rehearsal condition resulted in an increased use of rehearsal in people with intellectual disabilities and improved memory performance in the primacy portion of the memory curve. In addition, the passive strategy condition adversely affected the use of rehearsal strategies in people without intellectual disabilities and depressed their memory performance in the primacy portion. These and other studies (e.g., Brown, 1974; Butterfield, Wambold, & Belmont, 1973) provided compelling experimental evidence for the rehearsal deficit explanation of intelligence-related differences in short-term memory.

Executive Process and Self-Management

Studies of the rehearsal deficit hypothesis established three important findings that needed explanation. First, instruction could be used to test hypotheses about the cognitive mechanisms that underlie intelligence- and age-related differences in memory performance (Belmont & Butterfield, 1977; Butterfield et al., 1980; Campione & Brown, 1977). Second, intelligence-related differences in short-term memory were ubiquitous, but they could be mitigated by the provision of instruction that supported strategy production (Bray & Turner, 1986; Ferretti & Cavalier, 1991). Third, people with intellectual disabilities often failed to transfer strategies that they learned and had improved their memory performance (Borkowski & Cavanaugh, 1979; Campione & Brown, 1984). Said differently, people with intellectual disabilities were strategically passive, and they could be taught to produce strategies that positively impacted memory performance. However, they did not seem to spontaneously generalize these strategies. This raises a fundamental question: Why were they unable to transfer strategies that had positively impacted their memory performance?

Belmont, Butterfield, and Ferretti (1982) reviewed instructional studies that were reported to promote strategy generalization. The instructional protocols used in these studies targeted subordinate strategies as well as superordinate executive processes and metacognitive knowledge that were thought to influence strategy production, and transfer (Butterfield & Ferretti, 1987). Belmont, Ferretti, and Mitchell (1982) referred to superordinate knowledge and processes as self-management skills because they could be used to regulate goal-directed planning and strategic problem-solving. For example, Kendall, Borkowski, and Cavanaugh (1980) taught students with mild intellectual disabilities to use a self-interrogation strategy to generate images that linked items during paired-associate learning. In addition, students were provided feedback about the effectiveness of the self-interrogation strategy. The feedback was interpreted by Belmont, Ferretti, and Mitchell (1982) to indirectly influence the students' superordinate processing. Kendall et al. (1980) reported that students who received feedback performed better on a triadic-associates task than those who did not receive feedback. This finding was taken as evidence by Belmont, Ferretti, and Mitchell (1982) for the influence of self-management skills. Similar conclusions about intelligence-related differences in strategy transfer and self-management skills were drawn by other researchers (see Ferretti, 1989; Ferretti & Cavalier, 1991).

I would be remiss if I failed to note that instructional studies designed to validate a process explanation of intelligence-related performance differences have not satisfied the inferential conditions needed to draw an irrefutable conclusion about the self-management hypothesis (Belmont & Butterfield, 1971; Brown & Campione, 1978; Ferretti & Cavalier, 1991). In brief, proponents of the instructional approach believe that instruction can be used to validate a theoretically motivated analysis of the processes underlying task performance (Ferretti & Cavalier, 1991). Predictions should then follow from this analysis about the processes that are putatively responsible for individual or group differences in performance. Experimental tests of these predictions should show that teaching people who did not spontaneously use these processes improved their performance. In contrast, the performance of people who already use these processes should be unaffected by the same instruction. To my knowledge, these conditions have never been met in the instructional literature.

Furthermore, proponents of the self-management hypothesis may have underestimated the strategic proclivities of people with intellectual disabilities (Bray, Fletcher, & Turner, 1997; Ferretti & Cavalier, 1991). The literature shows that people with intellectual disabilities can be strategic without self-management support when the task is not too difficult (Bray & Turner, 1987; Spitz & Borys, 1984), they understand the task requirements (Bray & Turner, 1987; Bray et al., 1997), and they possess the content knowledge about the domain in which the problem-solving occurs (Bray et al., 1997; Brown, Bransford, Ferrara, & Campione, 1983). Each of these factors is known to affect functional working memory capacity (Ferretti & Cavalier, 1991; Ferretti & Butterfield, 1992; Spitz & Borys, 1984).

Questions remain about the status of the self-management hypothesis as represented by advocates of the instructional approach to validating process theories of intelligence. The literature shows that people with intellectual disabilities can be spontaneously strategic when the task requirements do not overtax their functional memory capacity (Ferretti and Cavalier, 1991). However, questions about the self-management hypothesis should not raise doubts about the practical benefits of training self-management skills. The literature clearly shows that self-management training can have a salutary effect on the performance of people with intellectual disabilities (Ferretti & Cavalier, 1991; Ferretti, Cavalier, Murphy, & Murphy, 1993; Wehmeyer, 2007). This finding is important because the inclusion of people with intellectual disabilities in normalized environments presupposes their ability to set personal goals, monitor performance, and be less reliant on external conditions for controlling their behavior (Ferretti & Cavalier, 1991; Ferretti et al., 1993). In addition, the capacity of people with intellectual disabilities to manage their behavior accords dignity, reduces the behavioral and economic costs of dependency, and increases their potential to live and work in settings with limited supervision (Ferretti & Cavalier, 1991). These highly desirable outcomes are consistent with the core values that undergird our system of representative democracy (Wehmeyer, 2001).

Self-Determination

Much of the theoretical work about individual differences in intelligence has been concerned with identifying the cognitive processes that distinguish people with intellectual disabilities and their normally achieving peers. As I mentioned earlier, this was a natural extension of psychometricians' conjectures about the psychological processes that were responsible for individual and group differences in intelligence (Ferretti & Belmont, 1983). This research resulted in the development of new inferential methods for studying intelligence-related differences in those processes, and while the findings were not always directly applicable, they gave impetus to the development of instructional techniques for improving students' self-regulatory skills in educational contexts (e.g., Hacker et al., 2009).

Studies of self-management in the behavioral tradition (Ferretti & Cavalier, 1991; Ferretti et al., 1993) have been less concerned about uncovering the underlying psychological processes that account for intelligence-related differences in academic performance. Rather, most of this work was done to establish the efficacy of training that mitigated the adaptive difficulties experienced by people with intellectual disabilities (Ferretti et al., 1993). The focus on the practical aspects of intelligent adaptation was driven by parental opposition to the institutional segregation of students with intellectual disabilities and the ethical and legal imperatives to provide normalized experiences in inclusive settings (Wehmeyer & Shalock, 2013). As more normalized opportunities were made available and students were expected to participate in transition planning (Wehmeyer, 2001), the notion of a disability was reconceptualized as a fit between the person's capacities and the environmental demands rather than as an intrinsic property of the person (Ferguson, Ferguson, & Wehmeyer, 2013). Researchers and practitioners began to focus on abilities instead of disabilities. As we have seen, people with intellectual disabilities can demonstrate surprising competencies under supportive conditions. In short, there was a pressing need to identify interventions that empowered people with intellectual disabilities to realize their self-determined goals (Wehmeyer, 2007).

Self-determination is a construct that implies that people cause themselves to act by internal forces instead of being compelled to act by external agents (Wehmeyer, 2001). Self-determined actions are volitional in the sense that they are the result of conscious choices. Choice making is an important aspect of self-determination because it involves exercising control over one's fate (Wehmeyer, 2001). Viewed this way, self-determination is a form of self-regulation in which self-determined people choose to act to reduce the discrepancy between their goals and current state (Mithaug, 1993). This conception is remarkably similar to the view espoused by information-processing theorists (e.g., Newell & Simon, 1972). However, it has a motivational aspect because it accounts for the psychological effects of failure on expectations about the likely success of future choices. Unfortunately, the evidence shows that people with intellectual disabilities have had relatively fewer opportunities to exercise choice (Wehmeyer, 2001), and when they have, they often experience failure (Wehmeyer, 2007). The antidote to low expectations is to create frequent opportunities for choice making in situations that that have a high likelihood of success and encourage realistic assessments of likely outcomes (Mithaug, 1993). In short, self-determined decision-making depends on self-management skills (Wehmeyer, 2001).

Wehmeyer's (Wehmeyer, 2001, 2007; Wehmeyer, Agran, & Hughes, 1998) functional model identifies the conditions that influence the development of self-determination and the functions that self-determination serve. According to the model, self-determination develops as people acquire attitudes and skills that promote a sense of causal agency. The development of self-determination depends upon opportunities to experience success when people act as causal agents. As a result of these experiences, people develop expectations and beliefs about their causal efficacy. Of course, supports are needed to ensure that causal actions are met with success and also to develop the self-regulatory skills needed to set and achieve realistic goals. When people experience success as causal agents, they develop a greater sense of autonomy, empowerment, and self-realization. Wehmeyer's functional model has been used to develop self-determination interventions for students with intellectual disabilities. These interventions have been shown to have a causal influence on students' self-determination (Wehmeyer, 2015), their participation in educational planning (Wehmeyer, Palmer, Lee, Williams-Diehm, & Shogren, 2011), and employment and community inclusion outcomes (Powers et al., 2012). In sum, there is a substantial and growing body of evidence about the heuristic value of self-determination theory and the efficacy of self-determination interventions.

Conclusions

I began this paper by providing a brief overview of problem-solving theory to situate Norman Ellis's (1963, 1970) contributions to the study of intelligence-related differences in short-term memory. Ellis was the first scholar to experimentally investigate the structural characteristics of short-term memory in persons with intellectual disabilities, and he was among the first to provide evidence about strategic aspects on memory. In short, Ellis (1963, 1970) conducted some of the earliest and most influential studies of structural and strategic aspects of intelligence-related differences in memory performance. Subsequent studies provided evidence that was inconsistent with the predictions of stimulus trace theory, and investigators that followed Ellis developed more refined methods that allowed for the direct measurement of variables that influence strategic behavior. While Ellis recognized the theoretical existence of executive processes, he did not investigate their influence on intelligence-related differences in memory and problem-solving. Nevertheless, his work inaugurated decades of research about the instructional and contextual conditions that influence the strategic self-regulation of memory processes and, indirectly through the influence of future researchers, the conditions that affect the self-determination of people with intellectual disabilities.

Philosophy of Care

Maya Matheis

Philosophy of Care

Individuals with intellectual disabilities have been one of the most marginalized and disadvantaged groups within society. Historically, individuals with intellectual disability have been shunned, considered "mentally ill" or "deviant," and treated as less than human (Kanner, 1967; Karten, 2015; Wolfensberger, 1972). In the past century, considerable advances have been made to improve treatment and care for individuals with intellectual disability. The deinstitutionalization movement in Europe and North America has made significant strides in reducing the number of individuals with intellectual disability confined to residential facilities (Mansell & Ericsson, 2013). Our understanding of intellectual disability has evolved from a medical model, in which it is viewed as a "static and rather hopeless condition," to a developmental model, in which individuals are considered capable of learning and developing (Horejsi, 1975, p. 26). Attitudes and policies have shifted toward emphasizing social integration and inclusion for individuals with disabilities. This chapter discusses major philosophical shifts in the field of intellectual disability since the twentieth century, including reviews of concepts related to deinstitutionalization, normalization, social inclusion, self-determination, and person-centered planning.

Deinstitutionalization

Deinstitutionalization has been one of the most influential and important concepts in the field of intellectual disability in the past 50 years. The movement away from models of long-term residential institutional care toward community-based services is at varying stages around the world. Scandinavian countries have been at the forefront of the movement, with laws in Sweden and Norway protecting the right to community-based services (Tøssebro, 2004, 2016). Deinstitutionalization is in its late stages in the United States, the United Kingdom, Ireland, Canada, and Australia (Mansell, 2006; Mansell & Ericsson, 2013). In the United States, the number of individuals with intellectual disability or other developmental disabilities living in state institutions decreased from 131,345 in 1980 to 29,768 in 2016—a 77% reduction (Coucouvanis, Lakin, Prouty, & Webster, 2006; Larson et al., 2018). Deinstitutionalization is in its early stages, with community-based placements becoming more commonplace, in European countries such as Germany, Spain, Austria, Belgium, Italy, Greece, and Portugal (Beadle-Brown, Mansell, & Kozma, 2007; Buchner, 2009; Mansell & Ericsson, 2013;

Martinez-Leal et al., 2011), as well as countries in Asia such as Singapore, Japan, and South Korea (Jeevanandam, 2009). However, institutional care remains the norm in many countries across the world (Jeevanandam, 2009; Lin, Hsu, Kuo, & Lin, 2013; Lin & Lin, 2011; Martinez-Leal et al., 2011; Mercadante, Evans-Lacko, & Paula, 2009; Vann & Šiška, 2006).

The deinstitutionalization of services for individuals with intellectual disability and other developmental disabilities has had a very different process and timeline compared to the deinstitutionalization of residential facilities for individuals with mental illness (Landesman & Butterfield, 1987). The movement to dismantle mental asylums and residential state hospitals in Europe and North America began following World War II, as such facilities came under scrutiny for poor living conditions and treatment of patients (Fakhoury & Priebe, 2007; Paulson, 2012). In the following decades, the civil rights movement, changes in the conceptualization of mental illness, and advances in psychopharmacology contributed toward a shift in mental health service delivery (Paulson, 2012). The process of deinstitutionalizing services for individuals with developmental disabilities did not start until the late 1960s and early 1970s, with the publication of *Changing patterns in residential services for the mentally retarded* (Kugel & Wolfensberger, 1969) representing a significant change in the field's conceptualization of services (Landesman & Butterfield, 1987; Mansell & Ericsson, 2013). The movement was heavily influenced by normalization ideology, which posited that social integration would be in the best interest of individuals with intellectual disability (Culham & Nind, 2003; Landesman & Butterfield, 1987).

In the United States, the process of establishing alternatives to residential institutions was begun in a handful of states during the 1960s, including Connecticut, Nebraska, and California (Horejsi, 1975). However, state institutions didn't begin to close until the 1970s, with the majority of closures and development in community services occurring in the 1980s (Horejsi, 1975; Landesman & Butterfield, 1987; Mansell & Ericsson, 2013). The Developmentally Disabled Assistance and Bill of Rights Act (P.L. 94-103, , 1975), which introduced the requirement of protection and advocacy services for individuals with developmental disabilities, required that states develop plans to "support the establishment of community programs as alternatives to institutionalization" and to "eliminate inappropriate placement in institutions of persons with developmental disabilities" (89 Stat. 481).

Defining Deinstitutionalization

While a large focus within deinstitutionalization is the closure of long-term residential facilities for individuals with developmental disabilities, it also emphasizes the development and sustainment of alternative forms of care within community settings. Horejsi (1975) described deinstitutionalization as a conglomeration of four interrelated activities:

1. Preventing the admission of persons to institutional facilities by finding and developing alternative community methods of care and training
2. Returning to the community all institutional residents who have been prepared through programs of rehabilitation and training to function adequately in appropriate local settings
3. Establishing and maintaining a responsive residential environment which protects human and civil rights and which contributes to the expeditious return of the individual to normal community living whenever possible
4. Promoting public acceptance of retarded persons as neighbors, employees, and citizens possessing civil and human rights (p. 10)

This definition underscores the importance of community-based care, the continuing role that institutions and service systems play in caring for this population, and an emphasis on human rights within the deinstitutionalization process. In his model of deinstitutionalization, Horejsi (1975) described a comprehensive support system for individuals with developmental disabilities beyond residential services, including child development services, public education, family support services, and vocational services. He also called for the involvement of parent/family advocates as well as individuals with intellectual disability in designing and improving community-based programs, proposing that individuals with intellectual disability hold places on advisory boards. The exact configuration of services, Horejsi (1975) maintained, would need to be individualized to the needs of specific regions, stating that "deinstitutionalization does not occur in a vacuum. A whole host of economic, political, cultural, and social factors affect what can or cannot be done at a particular point in time in a particular area" (p. 40).

Horejsi (1975) also distinguished deinstitutionalization from institutional reform and decentralization, two similar but distinct concepts. He described "institutional reform" as referring to the improvement of institution-based care and "decentralization" as referring to the dissolution of large state facilities in place of smaller facilities dispersed across a region. As can be seen by these definitions, both institutional reform and decentralization retain the model of long-term residential institutions and lack the emphasis on community-based services that characterizes deinstitutionalization.

Associated Outcomes and Costs

A foundational premise of deinstitutionalization is that community-based services provide individuals with developmental disabilities with a better standard of living and improved functioning (Chowdhury & Benson, 2011; Mansell & Ericsson, 2013). As the process of deinstitutionalization has progressed around the world, research has examined the associated outcomes for individuals with intellectual disability. A comprehensive review of studies examining outcomes associated with deinstitutionalization published in English between 1997 and 2008 found that, compared to institutions, community-based services were associated with superior community participation, social networks, family contact, quality of life, adaptive behavior, self-determination/choice, and user/family satisfaction (Kozma, Mansell, & Beadle-Brown, 2009). This review also found that these findings were similar in different countries, across variations in service structures and socioeconomic factors. Chowdhury and Benson (2011) conducted a review of literature examining the specific construct of quality of life, with results indicating that community-based living following deinstitutionalization was associated with better quality of life for individuals with intellectual disability. Another comprehensive review examined health-related outcomes in 14 European Union countries, finding that late-stage deinstitutionalization was associated with the lower presence of certain health conditions (e.g., chronic bronchitis, osteoporosis, gastric ulcers) among individuals with intellectual disability compared to early-stage deinstitutionalization.

Individual factors have been found to influence outcomes related to deinstitutionalization. In their comprehensive review of deinstitutionalization research, Kozma et al. (2009) found that better adaptive skills are associated with better outcomes, particularly in relation to community participation, social networks, and self-determination. A general finding from the literature indicates that individuals with higher support needs, such as challenging behavior, experience worse outcomes (Kozma et al., 2009; Mansell, 2006). Individuals with challenging behavior have been found to be more likely to remain in institutional settings and to be re-institutionalized after the transition to community-based services (Beadle-Brown et al., 2007; Mansell, 2006).

As deinstitutionalization has progressed, research has also focused on comparing the associated costs of institutional and community-based services. Findings from the United States have consistently demonstrated that community-based services are less costly than state institutions (Campbell & Heal, 1995; Knobbe, Carey, Rhodes, & Horner, 1995; Stancliffe & Lakin, 1997). Research in the United Kingdom has found the cost of community-based services for individuals with intellectual disability to be higher compared to institutional care; however, the associated costs of community-based services were observed to be decreasing over time (Hallam et al., 2006).

Opposition and Challenges

Much of the opposition and resistance to deinstitutionalization stemmed from concerns regarding the transition in service delivery systems rather than disagreement with the concept of deinstitutionalization (Landesman & Butterfield, 1987; Mansell & Ericsson, 2013). During the early stages of deinstitutionalization in the United States, Scandinavia, and the United Kingdom, many parent and family advocates expressed concerns that alternative services were insufficient to meet the needs of their relatives with intellectual disability and that the transition in residential setting would have negative effects on their family member's functioning (Landesman & Butterfield, 1987; Mansell & Ericsson, 2013). Parent advocacy groups voiced concerns that individuals with developmental disabilities would be vulnerable in community settings and that community-based residences would have inadequate support and continuity of care (Landesman & Butterfield, 1987). In the decades following, parental and familial attitudes regarding deinstitutionalization have become more positive, though concerns still remain regarding the availability of alternative resources (Mansell & Ericsson, 2013). These concerns are also shaped by the changing political and economic climates in Europe and the United States, as fiscal conservatism has broadly resulted in the reduction of social services (Mansell & Ericsson, 2013).

Related to these concerns is de-differentiation, a common consequence of deinstitutionalization (Sandvin, 1996). De-differentiation describes "the loss of special, separate policies and service structures for people with intellectual disabilities and their replacement by general policies and structures" (Mansell, 2006, p. 11). The replacement of specialized services with those that serve a range of populations creates competition for these resources with other client groups, such as the elderly, individuals with physical disabilities, and individuals with mental illness. De-differentiation is also a result of the social model of disability, which perceives specialized services as discriminatory (Bickenbach, Chatterji, & Badley, 1999; Mansell, 2006). The combined effect is that the specific needs of individuals with intellectual disability may go unmet. As noted by Mansell (2006):

> A critical question for proponents of better-quality services for people with intellectual disabilities will be how they can achieve the benefits of social integration for individuals and for the whole group while at the same time retaining enough knowledge and recognition to ensure that special needs are noticed. (p. 13)

The challenges of deinstitutionalization lie thusly in the development and maintenance of a service system that simultaneously allows individuals with intellectual disabilities to be socially integrated within communities and that provides services specifically designed to address their needs and help them develop, while also ensuring the availability of sufficient resources.

Normalization

The ideology of normalization was a dominant philosophy in the field of intellectual disability for several decades and was a driving force behind deinstitutionalization. The concept of normalization originated in Scandinavia with efforts to reform services for individuals with intellectual disability in the late 1950s and 1960s (Bank-Mikkelsen, 1969; Nirje, 1970). The first definition of normalization was developed by Bank-Mikkelsen (1969), the head of the Danish Mental Retardation Service, who described it as "letting the mentally retarded obtain an existence as close to the normal as possible" (p. 227). This concept was further developed by Nirje (1970), who was the first to develop it into an ideology with accompanying principles and who applied it to policies pertaining to services for individuals with intellectual disability. His work emphasized providing individuals with disabilities equal rights and opportunities, defining the normalization principle as "making available to the mentally retarded patterns and conditions of everyday life which are as close as possible to the norms and patterns of the mainstream of society" (Nirje, 1969, p. 181). Nirje (1985) also introduced the concept of social integration, which he described as the opportunity "to be yourself—to be able and to be allowed to be yourself among others" (p. 67).

Wolfensberger (1972) later introduced normalization to the United States along with an accompanying set of guidelines for applying the ideology to a broad array of human services.

Wolfensberger's definition of normalization described it as the "utilization of means which are as culturally normative as possible, in order to establish and/or maintain personal behaviors and characteristics which are as culturally normative as possible" (Wolfensberger, 1972, p. 28). This definition clarifies "normal" to be relative to one's social context and also describes normalization as both a continuous process and a goal. By supporting individuals marginalized within society to adopt culturally typical behaviors, Wolfensberger (1972) argued that social stigma could be decreased, leading to increased social acceptance and social value. His model of human services and human management called for action within interpersonal interactions and at a societal level, with supports for both physical (e.g., location, access) and social (e.g., programming, public perception) integration within the community.

Criticism and Controversy

As pointed out by Landesman and Butterfield (1987) in their analysis of normalization, this ideology is built on the assumption that the environment plays a large role in an individual's functioning, with access to typical activities and settings increasing quality of life. When applied to service design and delivery, this philosophy promotes deinstitutionalization and community integration for living, employment, and recreational activities. While this ideology received widespread support and was deeply entrenched within the field of intellectual disabilities for some time (Culham & Nind, 2003; Landesman & Butterfield, 1987), it was not without its critics. Direct opposition to normalization centered upon concern that individuals with intellectual disability would be at risk in mainstream community settings and that they would benefit more from environments designed to be protective and nurturing (Landesman & Butterfield, 1987). Given that Wolfensberger's guidelines for implementing normalization action in service delivery outlined multiple levels of support, these early concerns were largely centered on the practical implementation of normalization and the risks of deinstitutionalization rather than the theoretical underpinnings of normalization.

Criticism of the ideology of normalization gained traction with the rise of the social model of disability (Culham & Nind, 2003). Within the social model of disability, disability is viewed as a social construct, as opposed to the medical model, in which disability is viewed as a deficit or defect within an individual (Bickenbach et al., 1999; Oliver, 1990). The social model of disability was embraced by disability advocates and civil rights activists, who argued that the difficulties experienced by individuals with disabilities are due to social attitudes about their abilities and needs. Critics questioned the expectation that individuals with intellectual disability should act "normal," raising concerns that normalization emphasized assimilation with societal standards, and placed the responsibility on individuals with disabilities to conform in order to receive social acceptance and respect (Culham & Nind, 2003; Northway, 2002; Perrin & Nirje, 1985; Shaddock & Zilber, 1991). Advocates argued that individuals with disabilities should embrace their differences, following in the footsteps of civil rights movements and empowerment strategies used by other marginalized groups. Culham and Nind (2003) noted that individuals with intellectual disabilities were one of the last marginalized social groups to which this consideration of human rights and empowerment of diversity has been applied and that the ideology of normalization insulated this population from empowerment. They commented that "while other groups have come to regard themselves as strong…the assimilation of normalization has led only to a begrudging acceptance for people with an intellectual disability" (Culham & Nind, 2003, p. 71).

Wolfensberger and Nirje held that these criticisms stemmed from "misconceptions" and "preconceived associations" of normalization (Perrin & Nirje, 1985; Wolfensberger, 1983). Perrin and Nirje (1985) commented that:

> Probably the most common misinterpretation of the normalisation principle is the mistaken belief that it means mentally handicapped people must be expected to, indeed be forced to, act 'normal,' ... normalisation does not mean normalcy; it does not mean that people should be normalised ... normalisation means the acceptance of a person with their handicap within 'normal society.' (pp. 69–70)

Wolfensberger (1983) attributed much of the controversy to the connotations invoked by the term "normalization," describing its nomenclature as "unfortunate" (p. 234). As such, he sought to distance his model from such criticism and to clarify its original intentions by discarding the term "normalization" and replacing it with the term "social role valorization."

Social Role Valorization Theory

Wolfensberger (1983) proposed that the term "social role valorization" (SRV) replace "normalization," believing that this new term better encapsulated his ideology and his applied model. He further contextualized the new term within the "recent insight that the most explicit and highest goal of normalization must be the creation, support, and defense of valued social roles for people who are at risk of social devaluation" (Wolfensberger, 1983, p. 234). In his work introducing the new term, Wolfensberger also re-emphasized the cultural relativity of his original definition of normalization and reiterated the elements of his model pertaining to actions directed at reducing social stigma and changing public perception of marginalized groups. Like his original conceptualization of normalization, Wolfensberger's SRV theory extended to all socially marginalized groups and was nonspecific to individuals with disabilities.

While Wolfensberger first introduced SRV as a refinement of an existing set of principles, it is largely viewed as a unique theory due to the extent to which it has since been developed (Cocks, 2001; Kumar & Singh, 2015; Lemay, 1995; Wolfensberger, 2000). Wolfensberger's later writing on SRV situates it within complex sociological theory about social roles and needs (Cocks, 2001; Kumar & Singh, 2015). The focus of SRV is on the socially devalued individual, who is likely to be socially excluded, treated poorly, and denied autonomy (Cocks, 2001; Lemay, 1995). As described by Wolfensberger (2000):

> The key premise of SRV is that people's welfare depends extensively on the social roles they occupy… This implies that in the case of people whose life situations are very bad, and whose bad situations are bound up with occupancy of devalued roles, then if the social roles they are seen as occupying can somehow be upgraded in the eyes of perceivers, their life conditions will usually improve. (p. 105)

Within this framework, service systems influence the way their clients are viewed by the larger community and thus are called upon to go beyond rehabilitation to address the devaluation experienced by these individuals. Two main processes work to place individuals in positive social roles with the goal of preventing and mitigating social devaluation: enhancing the social image of vulnerable groups and enhancing the competencies of vulnerable individuals (Cocks, 2001; Lemay, 1995; Wolfensberger, 2000). Critics of SRV note that this framework still places the burden on individuals with disabilities to engage in certain behaviors and to develop certain competencies in order to be accepted and valued by society (Culham & Nind, 2003; Kumar & Singh, 2015).

The Legacy of Normalization

Since its introduction, the ideology of normalization has continued to be refined and expanded, with its principles heavily influencing social and educational policy in Europe, the United States, and Australia. Normalization was a major impetus for deinstitutionalization in Europe and the United States, and its focus on social integration is at the foundation of many of the service structures aimed at supporting individuals with intellectual disability (Buell & Minnes, 2006; Landesman & Butterfield, 1987). Its emphasis on social integration and human rights for individuals with intellectual disability helped pave the way for philosophies of social inclusion, empowerment, and self-determination (Culham & Nind, 2003; Kumar & Singh, 2015).

Inclusion

The philosophy of inclusion became dominant in the field of intellectual and developmental disabilities in the late 1990s and early 2000s and is now a central part of our contemporary conceptualization of social policy (Power, 2013). Inclusion broadly describes increased participation in community-based activities and social networks (Abbott & McConkey, 2006). The major goals of inclusion for individuals with intellectual disability are to ensure that they "have full and equal access to health care, social roles, and relationships that are equal to their non-disabled peers" (Bollard, 2009, p. 5).

Social inclusion can trace its theoretical roots back to normalization, which laid the foundation for conceptualizing social integration for individuals with cognitive disabilities (Culham & Nind, 2003; Renzaglia, Karvonen, Drasgow, & Stoxen, 2003). However, inclusion differs from integration due to its emphasis on participation, as well as the foci of change. Within normalization, individuals are encouraged to adopt socially typical behaviors to gain access to community activities and social networks (Culham & Nind, 2003). The approach of inclusion places the responsibility on society to ensure that all individuals are able to participate, with inclusion conceptualized as a basic human right (Culham & Nind, 2003). The movement toward inclusion was influenced by growing awareness that individuals with intellectual disability continue to experience social isolation even when living in community settings, which has led to the description "asylum without walls" (Hall, 2005). This shift in thinking looked beyond integration to focus on creating an inclusive environment, rather than bringing individuals with intellectual disability into environments to which they must learn to adapt and conform (Culham & Nind, 2003; Renzaglia et al., 2003).

The Philosophy of Inclusion

While social inclusion has been conceptualized in a myriad of ways, most definitions emphasize meaningful interaction with the community, use of community facilities, and large social networks (Simplican, Leader, Kosciulek, & Leahy, 2015). Independent living (Duggan & Linehan, 2013), participation in economic systems, and employment (Hall, 2005; Hall & McGarrol, 2012) have been highlighted as important aspects of inclusion. Literature on inclusion has also emphasized the significance of "belonging" in a community, with belonging defined as "meaningful engagement and reciprocal relationships within local neighborhoods or networks between people with and without disabilities" (Power, 2013, p. 69).

An ecological model developed by Simplican et al. (2015) focuses on the functional aspects of social inclusion, conceptualizing it as the interaction between the domains of interpersonal relationships and community participation. These domains are theorized to interact and strengthen each other: by developing meaningful relationships with other people, community participation will increase, and, in turn, increased community participation will lead to the broadening of one's social network. Within this model, independent living and employment can be considered as factors that promote and facilitate the domains of interpersonal relationships and community participation, highlighting the ways in which various processes build upon each other to create social inclusion.

The primary aim of inclusive philosophy is to improve the lives of individuals marginalized and excluded from society. As described by Renzaglia et al. (2003), inclusion works to improve the quality of life of individuals with intellectual disabilities through three processes: "a) empowering individuals to have control over their own lives, b) providing individuals with the opportunity to select the lives of their choosing, and c) conferring individuals with the sociopolitical power to defend their choices" (p. 141). Inclusion also aims to better society as a whole by maximizing individual productivity and contribution through the process of making communities welcoming and accepting of differences (Renzaglia et al., 2003). The concept of "universal design," borrowed from architecture, refers to the creation of physical and social spaces designed to accommodate the needs of special populations (Renzaglia et al., 2003). By designing and planning for a diverse array of needs and abilities, inclusion aims to ensure universal participation.

Barriers and Challenges

The path to social inclusion for individuals with intellectual disabilities has been hindered by a number of social and structural barriers. A review of research examining environmental factors affecting community participation among individuals with intellectual disability identified lack of transportation and negative attitudes in the community as two major impediments toward participation, particularly in regard to participation in leisure activities (Verdonschot, de Witte, Reichrath, Buntinx, & Curfs, 2009). A qualitative study conducted by Abbott and McConkey (2006) surveyed individuals with intellectual disability on their perceived barriers to inclusion, identifying four main barriers: lack of necessary knowledge and skills (e.g., literacy, numeracy, knowledge of area), role of support staff and service managers (e.g., limited independence, short staffed), location of residence (e.g., lack of transport, few community activities/facilities in area), and community factors (e.g., negative attitudes, lack of advocacy/volunteer groups).

Limited opportunities for paid employment has also been highlighted as a significant barrier (Hall, 2005; Hall & McGarrol, 2012). Unwelcoming employment settings and shortage of services providing vocational training and/or support contribute to this, along with policies that disassociate social benefits and employment (Hall & McGarrol, 2012). These factors limit economic inclusion and choice-making, hindering participation in economic as well as social spheres. Hall and McGarrol (2012) have commented that our binary conceptualization of employment and care contributes toward the difficulty that individuals with intellectual disabilities experience in this regard and that reconceptualizing the contributions and positions for this population in the workplace will be necessary for inclusion. Similarly, Kittay (2001) has suggested that the emphasis in the literature on independent living creates a barrier to inclusion, as many individuals with intellectual disability require some degree of support and assistance, noting that "perhaps a way of including the severely intellectually impaired person and bestowing the dignity of citizenship is to interpret what it means to live independently, to be employed, and to be productive, in very broad terms" (p. 569).

Self-Determination

The concept of self-determination is prominent in multiple disciplines, including political science, philosophy, and social psychology (Wehmeyer, 1999). Broadly, self-determination refers to one's ability to determine one's own fate (McCorquodale, 1994; Quane, 1998). Many human and civil rights groups, including the United Nations, have declared self-determination a basic human right and consider it a precondition for other human rights (McCorquodale, 1994; Wehmeyer, 2005). Self-determination theory, which is concerned with understanding the motivations behind the behavior of individuals, became prominent in the area of personality psychology in the 1970s (Deci & Ryan, 2008). However, it wasn't until the 1990s that self-determination became an important construct in the fields of education and disability advocacy, following the funding of several projects aimed at promoting self-determination in children and youth with disabilities in the United States by the Office of Special Education Programs (Wehmeyer, 1999). Currently, self-determination is at the core of many policies related to education and disability.

The Philosophy of Self-Determination

Self-determination has been defined in numerous ways in disability and education literature, with models and definitions emphasizing the human rights aspect of the concept, personal choice, and empowerment (Malian & Nevin, 2002; Wehmeyer, 1999). Turnbull and Turnbull (2001) described self-determination as "living one's life consistent with one's own values, preferences, strengths, and needs and implicitly doing so free from external influences" (p. 58). Although several measures have been developed to measure constructs and skills related to self-determination, it itself is conceptualized as an unmeasurable heuristic used to describe behavior or a state characteristic (Wehmeyer, 2005). For individuals with intellectual disability, self-determination is an important component of social inclusion, as it allows them to navigate social environments and become active participants (Renzaglia et al., 2003).

Wehmeyer, Kelchner, and Richards (1996) developed a definitional framework for self-determination for individuals with intellectual disability through a combination of review of the relevant literature and interviews with self-advocates. This framework defines self-determination as "acting as the primary causal agent in one's life and making choices and decisions regarding one's quality of life free from undue external influence or interference" (Wehmeyer et al., 1996, p. 632). As such, self-determination describes when an individual brings about events in his or her life without an unacceptable level of interference from others. The model developed by Wehmeyer et al. (1996) also identified four essential characteristics of self-determination: autonomy, self-regulation (e.g., self-monitoring, self-reinforcement), psychological empowerment (i.e., perceived control), and self-realization (i.e., self-awareness of strengths and limitations).

Self-Determination for Individuals with Severe and Profound Intellectual Disability

Self-determination is often misinterpreted as being synonymous with independence or self-reliance, which limits the degree to which this construct can be applied to individuals with severe and profound intellectual disability, as individuals with severe cognitive impairments often require support in daily life activities as well as decision-making (Turnbull & Turnbull, 2001; Wehmeyer, 2005). A survey conducted with teachers in the United States found that teachers working with students with severe cognitive impairments considered self-determination to be significantly less important for future success than teachers working with students with mild impairments (Wehmeyer, 2005; Wehmeyer, Agran, & Hughes, 2000). Wehmeyer (2005) has commented that misperceptions in the field conflating self-determination with self-sufficiency and control have created a barrier to self-determination for individuals with severe disabilities. To address this issue, he developed a refined definition of self-determination to specify that "it refers to people acting volitionally, based on their own will" and that individuals with severe impairments can "be supported to act more volitionally" (p. 117).

Turnbull and Turnbull (2001) proposed a framework for conceptualizing the application of self-determination principles for individuals with significant cognitive disabilities. Their framework emphasizes the role of trusted allies, who often have an established relationship with the individual, in supporting individuals with severe disabilities in acting volitionally. Two steps are recommended: (1) individuals with severe impairments should develop an awareness of their functional limitations and build alliances with allies to help support them; and (2) allies should collaborate with individuals with disabilities to support them in decision-making and, when necessary, make decisions for them, taking into consideration their "values, preferences, strengths, and needs" if they were able to make the decision independently (Turnbull & Turnbull, 2001, p. 57).

Teaching Self-Determination

Self-determination has become an important aspect of education for individuals with intellectual disability. The special education system of the United States involves students with disabilities in the development of goals for their own individualized education programs (IEPs) and transition plans (Martin & Marshall, 1996; Wood, Karvonen, Test, Browder, & Algozzine, 2004). Educational policies for students with disabilities also emphasize the development of self-determination as a critical component of the educational process (Test, Karvonen, Wood, Browder, & Algozzine, 2000; Wehmeyer, 1999).

Self-determination is understood as a trait that emerges through interactions with the environment (Malian & Nevin, 2002). As such, self-determination is considered teachable (Malian & Nevin, 2002; Martin & Marshall, 1996;Renzaglia et al., 2003 ; Test et al., 2000). Wehmeyer (1999) developed a function model of self-determination to guide interventions aimed at promoting self-determination for individuals with and without disabilities. This model identified the following component elements of self-determined behavior: choice-making, decision-making, and problem-solving skills; goal-setting and attainment skills; self-observation, self-evaluation, self-reinforcement, and self-instruction skills; self-advocacy and leadership skills; internal locus of control; positive attributions of efficacy and outcome expectancy; and self-awareness and self-knowledge (Wehmeyer, 1999).

The development of self-determination should be a lifelong process, with instruction beginning at young ages and following a developmental trajectory (Renzaglia et al., 2003; Test et al., 2000). Numerous instructional strategies and materials have been developed to support educators in teaching students skills related to self-determination (Renzaglia et al., 2003; Test et al., 2000; Wehmeyer, 1999). The most common method of instruction in teaching self-determination is direct instruction, in which a skill is introduced, practiced, and then applied (Renzaglia et al., 2003). Curricula have been developed for individuals with disabilities across the lifespan, as well as measures to assess the effectiveness of such curricula. In selecting a curriculum to teach self-determination, Test et al. (2000) recommend reviewing materials for fit in regard to intended audience, relevancy of skills, prerequisite skills, ease of use, types of materials, supporting evidence, and time/financial cost. Generalization of skills to natural environments is a particularly important aspect of instruction, as this is necessary for skills to manifest into self-determined behavior. In working toward the goal of generalization, educators should aim to maximize opportunities to learn and practice skills.

Self-Determination and Inclusion

For individuals with intellectual disability, self-determination is necessary for achieving full inclusion. Components of self-determination, such as problem-solving and decision-marking skills, allow individuals to navigate the environment and actively participate in their communities. Self-advocacy is also critical, as it allows individuals with disabilities to communicate their needs as individuals and as a group. Unlike among other historically marginalized groups, self-advocates have largely been absent from the movement toward social inclusion for individuals with intellectual disabilities (Abbott & McConkey, 2006). While individuals with cognitive impairments may require supports, qualitative research has demonstrated that they have insight into their experiences of exclusion and their needs (Abbott & McConkey, 2006). Educators, caregivers, and service providers can support individuals with intellectual disabilities in developing self-advocacy skills and by promoting opportunities for decision-making and leadership. Creating environments that are receptive toward active participation of individuals with intellectual disability and that provide opportunities for self-determined behavior is necessary in working toward inclusion (Renzaglia et al., 2003).

Person-Centered Planning

Person-centered planning (PCP) describes an approach to assisting individuals with disabilities in planning their futures and organizing their support structures (Clark, Knab, & Kincaid, 2005; Sanderson, 2000). The process of PCP aims to empower individuals with disabilities by including them in discussions and decision-making pertaining to their care, with the main goal to "aid an individual in developing meaningful life goals based on his or her strengths and talents, utilizing individual, natural, and creative supports and services" (Clark et al., 2005, p. 429). The approach of PCP developed in the 1980s out of the normalization movement within the United States and was quickly embraced within the United Kingdom (Clark et al., 2005; Holburn, 2002). PCP has become widespread in the field of intellectual and developmental disabilities, with educational and service policies in the United States, the United Kingdom, and Australia requiring PCP practices (Holburn, 2002; Ratti et al., 2016).

The Philosophy of PCP

In its development, PCP was greatly informed by the social inclusion movement and theories pertaining to self-determination (Holburn, 2002; Sanderson, 2000). The central tenant of PCP is that an individual is viewed as a person first and foremost and that his or her diagnosis, disability, or areas of weakness are not a focus of plan development (Clark et al., 2005; Holburn, 2002; Sanderson, 2000). Emphasis is placed on personal choice and empowering individuals to envision their desired future. Self-advocacy is developed by encouraging individuals with disabilities to voice their questions and interests. While PCP is focused on planning for the future, the process of developing goals inherently involves the evaluation of current quality of life and conditions, giving individuals with disabilities opportunities to address their unmet needs. The person-centered and strength-based aspects of PCP result in an approach that is focused on individual capacities and possibilities rather than deficits and available service supports.

Components of PCP

The term PCP is used to describe a broad approach rather than a specific technique. Many manualized interventions based on the PCP framework have been developed with widespread implementation, including Personal Futures Planning (Mount, 1994), Planning Alternative Tomorrows with Hope (PATH; Pearpoint, O'Brien, & Forest, 1993), the McGill Action Planning System (MAPS; Vandercook, York, & Forest, 1989), Individual Service Design (O'Brien & Lovett, 1993), Essential Lifestyle Planning (Smull & Harrison, 1992), and Whole Life Planning (Butterworth et al., 1993). These various interventions have been designed for application within specific organizational structures but share the overarching structure and philosophy of PCP.

The basic process of PCP involves the formation of a team consisting of people committed to the well-being of the individual (e.g., family members, staff, teachers, community members), encouraging the individual to describe the life he or she wants, and the development of a plan with short- and long-term goals in collaboration with the team and the individual (Clark et al., 2005; Holburn, 2002). Sanderson (2000) identified five key features of PCP:

1. The person is at the center.
2. Family members and friends are partners in planning.
3. The plan reflects what is important to the person, their capacities, and the support they require.
4. The plan results in actions that are about life, not just services, and reflect what is possible, not just what is available.
5. The plan results in ongoing listening, learning, and further action (pp. 3–7).

These five features emphasize the importance of taking a strengths-based and community-centered approach to developing an individual's plan. To promote the inclusion of individuals with intellectual disability in the planning process, PCP commonly involves the replacement of professional jargon with everyday language as well as pictures and graphic displays (Clark et al., 2005).

Challenges and Evidence

Empirical evaluation of PCP is complicated by the broadness of the approach, implementation variations, and challenges in measuring related constructs (Holburn, 2002). A recent systematic review found that while there are discrepancies across research studies, there is some evidence to indicate that PCP has a positive impact on outcomes across the lifespan (Ratti et al., 2016). PCP was found to have significant positive impact on community participation, as well as moderate positive impact on quality of life, participation in activities, and everyday choice-making. However, the review found no evidence that PCP increased self-determination, improved adaptive functioning, or increased decision-making related to care. These findings suggest that while evidence supporting PCP is limited, it has been demonstrated to help individuals with intellectual disability in certain domains. Further research is necessary to examine long-term and large-scale outcomes.

Some have voiced concerns that PCP is simply a "paper planning exercise" that has little impact on outcomes for individuals with intellectual disabilities (Claes, Van Hove, Vandevelde, van Loon, & Schalock, 2010; Ratti et al., 2016). Researchers have noted the tendency for PCP practices to fade after initial plan development, without updates or progress monitoring (Holburn, 2002; Menchetti & Garcia, 2003; Ratti et al., 2016). The implementation gap is likely to be larger in contexts lacking sufficient resources. Kaehne and Beyer (2014) noted that, in order for PCP to be successful, it must be embraced at the institutional level by all stakeholders. Further attention and research should be focused on PCP implementation fidelity, individual and programmatic evaluation, and plan progress monitoring in an effort to decrease the implementation gap.

Conclusion

Since the 1950s, considerable shifts have occurred in our conceptualization of care for individuals with intellectual disability. The principle of normalization paved the way for the deinstitutionalization and social inclusion movements. Philosophies of self-determination and person-centered planning currently have widespread influence on service structures related to education, employment, and community-based supports. Despite these advances, individuals with intellectual disability still face considerable stigma, prejudice, and social ostracization. Institutionalization remains a reality for many individuals with intellectual disability across the globe, including in the United States. Policies and interventions designed to promote social inclusion face many structural and social barriers. Continued effort is needed to advocate for the rights of individuals with intellectual disabilities, to empower and support self-advocates, and to refine our strategies of creating a society in which individuals with intellectual disabilities are welcomed, valued, and treated with respect.

Quality of Life

Haris Memisevic and Mirjana Djordjevic

Introduction

Quality of life (QOL) has become a major topic of many scientific disciplines in the last couple of decades. The concept of QOL has been studied extensively from many perspectives and within many scientific fields such as medicine, economics, and the social sciences (Cummins, 2005). As an indication of the scientific interest in QOL, we will mention that there were (up to December 31, 2017) 74,069 documents in the SCOPUS database that contained the term QOL in its title. Out of this number, there were 59,234 scientific articles, 5610 review articles, and 926 book chapters. In Fig. 6.1, we present the number of articles containing QOL in their titles in the last 5 years.

There are even three journals indexed in the Web of Science that, in its title, have the words QOL. In addition to this, there are numerous books and monographs on the QOL topic. From all this, it is quite obvious that the interest in this topic has not diminished.

Increased interest in QOL research can also be reflected in the number of theses containing QOL in their titles. By examining the Open Access Theses and Dissertations database, for the period of 2014–2017, there were 1,254,251 defended theses (PhD, MS, and MA) in different languages (English, Portuguese, Spanish, Swedish, Japanese, Finnish, French, German, Czech, Hungarian, Greek, Norwegian, etc.) and within different departments (psychology, mechanical engineering, chemistry, education, electrical engineering, physics English, computer science, electrical and computer engineering, history, medicine, economics , civil engineering, sociology).

The topic of QOL has been investigated widely in the context of human development. For example, how does QOL change through different age stages? It has also been studied cross-culturally. Are there differences in the QOL among nations and cultures? Next, QOL has been compared across disability categories (Memisevic, Hadzic, Ibralic Biscevic, & Mujkanovic, 2017). Obviously the topic is very broad, and many approaches and perspectives can be taken in studying the QOL.

In writing this chapter, the authors were faced with many dilemmas. What should be our main focus in this chapter? QOL in general, as it applies to all human beings and universally conceptualized, different parts of QOL? Or should we write about it specifically in terms of QOL for people with intellectual disability? Although the major part of QOL is universal or universally

applied, there are, however, some aspects of it that pertain to people with disabilities only. Further on, there are some issues that pertain only to people with disabilities in certain parts of the world. Thus, we attempted to cover as many different topics as possible within this chapter, with the main focus on universal dimensions of QOL in people with ID and its general principles regardless of culture and identity factors

There is almost no medical condition, disability, nor group for which there is no QOL study. This voluminous work in the QOL field best reflects its importance in human life. QOL is a shared goal, one we would all like to improve, however elusive the goal may be. The field of intellectual disability (ID) was not spared from this increased general interest in the QOL concept.

In relation to the field of ID, the concept of QOL was embraced during the 1980s as a sensitizing notion and an overarching principle for service delivery (Schalock, 2000). In fact, the relationship between QOL and ID is a reciprocal one. Schalock, Verdugo, and Gomez (2017) propose that QOL has affected the field of intellectual disability in five different ways. It fostered the development of individualized supports, evidence-based practices, personal outcomes, quality improvement, and a catalyst for organization and system-level transformation. Given the fact that the QOL concept changed with time, it is unsurprising that it has not always been used for benefitting people with ID. For example, not so long ago, the very concept of QOL was used in argumentation to deprive persons with ID some basic rights to people with intellectual disability. There were several court cases in the United States where fundamental rights to life were denied to people with ID on the grounds of QOL. All this led to Baby Doe Law that stated that a child's quality of life is not a valid reason for withholding medical care.

Unfortunately, the issue of human rights still dominates the field of ID in many developing countries. As an example of this, we can take the numbers of institutionalized persons with ID in developing countries or the issue of legal capacity; in some countries, it is still a common practice to deprive legal capacity to people with ID. As we can see, many issues that people with ID are facing are region-specific. However, there are many universal topics that are relevant to people with ID throughout the world. All individuals with ID need to have the access to appropriate health services, support services, rehabilitation, education, employment, recreation, etc. Obviously there is a hierarchical nature of QOL dimensions. For example, before any talk on support services, people with ID need to have their basic human rights fulfilled, such as choosing their residence. Much research has been devoted to etic (universal) and emic (culture-bound) properties of the QOL concept. In relation to people with ID, besides having in mind etic and emic properties of the construct, we also need to consider disability-bound factors. Social support, social integration, internal control, autonomy, self-determination, and independent decision-making are all factors that need to be taken into account when talking about the QOL in people with ID (Schalock, 2004a, 2004b). Identity factors such as age, gender, etiology, and level of intellectual disability are yet another group of factors that might have an impact on the QOL.

Human rights movements and conventions stemming from their work have a significant role in improving the QOL. Currently, there are more than 40 worldwide treaties and conventions dealing with the human rights of people with disabilities (Schalock & Verdugo, 2012). One of the most important conventions is certainly the UN Convention on the Rights of Persons with Disabilities (UNCRPD, 2006). The UNCRPD is currently signed by 153 states. Given its role in promoting the rights of people with disabilities, it definitely warrants a short description. The objective of the UNCRPD, as stated in the Article 1, is to promote, protect, and ensure the full and equal enjoyment of all human rights and fundamental freedoms by all persons with disabilities and to promote respect for their inherent dignity. UNCRPD has been a major quantitative and qualitative step forward in that it considers both the environmental supports and individual needs (Verdugo, Navas, Gómez, & Schalock, 2012).

As we have already pointed, studies on the QOL of people with intellectual disability follow the general incremental trend. In addition to this, QOL outcomes are becoming the target for intervention and a measure of success of different support programs (Memisevic, Hadzic, Zecic, & Mujkanovic, 2016). This is an indicator of the human rights approach that is currently dominating the field of ID.

Prior to embarking on the task of defining the QOL and describing individual QOL indicators, let us try to trace down the historical development of QOL concept. Then we will offer some contemporary QOL definitions and consider the breadth of the QOL concept.

History

The very phrase QOL was first used after the World War II, and since then it has been overused and infrequently defined (Meeberg, 1993). In the beginning, the term was equated with material goods: a house, a car, money to travel, and money to retire. Only later was the term broadened to capture the concepts such as education, health, and welfare (Farquhar, 1995). A “good life” is a life filled with happiness and meaning (Wolf, 1997).

The phrase “quality of life” was popularized in the 1970s as a global taxonomy used in the context of healthcare where it has been linked with sociology, medicine, psychology, economics, geography, social history, and nursing (Milton, 2013). However, we can trace back the origins of writings on QOL to the ancient Greek philosophers. Back in those days, QOL was referred to as a good life, happiness, well-being, and satisfaction. These were viewed as civic virtues that demanded cultivation (Schoch, 2006).

Ancient philosopher Aristotle (384–322BC) spoke about “good life” and the impact of public politics on its improvement. Philosophers following Aristotle were also interested in “the good life” and how to achieve it. Maybe most pertinent to this chapter is the view of Epicurean philosophy which states that happiness and a good life can be achieved through the possibility of making one’s own choices – self-determination (Cheung Chung, 1997). However, philosophers have never agreed upon the final and all-encompassing definition of QOL.

The history of research regarding QOL in people with ID is significantly shorter than that of the general population. This is a result of the priorities in the civil rights movements: certain preconditions had to be fulfilled before dealing with QOL.

One such issue is existential – right to life! People with intellectual disability have been oppressed throughout history. As a result the QOL for this category of people was not regarded as important.

This attitude originated from the widespread deprivation of human rights to people with ID in the past. This included rights such as forming intimate relationships, marriage, education, employment, self-determination, etc. Negative societal attitudes were best reflected in inhumane treatment practices for persons with ID such as institutionalization, asylums, involuntary sterilization, overmedication, and cruel punishments (Griffiths et al., 2006).

In the last four decades, there has been a significant improvement in societal attitudes toward persons with ID, and QOL becomes a major topic in the discourse in the field of ID. Many reasons contributed to this significant focus on QOL. Schalock, Verdugo, and Braddock (2002) identified four such reasons on the emphasis on QOL. The first reason deals with the change in attitudes on how QOL can be improved. Earlier views strongly associated the QOL concept with the advances in medical field. However, other aspects of a person's life are equally important, such as personal and environmental aspects. The second reason on the focus on QOL comes from the normalization principle. This principle postulates the need to provide same life conditions to all people regardless of the presence of disabilities. The third reason is the increased self-determination and empowerment of persons with ID. The fourth and last reason is the reconceptualization of QOL construct. This new view (concept) of QOL views both QOL components, subjective and objective, as equally important.

QOL Definitions and Conceptualizations

Defining the QOL and the answer as to what it constitutes is not as simple as it might seem. QOL can be conceptualized either as conditions of life or as experiences in life. It can also be considered for individuals or for a society as a whole (McCall, 1975, in Meeberg, 1993). In addition to having subjective and objective dimensions, the QOL construct can be viewed as either unidimensional or multidimensional. The fact that everybody uses the term QOL on an everyday basis, from advertising executives to politicians, thus contributes to multiple interpretations and poor definitions of the QOL concept (Haas, 1999).

In spite of all abovementioned difficulties in defining and conceptualizing QOL, there is consensus in the QOL literature about three things: First, QOL is subjective by nature; second, the various core dimensions are valued by persons differently; lastly, the value attached to each core dimension varies across one's life (Schalock, 2000).

Independently of the consensus in the literature, the fact is that QOL concept can be viewed from many perspectives. From the possible perspectives, we will focus briefly on the medical and social.

Medical Concept

The initial conceptualizations of QOL were related to the health status of the individuals. Most research on the medical perspective regarding the QOL has been done by the World Health Organization (WHO). Health, defined by WHO, is a state of complete physical, mental, and social well-being. Defined in such a way, health can easily be used as a synonym for QOL. The World Health Organization work group (WHO, 1995) defined QOL as the "individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and norms." It is obvious that this definition puts a strong emphasis on the subjective perception of QOL of the person.

According to the WHO, the QOL domains are physical health, psychological health, social relationships, and environment. Some equate it with well-being. In the context of health, most would agree that QOL decisions should be oriented toward improving and benefitting patients' lives (Keyserlingk, 1979; Meeberg, 1993).

However, the use of QOL term has diverse and inconsistent meanings in the healthcare literature (Milton, 2013). Very rarely do researchers define the concept at all, which leaves us unclear about what they are specifically referring to when speaking about the QOL (Meeberg, 1993). The WHO model of QOL has been employed widely in studies examining certain medical conditions but not so much with people with intellectual disability.

Social Concept

The field of ID has embraced the social view on QOL (Cummins, 2005). Within the social perspective, the concept of QOL reflects the following principles: (1) QOL consists of the same factors for all people, (2) QOL is achieved when a person's needs have been met, (3) QOL is a multidimensional construct that is affected by individual and environmental factors, and (4) QOL has both subjective and objective components (Verdugo et al., 2012). It is important to note that subjective and objective indicators do not carry the same weight in overall QOL. Authors mainly agree that the subjective perception is more important in assessing the overall QOL than objective (Day & Jankey, 1996). The objective side of QOL mainly deals with the socioeconomic status of the individual. As the very name indicates, the objective side could be assessed through someone's health status and functional ability.

One of the most widely used models of QOL in people with ID is the one formulated by Schalock and Verdugo (2012). This model includes eight core QOL domains: (1) emotional well-being, (2) interpersonal relations, (3) material well-being, (4) personal development, (5) physical well-being, (6) self-determination, (7) social inclusion, and (8) rights. Again, as is the case with WHO model, each of these domains has its own indicators and descriptors. However, the QOL domains most often associated with policy and practice guidelines for services for people with intellectual disability are inclusion, independence (personal development), and choice (Beadle-Brown, 2006).

General Indicators of QOL

QOL domains are universal for all people. In order to assess the QOL, each domain has its own indicators that need to be sensitive to personal and cultural specificities. In addition to this, indicators need to fulfill some basic criteria, such as importance for the individual, relevance, and to contribute to the overall QOL improvement (Schalock et al., 2005). There are numerous indicators of QOL. When asked what is a good QOL, most people will readily list elements such as health, happiness, family, friends, job satisfaction, marriage and intimate relations satisfaction, and so on. How people rank these QOL indicators in terms of importance is a different story. Most people rate health as the most important factor in QOL. However some people are healthy and lonely and do not feel they have a good QOL. The reason for this is that the QOL indicators differ in their universality in relation to geographic region and they also differ within micro, meso, and macro systems.

Lastly, indicators differ among individuals. Many authors point to the fact that there must be a difference made between subjective and objective QOL indicators (Headey & Wearing, 1992; Pacione, 1982; Schneider, 2005). These two groups of factors are not mutually exclusive however, and if we are to measure QOL validly and reliably, both subjective and objective indicators must be used in the QOL assessment (Das, 2008; Diener & Suh, 1997). In an additional effort to conceptualize QOL more clearly, Cummins (2005) suggests introducing a clear hierarchical organization of indicators from general to specific while simultaneously controlling for the so-called "causal" variables. These variables, together with the environmental characteristics, exert their complex influence on the indicators. According to Cummins (2005), general QOL indicators are related to specific QOL domains' indicators. Specific domains' indicators are influenced by objective (goods and services) and causal variables (perceived deficit in goods and services). Complexity of the relations that indicators have with different factors can be summarized in three-element system consisting of life conditions, subjective well-being, and personal values and aspiration (Felce & Perry, 1995).

Objective indicators can easily be observed by others and are thus called life conditions or life events. Life events include economic, political, cultural, familial, or natural events outside of the direct control of the individual (Goode, 1990). It also encompasses some characteristics of the individual such as health and socioeconomic status. Objective indicators are much easier to define and measure than subjective indicators. Subjective indicators represent personal perceptions and individual assessment of objective indicators and thus are harder to measure. Although there is no universally accepted list of QOL indicators, there are several available examples.

Many of the examples of QOL were specified in the European Conference in Rio de Janeiro (Quarrie, 1992). The conference committee came to the conclusion that QOL indicators can be divided into four basic groups of indicators – social, economic, environmental, and institutional-political. Each of these groups was further divided into smaller subgroups, resulting in a total of 76 indicators. In the European Commission final report, nine key indicators are mentioned: material living conditions, productive or main activity, health, education, leisure and social interactions, economic and physical safety, governance and basic rights, natural and living environment, and overall experience of life (Eurostat, 2017).

Similarly extensive, the division of indicators provided by Henderson and Lickerman (2000) consists of 12 groups of indicators: education, employment, energy, environment, health, human rights, income, infrastructure, nationals, publics, recreation, and shelter indicator.

QOL Indicators for Persons with ID

In her inaugural talk as the president of the American Association on Intellectual and Developmental Disabilities (AAIDD), Susan M. Havercamp (2017) emphasized the notion that health and well-being are critical to QOL. Knowing what constitutes a good QOL for an individual might help us in designing programs for its improvement. A great role for improving QOL in persons with ID has been placed on support service providers. One way of improving the QOL is to employ person-centered planning and systems of support for individuals with ID (Verdugo et al., 2012). QOL can be seen as a relevant outcome measure for education, health, and social service programs (Schalock, 2004a, 2004b). In addition to this, knowing the challenges to improve the QOL resulted in many productive and innovative changes in service delivery principles and practices, evaluation strategies, and identification of personal outcomes reflecting the QOL (Schalock, 2004a, 2004b).

Although, as we have seen, there are many domains and indicators pertaining to the QOL, we will not systematically embrace any of these concepts but instead will write about what we believe are the most important aspects/dimensions/domains of QOL in persons with ID. As QOL, as a social construct, is measured through its indicators, we will focus our attention now on its most important constituents. As a result of numerous studies aimed at QOL assessment in persons with ID, 3 key factors, 8 domains, and 23 indicators stood out (Schalock & Verdugo, 2012; Verdugo, Arias, Gómez, & Schalock, 2010). This is shown in Fig. 6.2.

Besides these established QOL domains and indicators, we cannot speak about QOL in people with ID without mentioning some constructs that are closely related to their QOL. In the following text, we will describe some of these main constructs including empowerment, choice/self-determination, self-advocacy, inclusion, independent living, and person-centered planning and their relationship with QOL in persons with ID.

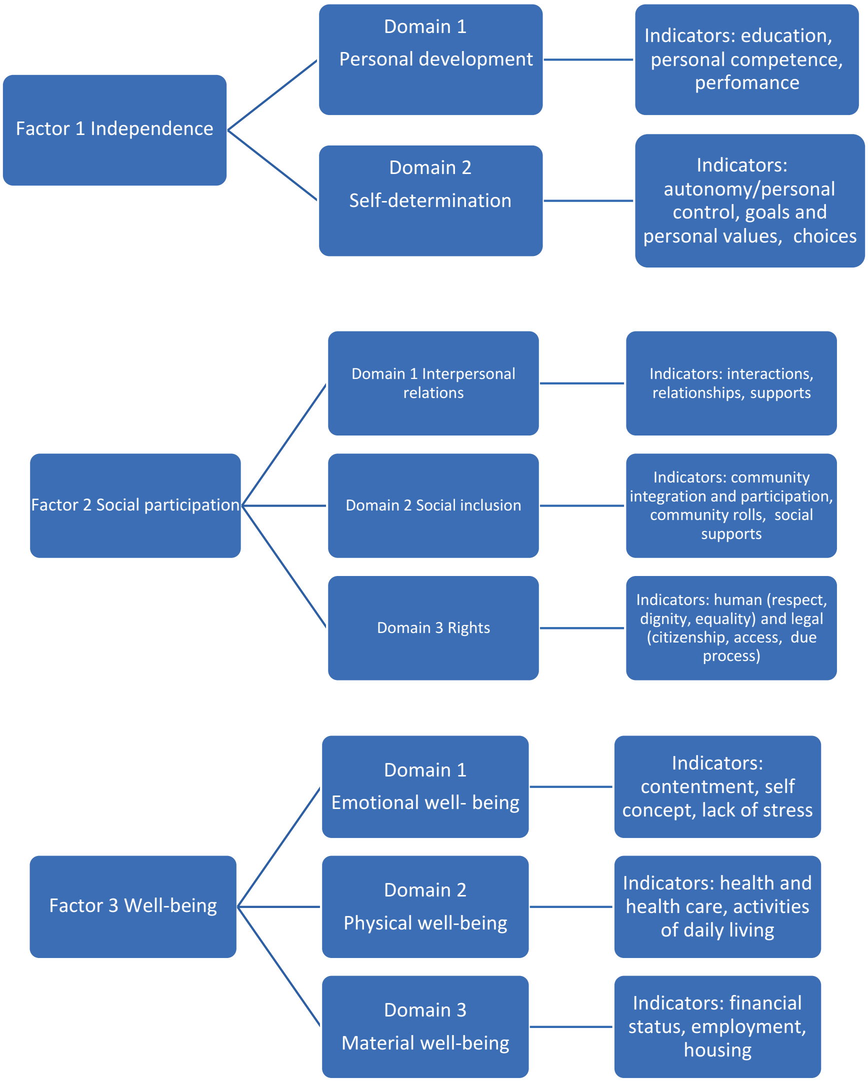

Fig. 6.2 Key factors, domains, and indicators of QOL for people with ID

Empowerment

Empowerment, as a term, has been used since the 1970s of the last century. It was first used by social service providers and researchers in relation to marginalized groups (Calvès, 2009). One of the first empowerment theories is the one developed by Freire (1974, in Calvès, 2009), which postulates that the duty and obligation of the educators are to help individuals develop a "critical consciousness," awareness of themselves and their situation, and the ability to make independent choices. In the 1990s, empowerment became a basic premise in rehabilitation of persons with disability. Special importance is given to independent decision-making, risk-taking of people with disabilities, as well as taking responsibility for the choices they made, and taking control of one's life (Emener, 1991, in Niesz, Koch, & Rumrill, 2008).

This empowerment concept allows people with disabilities to reject the role of the patient – a passive role imposed on them by the medical model of disability – and to accomplish the sense of personal power (Hayes & Hannold, 2007). The very concept of autonomy can be perceived in two ways – autonomy of action and autonomy as a capacity of persons (Miller, 1985, in Clark, 1988). Autonomy of action means that the person voluntarily and willingly implements actions he/she considers authentic, in line with her life values and goals. Autonomy as a capacity of persons means personal power of an individual to make decisions themselves, independently from other's opinions judgments and decisions.

Empowerment, according to Spreitzer (1996), is composed of four basic components: meaning, competence, self-determination, and personal control. Meaning is related to the coherence of the roles given to the person and the person's opinions, convictions, value system, and behavior. Competence, as the second component of empowerment, can be defined as an individual's conviction about their skills and abilities. Self-determination means the ability of the person to make their own choices without the influence from others. The last component of empowerment is personal control, which is defined as a level of the person's influence on the outcomes. The purpose of empowerment is to put a person with ID into the focus and prescribes that an individual has a very important role in organizing their life and everyday activities.

QOL is closely related to the concept of empowerment and personal autonomy. Improvement in empowerment contributes to (a) improved levels of information (people with ID need to have more information about the services and options which are at their disposal) and (b) values clarification (in order to make informed decisions, people need to have more information about the criteria and principles which need to be respected in decision-making) (Clark, 1988).

Different life periods carry various roles and options and put the person with ID in situations to make decisions, compare information, assess the outcomes, and then make informed decisions about their life. The transition period from adolescence into adulthood, which is usually between the ages 18 and 25, is especially sensitive as it is the period of many major choices. People with ID need to be especially empowered in this period to decide how they want their lives to look (Curryer, Stancliffe, & Dew, 2015).

An international study (Canada, United States, Belgium, and France) examining the link between empowerment and QOL has shown that autonomous functioning, self-regulation, psychological empowerment, and self-realization are statistically correlated with QOL; the stronger the empowerment, the better the QOL for the individual with ID (Lachapelle et al., 2005). Psychological empowerment predicts QOL outcomes and lower level of financial support for people with ID, and higher levels of autonomy predict independent living of persons with ID (Shogren & Shaw, 2016).

Choice/Self-Determination

One of the fundamental human rights is the ability to make choices regarding one's life, such as place of residence, marriage partner, friends, etc. Ability to choose is considered to be an essential component of QOL. Choice involves the concept of self-determination (Smith, Morgan, & Davidson, 2005). Thus, promoting choice options and self-determination for people with intellectual disability has become a best practice in the field of ID (Wehmeyer & Abery, 2013). According to them, self-determined actions have four essential characteristics: (1) the person acts autonomously, (2) behavior of the person is self-regulated, (3) the person initiates and responds to events in a psychologically empowered manner, and (4) the person acts in a self-realizing manner.

Self-determination influences QOL in many ways, such as through social and vocational integration, rehabilitation, and habilitation goals (Nota, Ferrari, Soresi, & Wehmeyer, 2007). However, as QOL is a complex social construct consisting of many components, self-determination is not equally strongly related to all its constituents. For example, research has shown that self-determination is a good predictor of personal development and personal fulfillment (McDougall, Evans, & Baldwin, 2010). Also of note is the potential susceptibility of self-determination to training. Components of self-determination such as choice-making skills, decision-making skills, goal-setting, and self-awareness skills can all be promoted and improved in individuals with ID (Wehmeyer & Abery, 2013). However, these attempts to improve self-determination skills in persons with ID must be followed by education and training of the support service staff. In addition to this, actions aimed at raising the awareness of wider society should also be undertaken. As an example of this, let us shortly explore the issue of sexuality in persons with ID, as this is viewed as a complex issue. Even parents of persons with intellectual disability express concerns regarding the sexuality of their children and believe that expert support is needed to deal with this issue (Isler, Beytut, Tas, & Conk, 2009). Research has shown that there is a need for the education of caregivers and a need to discuss sexuality issues at societal and policy levels (Mcguire & Bayley, 2011). This in turn will help persons with ID to better deal with their sexuality and make decisions regarding their sexuality.

Self-Advocacy

Self-advocacy is a civil rights movement of and by people with ID which serves as a method of empowering people with ID (Friedman, 2017). This movement originated in Sweden and then gradually expanded to other parts of the world. Self-advocating means the ability and possibility to speak on behalf of yourself. It means that the persons with ID may express themselves freely, make their own decisions, have the right to dignity, and take over control of their own lives and is a means to fight against discrimination.

It is particularly important in transition years, when people make important choices in their lives. This is especially evident when students with ID are finishing their formal schooling. After exiting school, many former special education students cannot plan their future, remain unemployed or underemployed, and experience a quality of life remarkably different from their nondisabled peers (Martin, Huber Marshall, & Maxson, 1993). Fortunately, as with self-determination, self-advocacy skills can be learned. During the school years, students should master self-management skills as they move through the grades; students learn self-advocacy by participating in their IEP meetings, learning to develop the IEP, and then managing it (Martin et al., 1993). Students with ID require intentional training to further develop their self-advocacy skills. Training in self-advocacy for people with ID should encompass strengthening mutual trust among persons with ID, focusing on joint problems and interests, strengthening self-respect, and introducing people with ID to their rights and responsibilities (Bilić, Bratković, & Nikolić, 2004).

Inclusion

There is no universally accepted definition of the term inclusion. The definition changed over time. Some authors perceive inclusion as a movement (Karagiannis, Stainback, & Stainback, 2000), while others see it as a philosophy or belief system (Florian, 2000; Ryndak, Jackson, & Billingsley, 2000). Inclusion as a civil movement has its roots in Western Europe, where it first developed with the aim to improve human rights of people regardless of their nation, religion, sexual orientation, disability, etc.

Four steps (phases) can be identified in the process from exclusion to inclusion: (1) exclusion of people with disability from society; (2) technical inclusion, which means satisfying basic needs of people with ID and support in their least restrictive environment; (3) legal inclusion, the laws and legislation protecting the rights of people with ID and emphasis on their autonomy, independence, and dignity; and (4) ethical inclusion, which stresses fulfilling interpersonal relations and acceptance of differences (Clapton, 2009).

Inclusion of persons with ID is usually viewed through the prism of educational inclusion. We will, however, say something about social inclusion, which is a broader concept and encompassed education inclusion as well. Social inclusion of persons with ID includes total access to activities, social roles, and interpersonal relations (Partington, 2005). Simplican, Leader, Kosciulek, and Leahy (2015) provide an ecological model of defining social inclusion, consisting of subcomponents: individual (characteristics of the person), interpersonal (attitudes, relations with the environment), organizational (socioeconomic characteristics of the family, access to support services), social (availability of services, type of accommodation, self-advocacy groups), and social-political level (legislature). Social inclusion depends on several factors: self-determination, autonomy, participation in policy-making, availability of social supports, and availability of transport (Verdonschot, De Witte, Reichrath, Buntinx, & Curfs, 2009).

Social inclusion is in many ways related to the QOL in persons with ID. Higher levels of social inclusion are related to enhanced personal satisfaction and higher level of QOL (Eliason, 1998). Persons with ID with more social interactions and interpersonal relations have better QOL (Lee McIntyre, Kraemer, Blacher, & Simmerman, 2004; O'Brien, Thesing, Tuck, & Capie, 2001). Piro (2017) pointed to the link between QOL and social inclusion, explaining that society set standards for all persons, and if an individual cannot fulfill these standards and assume social roles, then that individual will have lower QOL.

Independent Living and QOL

Independent living is strongly related to self-determination and the QOL. Not long ago, when the medical concept of disability still dominated the field, the consensus was that the majority of people with ID were not competent to live in the local community. As a result, they were placed in state-run institutions that "cared" for them for the rest of their lives. This process is widely known as institutionalization. Unfortunately, institutionalization of persons with ID is still a widely used model of social care in many parts of the world.

However, in developed countries, the reversed process, called deinstitutionalization, was sparked in the late 1960s and early 1970s by disability movements seeking better QOL for people with disabilities. The policy of deinstitutionalization was based on the notion that the QOL of people with ID will improve when they move from institutions to local communities (Chowdhury & Benson, 2011). Deinstitutionalization is now gaining its momentum throughout the world thanks to the human rights movement and international conventions, in particular the UNCRPD which stressed the right of people with ID to live in their local communities and exercise their rights as full members of the society. It is evident that the process of deinstitutionalization is strongly related to independent living of people with ID. One of the early conceptualizations of independent living was given by Gerben DeJong (1979), who views independent living as a social movement and an "analytic paradigm" that is redirecting the course of disability policy, practice, and research.

There are many benefits of living in the local communities rather than living in institutions, and these benefits are all related to the QOL outcomes. In a study by Emerson and Hatton (1996), the authors state some of these benefits such as increased use of community facilities, increases in adaptive behavior, increased opportunities for choice, increased contact with family and friends, better material standard of living, and increased acceptance by the community. However it is important to note that QOL outcomes depend mainly on the quality of the service offered by community-based residential services. Again, the role of service providers in the community was viewed as crucial component in the participants' QOL. In a review of 15 studies examining QOL of people with ID, authors found that relocation had a positive impact on QOL measures in participants (Chowdhury & Benson, 2011).

There are several types of community-based living options for people with ID. They are group-based homes, semi-independent, and independent living. It seems that a higher level of independence is related to better QOL outcomes. People living semi-independently experience less social dissatisfaction, use community services more frequently, have more participation in domestic tasks, and feel greater empowerment (Stancliffe & Keane, 2000).

It is important to note that the social care system poses many barriers to independent living for people with ID. Social service professionals still focus on the “risk” of living in the community and question the “capacity” of people with ID to live independently (Morris, 2004). It is of paramount importance that the legislature changes to include entitlement to independent living.

Person-Centered Planning

From the service-level perspective, one of the most important segments is person-centered planning. In order to understand the relationship between the disability, community, and organized services, the term person-centered planning (PCP) has been developed. PCP has its origin in Wolfensberger’s principles of normalization theory (Wolfensberger, 1972). Person-centered planning (PCP) can be defined in several ways. It is an individualized approach to organizing assistance and support to people with ID (Mansell & Beadle-Brown, 2004). PCP is an approach in which a person with disabilities designs and manages the support services and is strongly based in the person’s strengths and visions (Flannery et al., 2000). It is especially important due to its use as a vehicle to achieve the following goals for people with ID: rights, independence, choice and inclusion.

PCP is more than a theoretical concept; it is a specific method for bringing about positive changes in the lives of people with ID (Holburn, 2002). It is based on three important principles. First, it emphasizes aspirations and capacities of people with ID (instead of their weaknesses and shortcomings). Secondly, it includes the person’s family and mobilizes the wider social network in order to support the person with ID. Finally, it emphasizes providing the support required to achieve the goal set by the person with ID.

It is evident that PCP is strongly related to support services. What are the ways to make support services more person-centered? The answer to this question is borrowed from Cambridge and Carnaby’s work from Cambridge & Carnaby, 2005. Firstly, PCP should be legally regulated, that is, it should be given legal weight. As often as possible, persons with ID should have direct payments and control of their budgets. The focus should be shifted from *person-centered planning* to person-centered action.

The goal of PCP is to allow a person with ID to lead a meaningful life in a way that he/she wants, with the support of their circle of friends and their community. Principles of PCP are greatly affecting the support services provided to people with ID and thus improving them constantly. NGOs that provide such services need to be aware of PCP; fortunately, this approach is expanding widely throughout the world. Now the support services need to ensure that certain standards are in place if PCP is used in the field. For example, indicators of PCP can be assessed through the following questions (Parley, 2001):

- Does the person make everyday choices?
- Are they treated with respect?
- Do they take part in everyday activities?
- Do they have friendships and relationships?
- Are they part of their local community?
- Do they get a chance to work?
- Do they take part in important decisions about their life?
- Are their families’ views listened to?
- Are they safe from harassment and abuse?
- Do they get help to stay healthy?

Measuring QOL

> “If something exists, then it can be measured.” (Thorndike, 1904)

We are not sure how the concept of measuring and assessing the QOL can be applied meaningfully given that each individual has their own perspective on what it means to have a good QOL. Nevertheless, the instruments, questionnaire, and scales purporting to “measure” the QOL are on the constant rise. They are in line with the task to better understand the social construct of QOL in relation to many factors such as health status, disability, severity, aging, etc. Schalock et al. (2002) stated that the task of measuring QOL should take into account five basic principles, and within each principle, there are certain directions that need to be followed:

1. Measurement should encompass the level of achievement of individually valued life experiences. Within this principle it is necessary to take into account the theoretical basis of measurement, cultural and time differences, precise terminology, and categories stemming from the measurement itself.
2. Measurement should have a positive impact on the individual in the sense that he/she directs their will toward activities that are meaningful and pleasant for them. Measurement is focused on key life aspects that can be improved and is focused to identify non-adequately satisfied needs and creation of an action plan to satisfy these needs, and the results of QOL measurement are interpreted in relation to contextual factors, such as age, gender, etc.
3. Measurement's purpose is to determine the extent to which different QOL domains are related to QOL in general. It should be ensured that domains relevant to all people are encompassed, while the critical indicators can be different in relation to the age, culture, disability, etc.
4. Measurement should be performed in the context that is important for the individual – where he lives and spends time. Within this principle, it may be necessary to engage a proxy who would assess the QOL from the perspective of the person who cannot speak for themselves and choose the experience that is most appropriate for that person.
5. Measurement is based on both universal life experiences and unique personal experiences. It is necessary to measure both objective and subjective QOL aspects, encompassing both cognitive and affective components and by using quantitative and qualitative techniques.

Many individuals with ID are willing and able to discuss their QOL. Consequently, researchers should use all available and efficacious methods to enable a person with ID to report about their life experiences. This may include simplifying questions for individuals with ID (by using simple and concrete examples) as well as simplifying response methods (by using assistive technologies, e.g., pictures). Researchers should be aware of bias, given the fact that persons with ID are susceptible to giving socially desired responses. In order to ensure this, prior to any measurement of QOL, individuals with ID should be asked how well they understand items (perhaps through the use of pretest questions or formal tasks – as in the case of ComQol-ID, Cummins, 1993) (White-Koning et al., 2005).

In extreme cases, when the person with ID is not able to report about their life experiences, even with accommodations (as in the case of people with severe or profound ID), the most common way to assess their life situation is through the use of proxies (parents, caretakers, legal guardians) (Verdugo, Schalock, Keith, & Stancliffe, 2005). But, these data obtained from proxies should not replace self-reporting of the persons with ID themselves.

Respecting all these principles and direction in QOL measurement, Claes, Van Hove, van Loon, Vandevelde, and Schalock (2010) stated that the measurement results of QOL in persons with ID should reflect their personal, organizational, and macro-level situation. On personal plan, QOL results should provide information on each of the eight QOL domains. Results of QOL measurement on organizational level can be used to determine the predictors of QOL and their effect in predicting the outcomes. QOL measurement has also great impact on macro level, in shaping, creating, and planning the policies and in financing the services for persons with ID.

In order to find a perfect instrument for QOL assessment in persons with ID, one that has excellent psychometric properties, which is culturally specific and economic, Li et al. conducted a theoretical review of 309 studies (Li, Tsoi, Zhang, Chen, & Wang, 2013). Their research determined nine instruments that satisfied all criteria and were used to assess QOL in people with different levels of severity of ID. The number of items varied from 7 to 58, and the time needed to fill out the questionnaires was between 20 and 45 min. Only three instruments were used to assess both subjective and objective aspects of QOL (ComQol-ID, Cummins, 1993; QOLQ, Schalock & Keith, 1993; POS, Van Loon, Van Hove, Schalock, & Claes, 2009), while the remaining six assessed subjective components only (CQ, Stancliffe & Parmenter, 1999; HSIS, Ruddick & Oliver, 2005; LSS, Heal & Chadsey-Rusch, 1985; MLSS, Harner & Heal, 1993; PWI-ID, Cummins & Lau, 2005; MAMP, Bonham et al., 2004). Similar theoretical research was conducted by Townsend-White, Pham, and Vassos (Townsend-White, Pham, & Vassos, 2012), with the aim to find the most appropriate instrument for QOL assessment in persons with ID and comorbid behavioral issues. The review encompassed studies published between 1980 and 2008 and resulted in six instruments (MLSS, Harner & Heal, 1993; ComQol-ID, Cummins, 1993; QOLQ, Schalock & Keith, 1993; PWI-ID, Cummins & Lau, 2005; QUOLIS, Ouellette-Kuntz, 1990; EQLI, Nota, Soresi, & Perry, 2006). Analyzing these instruments, authors conclude that there is no specialized instrument that would measure QOL in persons with ID and comorbid behavioral difficulties. In order to increase variety and the number of instruments aimed at measuring QOL in persons with ID, authors emphasize the need to develop instruments based on the theoretical concepts of QOL.

Short Overview of the QOL Research in People with ID

Many studies point to the fact that people with ID have lower QOL than people without ID. In a study conducted in Taiwan, authors found that 42.9% of people with ID do not use local community services and do not have much interaction with education, employment, and social inclusion. In the study, adaptive behavior skills and educational level were identified as predictors of higher QOL. The place of residence was the strongest predictor for utilization of community services (Chou et al., 2007).

Results of the research comparing the QOL in adults with ID in Italy and Australia found no differences between them, but both groups achieved lower scores in the domains of material well-being, health, productivity, and community. The users in both countries were most dissatisfied with the “community living” domain (Verri et al., 1999). Other authors report similar results. For example, Bramston et al. reported that people with ID are best satisfied with the health domain and less satisfied with the domains of privacy and social inclusion (Bramston, Chipuer, & Pretty, 2005).

Investigators have also examined some demographic variables related to the QOL and found that male gender, lower severity of ID, and family environment contribute to better QOL (Simões & Santos, 2017). The type of residence frequently plays a role in QOL. Tamaš (2015) reported that the best QOL was found in adults with ID who are living independently with support, while the lower QOL was found for persons with ID living in families and institutions. A plethora of research supports the notion that living in local community improves the QOL in persons who were previously institutionalized (Chowdhury & Benson, 2011; Felce & Emerson, 2001; Kozma, Mansell, & Beadle-Brown, 2009; O’Brien et al., 2001; Walsh et al., 2010).

Age and gender effects were also examined in relation to the QOL. Older women reported significantly lower subjective well-being (SBW) and less positive self-concept than men on all measures, except subjective age, although gender accounted for less than 1% of the variance in well-being and self-concept. Smaller gender differences in SWB were found in younger than in older groups. Statistically controlling for gender differences, marriage status, health, and socioeconomic status decreased gender differences in SWB. Cohort differences in SWB are reported as well (Pinquart & Sörensen, 2001). Friedman and Rizzolo (2018) emphasize the importance of interactions with friends in adults with ID as a significant variable in predicting the QOL. They reported that satisfaction with friends increases the odds of being included in community and fulfillment of various social roles by four times.

Duvdevany and Arar (2004) reported similar results, pointing that the quality of friendships is closely related to the subjective well-being in persons with ID.

Mothers of adult individuals with severe ID reported that for the QOL of their children the most crucial factors are participation in recreation activities and hobbies. After these factors, in importance, is the belonging to local community and satisfaction of their needs (Lee McIntyre et al., 2004). A survey of experts and parents of adults with severe ID living in the community indicated that various social roles, participation in hobbies, and vocational activities might have a positive impact on the QOL of people with severe ID (Hartnett et al., 2008).

Concluding Remarks

Quality of life has become a topic of major importance in the field of intellectual disability. And rightly so. In this chapter we described different models of QOL as well as its different components. We can confidently say that QOL of people with ID is steadily improving all over the world. Many factors contribute to this widespread improvement in QOL for people with ID. These factors are related to improved legislature supporting human rights of people with ID in many countries. In addition to this, numerous technical and medical advances have also contributed to the better QOL. In order to further advance QOL in people with ID, it is necessary to empower them to fully participate in their local communities. The role of support service providers is also very important in this regard. These providers need to incorporate the concepts of empowerment, self-determination, inclusion, and independent living, in their policies and practices in order to enhance person-referenced QOL outcomes. In conclusion, it is obvious that the concept of QOL is complex and many questions regarding it remain unanswered. However, we should be optimistic. The emphasis in QOL research has shifted from human rights issues to identifying factors that will reduce the gap in QOL regardless of the presence of intellectual disability. “

Service Delivery Models

Anne M. Bowers

Introduction

People with intellectual disabilities may require an array of services to meet their multifaceted health, daily living, and social needs. The implications of these vast needs indicate that a multidisciplinary, person-centered approach is necessary for comprehensive service delivery. There are a variety of ways services can be coordinated and provided. This chapter discusses the development of service provision and reviews the types of services individuals may utilize over time. Four conceptual models demonstrate paths of service delivery for persons with I/DD and illustrate differing mechanisms of coordination and opportunities for self-direction within each framework. These models are considered in context of individual care needs, life stage, and sources of natural support, as well as significant system-level constraints that impact the delivery of services to people with I/DD.

Evolution of Service Delivery

Until the late 1970s, large residential care facilities were the primary source of daily care and long-term services for people with I/DD in the USA. In large congregated institutions, care and services are available around the clock and delivered to residents on-site. Although there are still persons with I/DD in large residential care facilities, these institutions have historically provided costly but often inadequate services and care, giving too little consideration to the respect, dignity, quality of life, and holistic needs of residents. Disability advocates opposed institutionalization for its infringement upon the human rights and autonomy of persons with disabilities. Deinstitutionalization and the Independent Living Movement (ILM) led to increases in the number of individuals living in noninstitutional settings (White, Lloyd Simpson, Gonda, Ravesloot, & Coble, 2010). Today, more people with I/DD are living in communities of their choice. The ILM and disability rights activism has also stimulated the self-advocacy of people with I/DD and furthered the availability and accessibility of education, employment, and social opportunities for community members with disabilities.

Systems of long-term services and supports (LTSS) have shifted from institutionally based care to less restrictive care and services provided in home- and community-based settings (Lind & Archibald, 2013; Turygin, Matson, & Adams, 2014). This transition in the values of service provision moves away from the "medical model, with a strong custodial component" toward a "developmental model, in which enhancement of

skills and the promotion of social independence is the main goal" (Alvarez, 2016). The shift reflects the increased application of person-centered approaches in service delivery for people with I/DD. Person-centered delivery approaches provide services in context of an individual's care requirements, personal preferences, and environmental circumstances and position users as equal partners in the management and monitoring of their care (Bowers, Owen, & Heller, 2017). In person-centered approaches, services are specifically structured to meet a person's unique health and social needs and actively facilitate the individual's input and involvement with their care planning and coordination. Many contemporary service delivery models for people with I/DD are based in person-centered approaches that promote independent living, community participation, and individual development.

Service Domains

A person-centered approach to service delivery recognizes that people with I/DD need more than just medical-related care. Individuals should be expected to vary in the type and number of services and supports they require. From early childhood to the late stages of aging, individuals with I/DD should engage with a variety of services to maintain their health, fully participate in their communities, and realize their personal aspirations. Service areas (also called domains) can include medical, support, education, social, employment, community living, and long-term care (Table 7.1).

Medical Care

Medical care services include the primary specialty, preventive, rehabilitative, inpatient, outpatient, and emergency health care that an individual may need. Regular medical care services are important for maintaining the health of people with I/DD who are more likely to have call co-occurring medical conditions and complex health profiles. Medical professionals provide diagnostic testing, functional assessment, and evaluation of the disability condition in early life, adolescence, and young adulthood. Clinicians monitor the health of adults with I/DD and provide necessary care, preventive screening, and appropriate medical intervention as these individuals age (Peacock & Rhodes, 2016). People with I/DD may also require more specialized care than other patient groups in every stage of life. Specialists in psychiatry, cardiology, podiatry, neurology, dentistry, occupational therapy, and behavioral health, among others, can all be a part of the multidisciplinary provider team involved in the lifelong care of a person with I/DD.

Direct Support

Direct support services refer to the provision of individual support and general care for persons with I/DD and their families, both in the home and in community settings. The purpose of these services is to support people with I/DD in completing tasks and in achieving their short- and long-term personal goals. Direct support workers may help individuals with basic activities of daily living, such as eating, dressing, grooming, bathing, and getting around house. Direct support workers can also help individuals with I/DD in instrumental activities of daily living, such as cooking, cleaning, shopping, exercising, transportation, taking medication, and managing money. Direct support care help people with I/DD live independently and participate in the community. Support services can also provide respite care services to relieve family caregivers, who provide a sizable portion of direct support for people with I/DD in the USA. Depending on an individual's functional ability, medical complexity, life stage, and level of family involvement, individuals with I/DD may need direct support services at all times, while others may need only part time or intermittent support services.

Table 7.1 Service domains for individuals with I/DD

Domain	Service description	Examples
Medical care	Primary, specialty, preventive, rehabilitative, inpatient, outpatient, and emergency health care that an individual with I/DD may need over the life course	• Diagnostic testing and evaluation • Preventive screenings • Multidisciplinary health care
Direct support	Direct support and general care for individuals with I/DD in home- and community-based settings, including assistance with activities of daily living	• In-home direct support care • Respite services for family caregivers
Community living	Noninstitutional housing, community-integrated dwellings, and residential services for individuals with I/DD	• Independent living • Supported community living arrangements
Education	Special education, transition services, vocational training, and post-secondary education for children and adults with I/DD	• Special education • Transition planning • Vocational training
Employment	Services for adults with I/DD related to finding job opportunities and maintaining regular, paid work	• Independent employment • Supported employment • Job coaching
Social and leisure	Services providing recreational activities, socialization, travel, continuing education, and personal development opportunities for community members with I/DD	• Sports leagues • Social clubs • Volunteering
Long-term care	Institutionally based residential services and care for people with I/DD who may need continuous, intensive medical treatment	• Nursing homes • ICF/MRs

Community Living

Community living services refer to noninstitutional housing and residential services for individuals with I/DD. Noninstitutional residential settings include living at home with family, living independently in an apartment or house (with or without direct support services), or supported community living arrangements. Supported community living arrangements are typically group homes, family homes, and apartments where 2–8 adults with I/DD reside and receive oversight from continuously present direct care providers and support staff. Direct care workers in such group living arrangements are typically employed by a not for profit (NFP) organization or a community developmental services agency. Supported community living can provide more intensive direct care to people with I/DD as needed, as well as assist in the coordination and organization of the array of services utilized by residents. These noninstitutional residential settings serve to promote the community integration and independent living of persons with I/DD.

Education

Educational services include special education, transition services, vocational training, and post-secondary education for people with I/DD. Educators contribute to the diagnosis and evaluation of the disability condition, especially in early life stages of people with I/DD. In primary and secondary school-based settings, students with I/DD and their families and caregivers can participate with teachers and school administrators in developing an individualized education program (IEP) to establish learning accommodations and optimize curriculum delivery and classroom supports for a student. Many students with I/DD are educated in integrated classrooms with the appropriate accommodations. Others may be enrolled in special education programs throughout their primary and secondary school years. Transition services are another type of educational service that assists individuals in planning and preparing for life after school. Transition services help individuals with I/DD identify their long-term goals and plan for housing, employment, and options for further education. Students with I/DD may elect to receive vocational training to gain skills in a specific career area. Additionally, a growing number of students with I/DD continue with postsecondary education, including college degree and certificate programs.

Employment

Employment services are services for adults with I/DD related to finding job opportunities and maintaining regular, paid work. Employment services are important for the productive community living of adults with I/DD. Many people with I/DD work independently in integrated settings with coworkers who typically do not have disabilities. Employers can provide job accommodations to increase the accessibility of the workplace for employees with I/DD, including plain language training and modified work arrangements. Individuals and their families and caregivers may also partner with local state agencies or NFP organizations that offer supported employment services for community members with I/DD. These organizations can help arrange customized employment opportunities, as well as provide job coaching services for persons with I/DD to assist them in interviewing, performing work-related activities, and engaging with coworkers.

Social and Leisure

Social and leisure services provide opportunities for recreational activities, socialization, travel, and personal development to community members with I/DD. Such services may include intramural and competitive sports leagues; creative art, music, theater, and hobby workshops and classes; adult day programs; summer camps; exercise groups and gym memberships; organized travel and outings; social clubs; religious fellowship; and volunteer activities. Leisure and social services give people with I/DD ways to engage with friends, meet new people, participate in community life, and develop their interests and skill sets. Some social and leisure services provide activities exclusively for individuals with I/DD, while others may be social and leisure activities open to the public that can allow persons with I/DD to integrate with more members of the community.

Long-Term Care

Long-term care services are intensive, institutionally based residential services and care for people with I/DD, including Intermediate Care Facilities for Individuals with Developmental Disabilities (ICF/MR) and nursing homes. Nursing homes are a common long-term care option for persons with I/DD in the advanced stages of aging or who have serious illness. However, younger individuals and adults who have more severe disabilities may sometimes receive their services from in ICF/MRs if they require consistent, active treatment that cannot be received in a community-based setting, like complex medical care, skilled nursing, or multi-provider behavioral health intervention (Turygin et al., 2014). Both ICF/MRs and nursing homes are considered large, residential facilities that are very costly and often inappropriate for members of the I/DD population who can live at home and in the community with the appropriate supports.

Contexts of Provision

The delivery of an array of services to a person with I/DD will be influenced by a variety of factors. Individual health status, medical complexity, life stage, and level of family support may also play a role in how services are provided and coordinated. These contextual elements and their interplay help define an appropriate framework of service delivery.

Health Status and Medical Complexity

Intellectual disabilities are lifelong problems which are often accompanied by co-occurring health issues such as seizures, dementia, and motor disorders (Courtenay, Jokinen, & Strydom, 2010; Matson & Shoemaker, 2009; Turygin et al., 2014). Additionally, comorbid psychopathology and challenging behaviors are much more common among people with I/DD relative to the general population (Matson & Shoemaker, 2009). Complex medical conditions and dual diagnosis can impact the physical mobility, personal capacity, and participation of individuals with I/DD (Matson & Shoemaker, 2009), especially those in their late senior years and those with serious illness. The functional ability and health status of a person with I/DD will determine the number and type of services needed and their degree of application.

The capacity to thrive in community-based settings will be impacted by the healthcare needs and medical complexity of an individual with I/DD. For certain individuals, an appropriate level of care may not be reasonably provided by family members or through community-based programs (Enquist, Johnson, & Johnson, 2012). As more intensive care and services become necessary, increased supports for daily living and decision-making, or long-term care services, may be appropriate (Turygin et al., 2014). These and other health-related factors can dictate an individual's level of need and, in turn, impact the model of service delivery best suited for a person with I/DD.

Changing Needs with Age

As a person with I/DD ages, their medical, education, direct support, social, and employment service needs should also be expected to change. In childhood and early adult life stages, education, employment, and community living services will have greater importance for people with I/DD. Individuals with I/DD are more likely to have co-occurring health conditions that will increase the importance of medical care and direct support services (Peacock & Rhodes, 2016). Older adults with I/DD have earlier onset dementia and are more likely to exhibit psychiatric symptoms with age. As an individual with I/DD enters their senior years, long-term care services may be needed when an individual is no longer able to live independently in their home (Turygin et al., 2014).

Transitions from childhood to adulthood and beyond will affect personal circumstances, health status, and the number and type of services required for a person with I/DD (Peacock & Rhodes, 2016). The fluctuating importance of certain care and services in the various stages of life may impact the model of service delivery experienced by an individual with I/DD as their needs change over time. For example, as persons with I/DD grow older, their ability to self-direct and independently coordinate their services could decline.

Family Involvement

Family involvement has become a significant source of support for people with I/DD, especially as services and care were made more available in home and community settings. The shift to community living has enabled more individuals with I/DD to receive support from family members throughout their lives. An increasing amount of people with I/DD are living at home with family members or are living independently with the support of nearby family members than in previous decades.

The involvement of family members can influence the model of service delivery for an individual with I/DD. Support from family can impact how services are delivered to a person with I/DD, as family members may provide direct care, service coordination, finance management, supported decision-making, or assistance with individual and future planning as needed on an ongoing, often informal basis (Heller, Arnold, McBride, & Factor, 2012). Family members may play the role of primary service coordinator for an individual with I/DD. Advocacy from family members can help individuals with I/DD have more input and control over their service planning and care (Heller et al., 2012). A family member or caregiver may also petition for legal guardianship of an adult with I/DD, where the guardian is appointed to make decisions on behalf of the person with I/DD (Wood, Edwards, & Hennen, 2016). The degree of family involvement is contingent on the availability and willingness of family members to provide support, as well as their ability to provide the level of care required to meet a person's needs.

Models of Service Delivery

Engagement with multiple service domains, along with the contextual factors affecting delivery, determines the appropriate service delivery model for an individual with I/DD. Four conceptual models—uncoordinated, coordinator-supported, residence-based, and self-directed—represent common frameworks of service delivery for persons with I/DD in the USA. Each model has implications for comprehensive service delivery, as well as the level of self-determination and involvement of the individual receiving care. These model frameworks vary in their locus of control and method of coordination to demonstrate the spectrum of possibilities for service delivery to the I/DD population (Henman & Foster, 2015).

Uncoordinated Service Delivery Models

In an uncoordinated delivery model, a variety of services are delivered to a person with I/DD as available and deemed necessary. Arrows pointing inward from service domains toward the individual with I/DD, as shown in Fig. 7.1, position the person with I/DD as a passive recipient of services across domains in uncoordinated delivery models. Such a model depicts service delivery in its most rudimentary form; services are provided through multiple independent channels and are oftentimes sourced through different funding streams. Siloed service delivery creates multiple points of contact, leaving opportunities for cross-domain coordination deeply fragmented (Henman & Foster, 2015).

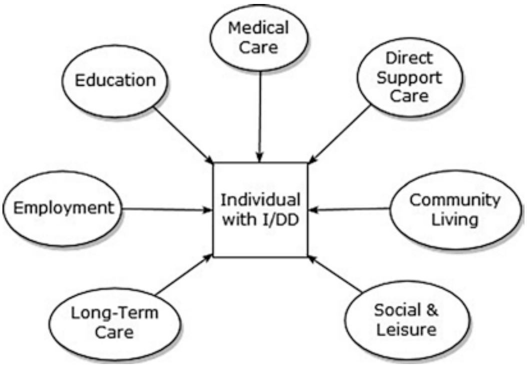

Fig. 7.1 Uncoordinated delivery model

Persons with I/DD essentially have services done to them in uncoordinated service delivery (Henman & Foster, 2015). Recipients are subject to inadequate, imposed, and likely disorganized service delivery in these types of frameworks. Consequently, uncoordinated models often transpire in service delivery to people with I/DD who cannot participate in planning and coordination activities or who have limited self-agency due to the nature of their disability condition, terms of guardianship, or otherwise. User engagement may also depend on residential setting, age, as well as program availability, eligibility, and accessibility, which can impact the achievement of comprehensive service provision in uncoordinated models of delivery for people with I/DD.

Coordinator-Supported Service Delivery Models

In the coordinator-supported delivery model, one or more case workers or service coordinators initiate, organize, and coordinate the care of an individual, as indicated by the arrows pointing outward from coordinators (shaded in gray) toward various, discrete services in Fig. 7.2. Coordinators then ensure the services are received, as illustrated by the arrows pointing from coordinators inwards toward the person with I/DD. A single case worker or coordinator may plan and organize all a person's services across domains (sometimes known as a "case manager"). Alternatively, multiple case workers or service coordinators may be involved in the delivery of services from separate domains; this

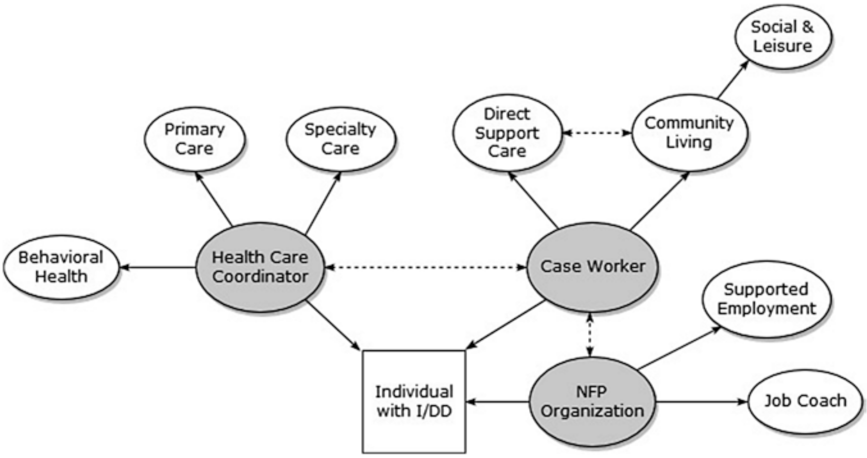

Fig. 7.2 Coordinator-supported delivery model

can be more common when service domains are administered under different funding arrangements (Henman & Foster, 2015).

The individual with I/DD's centralized position in the framework illustrates how coordinator-supported models can allow for better, more comprehensive service delivery. In addition to organizing multiple (and often complexly delivered) discrete services, a defining feature of the coordinator-supported model is linkages of cross-domain service coordination. The dotted-line arrows represent how coordinating entities within and between various domains should communicate regularly and work together to arrange and monitor the rendering of services based on a person's care plan and evolving needs. Improved accessibility, quality, and person-centeredness of service delivery are benefits of enhanced coordination in coordinator-supported models for people with I/DD. However, there is risk of model underperformance if coordinators are inexperienced or have an excessive caseload, have underdeveloped relationships with their clients with I/DD, or organize and direct care without eliciting input and feedback from the individual. If coordinators act as service "gatekeepers," their "role can undermine individual choice, autonomy and control" (Henman & Foster, 2015). Continuously updated individualized service planning is an important key to the success of coordinator-supported models.

Residence-Based Service Delivery Models

Residence-based delivery models share similar features to coordinator-supported delivery models, where a single case manager organizes all services across domains for an individual. However, unlike coordinator-supported delivery, residence-based models are characterized by the centralized coordination of services across domains as an aspect of a person's supported community living arrangement, such as a community-based group home for adults with I/DD (Henman & Foster, 2015). All services are typically organized by one to three residential coordinators who, along with other direct support staff members, are usually employed by NFP organizations or social service agencies that provide community living services for people with disabilities. Residential coordinators frequently provide service coordination for other members of the home.

Residence-based models can streamline the delivery of comprehensive services and supports, as illustrated by the arrow pointing from the residential coordinator toward the person with I/DD in Fig. 7.3. This type of service delivery model can be useful for higher need individuals who need daily direct support care, community living assistance, as well as help with arranging medical care, maintaining supported employment, and

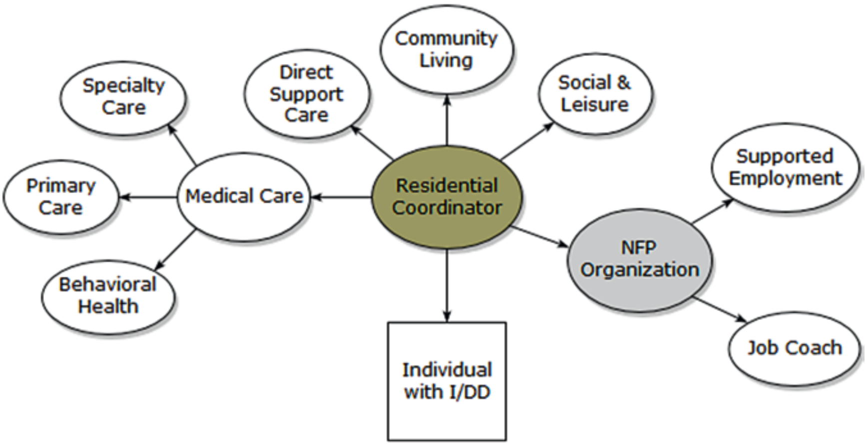

Fig. 7.3 Residence-based delivery model

accessing social activities. Residence-based models can help enhance coordination and delivery when the same services, providers, or community programs are needed and received by more than one member of the household. Much like in coordinator-supported models, impeded choice, autonomy, and control can result from residential coordinators acting as “gatekeepers” to services. This underscores the need for deliberate and continuous person-centered planning with persons who have I/DD and their family members to ensure resident participation, care preferences, and feedback are documented and reflected in provision.

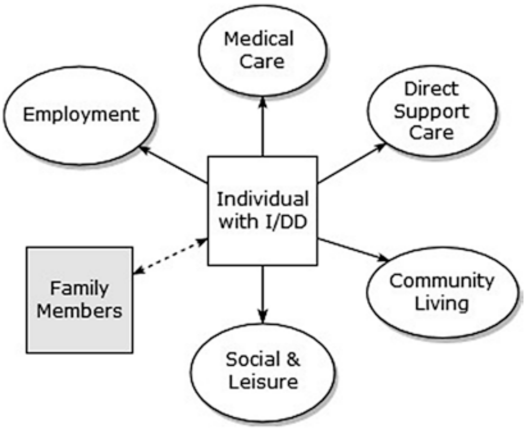

Fig. 7.4 Self-directed delivery model

Self-Directed Service Delivery Models

Self-directed service delivery arrangements are increasingly common since the ILM. In self-directed models, all services across domains are planned and organized by the person with I/DD (Heller et al., 2012). Self-directed delivery epitomizes an ideal model where the individual with I/DD exercises full autonomy and control over their service structure and management (Henman & Foster, 2015). The individual is considered to have the greatest understanding of their needs and wishes for their own care (Henman & Foster, 2015). Accordingly, such models position the individual with I/DD as the central authority of service delivery. The arrows pointing outward from the individual toward their services (Fig. 7.4) show how this model enables the greatest degree of person-centered delivery, with users selecting and scheduling providers and directing services in the way that best meets their individual needs and preferences.

When users coordinate their own care, they assume responsibility for the delivery and payment of services. This may hinder the adoption of self-directed models, especially if accounting for the quality and payment of services is unduly burdensome on an individual. If service availability is sparse, or individuals lack the appropriate funding resources to pay for care, the self-directed model may be ineffective (Henman & Foster, 2015). Familial involvement can be an asset to individuals self-directing their own services. Family members can provide support with navigating delivery systems and transitions, as represented by the dotted-line arrows between the person with I/DD and their family members in Fig. 7.4. Individuals with I/DD may also receive support with self-directed services from a local Center for Independent Living (CIL) or another community agency that advocates for the independent living of people with disabilities. These sources of support are important for many individuals with I/DD living independently in self-directed service arrangements.

The four conceptual models discussed, along with health status and medical complexity, age-related changes in needs, and degree of family involvement, shape the way services are delivered to a person with I/DD. However, service delivery is not impacted by these factors alone. Numerous system-level aspects also affect the provision of services to people with I/DD of all ages.

Delivery System Constraints

Service delivery can be complicated by a number of broader social, environmental, and policy-related contingencies. In most cases, such issues cannot be directly controlled by persons receiving care. Rather, these factors require attention and innovation at the system level to improve service delivery to community members. Delivery model success for individuals with I/DD will depend on service availability, accessibility, quality, and system integration.

Availability and Access

Accessing home- and community-based services (HCBS) is a major determinant of delivery model feasibility. When the full spectrum of services is locally unavailable, people with I/DD may not receive all they care they need in community settings. Low service access is largely driven by inadequate networks of HCBS providers, especially in rural areas of the country. This can contribute to the risk of unnecessary institutionalization of people with I/DD. Along with federal and state governments, administrators of Medicaid and Medicare (the primary providers of healthcare insurance to people with disabilities in the USA) are working to decrease state LTSS waitlists and reform payment structures for improved service access and better provider networks (Enquist et al., 2012; Lind & Archibald, 2013). Still, models of delivery are liable to be constricted by the breadth of available services for persons with I/DD in the community. Coordinator-supported models may predominate if service access is limited enough to preclude opportunities for self-direction.

Service Quality

The common conceptualized models of delivery for people with I/DD assume that provision is achieved when a service is accessed. However, a critical obstacle to delivery model effectiveness is the extent to which members of the I/DD population can obtain needed services that are of high quality. Although services may be available, there is no guarantee they provide timely, person-centered care for a person with I/DD. For example, many primary and specialty care providers have little medical training in intellectual and developmental disabilities and choose not to treat patients with I/DD due to low reimbursement rates from payers such as Medicaid and Medicare (Silberman et al., 2009; Williams & Ervin, 2016). Incomplete standard measures of quality for disability-related services add to the extensive variability in care delivered to people with I/DD (Enquist et al., 2012; Iezzoni, Marsella, Lopinsky, Heaphy, & Warsett, 2017). Without change, quality-related issues will continue to hamper effective service delivery to the I/DD population.

Workforce Challenges

Another major issue impacting individuals with I/DD living in the community is the limited number of qualified, professional in-home caregivers. The shortage of direct support workers (DSWs) in the USA has been identified as a concerning industry trend (Brown, Lash, Wright, & Tomisek, 2011). DSWs make independent and community-supported living viable for individuals with disabilities who may require daily support and care at home. However, DSWs are frequently underqualified, undertrained, underpaid, and insufficiently available in rural regions (Brown et al., 2011; Enquist et al., 2012). Oftentimes, family members step in to provide care for people with I/DD if professional direct support services are unavailable. The scarcity of DSWs places additional stress on the families of individuals with I/DD to informally deliver needed support. Overreliance on families to provide coverage for gaps in needed care is not a sustainable path for community-based service delivery (Bowers et al., 2017). Nevertheless, shortages of DSWs and other providers of HCBS make it increasingly difficult for people with I/DD to access and self-direct care services.

System Integration

Many individuals with I/DD are subject to siloed service delivery. Services for people with I/DD are often delivered by different agencies and through separate funding arrangements, commonly leading to misalignment (Alvarez, 2016; Lind & Archibald, 2013). As previously discussed, this creates numerous points of contact and fragments cross-domain coordination. Divisions in delivery structures may engender service underuse, misuse, and the likelihood of unmet needs. Extensive coordination efforts are typically necessary to prevent service disruptions. The complexity of multichannel service provision can be problematic for achieving person-centered delivery and maximizing the potential for self-direction by individuals with I/DD. Integrated systems, on the other hand, bring service domains together to streamline their provision, management, and financing. System integration creates a centralized point of planning and contact for users and decreases the need for cross-coordination efforts. In this way, integrated systems can better support person-centered delivery by reducing possibilities for gaps in needed care related to service access and coordination issues. Self-directed structures may better flourish in simplified, integrated systems that facilitate user-coordination of multiple services.

Conclusion

Service delivery to the I/DD population has evolved over time. The growth in community-based services signaled a fundamental change in service provision to people with I/DD from primarily medicalized models to person-centered approaches to care. Person-centered approaches offer services in context of an individual's needs and preferences and prioritize user involvement in care planning and management. This is important for individuals with I/DD who may receive an array of services over the life course, including medical, direct support, community living, education, employment, social and leisure, and long-term care services. Person-centeredness supports comprehensive provision to meet all an individual's needs.

Delivery framework utilization and the degree of user involvement can be impacted by several contextual factors, including co-occurring health issues and complex medical conditions, changing needs with age, and family involvement. Four conceptual models—uncoordinated, coordinator-supported, residence-based, and self-directed—are identified as common methods of service delivery for persons with I/DD. Each of these models differs in its mechanisms of coordination and potential to support self-determination in service provision. Still, improvement is needed at the system level to expand the availability, accessibility, quality, and integration of services. Without system innovation, such issues will continue to shape opportunities for effective, person-centered provision and user self-direction in service delivery for individuals with I/DD.

Comorbidity and Intellectual Disability

8

Larry Burd, Michael Burd, Marilyn G. Klug,
Jacob Kerbeshian, and Svetlana Popova

Comorbidity has been defined as the "existence or occurrence of any additional entity during the clinical course of a patient who has the index disease under study" (Feinstein, 1970) Comorbidity is commonly used to refer to the presence of a second or multiple conditions alongside a primary condition of interest. In a technical context, the term refers to the greater than chance likelihood that the presence of one condition will be accompanied by a second or multiple conditions. The presence of the comorbidities would be observed in the population at a higher rate than the product of the base rates would suggest. In this chapter, we concentrate on comorbidity in the context of developmental neuropsychiatric disorders primarily in children.

Comorbidity is often anticipated as a component of many disorders (Burd, Klug, Martsolf, & Kerbeshian, 2003; Feinstein, 1970; Kerbeshian & Burd, 2000). For example, people with intellectual disability (ID) may also have increased rates of attention deficit hyperactivity disorder autism and epilepsy in comparison to people without ID (Burd et al., 2003; Burd, Li, Kerbeshian, Klug, & Freeman, 2009; Kerbeshian & Burd, 2000; Peng, Hatlestad, Klug, Kerbeshian, & Burd, 2009; Weyrauch, Schwartz, Hart, Klug, & Burd, 2017 May). Comorbidities are important from a clinical standpoint as they influence disease activity, prognosis, medication choice, adverse effects, treatment response, patient compliance, and health care costs (Aslam & Khan, 2018). Comorbidities often have a major negative impact on quality of life, increasing functional disability, independent of disease activity. Comorbidities increase the risk for suboptimal care of coexisting disorders and the psychosocial milieu that accompany these comorbidities.

Diagnostic approach is central to understanding comorbidity. Traditionally, diagnosticians could be conceptualized as "lumpers" who *perceive* a broad phenotype encompassing multiple impairments or various behavior disorders as components of the phenotype. Lumpers tend to see conditions as hierarchical in nature, with

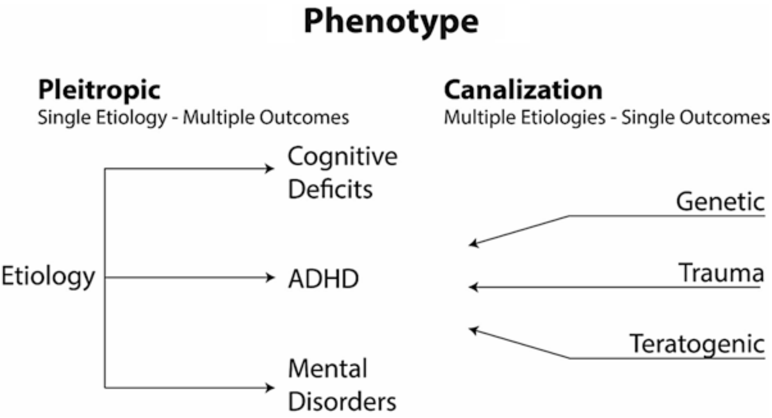

Fig. 8.1 Description of the two most common approaches to diagnoses of neurobehavioral disorders

diagnoses of greater severity, complexity, or impact trumping and incorporating diagnoses of lesser severity, complexity, or impact. Examples of this dynamic can be seen when autism spectrum disorder trumps the specific semantic pragmatic language disorder often present in people with ASD, or in instances where trisomy 21 eclipses problems related to prenatal alcohol exposure. Pleiotropy is roughly the genetic equivalent of the concept of multipotentiality (Fig. 8.1). The term pleiotropy reflects the idea that a common element or a single gene may lead to multiple alternate outcomes or phenotypes, presumably modified by the background of other genes or elements, or epigenetic factors. The concept of equifinality is that of different genes or elements merging into a common outcome or phenotype. The concept of phenocopy also has a similar effect. Canalization refers to a measure of resistance to change of outcome from a single element or a gene, irrespective of the influence of background elements of other genes, epigenetics, or other modifying factors. For example, heavy prenatal use of alcohol may lead to a certain configuration of the eyes and the face, but not to a third eye. Two eyes are heavily canalized, even if there are congenital cataracts, anisophthalmia, etc.

Alternatively, other diagnosticians utilize a broad approach where multiple *different* causes result in a constrained but recognizable pattern or disease phenotype. This approach is *equifinality or convergent homology* canalization (Fig. 8.2). Common examples are genetic causes or environmental causes (prenatal alcohol exposure), intellectual disability, autism spectrum disorders, or cerebral palsy. In practice most clinicians utilize the two approaches together and provide a useful approach to understanding clinically relevant factors that may clarify etiological diagnosis or inform treatment planning (Fig. 8.2). An example of this combined approach can be seen in the diagnosis of fetal alcohol spectrum disorders. Prenatal alcohol exposure is the causal etiology of FASD; however, smoking, maternal depression, prematurity, and drug use are other important elements in the epidemiological causal chain of events, and merit consideration in the diagnosis of fetal alcohol spectrum disorders. These additional elements would be considered as effect modifiers for prenatal alcohol exposure modifying the phenotype both during pregnancy and during postnatal development.

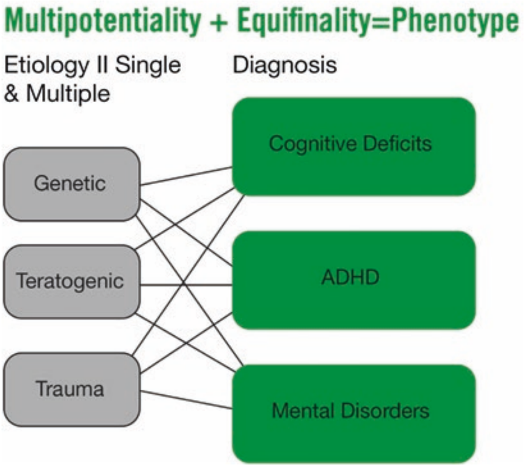

Fig. 8.2 Graphic representation of the components in the construct of multipotentiality

The phenotype of fetal alcohol spectrum disorders is highly variable and is both age and development dependent (Johnson, Moyer, Klug, & Burd, 2017 online first; Weyrauch et al., 2017 May). Clear examples of this variability are the increased risk for development of a substance use disorder *and* contact with the juvenile justice system for individuals with fetal alcohol spectrum disorders. These factors are not apparent in infancy but emerge during childhood and adolescence and may appear as longitudinal comorbidity. In clinical practice it is important to be aware of changes in phenotype in response to age and development. For example, it is important to understand that individuals with FASD have increased rates of contact with juvenile corrections and substance use disorders, and consequently monitor their behavior for signs of issue. These problems are foreseeable risks and should not surprise parents of these children when they reach adolescence. It is important to note that while the risk for these problems is increased in these populations, the problems are not inevitable.

Adverse childhood experiences are frequently seen concurrently with FASD. Adverse childhood events are important effect modifiers, which increases the risk for a variety of problematic health outcomes throughout the life span. In a study comparing FASD participants against non-FASD controls we found large increases in rates of adverse events in patients with FASD compared to controls (in preparation). We examined the role of adverse childhood experiences in people with FASD and the number of comorbid neuropsychiatric disorders compared to the number of adverse childhood experiences and comorbid diagnoses in a group of non-FASD controls. This relationship is summarized in Figs. 8.3 and 8.4.

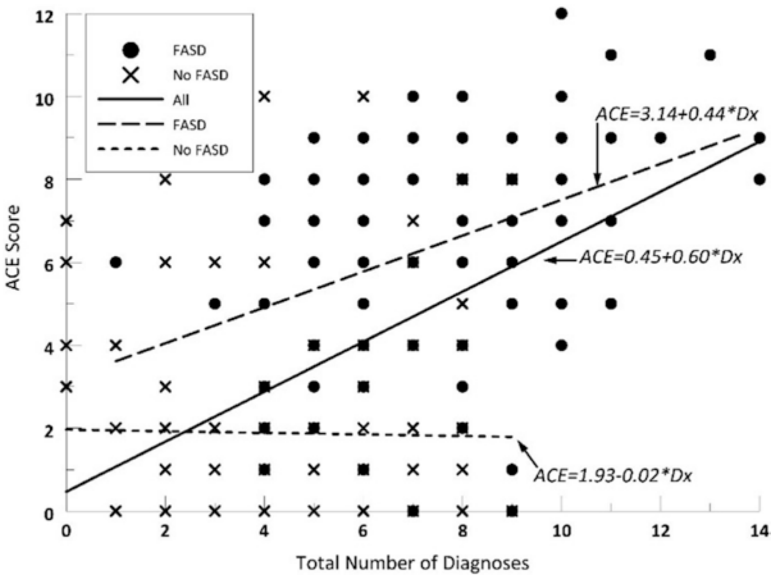
Children with FASD who had multiple diagnoses also had higher ACE scores. A visual depiction of the relationship between ACEs and the number of diagnoses is presented as a nomogram (Fig. 8.3).

The 10 traditional adverse childhood experiences (ACEs) and placement in foster care or residential care programs making a total of 12 possible variables.

The number of adverse childhood experiences appears to be an important effect modifier of risk for comorbid neurodevelopmental disorders in people with FASD but is much less important for non-FASD controls.

In Fig. 8.5 we present a disease specification approach that is also central to the issue of comorbidity. The broad phenome of conditions of interest (childhood developmental disorders) can be examined by the study of multiple phenotypes (phenomics), which comprises a catalogue of phenotypes used to diagnose the different expressions of diseases and disorders.

Fig. 8.3 The relationship between adverse childhood experience and comorbid neurobehavioral diagnoses



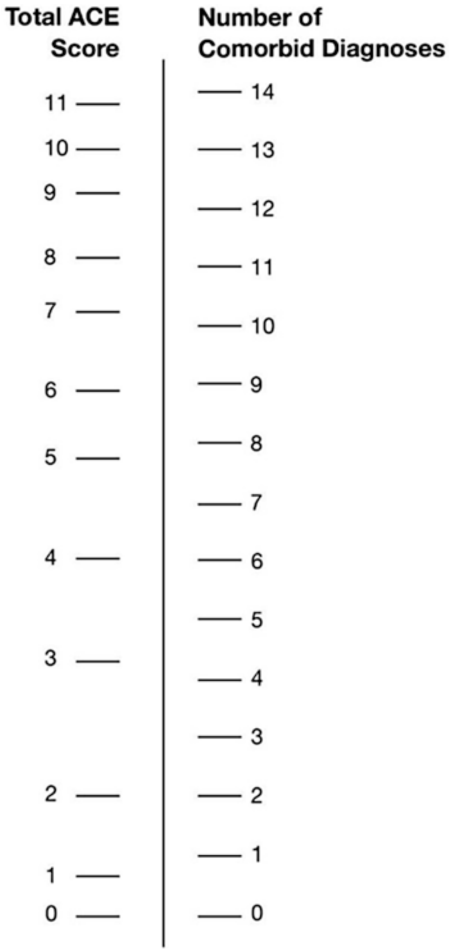


Fig. 8.4 A nomogram depicting the relationship between increasing (ACE) rates of adverse childhood experiences and associated comorbid neurobehavioral disorders

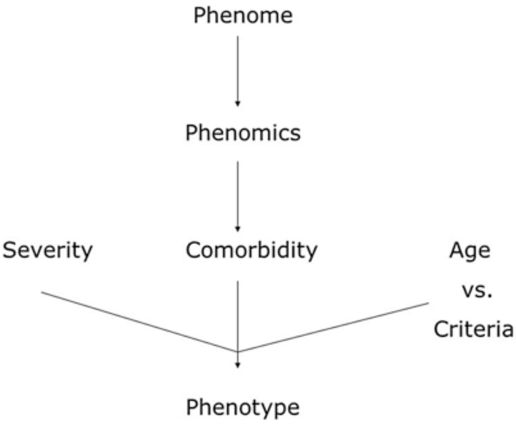

Fig. 8.5 Relationship between all diagnosis phenome and individual disease phenotype in a patient

Most neurodevelopmental disorders have multiple diagnostic features (nosology) that comprise a diagnosis, and these features are typically assessed dimensionally (mild, moderate, severe, or on a symptom diagnostic spectrum such as motor tic disorder, vocal tic disorder, and Tourette syndrome) and on categorical (yes or no) criteria. Figure 8.6 presents the concept of intellectual disability as a comorbid finding in fetal alcohol spectrum disorders and its impact.

Fetal alcohol spectrum disorders and autism spectrum disorders are clear examples of dimensional diagnostic categories which have evolved from more specific categorical diagnoses such as fetal alcohol syndrome, fetal alcohol effects, or alcohol related neurodevelopmental disorders. Autistic disorder, childhood disintegrative disorder, PDDNOS, infantile autism, or childhood onset pervasive developmental disorder also reflects the shift to appreciation of a phenotypic spectrum (Burd, Fisher, & Kerbeshian, 1988; Burd, Fisher, & Kerbeshian, 1989; Fisher, Burd, & Kerbeshian, 1987).

The impact of comorbidity on diagnostic boundaries has profound implications when studying the prevalence, etiology, diagnostic clarity, treatment strategies, and prevention for disorders. A conceptual overview of comorbidity expression suggests that several components merit consideration. Following is a list of the eight components of a comorbidity logic model.

Logic model components of comorbidity

1. Comorbidity increases the complexity of care.
2. Adversity increases the risk for comorbidity.
3. Comorbidity increases the risk for additional comorbidity (the complexity principle).
4. Increasing comorbidity increases diagnostic uncertainty.
5. The prevalence of comorbidity increases with age.
6. Increasing comorbidity increases service utilization and cost of care.
7. Comorbidity decreases access to evidence-based treatments.
8. Comorbidity decreases the likelihood of optimal outcomes.

In clinical practice or research settings, the complexity model may be a function of categorical diagnostic symptom counting (e.g., identification of multiple discreet diagnoses) versus use of

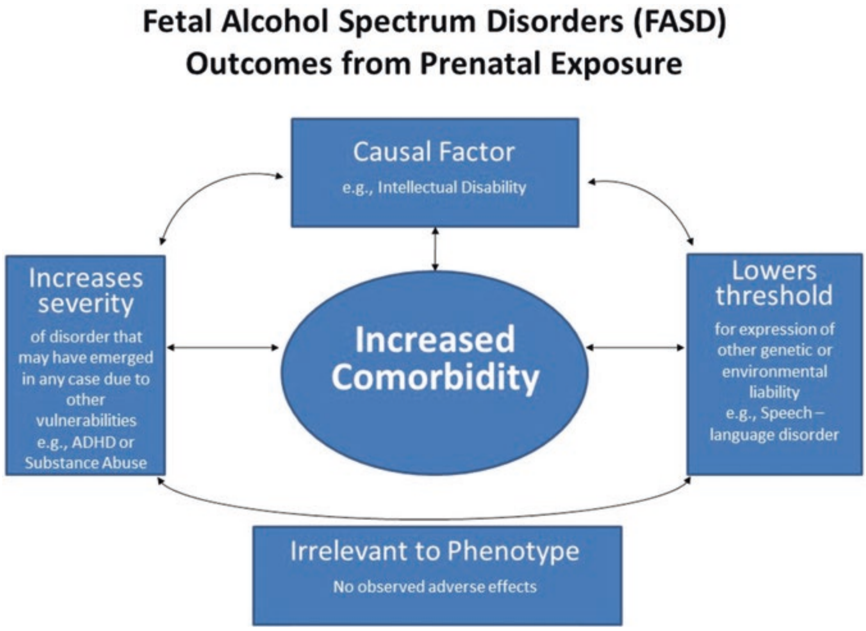

Fig. 8.6 Graphic presentation of factors influencing comorbidity in fetal alcohol spectrum disorders

a broad diagnostic category to subsume the comorbid diagnoses. For example, the overlap of some symptoms of ADHD with symptoms of a manic episode will require fewer additional manic symptom criteria in an ADHD child to make a diagnosis of mania, than in a child without ADHD. Symptoms may be double counted and reduce the threshold for additional comorbidities.

We will provide a brief discussion of each of the logic model components. Where appropriate, we will utilize health claims data and our clinical experience to illustrate each of the comorbidity components. The health claims data and our patient registries have been utilized within other studies of cost and service utilization and phenotype specification (Burd et al., 2001; Burd et al., 2002; Burd, Klug, Coumbe, & Kerbeshian, 2003a; Burd, Klug, Coumbe, & Kerbeshian, 2003b; Peng et al., 2009). For this analysis, we utilized inpatient and outpatient data on 179,873 unique individuals collected over the past two years. The sample's average age was 9.8 years (s.d. 5.4) and ages ranged from 1 year 18 years. This data excluded infants, thus accounting for childbirth expenses, which would skew the results. Just over half of participants (51.1%) were male. The average number of claims per child in the two-year period was 5.1 (s.d. 6.0) and ranged from 1 to 180. We identified 30 individual behavioral diagnoses and the major diagnostic category (MDC) for each claim using the ICD-9 3 digit designations. The average number of behavioral diagnoses per child was 0.14 (s.d. 0.57) and ranged from 0 to 13. After analyzing this data, several conclusions were reached, which are discussed below.

Comorbidity Increases Complexity of Care

It's often difficult for patients or families to decide which diagnoses are priorities for their limited time and funds. Multiple comorbid disorders often require multiple care providers. If a patient sees multiple providers, which one(s) should parents/caregivers prioritize (e.g., home programs for physical therapy, sensory impairments, medications, and/or mental health treatments)? How many appointments at how many different locations are reasonable? Is buying eyeglasses more important than medication for sleep? Patients and caretakers can be overwhelmed by multiple, often conflicting treatment recommendations for patients with comorbidity. This can lead to problems with anger, discouragement, and huge financial burdens for families and health care funders.

In Fig. 8.7 below we present a hypothetical situation depicting increasing complexity of care for a child with increasing comorbidity. The child is born to a mother who was abused and has alcohol use disorder. The father has ADHD, abuses alcohol, and has anger management issues.

This sequence of developmental events increases complexity of care and the cost of care.

Adversity Increases Prevalence and Risk of Comorbidity in Neuropsychiatric Disorders

Prevalence rates of common neurodevelopmental disorders are seen at elevated rates among children with exposure to adverse childhood events (Weyrauch et al., 2017 May). We used claims data for 1506 children with ID to find common comorbid diagnoses. ADHD is by far the most prevalent comorbid condition (42%), and is roughly four times as prevalent as other disorders. Several other disorders were also prevalent among people with ID (Fig. 8.8).

Children with ID are at far greater risk for these comorbidities, when compared to children without ID. However, the risk for a disease doesn't always follow prevalence, meaning that the comorbid disease that children with ID have the most frequently (ADHD) is not the one they are at the most risk for (conduct disorder) (Fig. 8.8). ADHD is very prevalent in children with ID and they are 10 times more likely to have ADHD than other children. However, children with ID are almost 16 times more likely to develop conduct disorder than other children, and 12 times more likely to have an ICD-defined emotional disorder (Fig. 9.9).

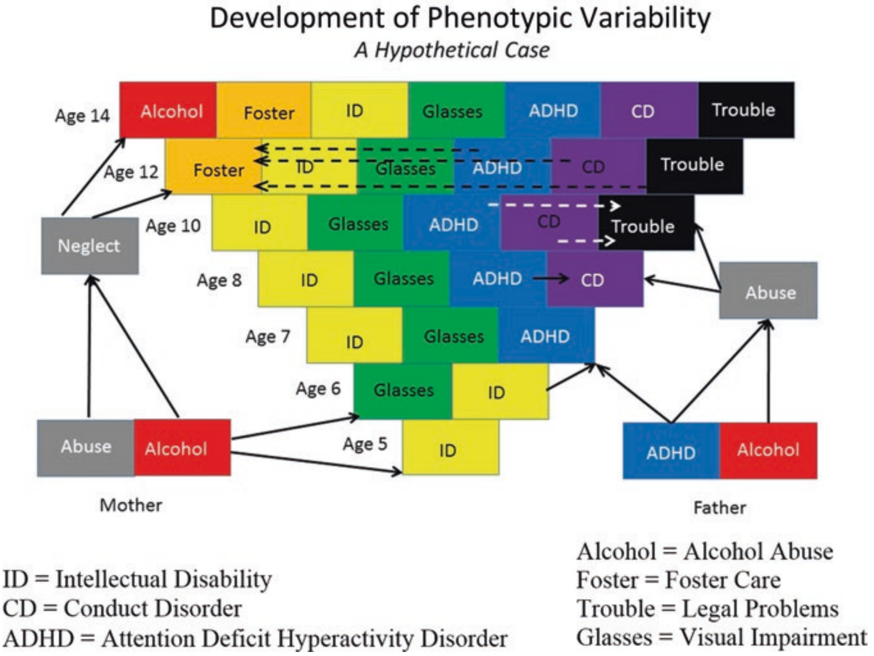

Fig. 8.7 Increasing complexity of ID and the individual phenotype of a person with ID with age. Age 5: The child is diagnosed with an intellectual disability, possibly related to maternal drinking during pregnancy. Age 6: The child needs glasses. Age 7: The child has been diagnosed with ADHD, as is the father. Age 8: The child is abused by the father. Learning and behavior issues emerge at school. Age 10: The child develops conduct disorder. Age 12: Neglect and abuse by the parents, trouble in school, and increasing behavioral impairments lead to foster care placement. Age 14: Substance abuse emerges as a concern. *ID* intellectual disability, *CD* conduct disorder, *ADHD* attention deficit hyperactivity disorder, *Alcohol* alcohol abuse, *Foster* foster care, *Trouble* legal problems, *Glasses* visual impairment

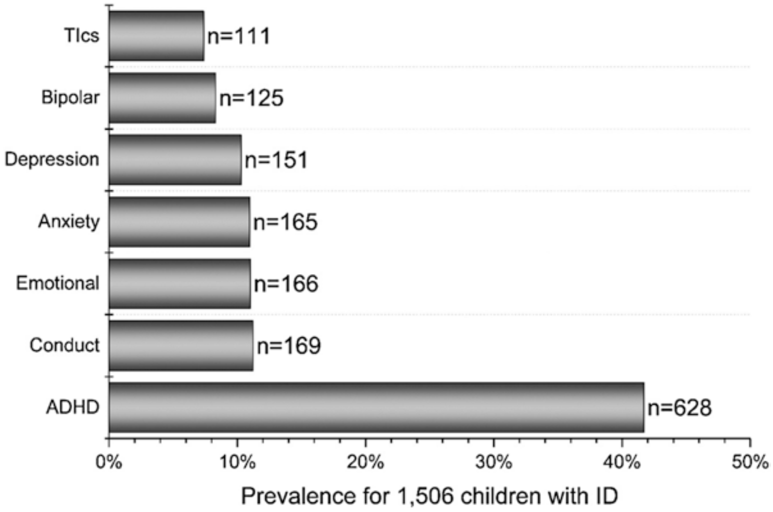

Fig. 8.8 Prevalence of seven most common comorbid behavioral diagnoses for children with ID

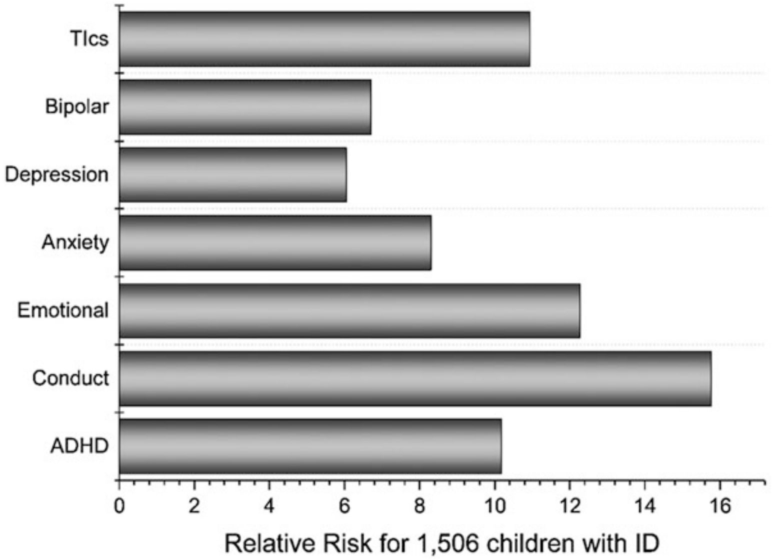

Fig. 8.9 Relative risks of seven most common comorbid behavioral diagnoses for children with ID

Comorbidity Increases Risk for Additional Comorbidities (The Complexity Principle)

Over the past 30 years, we have often observed that the presence of one comorbidity increases the risk for another comorbid disorder. We have described this as the complexity principle. We demonstrate this principle using health claims data for people with ID. As ADHD was the most prevalent comorbid diagnosis seen in children with ID (41.7%) we divided the ID children into those without ADHD (*n* = 878) and those with ADHD (*n* = 628). Figure 8.10 shows the risk of emotional disorder, anxiety, and depression diagnoses for these two groups. ID children with ADHD have a much higher risk of these additional comorbid diagnoses than those without ADHD.

For example, the risk of conduct disorder is 6.6 times more likely for ID children and 28.6 times more likely for ID children with ADHD (compared to children without ID). This means that children with ID and ADHD have over 4 times the risk for conduct disorder than a child

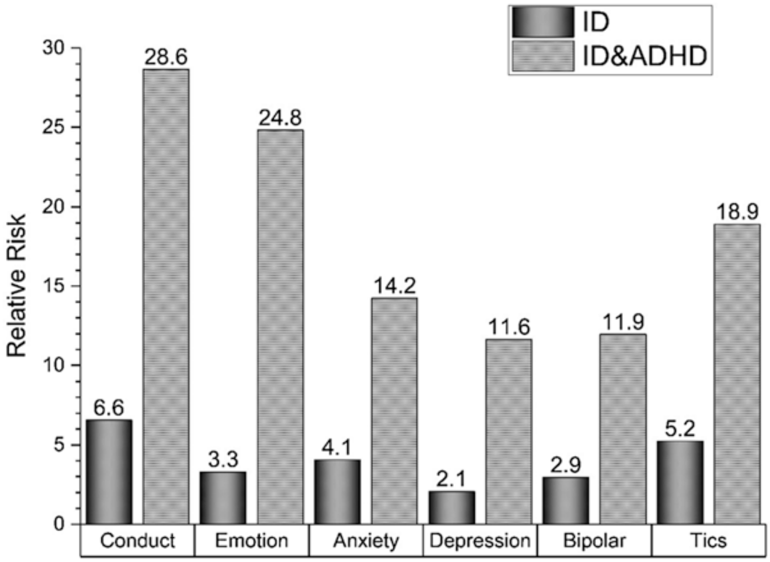

Fig. 8.10 Relative risk of having a second comorbid condition given ADHD previously exists for 1056 children with ID

who just had ID (28.6 compared to 6.6). A child with ID and ADHD is 25 times more likely to have an emotional disorder compared to children without ID, which is 7 times more likely than those with just ID (24.8–3.3). Having ADHD increases the risk of these common conditions by 3.5 (anxiety) to 7.5 times for ICD-defined behavioral and emotional disorders.

This demonstrates that just having one comorbid condition (e.g., ADHD) as well as an existing condition (e.g., ID) greatly increases the likelihood of having another comorbid condition (e.g., conduct or emotional disorder). The likelihood of complexity extends from these examples of having two comorbid conditions to having three or even four comorbid conditions. Figure 8.11 shows 878 children with ID only (left side), and 628 with ID and ADHD (right side). The prevalences of having conduct disorder, anxiety, or emotional disorder diagnoses as second, third, or fourth comorbid conditions are shown in the diagrams inside each box. Though the box on the left (ID only) is larger than the shaded box on the right (ID and ADHD) because it represents more children (878 vs. 628), the figures inside are smaller on the left side indicating only 98 children with ID have a lower prevalence of conduct disorder, anxiety, and emotional disorder as comorbid conditions (compared to 276 on the right, ID and ADHD). As demonstrated in Fig. 8.12, the presence of ADHD alongside ID increases the risk for multiple other neurodevelopmental disorders.

About 5% (3.6% + 0.23% + 0.23% + 0.57%) of the ID children have conduct disorder while 20% (10.2% + 1.9% + 3.8% + 4.5%) of children with ID and ADHD children have conduct disorder (over four times as many). Similarly, 5.4% (4.3% + 0.23% + 0.23% + 0.57%) of children with ID have anxiety and 18.8% (9.6% + 1.9% + 3.8% + 3.5%) of children with ID and ADHD have anxiety. ICD-defined emotional disorders increase from 3% in children with ID only to 22.3% in children with ID and ADHD.

Complexity increases for both groups, when viewing children with two of these comorbid conditions. For the conditions of conduct disorder and anxiety disorder, there are 0.46% (0.23% + 0.23%) of the children with ID and both of those comorbidities, and 5.7% (1.9% + 3.8%) of the children with ID and ADHD have conduct disorder and anxiety, a 12-fold increase. For a combination of anxiety and emotional disorder, 0.8% (0.23% + 0.57%) of children with ID have those two comorbidities, and when ADHD is added as a comorbidity, 7.3% (3.8% + 3.5%) of children have the two additional

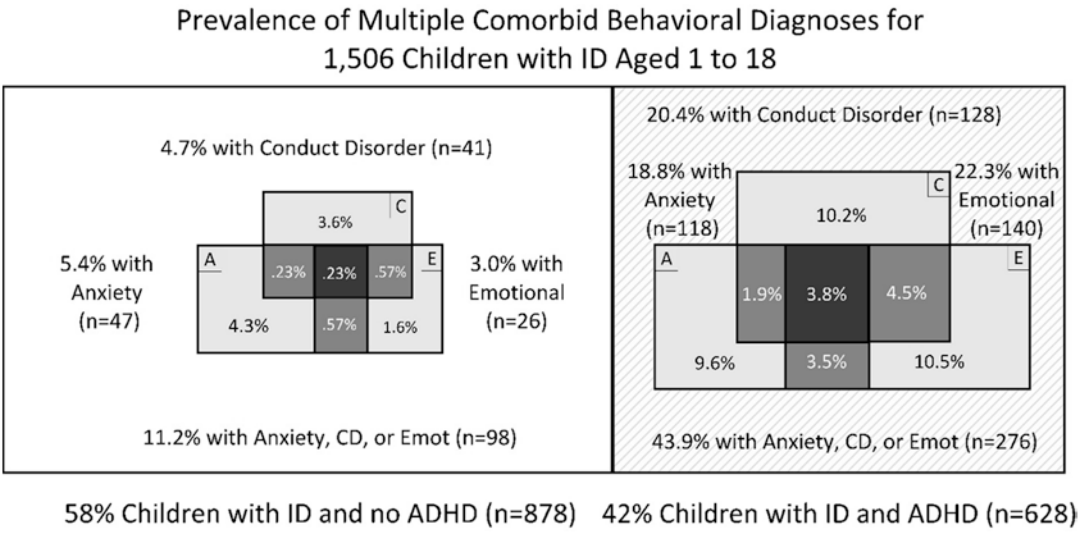

Fig. 8.11 Prevalence of one to three additional comorbid conditions beyond ADHD for children with ID

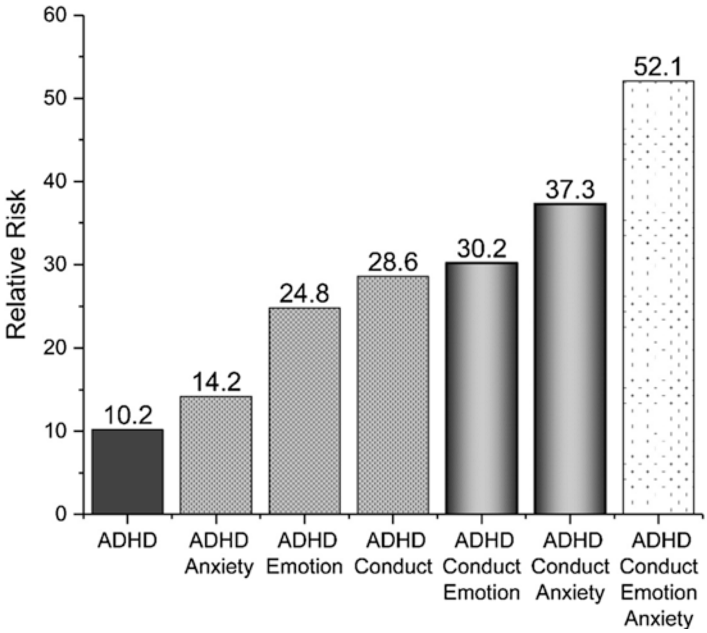
Fig. 8.12 Relative risk of multiple comorbid conditions in children with ID



comorbidities. Adding more complexity (three of these diseases are comorbid together among both groups of children), we observe that 0.23% of the children with ID have three comorbidities of conduct disorder, emotional disorder, and anxiety disorders (center square). 3.8% or over 16 times that many children with ID and ADHD as a fourth comorbidity have those three diagnoses.

The increase in the likelihood of complexity can also be seen with the relative risks of having one, two, three, or four diagnoses (Fig. 8.12). A child with ID is 10 times more likely to have ADHD than a child without ID (first black bar). The child with ID is 14 to 29 times more likely to have a second comorbid disease, (anxiety, emotional disorder, or conduct disorder, three light gray bars) in addition to ADHD. A child with ID is 30 to 37 times more likely to have two comorbid diseases in addition to ADHD (two vertical striped bars). And finally, a child with ID is over fifty times more likely to have ADHD, anxiety, emotional, and conduct disorder in comparison to a child without ID.

Increasing Comorbidity Increases Diagnostic Uncertainty

As we have demonstrated above, children with ID or other behavioral illnesses are more likely to have comorbid illness, often more than one. Figure 8.13 shows the prevalence of children with two or more MDCs in the two years of claims data gathered. 47% of children with a behavioral diagnosis had two or more MDCs compared to 53% of those without a behavioral diagnosis. This trend quickly changed and children with behavioral diagnoses were more likely to have 3 or more (30 vs. 25%), 4 or more (19 vs. 11%), or even up to 7 or more MDCs. Children with ID (line) were even more likely to have multiple MDCs in the time span with 65% having just two or more MDCs.

There was a high likelihood for children within the sample to have multiple behavioral diagnoses (Fig. 8.14). 71% of children with depression had two or more behavioral diagnoses. This was also true for 59% of children with ID and 39% of children with ADHD. The probability of having three or more comorbidities ranged from 21% to 45% in this sample.

Comorbidity increases diagnostic complexity by presenting multiple disorders simultaneously. Clinicians often diagnose only the most distinctive disorders at the time of the evaluation. It is not uncommon for people to receive multiple different diagnoses as they move from clinician to clinician, and resultantly they often lose an appreciation for the whole child or the child within the context of the family, as they focus on the multiplicity of segmented diagnoses. This is similar to treating parts of the elephant rather than the whole elephant.

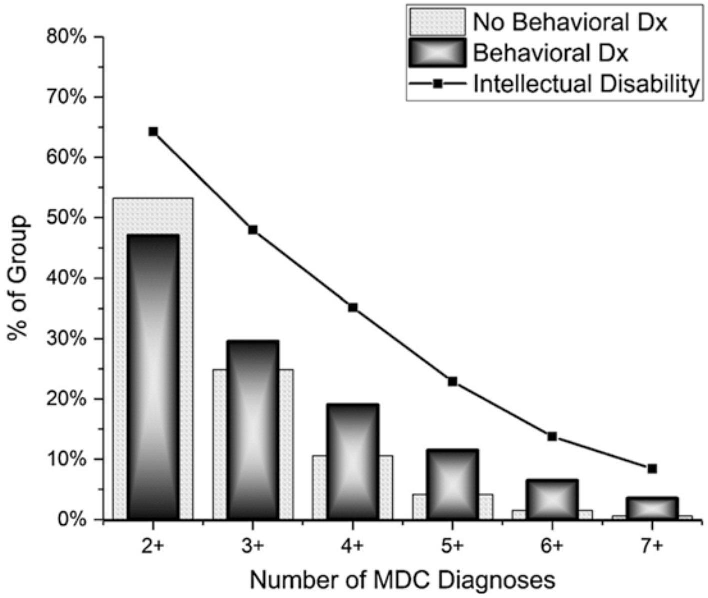
In a study of fetal alcohol spectrum disorder (FASD) we used our FASD patient registry to query the health claims data for information on cost of care and utilization. However, only about 8% of patients on the FASD registry could be identified by diagnosis in the claims data. This is partially because FASD was not specified in the ICD or DSM. The FASD registry contained many patients with 10 or more diagnoses. In the claims data, the diagnosis entered was often the reason for the visit (otitis media, headache). Since FASD was not entered in the registry, our ability to track cost of care, comorbid disorders, or service utilization and to aggregate this data by patient was limited. Even for more severe health related visits in the health claims data (surgical procedures, extensive diagnostic evaluations) FASD was usually not identifiable in the claims data. Children were often noted to have intellectual disability, seizure disorders, attention deficit hyperactivity disorder, or speech and language disorders, but FASD was not a diagnosis included for the visit. We were surprised by this since FASD is likely to be crucial in diagnostic formulation and in treatment planning (*FASD: Diagnosis informed care,* Unpublished manuscript).

The Prevalence of Comorbidity Increases with Age

Recognition of comorbidity is closely related to and dependent on both age and development. Figure 8.15 shows how the average age of children increases as the number of behavioral diagnoses increases. The average age for children with one behavioral diagnosis is 11.4. As the number of diagnoses increases over 8 comorbid conditions, mean age increases to 14.6 years.

Many of the comorbidities we see among patients we care for may have been present earlier but could not be diagnosed until later in

Fig. 8.13 Prevalence of children with multiple MDC diagnoses



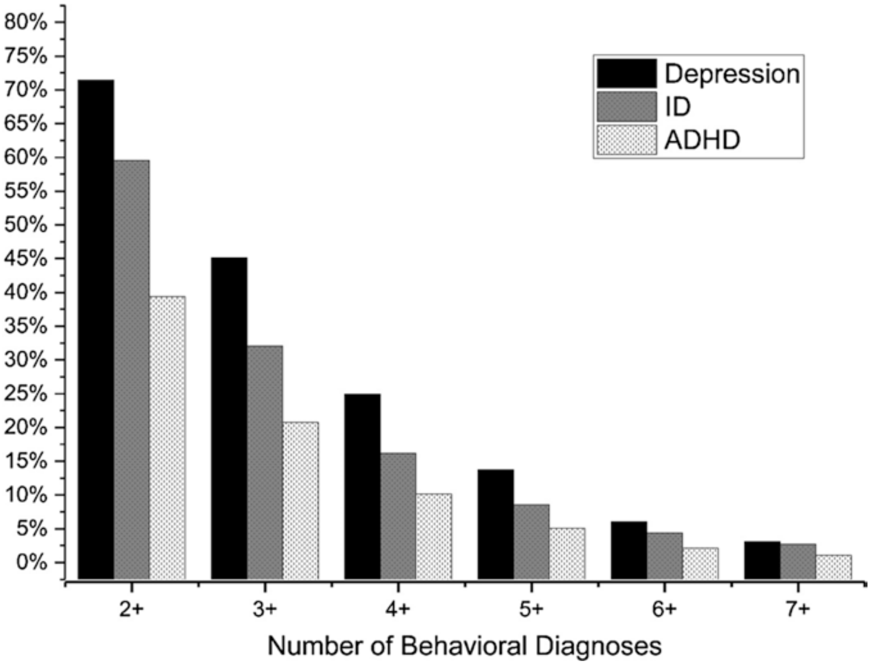


Fig. 8.14 Prevalence of children with multiple behavioral diagnoses by diagnoses

development. Attention deficit hyperactivity disorder, depression, speech and language disorders, and severe mental disorders are relevant examples. The development dependent expression of many of the key criteria for diagnosis is a key to understanding comorbidity (people must achieve a certain developmental level in order for us to reliably diagnose some problems). This duration of effect could be considered as heterotypic continuity, or alternatively longitudinal comorbidity. A classic example of this is seen in the identification of speech or language disorders in children

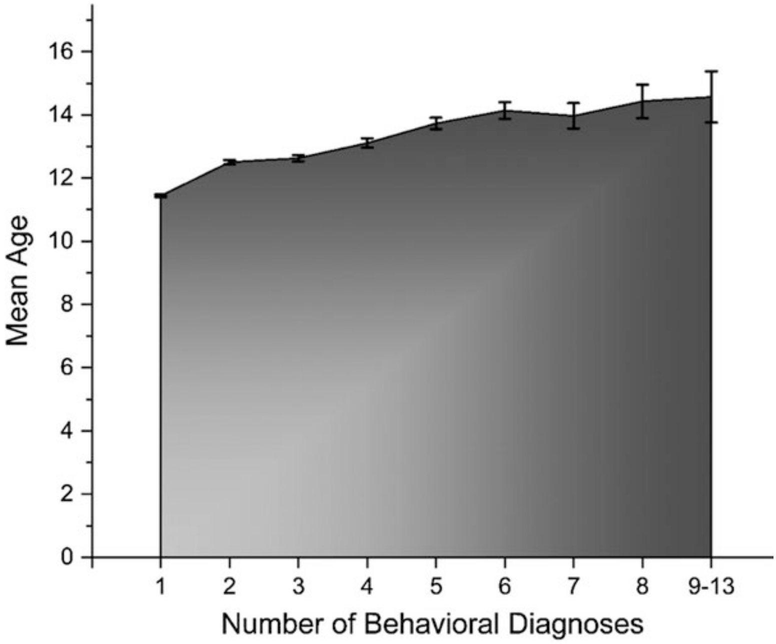

Fig. 8.15 Relationship between mean age and number of behavioral diagnoses for 15,366 children

under 12 months of age or the diagnosis of depression in infancy. A child must have reached a certain age in order to be able to reliably respond to questions about hallucinations or delusions in order for them to receive a diagnosis of some mental disorders. In some cases, children will not be able to express these problems until they reach adolescence. The expression of comorbidity can be limited by developmental impairments. For example, some complex clinical syndromes will be difficult to diagnose in the presence of severe intellectual disability (externalizing disorders or memory impairments).

Increasing Comorbidity Increases Service Utilization and Cost of Care

As is observed in routine health care, people with complicated diagnoses are seen to have higher costs of care. This observation remains true for children with comorbidity. When analyzing the total cost per year (including inpatient and outpatient costs) for 22,994 children with behavioral illness and 1506 with ID, we found the distribution of costs to be highly skewed (Fig. 8.16a). Transforming the data with logarithms showed two distributions of costs, valued under or over approximately 50,000 (Fig. 8.16b). This pattern was similar for the 1506 children with ID, so logarithmic transformations and categories of high and low were used for cost estimates.

Figure 8.17 (four parts) shows the scatter diagrams with regression lines using the number of behavioral diagnoses to predict yearly cost for low spenders (<=$50,000) and high spenders (>$50,000). The top two figures are for lower costs of care, 884 children with ID and 12,535 children with behavioral disorders. Lower costs significantly increase as the number of behavioral diagnoses increases for both groups. The correlation of diagnoses to cost was $r = 0.312$ for ID children and $r = 0.515$ for children with behavioral illness. The bottom two figures are for higher annual costs of care (<$50,000) for both children with ID and behavioral illnesses. The bottom two figures are for higher costs of care, 622 children with ID and 3581 children with behavioral illness. Though the relationships were different, higher costs also significantly increased as the number of behavioral diagnoses increased. Number of behavioral illnesses was significantly correlated with cost for ID children ($r = 0.0841$) and children with behavioral illnesses ($r = 0.123$).

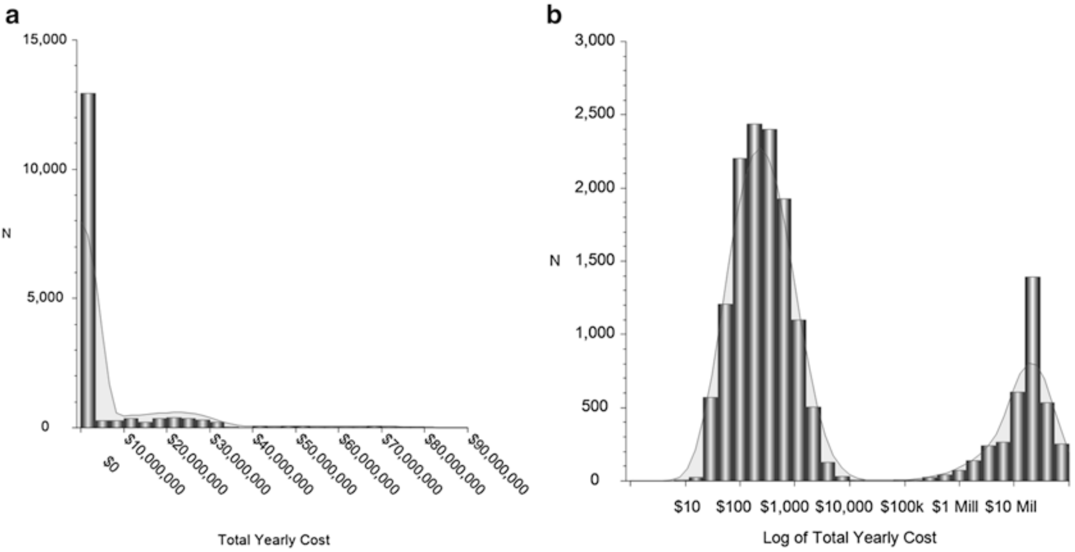

Fig. 8.16 Histograms of number of children in cost categories, original (**a**) and after a logarithmic transformation (**b**)

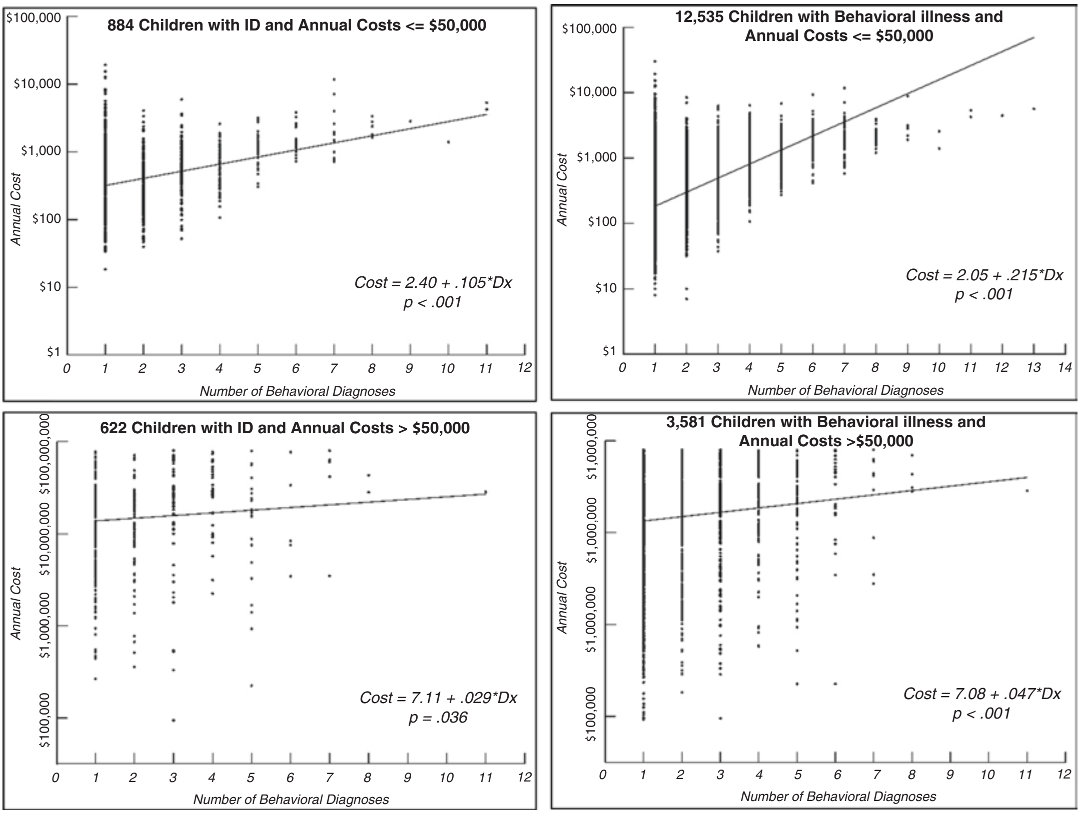

Fig. 8.17 Relationship between number of behavioral diagnoses and increased cost for children with ID or behavioral illnesses

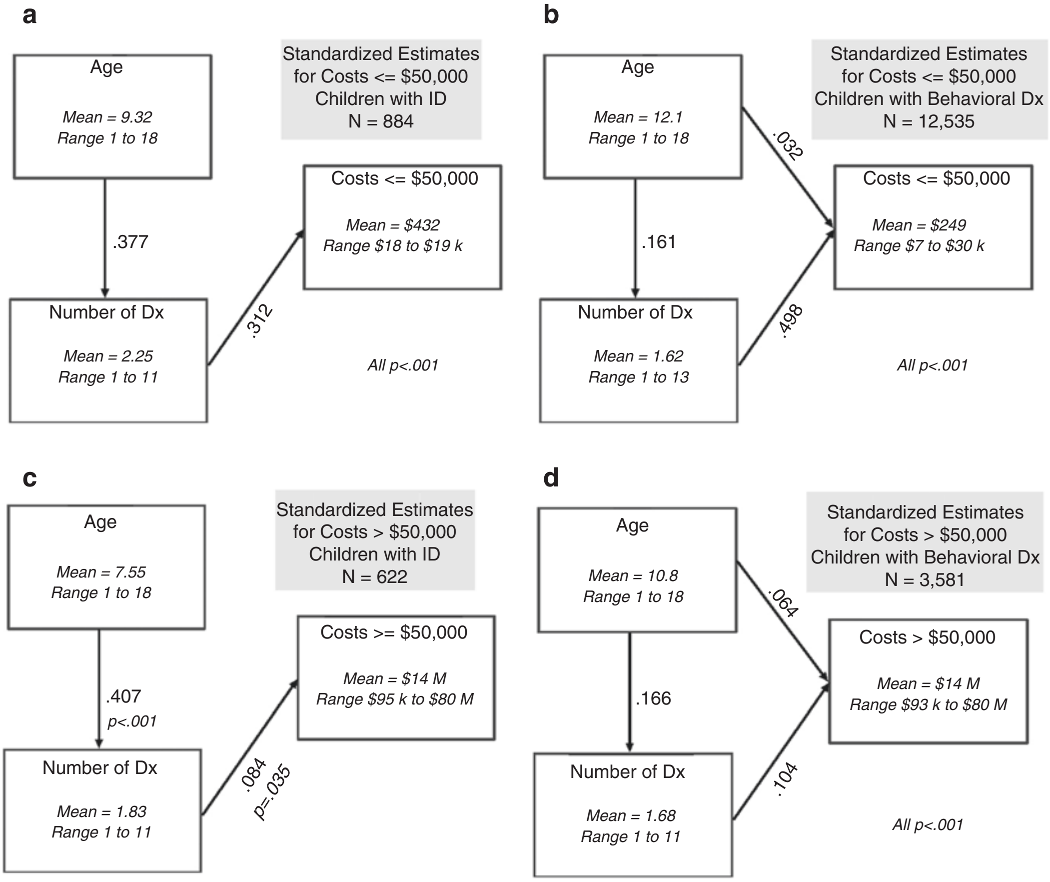

Fig. 8.18 Significant paths relating age and number of diagnoses to high and low costs for children with ID and diagnosed behavior disorder

Age was found to be related to number of behavioral diagnoses (older children had more diagnoses) (Fig. 8.18). Age may also directly or indirectly related to annual cost. Path diagrams can be useful to estimate and understand the full relationships between age, number of diagnoses, and expenses for participants within the high cost and low cost group. The four quadrants of Fig. 8.18 show how age and number of behavioral diagnoses relate to high and low annual costs for children with behavioral diagnoses and ID.

All diagrams show a relationship between age and number of comorbid diagnoses, the relationship is stronger (0.377 and 0.407) for children with ID (a and c). Also, all diagrams show a relationship between number of diagnoses a child has and their annual costs, though this relationship is stronger for children with lower (no expensive hospitalizations) costs (0.312 and 0.498) (a, b, c, d). This creates an indirect relationship between age and annual cost. Age has a direct relationship to annual cost for children with behavioral diagnoses (0.032 and 0.064).

Increasing Comorbidity Decreases Access to Evidence-Based Treatments

In most treatment studies participants are carefully selected to allow for precise examination of the intervention within a minimum sample size. Children with two or more disorders are often excluded from studies and as a result we have limited information on clinical presentation of complex developmental disorders in children and adults.

As a result, we have limited information on the benefits of multiple simultaneous treatments or the risks (adverse effects) from multiple interventions at the same time. This is an area of considerable concern. Do we spend huge amounts of money on interventions which negatively effect (affect) outcomes when delivered together? Are we selecting the optimal mix of treatments that maximize efficiency and benefits when used together? Equally importantly, how do we attribute either harm or benefit when a child is exposed to three, four, or more treatments at the same time? Put another way: Do we have sufficient variance in treatment response to detect either benefit or harm from 3 to 5 treatments utilized simultaneously?

Currently, we seem to operate with the belief that more intervention is better. For example: early intervention services in the home, center-based speech/language therapy, occupational therapy, preschool, and clinical behavior management with medication for sleep and separate medication for attention deficit hyperactivity disorder. This may be a form of therapeutic splitting influenced by both strategies to enhance reimbursement and therapeutic boundaries. Costs are enhanced, but it may be that this is the ideal combination with each intervention enhancing and optimizing the others. It may also be possible that this is just unnecessary duplication (e.g., the structure in preschool, occupational therapy, behavioral consultation, medication, and speech/language interventions overlap). Thus, only 1 or 2 of these interventions may account for the gains and medication or behavior consultation is unnecessary.

Increasing Comorbidity Decreases the Likelihood of Optimal Outcomes

Both the natural history and response to treatment for neurodevelopmental disorders are poorly understood (Burd et al., 2001; Burd et al., 2002; Burd et al., 2003a; Burd et al., 2003b; Kerbeshian & Burd, 2000). The impact of multiple disorders in clinical practice can also result in long-term impacts which can increase the risk for both additional comorbidity or long-term impairment from the combined effects of the disorders (Burd et al., 2003; Burd, 2016). Intellectual disability can have effects on long-term outcomes, and when these effects are combined with additional effects such as comorbid cerebral palsy, attention deficit hyperactivity disorder, or visual impairment, it is clear that more comorbidity nearly always results in additional impairment.

Discussion

Comorbidity increases both cost and utilization of services. The complexity principle is an important concept related to this finding. Increasing comorbidity increases the risk for additional comorbidity and the complexity of care. To illustrate this point, consider a young child who needs speech and language therapy and thus increases the demand on caretakers or parents. This child also needs occupational therapy, physical therapy, early intervention, frequent pediatric visits for multiple medication management, who wears glasses and has a hearing aid represents a huge increase in demand on the child's caretakers. These demands will affect which jobs the parents are able to do, and which promotions that they can accept compared to parents who don't have a child with multiple comorbid conditions.

We conclude with a brief discussion of several key points that have surfaced in this manuscript.

1. We enroll children in developmental therapies using an assumption of endless benefit. We have yet to clearly define benefits or adverse outcomes from multiple simultaneous therapies. We use therapy or multiple therapies as benign interventions and currently associate no downside from using multiple therapies concurrently.
2. Complexity increases both cost and utilization of services. Increasing comorbidity increases complexity which increases both service utilization and cost of care. For example, we have reviewed cases recently where children were sent home after multi-disciplinary assessments with dozens of recommendations.

Parents are forced to choose between what care the child needs and what care can be realistically provided. These choices are difficult as they pose limited affordable treatment options against the numerous treatments that were recommended. The level of care that can be implemented may be determined by travel schedule to different therapies, available time, and financial costs of these therapies. This is especially relevant for families with other children or where more than one child has ongoing health needs.

3. The uncovered or uncompensated cost of these therapies has been largely understudied. This concern applies even if services are funded by health insurance in countries with government-funded care. The implications of parents spending large amounts of money early in the child's life on therapies, travel, and time off from work, where the outcome is highly individualized, often limits funds they have for the care of themselves or other family members and for these children as they become older. Many parents describe this experience as "it's just often too much to hear about." They report feeling overwhelmed by the demands from multiple health care providers and rarely have access to someone to help them prioritize recommendations and to help allocate their resources.
4. Morbidity risk is somewhat predictable for some diagnoses but highly variable in expression. ADHD prevalence is increased in ID. But only some individuals with ID have ADHD. Monitoring for comorbidity should be built into routine care plans with systematic monitoring included within the context of ongoing care. A useful and emerging example is the understanding that increased adverse childhood events increase the risk for other neuropsychiatric diagnoses (submitted). There is an urgent need for strategies which assess whether or not we can prevent or diminish the prevalence and impact these comorbid conditions with early developmental interventions. The optimal developmental timing for these services also merits further examination. Further data regarding the intensity of services and what combinations are most effective or harmful could also be practically utilized.
5. Additionally, we need to optimize strategies and developmental interventions to most effectively treat comorbidity. For example, many children end up on multiple medications to treat multiple comorbid disorders. In some cases, these medications have an evidence-base for individual disorders (attention deficit hyperactivity disorder, depression, or obsessive compulsive disorder) in children. However, large-scale trials of routine clinical populations where children present three, four, five, or six of these other conditions are lacking. Studies of this type will require huge strategic investments in the future. We have very limited understanding of the potential benefits and risks of polypharmacy. Some agencies and parents refuse medications (especially for mental health diagnoses) even when the medications are well studied and offer demonstrable benefits. This seems to be biologically naïve and attributes a huge amount of a child's developmental impairments to disturbed emotions and relationships. This is often viewed by parents as blame. This is especially prominent in foster care where there is a growing mandate to avoid using medications for young children. Under careful examination, it is clear that this mandate applies mainly to mental health application, and is not seen similarly in regard to general medications. Psychological therapies face less critical assessment, despite possessing less evidence of efficacy for developing children.
6. Identification of optimal strategies early in the developmental course to reduce phenotype severity early in life is still limited. Can either early intervention or optimal intervention strategies prevent comorbidity from developing? Could this lead to a reduction in phenotype severity in the future? In populations of children with multiple complex disorders, we need better evidence to guide our practice. These conclusions suggest that a shift in our research practice is needed. It's time to embrace complexity and to begin studies capable of providing evidence to guide our care for these children and their families.

Part III

Parent/Professional Issues

Parent and Professional Organizations

9

Claire O. Burns, Georgia Shaheen,
and Shelley R. Upton

Introduction

Many resources exist to support individuals with intellectual and developmental disabilities (IDDs) in their daily life as well as promote inclusion in their communities. Family members, professionals such as clinicians and researchers, and community members play an important role in helping individuals with IDDs access the types of supports and services. To this end, several organizations have been developed to facilitate involvement. These include parent organizations for caretakers and family members as well as professional organizations for those whose vocations involve assisting with services for individuals with IDDs. Still others include community organizations, whose aim is to provide an inclusive and accepting society. This chapter reviews several of these organizations, their goals, and their functions.

History of Diagnosis

The most recent version of the Diagnostic and Statistical Manual, Fifth Edition (DSM-5; American Psychiatric Association, 2013) uses the diagnostic category "intellectual disability" rather than "mental retardation." This change in terminology is reinforced by a federal statute known as "Rosa's Law" (Public Law 111–256) which requires that first person language and the term intellectual disability be used in all federal laws. The law was named after an 8-year-old female with Down syndrome whose state representative and senator initiated legislation to enact this change in terminology. The reasons for this shift are (1) to avoid derogatory and pejorative language and (2) to emphasize the neurodevelopmental nature of the disability and the importance of early intervention (Harris, 2013). Intellectual disability has become commonly used in fields relevant to this population, such as medical and educational fields as well as advocacy groups and lay persons (American Psychiatric Association, 2013). Therefore, to be consistent with the current research and diagnostic practices, the term intellectual disability (ID) will be used throughout this chapter, even in reference to resources and articles published before this change that may have used the term mental retardation.

The current criteria for ID include impairments in intellectual abilities and adaptive skills, both of which are present during the developmental period. Severity levels are classified as mild, moderate, severe, and profound. Severity is determined by the level of impairment across conceptual, social, and practical domains. Prevalence rates of ID have been estimated

C. O. Burns (✉) · G. Shaheen · S. R. Upton
Department of Psychology, Louisiana State University, Baton Rouge, LA, USA

J. L. Matson (ed.), *Handbook of Intellectual Disabilities*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-030-20843-1_9

to be approximately 1%; however, prevalence rates vary across age range and severity level (American Psychiatric Association, 2013).

Although ID is a heterogeneous disorder that sometimes has no identifiable etiological cause, there are often prenatal, perinatal, and postnatal factors that are causally related to ID. These include genetic syndromes such as chromosomal disorders or sequence or copy number variations of a variety of genes. There are also high rates of co-occurring psychological and neurodevelopmental disorders in individuals with ID, including attention-deficit/hyperactivity disorder, mood disorders (i.e., depressive, anxiety, bipolar disorders), and autism spectrum disorder (American Psychiatric Association, 2013).

History of Services

A major shift in the field of developmental disabilities was marked by the administration of President John F. Kennedy. Prior to this time, services and supports for individuals with IDDs were minimal. The Kennedy family took an interest in the field of intellectual disabilities and founded the Joseph P. Kennedy Jr. Foundation to advance the field. President Kennedy's sister, Eunice Kennedy Shriver, in particular, was a major proponent of the advancement of advocacy for individuals with IDDs, and founded or laid the groundwork for many of the organizations reviewed in this chapter, such as the Special Olympics. Her son, Anthony Shriver followed in her legacy to found the Best Buddies organization (John F. Kennedy Presidential Library and Museum, n.d.).

In 1961, President John F. Kennedy created a Panel on Mental Retardation, which recommended improvements in service programs as well as research efforts. A meeting was held with representatives serving as coordinators of mental retardation programs from 38 states, with a stated goal that "the new organization would provide a vehicle for effective communication between the federal agencies and the various states concerned with research, training, programs and finance" (NASDDDS, 2018). One of the primary focuses of the report from the panel was the need for additional interdisciplinary research, with the recommendation that research institutes be created in academic settings such as universities. An additional goal was increased access to education for individuals with IDDs. Lastly, the third focus was on a "continuum of care" that included educational, social, and medical services in order to decrease impairments throughout the life span (Berkowitz, 1980). This panel resulted in the creation of the Maternal and Child Health and Mental Retardation Planning Amendment to the Social Security Act in 1963, which was the first legislation to increase research on intellectual disabilities and services for this population. This legislation resulted in funding for research projects focusing on etiology and prevention, as well as facilities that transcended the types of institutions that were commonplace at that time and served to provide access to treatment (John F. Kennedy Presidential Library and Museum, n.d.).

Parent Organizations

The Arc

The Arc of the United States is a community-based organization comprised of and for people with intellectual and developmental disabilities (IDD) that provides a multitude of services and support for individuals and their families across the life span (i.e., from birth, to school, to young adulthood, through their journey to employment, and even into the twilight year; Arc, 2011). The organization is dedicated to promoting and protecting the human rights of people with IDD and works to ensure that people with IDD have the services and supports they need to thrive in communities across the nation.

Prior to the 1950s, little was known about intellectual disability or developmental disabilities, and subsequently programs to support families and assist in the development and care for these individuals did not exist. During this time it was a common practice for doctors to recommend that these individuals be institutionalized

(Arc, 2018a). Displeased with this course of treatment and the lack of services, The Arc was established in 1950 through a grassroots movement led by parents and concerned community members across the country that fought for the rights of individuals with IDD to live as productive members of society rather than living their lives institutionalized (Arc, 2018d).

The organization initially aimed to alter perceptions surrounding children with IDD, educating parents and the public on the capabilities and potential these individuals possessed and could contribute to society (Arc, 2018a). The organization went on to allow access to services for those who were previously refused access to education and the right to work. The Arc is credited as the first known organization to finance research on intellectual and developmental disabilities (Arc, 2018c). As a result, The Arc was involved in better understanding the association between lead poisoning and brain damage in infants and children, advocated for legislation, and created a network of chapters including voluntary groups and professional organizations (Arc, 2018c).

In the United States, The Arc is one of the largest providers of supports and services to individuals with IDD through approximately 700 local and state chapters across the nation. Local chapters provide individual advocacy, programs, services, and supports for individuals with IDD and their families. State chapters lead state-level public policy advocacy, provide local chapter support, and some may also offer direct services (e.g., case coordination, special needs trust planning, public awareness, education). Services also include health care and free and appropriate public education, in addition to early intervention and familial supports. Vocational services aimed to allow access to employment and independent living skills are also primary goals for adults (Arc, 2011).

The Arc also implements several national programs that are funded by grants from government, private foundations, or other dedicated sources. These national programs include Autism NOW: The National Autism Resource and Information Center, Center for Future Planning™, Chapter Excellence Group, Down Syndrome Grant Program, FASD Prevention Project, Family Support Research and Training Center, HealthMeet®, Inclusive Volunteering, National Center on Criminal Justice Disability®, National Council of Self Advocates, National Sibling Council, Self-Advocates with FASD in Action (The SAFA Network), Arc@School, The Arc@Work™, Technology Programs, and Wings for Autism® (The Arc, 2018b).

The Arc is also one of the primary advocates protecting individuals with IDD and their families at the personal, local, state, and national levels. According to The Arc website, “Locally, individual advocacy is available through every local chapter of The Arc. At the state level, advocacy occurs with the executive and legislative branches of government, administrative agencies, school districts and other providers. At the national level, advocacy opportunities exist with regard to influencing federal agencies, policies and funding for disability programs and services” (Arc, 2011).

Easter Seals

Easterseals serves people and families throughout the United States who have physical emotional, intellectual, social, and educational needs (Easterseals, 2018). Easterseals works to provide individuals with disabilities an opportunity to live meaningful and productive lives by removing physical, cultural, attitudinal, and legal obstacles while also providing services and opportunities (Easterseals, 2018). In the United States, services are provided through a network of 73 local Easterseals and four international partners (Australia, Mexico, Puerto Rice, and Canada).

Following the death of his son, Ohio-businessman, Edgar Allen built a hospital in his hometown of Elyria, Ohio, out of his concern for the lack of adequate medical services available (Easterseals, 2018). Through this hospital, he discovered that it was a common practice to hide children with disabilities from public view. Following this discovery, he founded the National Society for Crippled Children in 1919 to make a difference in the way children with disabilities were typically treated. The seal was created during the spring of 1934 when the organization launched its first Easter "seals" campaign to raise money for services. A seal was created and donors showed support by placing the seal on envelopes and letters. In 1945, the organization expanded to include adults and returning WWII veterans. By 1967 the Easter "seals" campaign was so well recognized that the organization formally adopted the name "Easter Seals" (Easterseals, 2018).

Easterseals offers numerous home and community-based services and supports to individuals and families living with a disability. These resources are categorized into five distinct support areas: live (Programs: autism services, day care, in-home care, therapy, mental health), learn (Programs: accessibility, safety tips, transportation, guide for caregivers), work (Programs: employment and training, veteran reintegration, senior career employment), play (Programs: camping & recreation, respite services, brain games) and act (Programs: ways to give, advocacy, personal fundraising, Walk With Me, volunteer; Easterseals, 2018).

Condition-Specific Parent Organizations

As previously discussed, many individuals with IDDs have specific genetic or medical conditions that are related to delayed development. Although not an exhaustive list, some select organizations for parents and families of individuals with such conditions are reviewed below.

Families Affected by FASD (FAFASD)

FAFASD is an organization created by parents of individuals with FASD. This organization is designed to increase education surrounding FASD in communities and professional circles. FAFASD provides training on how to accommodate individuals with FASD, entitled "FASD and the Brain-Based Approach." These trainings are geared toward families of individuals with FASD, as well as professionals and caregivers who may have contact with individuals with FASD. The trainings are available both in person and online and are delivered by trained parents of children with FASD. Additionally, this organization aims to increase support for parents and families of individuals by providing resources and online social networking. Families within their social media (i.e., Facebook) group provide a network where families can seek advice. They also work to increase awareness surrounding FASD—in both intervention for people already diagnosed with FASD and prevention of FASDs by educating women of childbearing age (Families Affected by Fetal Alcohol Spectrum Disorder, 2018).

National Organization on Fetal Alcohol Syndrome (NOFAS)

NOFAS is a national organization established in 1990 dedicated to both prevention of FASDs and interventions for individuals already living with FASDs. Additionally, NOFAS provides support for women during pregnancy, as well as women who are birth mothers of children diagnosed with FASD. This support network operates within NOFAS and it is entitled Circle of Hope. The Circle of Hope aims to provide mentoring to women who have consumed alcohol during pregnancy which resulted in their child being diagnosed with an FASD. This network also works toward reducing the stigma surrounding mothers of children with FASDs and women who are struggling with alcohol addiction (National Organization on Fetal Alcohol Syndrome, 2018).

The NOFAS website provides an extensive database detailing resources available to families and individuals with FASD. The resources are sorted by state, as well as divided by whether the resource is for parents/caregivers or adults living with FASD. The resources available include diagnostic clinics, advocates, families, and doctors with experience treating FASDs. The website also provides extensive education surrounding FASDs and alcohol addiction, with various fact sheets about diagnosing, treating, and living with FASD. NOFAS also offers training and webinars geared toward families and medical professionals who work with individuals with FASD (National Organization on Fetal Alcohol Syndrome, 2018).

United Cerebral Palsy

United Cerebral Palsy (UCP) is a national nonprofit organization that was founded in 1949 by two families of children with cerebral palsy with the goal of improving their overall quality of life. Their website lists extensive resources geared toward helping individuals with cerebral palsy. These resources include helping families navigate health care, find affordable housing, and access education. UCP also connects families to international resources outside of the United States. Their website includes etiquette guidelines for individuals who interact with individuals with disabilities—including how to speak to people who may have difficulty hearing you and how to best interact with someone who uses a wheelchair (United Cerebral Palsy, 2018).

UCP connects individuals with disabilities and their families to the supports they need, whether that may be intervention services, therapy, assistive technology, finding a job, or accessing transportation. They also connect individuals with local affiliates who can work more closely and specifically to that individual's geographic area. These affiliates are located in the United States, Canada, and Australia. UCP also works in public policy, often advocating for legislation that increases funding and resources to improve quality of life in people with a disability. Their website offers links to contact congressional representatives directly as well (United Cerebral Palsy, 2018).

National Association for Down Syndrome

The National Association for Down Syndrome (NADS) is a nation organization founded in 1960 by the mother of a child born with Down syndrome. One of their earliest initiatives was developing their Parent Support Program. This program is designed to help parents of newborn babies with Down syndrome receive support and accurate information regarding their child's syndrome. NADS also provides education and seminars designed for health care workers and caregivers of individuals with Down syndrome. NADS works with governmental bodies to improve legislation for individuals with disability. They work on various initiatives that increase awareness and knowledge of Down syndrome and also offer resources for Spanish-speaking individuals. Although a nation organization, many of their services (e.g., support groups, welcome baskets) are only available in the greater Chicago, IL area (National Association for Down Syndrome, 2018).

National Down Syndrome Society

The National Down Syndrome Society (NDSS) is a national nonprofit organization that was founded in 1979 by parents of a child born with Down syndrome. They began with various initiatives to increase awareness and acceptance of Down syndrome, including designating October as Down Syndrome Awareness month. In 1995, NDSS organized the first Buddy Walk, which has grown to over 250 walks organized worldwide. The Buddy Walk aims to increase acceptance and inclusion of individuals with Down syndrome. In 2017, the Buddy Walk raised over $14 million that will go toward public policy and advocating initiatives for people with Down syndrome. NDSS characterizes itself as a human rights organization that works toward improving the lives of those born with Down syndrome (National Down Syndrome Society, 2018).

Much of their work is devoted to improving employment opportunities for individuals with Down syndrome. For example, their program, Even Strength, pairs individuals with job opportunities at major sporting events where they receive training. NDSS also works in public policy, advocating for legislation that helps individuals with Down syndrome more easily find employment. They have affiliates located across the country that help families contact the various supports they may need. These supports include parent support groups, trainings, interventions, and various recreational and social activities. Their website also includes numerous resources and fact sheets aimed to increase education surrounding Down syndrome (National Down Syndrome Society, 2018).

The 22q Family Foundation

The 22q Family Foundation is an organization geared toward families that aims to increase awareness of 22q11.2 deletion syndrome and provide support for families of individuals with the syndrome. This foundation provides retreats for caregivers of children with 22q deletion syndrome. Additionally, they organize various charity events to raise funding for research. Their website has an extensive database that lists various clinics, support groups, and other resources for individuals with 22q deletion syndrome and their families. Additionally, their website has resources to increase education about the syndrome. 22q Family Foundation works in various ways to connect families to resources or supports that a child may need throughout their life. Many members of their board work directly with education, providing consulting on Individualized Education Plans (IEPs) and awarding scholarships (22q Family Foundation, 2018).

The Angelman Syndrome Foundation

The Angelman Syndrome Foundation (ASF) is a national organization founded in 1992 dedicated to increasing support and funding for Angelman syndrome. They are one of the largest funders of research that examines therapeutic treatments and possible cures. ASF organizes numerous fundraising events every year to support their funding of research, including walks and marathons. They also host a yearly conference where scientists gather to present and discuss the latest research regarding Angelman syndrome. ASF's goals include improving the quality of life and the quality of care for individuals with Angelman syndrome. Their website also includes various resources that connects families with local and national resources and supports. ASF works to provide families and individuals with Angelman syndrome with education, housing, therapy services, medical services, and various recreational services. ASF has also partnered with numerous hospitals across the country to provide comprehensive care for children with Angelman syndrome (Angelman Syndrome Foundation, 2018).

Professional Organizations

American Association on Intellectual and Developmental Disabilities (AAIDD)

One of the most prominent professional organizations is AAIDD. AAIDD was founded in 1876 and was originally named the American Association on Mental Retardation (AAMR). AAIDD includes member both in the United States as well as 55 other countries and is an interdisciplinary organization that focuses on professional training, research, and supports. AAIDD publishes several research journals, specifically *American Journal on Intellectual and Developmental Disabilities*, *Intellectual and Developmental Disabilities*, and *Inclusion*, as well as measures such as the *Support Intensity Scale (SIS)* and the *Diagnostic Adaptive Behavior Scale (DABS)*. The organization also holds educational events and annual conferences, as well as provides educational resources (AAIDD, 2018).

The mission of this organization is to promote policies, research, and practice that pertain to and improve the quality of life of individuals with IDDs. Their three primary goals are to increase the abilities of professionals who work with individuals with IDD, promote societal inclusion and acceptance, and to maintain an organization that is effective at achieving these goals. AAIDD strives to improve the lives of individuals with IDD by promoting leadership and increasing skills of those working the field and promote education of students who are interested in careers in the field. Another goal is the protection of human rights (e.g., equality, dignity, respect, and choice) and support access to accommodations to increase participation in society and opportunities for choice and autonomy, as well as access to services such as education, vocational opportunities, and health care.

AAIDD further endeavors to promote inclusive attitudes and public awareness to promote inclusion on a societal level, as well develop partnerships with other organizations with the aim to further these goals (AAIDD, 2018).

American Network of Community Options and Resources (ANCOR)

ANCOR is a 501(c)3 organization and a nonprofit trade association for providers for individuals with disabilities. This organization focuses on private providers and their goals are to positively influence public policy, provide resources and development to providers, and to strengthen the community of providers to better provide integrated and long-term services. The mission of the ANCOR foundation is to "advance the ability of our members in supporting people with intellectual and developmental disabilities to fully participate in their communities" (ANCOR, 2018a). This organization also hosts annual conferences, provides trainings such as online courses and webinars, distributes publications, and provides resources for contacting ANCOR members. Resources targeting advocacy such as public policy principles and an advocacy toolkit are also included on their website (ANCOR, 2018b).

Association of University Centers on Disabilities (AUCD)

AUCD is a membership organization whose purpose is to promote interdisciplinary programs in universities and serves as a resource for local, state, national, and international organizations. Members of this organization include University Center for Excellence in Developmental Disabilities (UCEDD), Leadership Education in Neurodevelopmental Disabilities (LEND), and Intellectual and Developmental Disability Research Centers (IDDRC; AUCD, 2018). The aims of AUCD are to provide leadership, advocacy, and networking to connect these organizations on a national level. It also strives to promote communication both within this network as well as externally with other organizations (AUCD, 2018).

Intellectual and Developmental Disability Research Centers (IDDRC)

IDDRCs were founded in 1963 and were formerly referred to a Mental Retardation Developmental Disabilities Research Centers (MRDDRCs). IDDRC is a network of 14 sites funded by the Eunice Kennedy Shriver National Institute of Child Health and Human Development that serve as "center for excellence" for research on IDDs (AUCD, 2018). The sites included in the IDDRC are the Albert Einstein College of Medicine, Baylor College of Medicine, Children's Hospital of Boston, Children's Hospital of Philadelphia, Children's Research Institute/Children's National Medical Center, Hugo W. Moser Research Institute at Kennedy Krieger, University of California, Davis, University of California, Los Angeles, University of Kansas, Lawrence, University of North Carolina, Chapel Hill, University of Washington, University of Wisconsin, Madison, Vanderbilt University Medical Center, and Washington University (NIH, 2018).

The research aims of these centers include to increase understanding of factors and conditions related to IDD and to develop and implement evidence-based practices. Although centers are distinct, each supports many research projects (typically between 40 and 100) and principal investigators (20–70) per year. In addition to wide-scale research projects, sites also offer educational experiences such a pre- and post-doctoral fellowships as well as career development and training awards (AUCD, 2018).

National Alliance for Direct Support Professionals (NADSP)

NADSP is a national nonprofit organization. Their aim is to serve direct support professionals and advance practice standards and skills as well as encourage system reform. This organization emphasizes person-centered supports and stresses the importance of education and support of direct support professionals to achieve these supports. NADSP hosts annual conferences and provides access to a variety of training services, such as Front Line Supervisor (FLS) and Direct Support Professionals (DSP) certification (NADSP, 2018).

National Association of State Directions of Developmental Disabilities Services (NASDDDS)

NASDDDS represents US agencies that offers services to individuals with IDDs and their families. This organization works to provide agencies with the tools to develop support delivery systems. Principles of the organization include that individuals with DDs deserve to be treated with respect and dignity, make independent choices, participate in different areas such as family, community, and work, opportunities to achieve their full potential, and receive appropriate supports and services (NASDDDS, 2018).

The organization currently represents all 50 states in providing services to individuals with IDDs. It also sponsors conferences, projects such as National Core Indicators, State Employment Leadership Network, Community of Practice, and Evidence-Based Policy, and publications. The NASDDDS website also provides a resource library that includes resources on topics that include, but are not limited to: ADA/Olmstead, Behavioral Challenges, Case Management/Support Coordination, Closing Institutions, Employment, Housing, Managed Care, Medicaid HCBS Authorities, Preadmission Screening and Resident Review (PASRR), Person-Centered Practices, Quality, Self-Advocacy, Self-Determination/Self-Directed Services, Supporting Families, and General Information on Administering State Programs (NASDDDS, 2018).

TASH

TASH is a 501(c)(3) nonprofit organization that focuses on advocacy for individuals with disabilities. TASH was founded in 1975 under the name The American Association for the Education of the Severely and Profoundly Handicapped. Five years later in 1980 the name was changed to The Association for the Severely Handicapped, and then again in 1983 to the Association for Persons with Severe Handicaps (TASH). In 1995, it was decided by the Board of Directors that the acronym TASH would continue to be used but that the full name would be withdrawn. The primary goal is to promote participation of children and adults with disabilities and increase inclusion, in addition to decreasing inequality (TASH, 2018) (Table 9.1).

Community Resources

Special Olympics

The Special Olympics is an organization that promotes sporting events that are inclusive of children and adults with intellectual disabilities. The goals of this organization are to raise awareness about the abilities of those with IDDs, give an opportunity for the development of self-confidence, improve health, and “shift focus to what our athletes CAN do, not what they can’t” (Special Olympics, 2018). Sports included in the Special Olympics include badminton, basketball, Bocce ball, bowling, cricket, cross country skiing, cycling, equestrian, figure skating, floorball, floor hockey, football, golf, gymnastics, handball, Judo, kayaking, netball, open water swimming, powerlifting, roller skating, sailing, short track speed skating, snowboarding, snowshoeing, softball, swimming, table tennis, tennis, triathlon, and volleyball, among others (Special Olympics, 2018). Special Olympics participants include family members, professionals, and community members who participate as coaches, officials, and volunteers.

Like individuals without developmental disabilities, athletes with ID participate in sports not just for exercise but for social interaction and enjoyment (Harada & Siperstein, 2009). This is emphasized by researchers who have shown that, beyond cardiovascular health benefits (Wright &

Cowden, 1986), the length of time individuals were involved in Special Olympics is related to improved social competence and self-concept (Dykens & Cohen, 1996; Gibbons & Byshakra, 1989; J. Wright & Cowden, 1986), as well as self-worth and physical competence (Weiss, Diamond, Demark, & Lovald, 2003).

Best Buddies

Best Buddies is a nonprofit 501(c)(3) organization dedicated to promoting inclusion of individuals with IDDs through friendship, integrated employment, and leadership development. The program was started by Anthony Shriver in 1989 at Georgetown University and currently has programs in all 50 states of the USA as well as internationally in a total of 48 countries. In 2010, the Eunice Kennedy Shriver Act was passed and authorized the use of federal funds for the program. At the time of this writing, Best Buddies has a total of 2151 chapters with 109,033 participants (Best Buddies International, 2018).

Throughout its history, Best Buddies had included eight programs: Best Buddies Citizens, Best Buddies Jobs, Best Buddies High Schools, Best Buddies Middle Schools, Best Buddies Colleges, e-Buddies, Best Buddies Ambassadors, and Best Buddies Promoters. These eight programs are divided between the three main program pillars: One-to-One friendships (Middle Schools, High Schools, Colleges, Citizens, e-Buddies), integrated employment (Jobs), and leadership development (Ambassadors and Promoters; Best Buddies International, 2018).

A study by Hardman and Clark (2006), which included participants in the college program, found that university students as well as individuals with IDDs enjoyed the experience and engaged in mutually beneficial friendships. Individuals with IDDs also reported improvements in quality of life (Hardman & Clark, 2006). These findings strengthen the anecdotal accounts of individuals and family members that the Best Buddies program increases social inclusion and participation of those with IDDs.

Very Special Arts (VSA)

VSA, the international organization on arts and disability, was founded in 1974 by Jean Kennedy Smith and was originally named the National Committee Arts for the Handicapped (VSA, 2018). It was renamed Very Special Arts in 1985 and then simply VSA in 2010. The goal of this organization is to provide opportunities to participate in arts education for individuals with IDD. The aims of the VSA are to ensure that all individuals with disabilities have access to arts education as well as facilities and activities, to prepare educators and artists to teach students with developmental disabilities, and to promote opportunities for individuals to develop skills to enable them to pursue careers in the arts. Programs encompassed in this organization include arts education, professional development, cultural access, and community engagement. Some examples of specific programs include the VSA International Art Program for Children with Disabilities, VSA Emerging Young Artists Program, VSA Playwright Discovery Award Program, and the VSA International Young Soloists Award Program (VSA, 2018).

Conclusion

The last several decades have marked substantial advancement in the field of IDD and the collaboration between this field and the general community to promote inclusion of individuals with intellectual and developmental disabilities. Researchers recommend a family-centered support approach for families of children with intellectual disabilities (Dempsey, Keen, Pennell, O'Reilly, & Neilands, 2009), and so access to these types of supports is important for family members. Parent and professional organizations have been developed to serve as intermediaries to assist individuals with IDDs in accessing appropriate supports and services that may improve their quality of life. Community organizations such as the Special Olympics and Best Buddies also target goals such as social inclusion within society. The emotional wellness of children and adults with IDDs is even now an often overlooked component of support systems, and organizations whose goals emphasize the importance of societal inclusion and social and emotional support are crucial for optimizing the potential of these individuals. The organizations reviewed in this chapter, while not meant to represent an exhaustive list of all available resources, strive to improve the lives of those with IDDs and may serve as helpful and relevant resources for those people who seek to support them.

Staff Training and Supervision

10

John Rose and Abigail Gallivan

Introduction

High-quality training and supervision for staff working with clients with challenging behavior is considered to be a vital requirement in services for people with intellectual disabilities. Training can include a range of longer-term professional courses that lead to specific qualifications in a range of professions including medicine, psychology, social work, nursing, occupational therapy, and speech and language therapy. However, this chapter will focus on the brief training that is provided mainly for direct care staff who are working in residential and community services for people with intellectual disabilities. In particular, we will focus on training relating to reducing the challenging behaviors expressed by people with intellectual disability.

Challenging behavior has been defined as "culturally abnormal behaviors of such an intensity, frequency of duration that the safety of the person or others is likely to be placed in serious jeopardy, *or* behavior which is seriously likely to limit use of, or result in the person being denied access to, ordinary community facilities" (Emerson, 1995), estimates of the percentage of people in intellectual disability services who have challenging behavior varies considerably however, Emerson et al. (2001) suggest 10–15%. Challenging behavior may be the result of mental health issues or a wide variety of other causes in people with intellectual disabilities. It is therefore important for staff to have a good knowledge of managing both challenging behavior and mental health issues in this population.

Providing effective services for those with complex needs including challenging behavior is especially demanding for care staff (Campbell, 2011) and difficulties in doing so are a contributing factor to work place stress, a major problem in services for people with intellectual disabilities in the UK (e.g., Jenkins, Rose, & Lovell, 1997; Rose, Mills, Silva, & Thompson, 2013). Staff stress can lead to poorer quality interactions with clients (Rose, Jones, & Fletcher, 1998a, 1998b), lowered job satisfaction, burnout, and higher sickness rates (Rose, 1995). Failures to provide staff with the relevant skills, knowledge and motivation in dealing with challenging behavior is costly for the wellbeing of clients and staff alike (McKenzie, Paxton, Patrick, Matheson, & Murray, 2000), yet a gap has been noted between what is known to work in reducing challenging behavior and what staff do in practice (Campbell, 2011). This indicates the need for a

comprehensive training approach to ensure that all staff are updated with the approaches and techniques they require to work effectively and safely.

The implementation of knowledge acquired through training requires appropriate continued support as an important element to maintain effective services. This includes a range of staff supports such as ensuring staff have the right values base, knowledge and risk management skills and a space to reflect on their work through supervision (e.g., Rose & Burns, 2011). The leadership of staff is also important to ensure that these systems are maintained and practice leadership will also be considered (e.g., Deveau & McGill, 2014).

Short Training Courses for Direct Care Staff

There is a widespread belief in the benefits of staff training for improving staff performance (Campbell, 2007), and as a result staff training has been used to educate and support staff who work with people with intellectual disabilities across a broad range of areas. For example, the literature has highlighted the benefits of training for staff in working with clients who have experienced sexual abuse (Hames, 1996), in increasing self determination (Wong & Wong, 2008), enhancing interactions with clients (Finn & Sturmey, 2009; van der Meer et al., 2017), communicating about death and dying (Tuffrey-Wijne, Rose, Grant, & Wijne, 2017), working with people who have dysphagia (Chadwick et al., 2014), working with older people (Webber, Bowers, & Bigby, 2016), and raising awareness of mental health problems among staff (Costello, Bouras, & Davis, 2007; Rose, Rose, & Kent, 2012).

Over recent years, there have been significant developments in approaches to training staff who are working with clients with intellectual disabilities who exhibit challenging behavior. Previously, training focused on the management of challenging behavior (Grey, Hastings, & McClean, 2007), particularly on behavioral and physical interventions. One criticism of this approach was that it could increase the use of aversive methods with a group of people who were unable to consent, and that techniques could be implemented without a proper understanding of the function of a person's challenging behavior (Berryman, Evans, & Kalbag, 1994). Ethical and legal concerns have also been expressed about pain-compliance methods which have been used (Allen & Tynan, 2000). Alongside these concerns it has become evident that simply attending to the process of skill acquisition of clients is often unlikely to be sufficient to change the general approach and performance of staff in the workplace (Wong & Wong, 2008).

Over recent years there has been a much stronger emphasis in the development of training approaches on working within a broader organizational and interpersonal system to support people with Intellectual Disabilities with Challenging Behavior and Mental Health issues. These are organized within a number of frameworks; in a recent systematic review Cox, Dube, and Temple (2015) characterized them as: Positive Behavioral Support, Active Support, crisis prevention and response training (with a focus on Physical interventions), and communication training. However, the variety of possible frameworks can be extended by a variety of short-term training sessions that focus particularly on developing values and attitudes.

Positive behavior support is a set of research-based strategies used to increase quality of life and decrease challenging behavior by teaching new skills and making changes in a person's environment which combines values, theory and evidence-base and process (Gore et al., 2013). Active Support embraces Positive Behavioral Support with an emphasis on a range of approaches that enable people with intellectual disabilities to take part in a broad range of activities that have meaning to them so that ultimately they can exercise more control over their lives and become more independent and live as valued members of the community. As a result Active support has a focus developing staff skills in promoting engagement and developing service capacity to provide opportunities for people with intellectual disabilities and tends to take a whole systems approach with training integrated on a regular basis for staff (Koritsas, Iacono, Hamilton, & Leighton, 2008).

Ensuring that staff have an awareness of a broader context such as advocated in the Active Support approach has implications for training staff and more recent staff training has necessarily included a more extensive range of components. These include training in established behavioral methods but also training with a stronger emphasis on values and perceptions (e.g., Rose, Gallivan, Wright, & Blake, 2014). Other staff training has developed a focus on attributions, particularly the understanding of the cognitions, the emotional understanding of staff and how these are integral to the setting conditions for staff responses to challenging behavior (Grey et al., 2007). It is useful to consider how effective a more diverse approach to training has been, especially given the breadth of training now available as a result of a broader organizational focus. Due to the increased range of factors considered to influence challenging behavior many training studies focus on a broad range of outcomes so may be referred to on a number of occasions. As a result of these complexities we have chosen a different way to consider evaluations of training as: Crisis prevention and intervention; Increasing knowledge; Changing attributions; Emotional Intelligence; Communication and values based approaches and Environmental approaches. Throughout the chapter we will select examples of illustrative studies and the impact they have had in order to orient the reader to some of the main issues.

Crisis Prevention and Response Training

A number of studies have examined the effects of training on the quality of staff physical interventions in response to challenging behavior (e.g., Allen & Tynan, 2000; Baker and Bissmire (2000); Van Oorsouw, Embregts, Bosman, & Jahoda, 2010). The argument for focusing on developing staff ability to undertake physical interventions is to reduce the likelihood of injury for clients and staff because if staff do not feel safe, they will be unlikely to implement other behavioral or communicative strategies effectively (Allen, 1999).

One example of this approach to training is provided by Van Oorsouw et al. (2010) who adopted a quasi-experimental control group design consisting of two experimental groups and two control groups to investigate the impact of a 5-day training program for staff working with clients who exhibit challenging behavior. The training took place 1 day a week for 5 weeks and consisted of 25½ h of teaching on the causes of challenging behavior, early signs of escalation, and caring for colleagues involved in incidents and 7½ h teaching on physical intervention skills. An exclusion criterion was used to ensure that none of the staff had participated in any comparable training for at least 2 years and groups were matched in terms of their professional role, the severity of challenging behavior of the people they worked with and gender. Staff in the control group received the training once the study was completed. Following the training, a significant improvement was found in the levels of knowledge of staff and in the quality of their physical interventions.

Demonstrations of physical intervention techniques were videoed and analyzed using a standardized observation manual developed by the authors. In addition, knowledge and physical intervention scores remained significantly higher at 5-month follow-up in the intervention group than pre-training scores. No significant differences were found in the control group between pre- and post-training. However, staff knowledge and physical intervention scores at follow-up in the intervention group were significantly lower than immediately after training. This suggests that maintenance of high levels of knowledge and physical interventions may require additional input and regular refresher training.

McDonnell (1997) evaluated a 3-day course which aimed to develop a number of skills including skills in defusing situations and restraint, increasing understanding of challenging behavior, and increasing the confidence of care staff. At the end of the course all participants also demonstrated competence in physical restraint skills, they also showed a significant increase in self-confidence (measured by the Managing Challenging Behavior Confidence Scale), but no significant difference in knowledge (measured by the Violence Incident Knowledge Test). These results are of interest but as with all of the evaluations in this area they need to be treated with some caution as the design of the research could have been more robust, for example, in this case, as in others, participants were not randomly allocated to conditions and the numbers involved were small (22 participants). While it is important to ensure that staff are confident and have the ability to physically manage challenging behavior, it is perhaps a more essential skill to focus on preventing challenging behavior.

Increasing Knowledge

Most of the recent approaches to reducing challenging behavior include a preventative element and an element of developing knowledge of challenging behavior. While Allen and Tynan (2000) included physical skills in their training they also had a preventative and knowledge acquisition focus. They utilized a mixed design to compare a training program in which there were two groups of staff, one who had previously received the training ($n = 51$) and another who had not ($n = 58$). Training was carried out using the "Management of Aggression Training Program." The main emphasis of this program was the development of preventative approaches to challenging behavior through antecedent or ecological change (altering aspects of the environment that may trigger challenging behavior). It consisted of an introductory theory day followed by 1–2 days of physical intervention practice according to need. Staff who had previously undertaken training were identified from attendance lists at previous training sessions and compared to an "untrained" staff group with no previous record of training. Following training, a significant improvement was found in the levels of knowledge and confidence in the previously "untrained group" (who were now trained). However, staff with experience of training in the previously "trained group" also achieved significantly higher scores on knowledge and confidence compared to the "untrained" group scores post-training. It is possible that preexisting differences found between the groups (including length of service and nature of challenging behavior experienced by the staff) may have accounted for this variation. Matching participants in the two groups in this study would have addressed this issue and further increased the validity of the findings.

McKenzie, Sharp, Paxton, and Murray (2002), McKenzie et al. (2000), Kalsy, Heath, Adams, and Oliver (2007), and Gentry, Iceton, and Milne (2001) examined the effects of brief training on enhancing staff knowledge. The basic content of training included sections on the causes of challenging behavior, signs of escalation, and preventative strategies. All of these studies assessed 1-day training apart from Gentry et al. (2001) who evaluated a 3-day program.

McKenzie et al. (2000) investigated the impact of training on the knowledge of staff relating to challenging behavior. The study consisted of a training group and a control group who did not receive the training. Knowledge was measured with a questionnaire concerning the criteria for a learning disability, defining and managing challenging behavior and duty of care. Following the training, significant increases were found in the knowledge of the trained group in relation to defining a learning disability, duty of care and defining challenging behavior but not the management of challenging behavior. The authors suggest that this may be because staff who participated in the training felt the production of behavioral guidelines and functional analysis were outside the remit of their work. Follow-up data demonstrated that their overall knowledge scores remained significantly higher at 6 and 12 months after the intervention. The control group showed no similar increase in knowledge. This study was later replicated with 36 staff with similar results (McKenzie et al., 2002).

Gentry et al. (2001) investigated a 3 day "Interactive Staff Training" (IST) on levels of staff knowledge. The IST approach was developed by Corrigan and McCracken (1997) originally for use in psychiatric settings; the training also included elements directed at awareness of organizational and motivational barriers to the implementation of new knowledge and skills. Key features of the IST approach were to train staff as a whole group (including managers) who worked together, obtaining administrative support for changes, assessing staff needs prior to training, and forming a committee responsible for decision-making regarding the organization of the training. In addition to the topics typically covered, the training also included sessions on the organizational barriers to implementing strategies and practical implications of management guidelines. Significant improvements in staff knowledge were found following training, although no follow-up was conducted in this study.

Kalsy et al. (2007) examined if a 4-h workshop could improve the knowledge of staff who worked with clients with Down syndrome, dementia and challenging behavior. The intervention consisted of teaching on the disease course of dementia, health problems, behavioral descriptors, assessment, and intervention options. Significant increases in knowledge were found following the training, though the measure related to aging and intellectual disabilities not specifically to challenging behavior. Overall, results suggest that short programs can increase knowledge; however, there are some inconsistencies as to how much and which elements of knowledge are retained.

Changing Attributions

There is an increasing recognition that addressing the way that staff understand challenging behavior can have a significant effect on how staff behave towards clients (Ager & O'May, 2001; Rose, 2011). Weiner's (1980, 1993) work provides a basis for understanding the impact of attributions, suggesting that if care staff attributed greater personal control over their actions to a client they were less sympathetic and less likely to help them than if they attributed the causes of the challenging behavior to be due to factors which were outside of the client's personal control (Rose, 2011). Research has supported the role of controllability attributions in mediating helping behavior (Dagnan, Trower, & Smith, 1998; Hill & Dagnan, 2002), suggesting that staff who hold negative perceptions are more likely to confront clients (Jahoda & Wanless, 2005), which can be unhelpful and that controllability attributions can be altered.

Williams, Dagnan, Rodgers, and McDowell (2012) reviewed the evidence for changes in carers attributions towards the behavior of people with intellectual disabilities as a consequence of training in challenging behavior. Eleven papers were reviewed that generally used a behavioral framework for staff training. While none explicitly set out to change attributions 8 of the 11 papers they reviewed reported changes in attributions. This implies that changes in attributions can occur even though these are not identified as a focus for training.

Studies have used a variety of means to assess whether staff appraisal of challenging behavior can be altered by training interventions. Berryman et al. (1994) was one of the first studies to address staff attributions of challenging behavior and move beyond a traditional operant behavioral approach. They evaluated the effects of two types of 1-day training. One group received training in traditional behavior management while a second group received training in understanding behavior in relation to a person's past experiences and social context, including teaching on functional alternatives in communication and improving quality of life. The results indicated that staff in the latter group reported a significant increase in attributions for the cause of the challenging behavior as due to external reasons such as escape-avoidance processes and tangible reinforcement and a significant reduction in the selection of categories of internal attributions such as the clients' emotions and low self-esteem as causes of challenging behavior (measured by the Causal Attributions for Challenging Behavior Scale). This change was significantly different from the group who were provided with the traditional behavioral management intervention, who tended to attribute clients' challenging behavior as a direct result of internal processes within the client such as emotions. The differences between groups were maintained at 9-month follow-up suggesting that staff who received the training focusing on client experiences continued to consider more external reasons for the cause of challenging behavior. This result suggests that staff who received the training focusing on past experiences of clients would be more likely to help and support their clients through their challenging behavior (Rose, 2011).

The study also assessed how the training influenced the development of behavioral plans by staff. Significant differences were found between the two groups, with no significant changes over time found in the intervention plans of staff in the traditional behavior management intervention whereas the group who focused on past experiences demonstrated a greater emphasis on helping clients to achieve new skills and a greater emphasis on functional analysis in their plans. These changes are likely to have a beneficial impact on client outcomes.

Significant changes in attributions after training were also found by Kalsy et al. (2007) who also investigated changes in attributions in addition to knowledge following a 4-h training session. The Controllability Beliefs Scale (Dagnan, Grant, & McDonnell, 2004) was used to assess how much control care staff believed clients with Down syndrome and dementia had over their challenging behavior. Following the training, staff reported significantly lower controllability attribution scores for their clients, suggesting that significantly less control was attributed to clients over their challenging behavior. Again, this result would suggest that staff are more likely to try and understand the reasons for the challenging behavior they are managing with and to use more constructive approaches to management.

Studies of attributional change have not always found consistent effects. Tierney, Quilan, and Hastings (2007) assessed changes in attributions, emotional reactions, and feelings of self-efficacy of staff after attending a 3-day training on understanding challenging behavior. The training included teaching on behavioral and functional assessment, using a "Positive Behavioral Support Plan," coping with stress and provided techniques from the "Non Violent Crisis Intervention Training Programme." The program centered on crisis development and appropriate interventions during and following challenging behavior. Attributions were measured by the Challenging Behavior Attributions Scale (Hastings, 1997), emotional reactions by the Emotional Reactions to Challenging Behavior Scale (Mitchell & Hastings, 1998), and self-efficacy by a 5-item Likert scale. Following training, there were no significant changes in either attributions or emotional reaction scores but a significant increase was found in staff ratings of self-efficacy. Tierney et al. (2007) had wanted to establish whether a "typical staff training approach" (i.e., fairly standard material being covered, e.g., causes of challenging behavior, functional analysis, importance of communication, precipitating factors to challenging behavior) could lead to cognitive and emotional changes in staff. Their findings suggest that a "typical" training is likely to be sufficient to improve staff feelings of self-efficacy but is insufficient to alter their cognitions or negative emotional reactions to challenging behavior and that or more targeted approach may be needed which specifically includes information on values and the specific causes of challenging behavior.

Dowey, Toogood, Hastings, and Nash (2007) investigated whether a 1-day workshop could alter staff causal explanations of challenging behavior. The workshop was presented as a pre-training for later skills based training. Lectures, vignettes, and role-play exercises were used to teach staff about the causes of challenging behavior, including the role of the environment in shaping behaviors and aspects of Applied Behavioral Analysis. The training also included a lecture on quality of life issues such as choice, respect, community presence, and participation. Changes in attributions were measured using a modified subscale of the Self-Injury Behavioral Understanding Questionnaire (Oliver, Hall, Hales, & Head, 1996). This required participants to read 11 scenarios and select from four possible causal explanations for the challenging behavior that reflected behaviorally correct, behaviorally incorrect, internal emotional or internal organic explanations. Following training, there was a significant increase in the use of behavioral explanations compared to explanations relating to the emotional or organic state of the client. However, the increase in behavioral explanations consisted of a significant increase in both behaviorally correct and behaviorally incorrect explanations. This study implies that training can change causal thinking about challenging behavior and that staff may have gained a general understanding that challenging behavior can be related to environmental and situational reasons but 1 day may not have allowed enough time for staff to develop their thinking to answer the questions correctly.

McKenzie et al. (2002) also measured attributions in addition to knowledge, but only in a small subgroup of participants ($n = 14$). Attributions were measured using two methods. The first was a bipolar scale based on four attributional dimensions suggested by Munton, Silvester, Stratton, and Hanks (1999) which were internal-external, controllable-uncontrollable, stable-unstable, and global-specific. The second was open ended questions about the causes of challenging behavior, which were scored using Bromley and Emerson's (1995) categories which included a wide range of possible causes such as internal psychological state, environment, stimulation, communication, medical, mental illness, or escape (McKenzie et al., 2002). Practice was assessed in a 4-h assessment of a series of tasks set in relation to a selected client in accordance with the Periodic Service Review (PSR, La Vigna, Willis, Shaull, Abedi, & Sweitzer, 1994). Examples of PSR tasks included the accurate recording of a client's behavior, reactive strategies and treatments selected, and the appropriate use of reinforcement. This was done immediately after the training and at 8 weeks follow-up; however, no significant changes were found in staff ratings on attributional dimensions but a significant decrease was found in the selection of the category of "communication deficit" at follow-up compared to pre-training. This suggests that some attributions may have been changing. Significant changes were also found in staff practice following training. The authors concluded that attributional change does not play a key role in changing staff practice however, the numbers of staff involved were small and the design weak as there was no comparison group.

Rose et al. (2014) provided a 1-day training which focused on developing a positive attitude and understanding challenging behavior as an alternative means of communication. This was embedded within a PBS approach where staff attributions and attitudes were measured at four time points, 1 week prior to training, immediately before and after training, and after 2 months follow-up. Following training, significant changes in staff attributions and attitudes were recorded, after the training, staff judged challenging behavior to be less under clients' personal control than they had been prior to the training. The changes in attributions were consistent with findings by Berryman et al. (1994), Kalsy et al. (2007), and Dowey et al. (2007). In accordance with Weiner's model (Weiner, 1980, 1993), these findings should lead to a corresponding increase in the helping behavior of staff towards the clients they work with. Following training, staff also demonstrated significantly more positive attitudes towards working with people with intellectual disabilities and challenging behavior and staff retained a more positive attitude at 2 months follow-up.

This training was designed as a base for educating front-line staff on the principles of PBS and resulted in a positive impact on staff attributions and attitudes.

Enabling staff to develop the right attitude in working with clients with an intellectual disability and challenging behavior was considered fundamental to this training, and as a result there was an emphasis on attitude change.

Emotional Intelligence

Emotional Intelligence has been defined as "an array of emotional, personal and social abilities and skills that influence an individual's ability to cope effectively with environmental demands and pressures" (Bar-On & Parker, 2000, p. 1108). This has led to a number of training interventions that aim to develop emotional intelligence along with improvements in interactions between staff and people with intellectual disabilities that are designed to reduce challenging behavior (e.g., Embregts, Zijlmans, Gerits, & Bosman, 2017;

Zijlmans, Embregts, Gerits, Bosman, & Derksen, 2011; Zijlmans, Embregts, Gerits, Bosman, & Derksen, 2015).

Emotional Intelligence has been suggested as a focus for training after studies have found a link between staff emotions and the challenging behavior of people they care for. Wanless and Jahoda (2002) compared different methods of examining emotional and cognitive responses of staff who frequently worked with aggressive clients. They examined responses to descriptive vignettes and real incidents of aggression previously experienced by staff and found that staff experienced more negative emotions when recalling real incidents of aggression when compared to vignettes. Staff perceptions of their aggressive clients were often linked to their cognitive and emotional responses to the aggression they had experienced previously. Mills and Rose (2011) also found that negative emotions mediate the relationship between challenging behavior and burnout in staff. It has also been suggested that adaptive success by staff in working with people who have challenging behavior is determined by their emotional intelligence (Gerits, Derksen, & Verbruggen, 2004).

Zijlmans et al. (2015) focused on the effectiveness of staff training aimed at staff emotional intelligence and staff interactions with clients. The effects of the training on emotional intelligence, coping style, and emotions of support staff were investigated. Two-hundred and fourteen support staff working in residential settings for individuals with ID and challenging behavior were split into an experimental group of 76 staff and 138 staff in two control groups. Questionnaires addressing emotional intelligence, coping, and emotions assessed effectiveness. The emotional intelligence of the experimental group changed significantly more than the two control groups. The results with regard to task oriented coping and emotions were mixed. Follow-up data suggested that the improvements within the experimental group were present 4 months after the training concluded, suggesting the intervention was effective in improving emotional intelligence of support staff.

Embregts et al. (2017) extended this work on training to evaluate the effects on emotional intelligence and support staffs' awareness of the impact on their behavior based on interactional patterns. The support provided for staff focused on the needs for autonomy, relatedness, and competence. This intervention was a pre-post test control group design ($N = 29$), with 17 support staff in the experimental group. The training program initially focused on the concept of emotional intelligence and its significance for caring and teamwork over the first 2 days. Support staff also received feedback on their scores on the Bar-On Emotional Quotient-inventory (EQ-i) (Derksen, Jeuken, & Klein Herenbrink, 1998). This approach was used to formulate goals that were translated into individual developmental plans such as aiming to work in a more structured way or to improve an ability to understand the emotional needs of specific clients. Support staff were asked to work on plans individually with feedback and support from the trainers. Support staff were asked to make video recordings of themselves interacting with clients. These videos were reviewed by support staff and trainers together and linked to the training protocols which aimed to increase desirable behaviors related to emotional intelligence and their chosen specific goals. Trainers followed specific protocols for the description of responses such as contingent praise, and corrective comments to ensure consistency across sessions. On completion of training support staff received feedback on their new EI profiles, based on a newly administered EQ-i. Staff were also asked to make new video recordings of them interacting with their clients for a further evaluation. For both groups of staff video recordings of interactions with residents were analyzed. Interactional patterns in the videos suggested that the training had had a positive impact on the support that staff gave to residents in developing their autonomy, relatedness, and competence. These results suggest that training with a focus on emotional intelligence can improve staff interactions with residents and results are similar to more general stress management training with staff which has been shown to both reduce stress in staff and increase the amount of assistance staff provide to residents (Gardner, Rose, Tyler, & Cushway, 2005; Rose et al., 1998a). However, whether these results are achieved by increasing emotional intelligence or through some other means needs further scrutiny as other research suggests that emotional intelligence is not clearly linked to staff outcomes such as burnout and stress (Shead, Scott, & Rose, 2016).

Communication and Values Based Approaches

Some programs have targeted different elements of staff behavior with a view to change attributions of staff. Smidt, Balandin, Reed, and Sigafoos (2007) found that after the implementation of four, two and a half hour training sessions using a "MOSIAC" package (Model of Interaction for the Analysis of Interaction and Communication), there were some initial increases in the use of augmentative communication skills by staff (n = 18) and some small changes in attributions (measured by the CHABA). However, this was only maintained at follow-up (6 month and 12 month) by one organization out of three who participated. There was also little impact on challenging behavior recorded by staff which was ascertained through an audit of clients' incident forms.

The brief training described by Rose et al. (2014) which had a focus on attributional change also had an emphasis on encouraging staff to think about how they themselves would feel and respond in a situation where they were unable to communicate with a view to helping staff understand why challenging behavior might occur. This approach may have contributed to a change in attitudes and attributions by increasing staffs' understanding and empathy towards people with intellectual disabilities and challenging behavior.

Environmental Approaches

An alternative focus for staff training is provided by nidotherapy which attempts to reduce challenging behavior by changing the living environment to create a better fit between the person, their environment and society and in so doing reduce the frequency of challenging behaviors expressed by clients. Nidotherapy attempts to treat the problems of challenging behavior not by treating the behavior directly, but by changing the environment to create a better fit between the person and their environment (Tyrer, Sensky, & Mitchard, 2003). Nidotherapy has been applied to different chronic mental health problems (Tyrer, Kramo, Milošeska, & Seivewright, 2007), often when other interventions have failed. In a recent study (Tyrer et al., 2017), nidotherapy was introduced to staff by providing a series of structured staff training sessions to all staff involved in the direct care of clients over a period of 6 months. The four components of training include: (1) nidotherapy—person-environment understanding; (2) environmental analysis; (3) creation of a new environmental pathway (nidopathway); and (4) monitoring of the pathway. These training sessions were delivered to staff over a 6-month period. These training sessions are delivered with discussion in relation to actual episodes of challenging behavior that occur within the environment. In a randomized control trial staff in twenty homes either received training in nidotherapy or the enhanced care program approach (ECPA), the latter approach involved structured assessment of the person with challenging behavior, the development of individual goals, and monitoring of those goals. The duration of training provided was equivalent within each arm of the trial. A number of measures of challenging behavior were used to record incidents over the course of the trial. A total of 200 residents entered the trial, 115 allocated to the ECPA arm and 85 to the nidotherapy. No statistically significant reductions in challenging behavior were demonstrated over the trial in either group, but in the last 7 months, those allocated to nidotherapy had a 33% reduction in Modified Overt Aggression Scale scores and a 43% reduction in Problem Behavior Check List scores compared with much smaller reductions for the ECPA group. The changes on the MOAS were close to statistical significance over the last 7 months of the trial. This suggests that a nidotherapy approach may be worth exploring further as the delay in possible effect seems consistent with an intervention provided through staff in relation to environmental change where a delay in implementation and effect would seem likely.

Methodological Issues

The Tyrer et al. (2017) study of nidotherapy was one of the most methodologically robust of those reported as it was a cluster randomized control trial with blinding between the two intervention groups; however, it was the exception and there were a range of methodological weaknesses identified with many of the other studies reported here. In general, there was a lack of clear reporting with regard to the populations from which the samples were recruited, the numbers of staff prepared to participate compared to the numbers of staff invited to training or the numbers of participants lost to follow-up. In many studies there was also an absence of blinding procedures, some studies did not collect follow-up data and there was no consideration of factors that could confound the results, e.g., whether staff had recently attended other relevant behavior training. Another internal validity issue frequently identified was the accuracy of the main outcome measures used. For example, the measure used in Gentry et al.'s (2001) study that detected highly significant increases in staff knowledge scores was an "ad hoc" measure with no detail about its structure, development, reliability, or validity. Psychometric properties are also not reported for the 20-item knowledge quiz used in the study by Kalsy et al. (2007). McKenzie et al. (2002) employed a self-assessment visual analogue scale on which staff were required to rate how much they believed their knowledge of challenging behavior had changed following training. Therefore, subjective perceptions about improvements in knowledge, not actual changes, were obtained.

While there appeared to be a greater use of standardized tools for the measurement of attributions, there are still some issues. Tierney et al. (2007) found no changes in staff attributions following a 3-day workshop. They used the CHABA (Hastings, 1997) to measure attributions and the authors themselves highlight the low levels of internal consistency of the CHABA on several sub scales which may lead to these results being questionned. Another issue was that post-training scores were only gathered after 3 months and so their conclusion that training did not significantly change staff attributions may be inaccurate, as a better design incorporating both immediate and follow-up data collection may have shown that changes in attribution scores occurred but were not maintained at follow-up. McDonnell (1997) found that a large number of staff attributed their increase in confidence to the role-play exercises but there are also concerns about the generalizability of changes in staff attributions translating to a positive impact on working directly with clients.

The Impact of Short Staff Training

Despite concerns about the methodology of many of the studies, the evidence suggests that brief training has a role to play in increasing staff knowledge, for example, knowledge on intellectual disabilities, challenging behavior, and proactive and reactive strategies. The effectiveness of training of staff is consistent, at least with regard to immediate impact. The evidence also suggests that training can change staff attributions relating to challenging behavior in that following training, staff generally give more consideration to reasons external to the person (i.e., environmental or situational) as causes of challenging behavior with less focus on internal state. The literature also implies that training can improve staff confidence, emotional intelligence, the quality of physical intervention techniques and some other aspects of staff practice such as the development and implementation of behavioral guidelines. Increasing staff knowledge may alter the way staff approach clients, which could reduce the chances of incidents occurring (Van Oorsouw et al., 2010). It is recognized that in care services there are often poor levels of knowledge but all staff require the necessary knowledge to work with people with challenging behavior (Ball, Bush, & Emerson, 2004). As a result it seems important that all staff should have access to at least basic training to help them gain an appreciation of challenging behavior.

There is some indication from the studies discussed here that a "typical training approach" of a single day is sufficient to change levels of knowledge but may be insufficient to change staff attributions or emotional reactions, even where training is 3 days long rather than a single day. A more targeted approach which addresses values and beliefs of staff may be required for changes in these variables. The evidence for changing staff behavior is even weaker; however, some studies are starting to encompass measures of behavior change indicating some positive changes are possible (e.g., Embregts et al., 2017).

The Maintenance of the Impact of Training

The evidence suggests that there is a role for staff training and that it is important to train staff so that they can support individuals with intellectual disability and challenging behavior effectively. This leads to the implication that services need to ensure that all staff can become trained, understand what they are told and are able to apply what they have learnt consistently and over time. At present, much training is not mandatory particularly in relation to challenging behavior and there is a need for services to address training needs.

It would be beneficial for any organizational strategy to include a system which ensured that staff are regularly updated and those who require further training are identified. In the study by Berryman et al. (1994) changes in attributions were maintained at 9-month follow-up and the authors describe the use of biweekly supervision as a methodology for reinforcing the training intervention. This also implies that the role of supervision as part of an overall strategy to maintain improved staff performance may be important. It has been recognized that there is variation in what staff and employers deem to be the remit and responsibilities of their jobs (Campbell, 2011). For a multifaceted strategy to work, value must be placed on staff development by all involved. Recognizing the impact of organizational barriers on new learning, Gentry et al. (2001) and Dowey et al. (2007) used approaches that addressed aspects of organizational culture. Individualizing training for a team may improve the likelihood of training having an impact, by increasing the contextual fit between the taught ideas and their acceptability (Grey et al., 2007).

Rose and Burns (2011) and Rose, Harris, and Burns (2010) suggested a framework for staff support which provides a range of potential areas to support staff and prevent staff burnout. This framework includes staff support interventions that can be introduced proactively such as supervision and risk assessment but also reactive strategies such as appropriate physical skills training and responsive elements such as incident analysis and behavioral skills training. A modified version of this framework is provided in Fig. 10.1 which reframes many elements which were elements of a support framework in terms of training interventions and ongoing management functions that are likely to ensure that the benefits of training are maintained and applied effectively on a regular basis. This revised framework suggests a range of discrete areas of training that can be provided to staff over time dependent upon their needs and a range of organizational methodologies that can be used to maintain these skills. Some of these areas could be seen as universally applied to all staff such as ensuring that they are able to demonstrate appropriate attitudes and values. For example, all staff are likely to be involved with incidents of challenging behavior as a result they need to be able to record incidents accurately and in a way that can be understood by others. However, staff may not be required to formulate the reason for the challenging behavior as other staff such as psychologists or behavioral specialists may be available to support them to understand what is going on and develop collaborative formulations. Supervision and regular monitoring of performance by management would be an essential part of the development and monitoring

Proactive Training	**Reactive Training**	**Responsive Training**
• Person centered values and attitudes training • Increasing knowledge • Training on the communicative aspects of challenging behavior • Training on attributions of challenging behavior • Training on emotional intelligence • Training on Risk assessment/risk management culture	• Appropriate physical skills training	• Nidotherapy • Behavioral skills training. • Incident analysis • Formulation
Proactive Support	**Reactive Support**	**Responsive Support**
• Reflective practice groups • Supervision • Stress management processes	• Post incident support	• Individual support (formal and informal) • Psychological support

of staff performance to ensure that staff are interpreting and implementing their training effectively.

Models exist for the implementation of training focused framework described here, particularly, Positive Behavioral Support and Active Support; however, by reviewing the individual elements of training it may be possible to consider which elements are required in any particular environment and as a result target training interventions more precisely to the needs of the people with intellectual disability, thus focusing effort and resources more effectively.

The development of focus in training interventions has synergy with the idea of practice leadership in intellectual disability settings. In a qualitative study, interviewing managers of staffed group homes, Deveau and McGill (2014) identified monitoring staff performance, supporting new ways of working, shaping staff performance, influence of external agencies, and importance of participants' personal values and experiences as a set of themes for defining practice leadership. These themes resonate with the suggestions for implementing staff training interventions and further work by Deveau and McGill (2016) and Deveau (2016) suggests that effective practice leadership is associated with greater job satisfaction and positive experiences for staff.

Conclusions

Training for direct care staff is one important element of providing effective support to people with intellectual disabilities with challenging behavior. The evidence base suggests that short training courses can be effective; however, there is considerable variation in the results of evaluations and that a number of factors need to be considered to ensure training success and particularly in relation to any gains made by training. The evidence for any change in the behavior of staff and people with intellectual disabilities as a result of training also remains relatively poor with few studies examining these outcomes. However, it is clear that to provide effective and appropriate training to staff in direct care roles who work with people with challenging behavior requires considerable thought and organization which needs to be maintained in relation to the changing needs of the people with intellectual disabilities that they serve.

Multidisciplinary Teams

Patricia M. Noonan and Amy S. Gaumer Erickson

The complex nature of intellectual disabilities means that multiple professionals must work together to promote quality transition services and successful post-school outcomes. The composition of these teams may vary based on the complexity of a student's disability or disabilities, the student's age, and the context in which services are provided. Schools, community agencies, healthcare providers, and nonprofits can work together to provide quality supports and services for individuals, but there are innate challenges. This chapter explores how to achieve productive collaboration by incorporating specific strategies and developing necessary capacities for promoting and facilitating adult professional teaming.

Overview

Young adults with intellectual disabilities too often experience low post-school outcomes such as: (a) poor graduation rates from high school, (b) low employment rates after high school, and (c) low participation in post-secondary education. These outcomes often lead to lower quality of life and an increasing number of youths receiving Social Security or other welfare program benefits or being incarcerated (Johnson, Thurlow, & Stout, 2007; National Center on Secondary Education and Transition, 2004; Newman, Wagner, Cameto, Knokey, & Shaver, 2010; Taylor, Krane, & Orkis, 2010). One critical strategy for improving these outcomes is increased collaboration and teaming between professionals to facilitate seamless supports and services tailored to each individual.

For over two decades, the field has repeatedly acknowledged that interagency collaboration plays a critical role in positive post-school outcomes (Carter et al., 2009; Kohler & Field, 2003; Morningstar, Kleinhammer-Tramill, & Lattin, 1999; Noonan, Morningstar, & Gaumer Erickson, 2008; Noonan, Morningstar, & Lattin, 2008; Test et al., 2009). These critical linkages are significant factors in promoting higher employment and post-secondary educational outcomes, especially for students with intellectual disabilities (Bullis, Davis, Bull, & Johnson, 1995; Hasazi, Furney, & DeStefano, 1999; Rabren, Dunn, & Chambers, 2002; Repetto, Webb, Garvan, & Washington, 2002).

While collaboration between agencies supporting adults with disabilities is important, it is vital to establish linkages between agencies, the K-12 education system, and other relevant agencies early on, while students are receiving K-12 services and supports. Interagency collaboration

Series, https://doi.org/10.1007/978-3-030-20843-1_11

is critical to transition planning and related supports in middle and high school; additionally, it facilitates better linkages to adult agencies and higher outcomes for young adults with disabilities (Hasazi et al., 1999; Kohler & Field, 2003; Rabren et al., 2002; Repetto et al., 2002). In other words, for optimal success, we must start early in planning and providing important transition services, and educators should not be working in isolation from adult agencies who may later be providing critical supports.

In addition to promoting better post-school outcomes, much can be gained from increased collaboration between entities such as K-12 education, vocational rehabilitation, workforce investment, employment agencies, developmental disability organizations, social services, chambers of commerce, nonprofits, and others. Collaboration can lead to less duplication of resources, improved professional development, and a cross-flow of information (Blalock, 1996; Wehman, 1998). As we partner to meet the needs of young adults with disabilities in-school and post-school, we often learn that there are gaps in resources and supports which can be filled if understood and targeted. We also learn about other agency services, challenges, and overall goals, and piece together more meaningful supports specific to each individual.

While there is clearly much to be gained, working with other professionals to coordinate services and supports can be challenging. There are numerous barriers to interagency collaboration, including: (a) poor/inaccurate perceptions of outside agencies by school staff, students, and parents (and vice versa) and (b) nonexistent/ineffective procedures for collaboration between school and agency staff throughout the referral, eligibility, determination, and transition planning process (Agran, Cain, & Cavin, 2002; Benz, Johnson, Mikkelsen, & Lindstrom, 1995; Li, 2004). Additional research (Certo, Pumpian, Fisher, Storey, & Smalley, 1997) noted that there are other limitations inherent to the public school systems (i.e., locus of service delivery and staffing patterns) and the adult service sector (i.e., discrepancies between entitlement vs. eligibility and differing supports and services).

More specifically, barriers to interagency collaboration include: (a) lack of shared information on students across agencies; (b) lack of follow-up data on program recipients that could be used to improve transition services; (c) lack of attention to IEP post-secondary goals; (d) lack of systematic transition planning with adult agencies; (e) ineffectual interagency agreements; and (f) difficulties in projecting post-secondary needs and services (Johnson, Stodden, Emanuel, Luecking, & Mack, 2002; Noyes & Sax, 2004). In one study that examined collaboration among adult service providers, the most challenging barriers to overcome were the difficulty in merging professional culture differences and the loss of professional identities among agencies (Timmons, Cohen, & Fesko, 2004). In a review of multiple projects providing mental health services to youths with emotional disabilities, some of the challenges identified were blame and distrust among child-serving agencies, inflexibility, and fear of change (Hodges, Nesman, & Hernandez, 1999). Furthermore, the report concluded that to be effective, collaboration must occur at multiple administrative levels within an agency and across multiple agencies.

To summarize, early research on collaboration and transition succeeded in identifying the critical nature of building the relationships and linkages, as well as identifying barriers to effective professional collaboration in complex systems. Providing quality transition supports in middle and high schools to support positive post-school outcomes requires involvement and commitment from multiple agencies, the family, and the student, throughout both planning and implementation (Kleinhammer-Tramill, Rosenkoetter, & Tramill, 1994; Noyes & Sax, 2004). The ultimate goal of collaboration is to ensure a seamless transition from one agency to the next, thereby providing needed services with minimum disruptions (Halpern, 1994). To accomplish this, educators and agency professionals must successfully engage in collaboration.

Strategies for Collaboration

Interagency collaboration by nature is dynamic; it develops slowly over time as a group as well as between individual members representing agencies. Agencies, such as businesses, healthcare providers, social services, and educators begin to take specific steps toward productive partnerships (Johnson, Zorn, Tam, Lamontagne, & Johnson, 2003). Each agency participates within its own system, and at its own pace, yet continually develops toward providing better services in collaboration with others (Kleinhammer-Tramill et al., 1994; Timmons et al., 2004).

Collaboration as a concept may seem elusive, but research has lent clarity to the definition and construct of collaboration (including characteristics of collaborative activities). Abramson and Rosenthal (1995) defined collaboration as "a fluid process through which a group of diverse, autonomous actors (organizations or individuals) undertakes a joint initiative, solves shared problems, or otherwise achieves common goals." Research indicates that while collaboration is a complex concept, it can be broken down into a theoretical model that contains five variable dimensions: (a) governance, (b) administration, (c) organizational autonomy, (d) mutuality, and (e) norms (Thomson & Perry, 2006; Thomson, Perry, & Miller, 2007). These five dimensions can be assessed by the group, with targeted areas for improved collaboration through activities such as creating group norms and improved communication systems, adding relevant decision-makers as team members, and ensuring an equal balance of power among voices and participating agencies. Their work illustrates that many factors influence and support collaboration, which is an inherently complex concept.

Unsurprisingly, collaborative relationships take time to develop. Achieving optimal levels of interagency collaboration requires members to determine how to work together and to communicate effectively. Purposeful collaborative activities can be characterized as: (a) establishing mutual relationships and goals, (b) jointly developing structures and sharing responsibility, (c) sharing authority and crediting everyone with success, and (d) sharing resources and rewards (Mattessich, 2003; O'Looney, 1993; Parent Advocacy Coalition for Educational Rights, 1994; Walsh, Brabeck, & Howard, 1999). Specific behaviors and mechanisms have been shown to increase collaboration over time (Mancini, Marek, Byrne, & Huebner, 2004).

Researchers in a variety of fields have argued that collaboration develops in distinct stages of between three and seven steps (deFur, 1997; Dunst & Bruder, 2002; Frey, Lohmeier, Lee, & Tollefson, 2006; Gajda, 2004; Hogue, 1993; Peterson, 1991). Frey et al.'s (2006) model includes five clear stages: (a) networking, (b) cooperation, (c) coordination, (d) coalition, and (e) collaboration. Networking is characterized by awareness of the organization, loosely defined roles, and low levels of communication for the purposes of referral only. Cooperation, the second stage, is characterized by providing information to each other, somewhat defined roles, formal communication, and independent decision-making. Coordination, the third stage, is exemplified by sharing information and resources, defined roles, frequent communication, and some shared decision-making. The fourth stage is coalition, which consists of shared ideas, shared resources, frequent prioritized communication, and shared decision-making. Finally, the highest stage is collaboration, exemplified by members belonging to one system, frequent communication with mutual trust, and consensus reached on all decisions.

In 2003, Johnson et al. identified seven interrelated factors related to successful interagency collaboration, which are: (a) commitment, (b) communication, (c) strong leadership from key decision-makers, (d) understanding the culture of other agencies, (e) engaging in serious preplanning, (f) providing adequate resources for collaboration, and (g) minimizing turf issues. These factors were evident in professional partnerships, as adults felt it was part of their charge to learn other systems, build relationships with other agency staff, and gain support of their bosses (e.g., dedicated time, ability to contribute to joint activities, some level of decision-making) to participate. Professionals who collaborated gained an awareness of the culture of other agencies, such as pressures, organization structures, and priorities. That awareness and understanding led to more joint planning and less competition and hesitancy to partner on activities that supported youth and adults with disabilities.

A significant focus of collaboration research has been identifying what quality collaboration in transition looks like, as well as common characteristics of the educators and communities involved. The research led to the identification and description of the standard or goal for collaboration: when agencies collaborate, they function as one entity and are actively engaged in problem-solving, information sharing, and merging of resources (Cashman, 1995; deFur, 1997). When educators and agency professionals can function as one entity, individual members of the transition team are able to make better decisions, as the collective wisdom of the group provides many alternative solutions and ways to address needs (deFur, 1997). This benefits not only the agencies and the student but also families. These collaborative efforts result in families gaining role clarity and greater understanding of the differences between K-12 and adult services and supports, as well as the strengths and limitations of various service provider offerings.

Additionally, these collaborative efforts cannot happen once, or be time-limited. Successful interagency collaboration needs to be sustained, systematized, and characterized by: (a) key positions jointly funded by education and adult services, (b) monthly interagency planning meetings, (c) cross-agency training opportunities, and (d) the use of a variety of practices for collaboration and team-building (Benz, Lindstrom, & Yovanoff, 2000; Hasazi et al., 1999). Mechanisms such as ongoing teaming, joint training, and merged funding are important elements to keep collaboration efforts going over time to truly meet the vision of operating as one entity with strong collaboration.

Researchers have examined and identified specific strategies for increasing collaboration (Spath, Werrbach, & Pine, 2008). One strategy is the concept of "linking agents" (Crandall, 1977; Hamilton et al., 2002; Havelock & Havelock, 1971). A linking agent is a person who fulfills one or more of the four key roles to facilitate collaboration: (a) catalysts, who empower others to bring about change; (b) solutionists, who build awareness of the new ideas; (c) facilitators, who support the processes and procedures that effect change; and (d) linkers, who link to resources and help others receive the support, information, and expertise they need for long-term, sustainable change. The highly knowledgeable linking agent functions as the "go between" for numerous entities and agencies to bridge the implementation gap and facilitate change (Monahan & Scheirer, 1988).

In 2008, Noonan, Morningstar, and Gaumer Erickson identified eleven key strategies that high-performing districts implemented at the local-level related to interagency collaboration. The strategies are: flexible scheduling and staffing, follow-up after transition, administrative support, variety of funding sources, state-supported technical assistance, ability to build relationships, agency meetings with students and families, training students and families, joint training of school and agency staff, meetings with agency staff and transition councils, and dissemination of information to a broad audience. Research results indicated the clear need for a systematic approach to local community readiness and commitment of key stakeholders (i.e., special educators, transition coordinators, administrators, families, and agency staff). Many of the identified strategies required joint efforts of school administrators and staff, community agencies, and families—meaning that the task of increasing collaboration could not fall solely on one entity.

In 2014, Dr. Noonan and the Council for Exceptional Children published the book *Transition Teaming: 26 Strategies for Interagency Collaboration* (Noonan, 2014). The book provides secondary special educators and their adult agency counterparts with concrete strategies for building collaborative relationships. Part of the book focuses on strategies that individual educators can use immediately, such as reflection, increased awareness of partners, relationship-building activities, and outreach. Through these daily mechanisms, individuals expand their personal efforts toward collaboration. In the book, each personal strategy is identified and then described with specific activities and examples in detail. Strategies and activities include:

Strategy 1: Gain an understanding of how coworkers' jobs are related to transition.

- Interview school personnel to better understand charge.

Strategy 2: Increase awareness and knowledge of adult agency services.

- Develop or expand a list of community resources.
- Join community organizations and committees.

Strategy 3: Gain administrator buy-in.

- Present at a school board meeting.
- Update administration regularly via email or meetings.

Strategy 4: Communicate information about transition to coworkers.

- Present to coworkers.
- Provide information in a communal space.

Strategy 5: Communicate information about transition to local community.

- Develop an "elevator speech."
- Write an article for the local newspaper.
- Present to community organizations.

Strategy 6: Communicate information about transition to families.

- Disseminate information to families.
- Facilitate meetings with agencies, students, and families.
- Tour local agencies.

Strategy 7: Coordinate with coworkers to provide transition services.

- Assess your school's college and career readiness practices.
- Identify school assessment practices that support transition.

Strategy 8: Coordinate with community agencies to provide transition services.

- Connect your students to community agencies.
- Plan a collaborative project.

Strategy 9: Participate in professional development related to transition.

- Attend regional or state transition conferences.
- Join national organizations and attend national conferences.

Strategy 10: Participate in professional development sponsored by community agencies.

- Attend trainings provided by community entities.

In later chapters, *Transition Teaming: 26 Strategies for Interagency Collaboration* details a step-by-step process to form a functioning, action-oriented transition team. In the early 1990s, community transition teams (CTTs) emerged as a model of facilitating interagency collaboration, with the key function of creating linkages between education and adult services through teaming (Blalock & Benz, 1999). Community transition teams (also referred to as transition councils) are typified as being composed of local, community-level representatives of schools; disability-related agencies and community organizations; families and students; and other stakeholders who join together to improve local transition services for youths with disabilities. The theory behind this model is that community transition teams will be able to help students and families secure resources to accomplish their transition plan by improving the capacity of schools and communities to deliver better services (Benz, Lindstrom, & Halpern, 1995). Because community transition teams focus on services at the local level, they are better able to: (a) share resources, (b) hold informational fairs, and (c) influence local policies and procedures (deFur, 1999). Team membership often includes representatives of the local schools, students and/or former students, family members, One-Stop centers, vocational rehabilitation, developmental disability organizations, independent living centers, post-secondary training organizations, and local businesses (Halpern, Benz, & Lindstrom, 1992). Community transition teams work to create community cohesiveness and increase community capacity by avoiding service duplication and targeting emerging community transition needs (Clark & McDonnell, 1994). As Benz, Lindstrom, and Halpern (1995) reflected, systems change depends on the critical components of: (a) active participation of diverse stakeholders, (b) viewing change as a process and not as an event, and (c) local community partnerships that are supported by a larger structure that sustains and validates efforts.

Community transition teams work to identify needs, plan and implement new programs, and evaluate team efforts in order to modify and improve services for youths with disabilities. Structured teaming with the ongoing use of data to drive decision-making sustains transition teaming (Noonan, 2014). Through strategies 11–26, individuals expand their interpersonal efforts toward collaboration. In the book, each teaming strategy is identified and described with specific activities and examples in detail. Strategies and activities include:

Strategy 11: Develop a community transition team.

- Discuss your community's and students' needs.
- Generate a list of potential team members.
- Plan the first meeting.

Strategy 12: Identify a shared vision.

- Identify individual visions.
- Identify a team vision.

Strategy 13: Conduct community transition team meetings.

- Establish meeting norms.
- Use agendas and minutes.

Strategy 14: Organize your community transition team.

Strategy 15: Conduct community resource mapping.

Strategy 16: Host a community conversation.

Strategy 17: Determine team structure—critical representation, team organization.

Strategy 18: Engage in action-oriented teaming—annual planning, action planning, short-term projects.

- Create a detailed action plan spanning a specific period of time.
- Brainstorm specific activities that will lead to a commonly desired outcome.
- Provide sufficient, relevant details and include follow-up steps.

Strategy 19: Come to consensus.

- Adopt techniques for quick voting, weighted voting.

Strategy 20: Assess shared leadership.

Strategy 21: Use Data as a community transition team.

Strategy 22: Use data that is already available to your community transition team.

- Review post-school outcome and academic data.
- Discuss community data, such as employment data.

Strategy 23: Engage in data collection and information gathering.

- Utilize surveys to improve transition curriculum.
- Research to expand opportunities or services.
- Create your own survey.

Strategy 24: Plan for sustainability.

- Identify sustainability strengths and barriers.
- Launch a sustainability survey and develop sustainability goals.
- Apply for funding.
- Create brochures, articles, and products that preserve the history.

Strategy 25: Develop bylaws.

Strategy 26: Develop formal Interagency Agreements.

- Create Memorandums of Understanding (MOUs).

To further facilitate community transition teaming, Noonan and Gaumer Erickson (2013) developed a fidelity tool, where teams discussed several indicators and determined if each was in place. If it was not in place, teams brainstormed action items to promote better teaming. Indicators include:

1. Community transition team is established and includes critical representation based on community needs (e.g., school personnel, Centers for Independent Living, Department of Mental Health and Vocational Rehabilitation counselors, family members, employers).
2. Community transition team is representative of community and reflects community needs.
3. Community transition team has established a team name and used the Mini-Maps process to develop a shared vision with the expanded team.
4. Community transition team meets monthly at a minimum.
5. Community transition team has identified community and transition areas of need and prioritized five major goals. Entire team is knowledgeable of these goals.
6. Based on team goals, community transition team jointly developed an action plan that outlines activities, persons responsible, and timeline for reaching goals. Action plan is reviewed and updated at every meeting.
7. Team norms or ground rules have been established and agreed upon.
8. Meeting structure (i.e., agenda and timing) has been established and agreed upon.
9. An organizational system for tracking meeting notes, materials, and data has been established and is maintained.
10. A system of assigned or rotated roles (e.g., facilitator, note-keeper, time-keeper) is defined to assure high quality and effective meeting time.
11. Community transition team members have equal voice when planning team activities.
12. Process for reaching a team decision (i.e., consensus or majority vote) has been defined and adopted.
13. Building administration—that is, principal or district level administrator—attends community transition team meeting at least three times a year (e.g., fall, winter, spring) and receives agenda and minutes for every meeting.
14. Community transition team collaboratively reflects on areas of local need identified through data (e.g., Indicator 13 compliance data, drop-out data, graduation rates, outcomes, etc.).
15. Community transition team systematically uses data to drive decision-making.
16. Community transition team systematically shares information with appropriate district-wide staff and administrators.
17. Community transition team systematically shares transition information with community and families.
18. Community transition team systematically communicates with surrounding districts about team initiatives.
19. Transition-related professional development events are included on CTT meeting agendas for dissemination and discussion.
20. At least annually, community transition team revisits and updates an action plan that addresses the prioritized needs identified through data analysis.
21. District leadership is familiar with the contents of the action plan.
22. Community transition team membership is reviewed at least annually and new members are recruited.
23. A process is in place to welcome new members to team.
24. Bylaws have been developed by the community transition team.
25. Sustainability plan has been developed by CTT and is revisited at least annually.

On an ongoing basis, community transition teams can discuss the list of indicators in order to identify strengths as well as areas for improvement. The higher the degree to which teams address the indicators, the more likely they are to sustain membership and maintain a high level of functioning.

Competencies to Support Collaboration

Although specific strategies for interagency collaboration have been identified, professionals from both education and support agencies are not always provided foundational training on the behaviors necessary to develop collaborative working relationships or productive teams. Knott and Asselin (1999) surveyed secondary special education regarding the most important aspects of their jobs, and found that while teachers rated interagency collaboration as important, they did not know how to accomplish this task. Teachers also indicated that pre-service and in-service training needed to focus less on philosophical, historical, and legal foundations of transition and more on communication and interagency collaboration. Some felt that training should move beyond, "What is transition planning?" to "How do I accomplish planning that will lead to successful transitions?" (Knott & Asselin, 1999, p.3). Li (2004) surveyed 1000 secondary special educators and transition coordinators and found that educators as a whole recognized the importance of interagency collaboration (4.35 on 5.0 scale). This study also found that if the respondents were adequately trained in and committed to transition, they had higher perceptions of interagency collaboration and more transition involvement. Therefore, two major barriers to interagency collaboration are a lack of training in transition and a lack of commitment to transition activities (Li, 2004).

Collaboration must begin with adults using clear, purposeful behaviors to build relationships with each other. In its essence, "collaboration is a way of thinking and relating, a philosophy, a paradigm shift, an attitude change. It requires a set of behaviors, beliefs, attitudes, and values. The result is a sense of shared ownership, shared responsibility, shared success" (Bishop, Wolf, & Arango, 1993).

When educators and adult agency staff agree that building partnerships with others is part of their personal charge, they expand their efforts to identify and implement strategies to increase collaboration. These concepts and strategies can be embedded to improve transition outcomes for students. To increase collaboration between entities, professionals should focus efforts at the individual level on a daily basis. As we work to collaborate, the benefits are immense, as students with intellectual disabilities will have better access to higher quality services. Professionals will benefit from improved staff relationships and the cross-fertilization of ideas. This shared responsibility may bring expenses at times, but it also comes with decreased duplication of efforts. Despite the potential gains, many educators find themselves unable to implement collaboration strategies due to limitations in necessary inter- and intrapersonal competencies. To address this need, professionals can work to develop these competencies by learning the basics, practicing, taking risks, and working to increase self-awareness throughout the process. Six approaches can support educators and disability professionals in a self-improvement process, including:

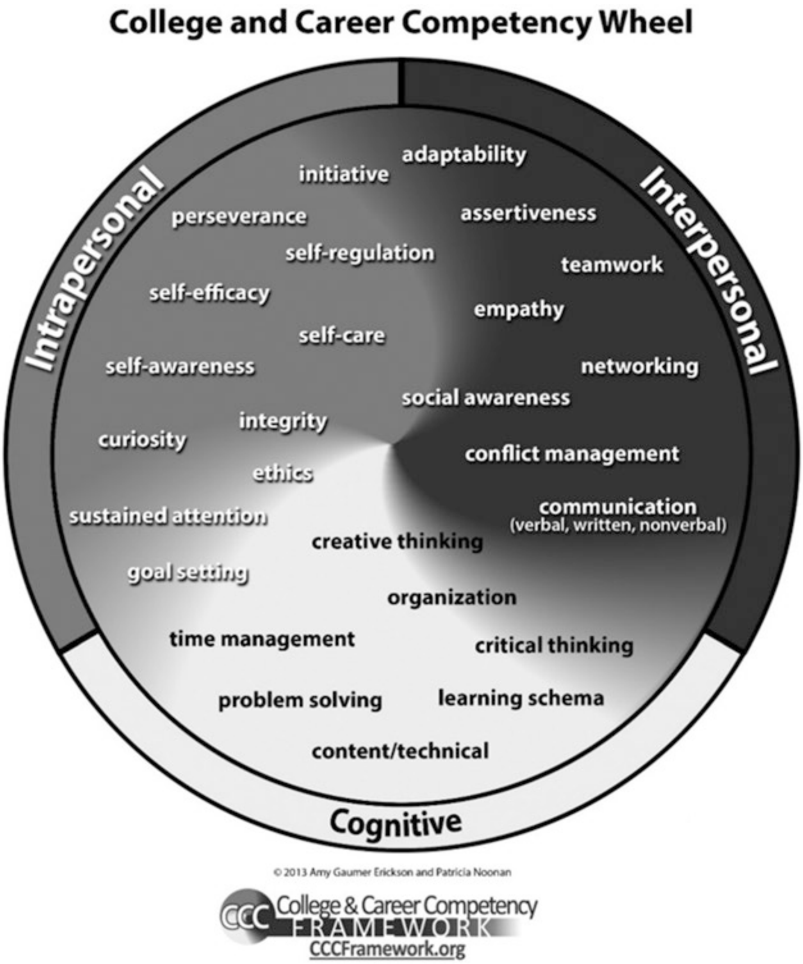
1. Speak a common language.
2. Learn services and agencies outside your own.
3. Partner with others to accommodate and meet their charge.
4. Employ action-oriented behaviors.
5. Work through past and current issues.
6. Believe that your collaboration abilities will improve.

Speak a Common Language

To speak a common language among professionals, we must begin describing students' intra- and interpersonal strengths in a consistent, easy-to-understand way to allow better communication between educators, adult agency staff, students, parents, nonprofits, and employers. As Noonan and Gaumer Erickson note in their 2018 book *The Skills that Matter: Teaching Interpersonal and Intrapersonal Competencies in Any Classroom,* college and career competencies can provide us a language to communicate with each other more meaningfully. Their work includes the *College and Career Competency Wheel*, which identifies 26 competencies critical to in-school and post-school success, categorized into three domains: intrapersonal (focusing on students' internal, reflective capacities), interpersonal (focusing on capacities related to cooperation and interaction with others), and cognitive (focusing on effectively processing and using information).

The 26 competencies can be considered social/emotional competencies, as well as critical employability skills for success in career paths and post-school education and training. Each of the 26 competencies has a foundation of evidence that they can be taught to adolescents, have demonstrable behaviors associated with them, and if developed, impact in-school and post-school achievement (see http://CCCFramework.org for Teacher Guides that summarize the research and provide details on instructional practices and assessments).

The *College and Career Competency Wheel* can be used to describe critical competencies for students' post-school success, but also to articulate an overall vision or purpose of a group. The competency wheel promotes a common language with students, teachers, employers, community members, law enforcement, etc. We can embed these competencies into our instruction and this will positively impact students with disabilities, gifted students, those at risk, and those on track, regardless of the student's career path. Additionally, professionals from adult services, nonprofits, and even families can understand and support the development of the competencies. As professionals from numerous disciplines examine and embrace the vision of better-prepared students, they are better able to work together, share resources, and advocate for policy changes to create more socially and emotionally engaged, career-equipped, lifelong learners. This common charge promotes collaborative behaviors from all sides.



Learn Services and Agencies Outside Your Own

In order to learn and work with services and agencies outside of your own, it is important to build relationships with other invested partnering agencies. To first learn and then truly partner with other entities, consider focusing on your networking abilities.

Networking includes these essential components:

- Create ties among individuals.
- Utilize ties for support to overcome barriers and achieve goals.
- Support others to overcome barriers and achieve goals (Gaumer Erickson & Noonan, 2013).

Consider the degree to which you currently network with agencies such as vocational rehabilitation, parent organizations, workforce centers, and nonprofits. You may be aware of a person working within an entity, and you may even have exchanged contact information or discussed a student. These are good steps in beginning to network and build relationships, but genuine networking requires more. To fulfill the components of networking, we not only create the connections or ties, but also use them for support to overcome barriers and achieve goals, such as coordinating services for a student in need. And more importantly, we use our connections to support other professionals to overcome barriers and achieve goals, even when it might not directly benefit our role or our students. In other words, we use our ties to make connections between others so that they build mutually beneficial relationships with others. In this way, we are not simply capturing contact information for later use, but instead are building and participating in a true professional network.

Partner with Others to Accommodate and Meet Their Charge Also

So often when we strive to collaborate with others, we make the mistake of primarily focusing on identifying and communicating our needs. While asking for help is important, we want to do so in a way that strives to build relationships with others based on authentic mutual understanding. Focusing on understanding and improving our assertiveness and empathy can help us build quality professional relationships for effective collaboration.

Assertiveness supports both making connections with others and keeping these relationships strong, and includes these essential components:

- Even when it's difficult, express my wants, needs, and thoughts.
- Even when it's difficult, respect what others want, need, and think (Gaumer Erickson & Noonan, 2013).

Before we can effectively express our wants, needs, and thoughts, we must first be aware of and understand them. To be truly assertive, in addition to articulating our points, we must respect others' points of view. Too often, professionals can operate in ways that are too passive or too aggressive, such as not genuinely engaging in discussion or dominating conversations and agendas. Assertiveness can benefit both adults who are too passive and those who are too aggressive by enhancing their ability to communicate more effectively. In groups, we have all experienced a dominating group member who directs decision-making without adequately listening to diverse perspectives. It is likely that these groups or teams are not functioning at high levels, and may not be effective in achieving goals or completing activities. As we self-assess our assertiveness, we may find that this is an area for growth through techniques like active listening, creating and using assertive statements, and ongoing reflection.

In addition to assertiveness, empathy supports the building and maintaining of relationships. To practice empathy as adults, we:

- Make efforts to understand others: their contexts, feelings, and behaviors.
- Communicate our understanding of someone's personal situation (Gaumer Erickson & Noonan, 2013).

While this can take time and require structures such as one-on-one time, private meeting space, and active listening techniques, striving to understand others is critical to working together effectively. Adult agencies are supported by different funding streams which often have supporting legislation, regulation, procedures, and processes. Different work cultures, pressures, timelines, and priorities influence the work of peer professionals. In working to build understanding and communicate that understanding, you will increase awareness of opportunities for mutual benefit and critical connections.

Employ Action-Oriented Behaviors

When working with others, it is often necessary to identify clear tasks or goals that you will work on and divide the work across the team. In emerging relationships, these early experiences accomplishing action-oriented tasks are critical ways to build trust and understanding. At times, adults and team members fail to accomplish important goals or long-term tasks. Often, the reason behind the failure is not a lack of desire to do the work, but a breakdown somewhere in the process. While a clear overall goal may be identified, adults at times lack the self-regulation necessary to accomplish each individual activity or task involved. This might include difficulty getting back on track when things do not go as planned. Self-regulation and teamwork can support our efforts to produce quality work in a timely fashion.

Self-regulation consists of four essential components:

- Plan for and articulate what you want to accomplish
- Immediately monitor progress and interference regarding your goal.
- Control change by implementing specific strategies when things are not going as planned.
- Reflect on what worked and what you can do better next time (Gaumer Erickson & Noonan, 2013).

Many of us have experienced working to accomplish a task, but then failing due to unforeseen events. Adults can practice self-regulation by identifying a clear goal or task, creating a detailed plan, and monitoring the plan for not only progress, but also challenges that might be preventing progress. If something is preventing progress, a critical piece of self-regulation (and one that many people have difficulty with) is taking action to address the barrier by identifying and using specific strategies to continue moving forward. Finally, it is necessary to reflect throughout the process. When we use self-regulation in this way, we are better able to meet deadlines as intended and achieve our overarching goals.

Basic teamwork components can support the success of individual team members as well as the overall functioning of the team. Teamwork consists of these essential components:

- Work effectively with others to achieve a common goal.
- Do your fair share of any team assignments.
- Share your ideas or express your opinions while being open to others' ideas, opinions, and perspectives.
- Respect your fellow team members even when you do not agree with them (Gaumer Erickson & Noonan, 2013).

Have you been on a team where members failed to address one or more of these components? Many of us have, and it is often a difficult teaming environment. Consider your strengths and areas for improvement for working on a team. As each team member works on personal behaviors and components, the team as a whole accomplishes more work of better quality, and membership is sustained.

Work Through Past and Current Issues

Many adult relationships suffer from the inability to address conflict, with people predominantly choosing avoidance as a response. While avoidance can be a good response in some conflict situations, more sophisticated responses of cooperation and collaboration yield better results and stronger relationships.

To manage conflict, consider these three essential components:

- Understand your natural response to conflict.
- Understand the context of the conflict, including the perspectives of all involved.
- Apply a conflict management approach that is appropriate to the situation (Gaumer Erickson & Noonan, 2013).

Understanding how we typically respond to conflict and learning new strategies for constructively addressing conflict supports our ability to work effectively with others. Conflict is a normal occurrence that happens often, but our natural response may include less desirable approaches, such as competition and avoidance. Building our self-awareness and employing strategies to better understand the context and perspectives involved can help us in trying alternate, more effective approaches to conflict.

Believe that Your Collaboration Abilities Will Improve

Sometimes we struggle to understand that just because we are not good at something at first, it does not mean that we cannot learn it or improve with effort. Self-efficacy refers to perceptions an individual has about his or her capabilities to perform at an expected level and achieve goals or milestones.

The main components of self-efficacy are:

- Self-efficacy increases with the belief that ability can grow with effort.
- Believe in your ability to meet specific goals and/or expectations (Gaumer Erickson & Noonan, 2013).

As we embrace collaborative opportunities, our outcomes may not initially be as successful as hoped. Mistakes are easily made in new partnerships as we struggle to understand context and perspectives of others. We must realize that our abilities to work with other professionals grow as we continue our efforts. With each small success in challenging tasks, our self-efficacy as collaborators grows.

Summary

While the task of increasing collaboration on a personal level through teaming strategies and/or personal competency development may seem overwhelming, focusing on small parts is a good approach. Even minor behaviors could add meaning to your work with students and young adults—positively impacting students' post-school achievement. Throughout this work, it is important to take risks. As we leave our comfort zone and expand how we conceive our work and how we support students, we will sometimes fail, but we will know that although we have not mastered that strategy yet, our abilities are growing as we take risks. Finally, as educators, we are often so thoroughly focused on providing supports to students that we rarely spend any time acknowledging our personal or team successes. Make time to acknowledge your own achievements, as well as those of your partners. This both sustains and expands the effort and allows us to be a part of a larger community all working toward improved post-school outcomes.

12 Reports and How to Write Them

Jerrica Guidry, Peter Castagna,
and Thompson E. Davis III

Introduction

Psychological testing has been a cornerstone of psychological practice for decades, spanning back to the initial development of intelligence. During the early 1900s, Sante De Sanctis and Alfred Binet developed the first mental tests to determine the "educability" of children with abnormal delays (as cited in Cicciola, Foschi, & Lombardo, 2014). From there, Binet revised his 1905 intelligence test a number of times, resulting in what he claimed was an objective, scientific way to measure the complex mental phenomenon known as intelligence (as cited in Cicciola, 2008). Intelligence tests are designed to measure a variety of mental functions, including reasoning, comprehension, and judgment. Since there are no universal biomarkers associated with intellectual disability diagnoses rely heavily on evaluation practices (Tasse, 2016).

It is estimated that approximately three million Americans have intellectual disability (Larson et al., 2001). Given the implications of an intellectual disability diagnosis, a thorough understanding of the diagnostic criteria is crucial. Significant shifts in diagnostic criteria, terminology, and expectations and inclusiveness over time have advanced the protection and quality of life of people with intellectual disabilities; however, changes have also inevitably caused confusion among some evaluators. For instance, what is now known as "intellectual disability," was previously termed "mental retardation." Increasingly, there have also been growing movements to include those with intellectual disability in areas such as education and employment (Fesko, Hall, Quinlan, & Jockell, 2012).

The American Association on Intellectual and Developmental Disabilities (AAIDD) defined "intellectual disability" in an individual in 2002 as someone with significant limitations in both intellectual functioning and adaptive behavior including social, practical, and conceptual skills, which begins before the age of 18. Although U.S. federal law (Developmental Disabilities Act of 2000; PL 106-402) defines the end of the developmental period for developmental disabilities at age 22, the end of the developmental period for intellectual disabilities has historically been set at the age of 18 (Schalock et al., 2010). AAIDD continues their definition of intellectual disability (ID) with intellectual quotient (IQ) score cutoffs at a standard score of 70, which is 2 standard deviations below the mean of 100 for most IQ tests.

The *Diagnostic and Statistics Manual of Mental Disorders* (*DSM-5*) agrees on the need to evaluate both intellectual functioning and adaptive

behavior; however, following new American Psychiatric Association guidelines, there is no set age where the developmental period ends. The *DSM-5* states that clinical judgment should be used to determine if the onset of intellectual disabilities happens during the developmental period even after the age of 18 (American Psychiatric Association, 2013). Clinical judgment should not just be the opinion of the assessor but should be based on the standardized tools in combination with relevant clinical evaluations (Schalock & Luckasson, 2013). As a result, evaluations for ID typically generate a great deal of data, background information, developmental history, medical history, etc. and frequently challenge practitioners to summarize this information in a succinct, practical format.

Begin with Consent

Informed consent is an ongoing process; the client is provided information about their rights and possible risks/discomforts that may be associated with the evaluation. This allows the clinician to uphold the rights to confidentiality in regard to the evaluation and report. The legal and mental capacity of the person on which the evaluation is being conducted will determine whether they are able to provide consent on their own behalf or if a legal guardian will be in charge of decisions. Legal capacity is the right to make decisions for oneself and have these decisions upheld (Devi, 2013; Quinn, 2011). Mental capacity refers to the individual's ability to make decisions cognitively; this differs from legal capacity, which looks more at the person's ability to express will (McSherry, 2015). There are multiple components of mental capacity including understanding, appreciation, reasoning, and choice. Figure 12.1 (adapted from Grisso & Appelbaum, 1998) explains what components to consider when determining a person's mental capacity. Individuals with ID often have parts, if not all, of their legal capacity revoked and are appointed guardianship with consideration of the severity of intellectual disability (Kohn, Blumenthal, & Campbell, 2013).

When conducting an evaluation, client's mental capacity and legal guardianship should be assessed before continuing. If legal guardianship is appointed to someone other than the client, the guardian should be well informed on the procedures continuously throughout the evaluation. Even if an adult with ID does not have the legal or mental capacity to provide informed consent, informed assent should be included so that all parties involved agree and understand their rights—a developmentally appropriate description of the procedures and testing to be conducted should be provided. Informed assent should be sought for those with a legal guardian. Children being assessed for ID should also receive informed assent regardless of mental abilities due to their vulnerable nature and their inability to make legal decisions. Furthermore, informed assent is a vital aspect of the rights to those with ID. Previous research has shown that individuals diagnosed with ID are more likely to respond affirmatively to questions despite not understanding what is being asked (Sigelman, Budd, Spanhel, & Schoenrock, 1981). Due to the contradicting nature of responses, the informed assent process should expand further than just yes or no questions and be phrased in a way relative to the client's mental capacity (Ramisch & Franklin, 2008). By providing informed consent and assent, the client and any participating third party (e.g., parents, legal guardian) understand the process as well as the risks the evaluation and report may entail.

Although state law may require legal guardians with decision-making authority to provide consent for clients with ID, psychologists should uphold a higher ethical standard by seeking assent from the client as well to continue services (Ramisch & Franklin, 2008). In a recent study by Horner-Johnson and Bailey (2013), most people diagnosed with ID were found to have the ability to consent or assent to psychological research processes in at least low-risk studies. More than half of the participants answered questions related to the consent process correctly and multiple sets of questions were piloted (Horner-Johnson & Bailey, 2013). While the evaluation and report consents are slightly different, the lit-

Mental Capacity Components

Understanding	Ability to understand treatment-related and diagnostic information
Appreciation	Ability to relate treatment information to one's own situation, in particular to nature of the diagnosis and the possibility that treatment could be beneficial
Reasoning	Ability to rationally evaluate treatment alternatives by comparing risks and benefits in light of potential consequences and their likely impact on everyday life
Choice	Ability to communicate a decision about treatment

Fig. 12.1 Components involved in determining mental capacity (Adapted from Grisso & Appelbaum, 1998)

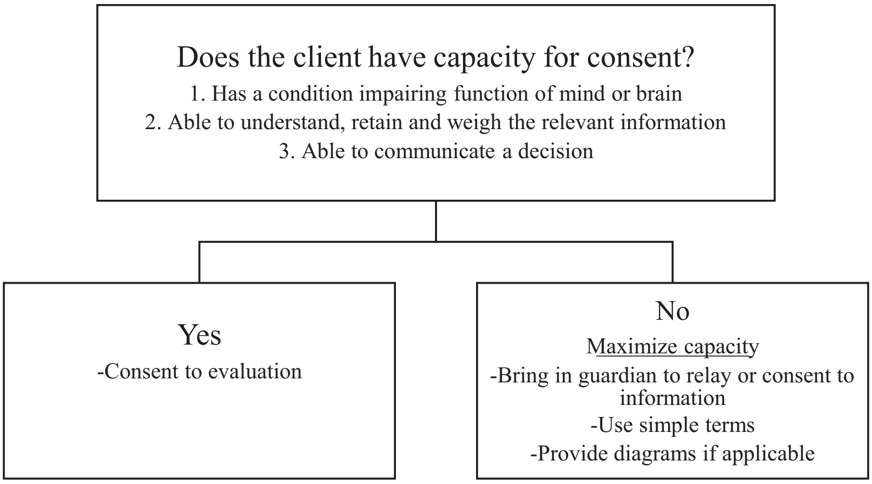

Fig. 12.2 Points to discuss when determining mental capacity (Adapted from Ministry of Ethics, 2014)

erature suggests that there is mental capacity to understand the overall process even with cognitive limitations. Determining mental capacity can be done by asking a variety of questions (see Fig. 12.2 adapted from the Ministry of Ethics, 2014).

There has been previous tension in the discussion of rights to those with intellectual disabilities and the caregiver roles. Moxley, Raider, and Cohen (1989) argued that family members are active agents in promoting the well-being of those with developmental disabilities. However, Qualls (1997) stated the need for balance between caregiver needs and the needs of the client to promote autonomy. The goals of the report should be the primary discussion when reviewing procedures at consent so that there is no confusion on what will be released in the report, particularly when the family and client are seeking services for intellectual disability.

Qualls (1997) stated that at any point in the life span of a client diagnosed with ID, families may be involved in providing support (e.g., emotional, financial, decision-making, direct care) for those who lack the full capacity to meet their own needs autonomously. The issue arises when families become fully enmeshed in the assessment process and lines begin to blur for the clients within the system (Ramisch & Franklin, 2008). Therefore, confidentiality should be discussed with caregivers by outlining what clinical aspects can or have to be reported. This discussion is especially important if a client only has legal guardianship in some, but not all, aspects of their life.

When producing a report for a client with a diagnosis of intellectual disability, there are multiple aspects to consider related to confidentiality, privacy, and privilege. The American Psychological Association Ethics Code states in 4.01 that psychologists have a primary obligation and take reasonable precautions to protect confidential information while recognizing the limits of confidentiality as regulated by law. The ethics code continues to say in 4.02 that psychologists should discuss confidentiality with the client including, to a reasonable extent, people who are legally incapable of giving informed consent and their legal representatives. If you are assessing a client with ID, the possible uses of the report, including who would have access to that information if consented and what could happen if there was possibly a subpoena issued for the report, must be discussed with the client and the legal guardian if possible. The discussion of confidentiality should occur before the start of the evaluation and well before any report is generated, typically during the informed consent process (American Psychological Association, 2017). Once consent and assent have been discussed, obtained, and sufficiently documented, it becomes important to consider the reason for the evaluation and subsequent report.

Rational Behind the Report

The purpose of writing a psychological assessment report is to create a comprehensive and integrated summarization and interpretation of the data generated during the assessment process, as well as place this developmental snapshot in the broader context of a client's varied background and developmental history. Moreover, the report should detail an assessment of the presenting problem and offer recommendations for the client. A report typically includes assessment data, behavioral observations, and relevant history combined using the informed judgments of an experienced clinician (Grills-Taquechel, Polifroni, & Fletcher, 2009). For clients with an intellectual disability, reports can be a way to communicate problems and challenges, and accommodations and recommendations to relieve difficulties occurring in their life. Research has shown that high-quality early intervention before the age of five leads to better long-term outcomes, making the early and accurate identification of ID and other developmental disabilities important (Guralnick, 2005). A concise and comprehensive report can help clinicians tailor interventions for those with ID, or even communicate concerns about a potential developmental issue before the condition is fully expressed for a subsequent examiner to consider. Therefore, an evaluator must report clearly and specifically as they can determine the trajectory of the particular client and the potential assistance they can gain access to.

Report writing addresses the client's presenting problem(s). Psychological reports allow a cohesive, linear timeline of the client's mental history, particularly for those with a lifelong diagnosis of ID. Reports are the ideal framework to parse out the concerns and tie them together with aspects of the client. Information should be gathered from a wide variety of sources in order to make comprehensive diagnostic determinations and treatment recommendations. As cited in Lichtenberger, Mather, Kaufman, and Kaufman (2004), Ownby (1997) described four purposes of an assessment report:

1. Answering the referral question as explicitly as possible
2. Providing the referral source with additional information when it is relevant
3. Creating a record of the assessment for future use
4. Recommending a specific course of action

Regardless of the evaluation purpose, the main goals of report writing are to generate hypotheses regarding a client's concerns, support or refute that hypothesis(es), and ultimately provide a conceptualization and recommendations for the client's specific difficulties. Reports that only focus on the data collected instead of a comprehensive interpretation of that data generate lackluster documents that disregard the intended purpose (Lichtenberger et al., 2004). O'Neill (1995) described three levels of clinician interpretations including the concrete level (e.g., only reporting scores), the mechanical level (e.g., reporting scores and the classification), and the individualized level (e.g., integrated reporting of scores). Reports written at the individualized level include the integration of history, behavior, and test results to detail the person instead of only focusing on the quantitative data. Reports interpreted at the individualized level are explanatory and the most useful (O'Neill, 1995).

In order to provide a comprehensive report, evaluations must be conducted in a concise, productive manner. Assessments for suspected ID can include an increased likelihood of test spoilage and noncompliance compared to other populations due to the nature of the existing problems. For instance, when administering an intelligence test, examiners must ensure that it is adequately assessing the client's abilities with regard to their current level of fine motor skills, vision/hearing issues, medical issues, and/or speech/language impairments. Professional judgment should be used to determine which intelligence test will correctly assess the client's cognitive abilities. All deficits should be mentioned in the report in relation to the client's performance on the intelligence testing (Reschly, Myers, & Hartel, 2002). More information on the types of intelligent tests available to assess for ID can be found in Chap. 22.

Critical Elements of a Report

There are various elements that are pertinent to a report in order to maintain a clear, comprehensive summary of the client. With a diagnosis of ID, omitted information could deny individuals needed services. The report should be based on a template that is organized in a logical manner.

Reports usually begin with a title so that readers of the report know what type of evaluation was conducted. Typically, the title is along the lines of "Psychological Evaluation" or "Psychoeducational Assessment." The title will depend purely on the type of evaluation given. Following the title, there should be identifying information which is usually presented in block format to avoid confusion as to whom the report belongs. The identifying information will often include the following:

- Name of examinee
- Date of birth
- Chronological age
- Grade (if testing a student) or occupation (if relevant)
- Name of educational or vocational placement
- Date (s) of testing
- Date of report
- Examiner's name
- Supervisor's name (if relevant)

Other information may be included in the identifying information section of the report depending on the purpose of the evaluation. The clinician may feel that other identifying information is necessary for the reader and can use clinical judgment to include this in the report. As long as the information is clear and concise, the details can be adjusted per the preferences of the assessor (Lichtenberger et al., 2004).

Reason for Referral

The reason for a referral is typically the next portion of the report. The primary concern of the client, his or her caregiver, and/or the family is outlined in this section, which sets the stage for the rest of the report. A person with ID may be referred for testing by his/her family, school districts, or a number of mental health agencies. These may include screening to determine eligibility for certain programs, a targeted assessment that focuses on a particular problem, a diagnostic assessment to assess strengths and weaknesses in an area, a counseling assessment with an emphasis on a client's ability to manage daily responsibilities, mandatory re-evaluations per guidelines, and/or progress evaluations to assess current interventions and progress (Sattler, 2001).

Understanding the referral question will ultimately determine the type of evaluation conducted and the specific recommendations for the client moving forward.

The reason for the referral section should ideally be no longer than one or two paragraphs. This section should include the name and positions (e.g., physician) of the referral source. The referral question may vary wildly. For example, referral questions may be in regard to whether the client is able to live independently, if the client can transfer to a group home/supervised location, or what academic environment and curriculum would best meet the client's strengths and abilities. After stating the problem succinctly, providing brief anecdotes or examples may help to get the point of referral across to the reader. Most referrals will concern the client's academic, adaptive, linguistic, cognitive, behavioral, or social development (Lichtenberger et al., 2004).

Background Information

Background information may be the next section of the report and is intended to provide a comprehensive summary of the client, while detailing overarching concerns. Collecting information from a variety of sources will aid in pinpointing the concerns and contributions from different perspectives. The information from each informant should be relevant to their first-hand knowledge (e.g., a physician giving medical or developmental history, teacher giving academic history). Information should come from those who interact with the client on a regular, if not daily, basis such as family members, caretakers, and/or group home workers. Background information may include history of development from medical, familial, educational, behavioral, and social perspectives. However, if the background information is not relevant to the referral concern, it is likely not needed within the report. Only include information that pertains to the primary concern and the test data interpretations, or that is necessary to clarify outstanding developmental concerns (e.g., a conflicting and confusing diagnostic history). Information that is personal and not pertaining to the purpose of the evaluation should also be left out of the report (Kamphaus & Frick, 1996).

The background section should be organized from topic to topic in a logical progression, preferably in chronological order. By keeping the information in order, the duration and the intensity of the concerns become salient. Each paragraph in the background section should be a separate topic (e.g., one paragraph on medical history, one on development, one on adaptive behavior). For reports involving suspected ID, developmental history is a critical topic to cover in the background information section and may include possible genetic or developmental diagnoses, relevant family history, as well as the mother's pregnancy, delivery, after birth complications, and developmental milestones throughout the client's life. Client medical and developmental history for an ID assessment can often be a muddled, error-ridden cluster of information that should be clarified in the report. All of the developmental and medical milestones and delays should be detailed in chronological order (Lichtenberger et al., 2004).

Given the complexity of assessing clients with suspected ID and the potential for different individuals and environments to elicit different behaviors and symptoms, multiple informants should contribute to the information provided in the report (Handen, 2007). Because there may be a limited capacity in those with severe ID, evaluating the symptoms of ID may not be possible beyond what is observed and reported upon by others. Multiple informants may include parents/guardians, teachers, aides, home workers, and/or social workers. Since most informants are seeing symptoms in different environments and/or perspectives, information is likely to conflict. The level of discrepancy should be discussed in the report with a hypothesis provided for why discrepancies or congruences may exist (e.g., behaviors only presenting in a certain setting or those that present across settings). Frequently, a problem behavior described by one informant will not be described by another informant, as agreement has been reported to be about 68.1% for some symptoms (Handen, Feldman, & Honigman, 1987). Such findings suggest that clinicians gather additional information when two or more informants disagree to determine the clinical utility of reported information (Handen, 2007). If there is any discrepant information among the sources, the examiner should try to account for the discrepancy with a logical explanation, which will provide a more balanced picture of the client.

Behavioral Observations

Behaviors observed during assessment as well as other settings should be included in the behavioral observations section of the report. Assessment settings are controlled to maximize attention and performance while one-on-one interactions occur. Because the setting is meant to optimize the performance of the client, the behaviors may not be congruent with behaviors displayed in other, albeit similar, settings (e.g., school). If the behavior in the session seems to generalize to multiple environments, it is best practice to confirm the behavior with other sources from various settings. Compiling a list of the behaviors observed in session can help to keep this section of the report organized. Interpreting behaviors in the report can help the reader to better understand the behaviors by combining hypotheses and observed behaviors into integrated statements. For instance, the evaluator must interpret and define behaviors in the context of the client conceptualization; if clinical symptoms of attention-deficit/hyperactivity disorder (ADHD) are reported, but a diagnosis of ADHD is not given, the evaluator must provide the interpretation that led to that decision (e.g., inattention symptoms were not reported to be clinically significant beyond what would be expected given the client's intellectual abilities). Reports should not consist of a string of behaviors observed in the session without interpretation nor should a list of hypotheses be presented without giving examples of behaviors (Lichtenberger et al., 2004).

It is important to observe and elicit adaptive behaviors for clients referred for ID. There are specific adaptive behavior scales and interviews that can be used to reflect an individual's ability to independently meet the needs and social demands on the environment. This behavior is one criteria required to make a diagnosis of ID. The operational definition of "limitations of adaptive behavior" from the AAIDD is to be at least two standard deviations from the mean for one of the three adaptive behaviors or for the overall score. Observing this behavior in session will give a general insight on the level of ID and functional impairment of the client.

Adaptive behaviors for an individual presenting with possible ID should be structured around the three domains of conceptual, social, and practical skills so that the report can parse out the symptoms for the diagnosis or diagnostic trends. Figure 12.3 explains the three domains of adaptive behavior adapted from the *Diagnostic and Statistical Manual of Mental Disorders Fifth Edition* (2013) under intellectual disability.

The first is the conceptual domain including skills in language, reading, writing, math, reasoning, knowledge, and memory (Parekh, 2017). These items can be tested using a variety of intelligent quotient (IQ) tests where a total score is derived from a standardized test to assess human intelligence. Achievement tests can also assess the conceptual domain which includes the application of the specific domain aspects. The conceptual domain can also be discussed in the test results section of the report. When reporting IQ and achievement scores, major discrepancies should be noted. The bigger the discrepancy as well as the lower the IQ score can help determine severity level (mild, moderate, severe, profound) and, in turn, the level of accommodations required.

The second domain is the social domain which includes empathy, social judgment, interpersonal communication skills, the ability to make and retain friendships, and similar capacities (Parekh, 2017). The social domain can appear in the report in a number of places, including behavioral observations, assessment measures, and a variety of informants (e.g., client, guardian, teacher, social worker). Depending on the severity level of the client, details on the social domain would differ in the report from something less problem-

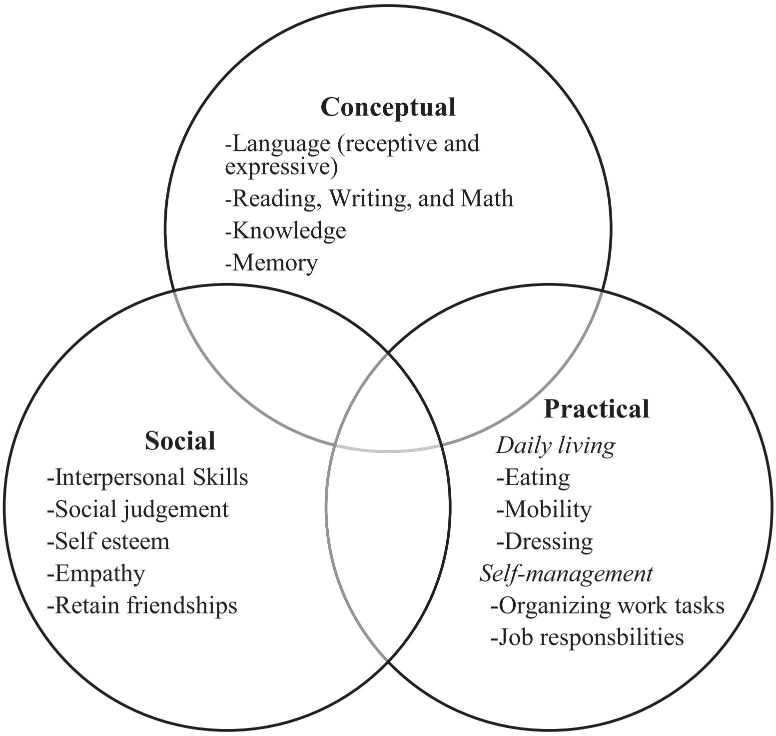

Fig. 12.3 The three domains of adaptive behavior that should be assessed (Adapted from APA, 2013)

atic (e.g., client being immature in social interactions) to more extreme (e.g., limited understanding of communication in speech and gesture).

The last domain is the practical domain centering on self-management in areas such as personal care, job responsibilities, money management, recreation, and organizing school or work tasks (Parekh, 2017). All three domains of adaptive functioning should be considered. An individual diagnosed with ID with a low IQ, but high adaptive functioning, would likely be considered mild severity, as they have the ability to care for themselves in a functional way. If adaptive functioning is not a strength (e.g., cannot feed oneself, get dressed, shower), the designation would likely be more severe ID. When including this domain in the report, an emphasis on the client's ability should be stressed in order to defend the diagnosis and severity level. Adaptive functioning can be found in its own section, under behavioral observations, or even under informant interviews. Placement of this information in a report depends on how the report is being organized (e.g., chronologically, etc.), which will be discussed later in this chapter. Further information regarding adaptive functioning testing can be found in Chap. 23.

Physical appearance can also be included in the behavioral observation section of the report, using a sentence or two about how the client appeared during the session (e.g., dressed appropriately, disheveled). Level of grooming and hygiene can be indicative of adaptive behavior and/or the amount of help the client needs (or currently receives). Client communication should be included in the report (e.g., how well the client engaged, whether they were nonverbal, and/or body language). If probed for response to failure or response to feedback during the session, reactions can be included in the observed behavior. Mood and temperament should also be included. People have varying temperaments in response to environment, styles of learning, and strengths and vulnerabilities (Brooks & Goldstein, 2001). If any factors were influencing the behavior in the session, it should be included in the report (e.g., the client was tired or hungry). Some writers include a statement of validity and reliability at the end of this session based on the information observed (e.g., the observed behavior is reliable since it was observed in all sessions).

Test Results and Interpretation

The test results and interpretation section of the report contain the tests administered, the data from the assessments, and interpretation of the data. This section of the report accounts for all of the data throughout the sessions: background history, behavioral observation, and test results. Choosing a basic format keeps the report organized in a logical manner. Format is typically found in three ways: domain by domain, ability by ability, or test by test. Whichever format is chosen should continue through the results section of the report. All three formats should include qualitative and quantitative data to inform the reader of the main findings (Lichtenberger et al., 2004).

The use of subheadings can help to keep this section organized and should move from broad to specific information about the client. For example, with intelligence testing, global IQ scores are reported first and then broken down into subtest scores and the respective strength and weaknesses. The main conclusions of the test interpretations can be in the first or last paragraph depending on the preference of having succeeding paragraphs describe why or having the paragraphs add up. The results should also move from standardized test data to information collected during observations and background history. Information can also be organized by themes, either with performance or with abilities in cognitive, linguistic, academic, social, or emotional domain (Lichtenberger et al., 2004).

The findings of the assessment should be considered to see how the data fit together. Lichtenberger et al. (2004) suggested several questions that can be asked to decide how the data should be incorporated:

1. How are the findings consistent?
2. What patterns of data support the common theme?
3. Which data are contradictory?
4. How can you explain the contradiction?

By looking at the consistencies and contradictions between assessment results and observations, a comprehensive picture can be formed of the individual ultimately making interpretations and recommendations easier (Lichtenberger et al., 2004). Interpreting should include examining the data, focusing on the person, describing what the person could and could not do, and reporting scores so they are concise and clear. Diagnoses should be included in this section of the report using diagnostic codes. When writing diagnostic impressions, data should be described to support the conclusion. Diagnosis can be the most important part of the report and should be considered carefully (Wolber & Carne, 2002).

Summary and Recommendations

Often (and unfortunately), the summary and recommendations sections of the report are the only sections read, as it recaps the valuable points of the report and guides the reader to services relevant to the diagnoses or concerns. Each section previously discussed in the report must be touched on in the summary; however, no new information should be brought forward in this portion of the report. Key points from the reason for referral, background information, behavioral observations, clinical impressions, and results sections should be included in the summary. The same wording should not be used so that the reader does not feel they are just re-reading the report. Instead, the information should be rephrased and shortened to give a quick overview. By highlighting the main points of the report in the summary, the reader can then lead into the recommendations knowing all the pertinent information (Lichtenberger et al., 2004).

The recommendations are based on the initial referral question, as well as the data and information collected during the assessment. For example, if the referral question focused on motor skills, the recommendation section of the report would focus on providing services or interventions to help improve motor skills, with attention paid to age and/or developmental level, degree of skill deficit, and intensity of impairment. Prior interventions should be considered when providing recommendations. For instance, if a client has a history of not responding to a particular intervention (with reason to believe it was well implemented), the clinician should explore alternative, empirically supported interventions. Recommendations should be informative and comprehensive, especially since the diagnosis of ID is for life (Lichtenberger et al., 2004). In formulating specific recommendations for a person with ID, Sattler (1998) suggests considering:

1. Do the results indicate a diagnosis of intellectual disability?
2. Is the person eligible for special services?
3. What are the least restrictive options for programming?
4. If mainstreaming or inclusion is possible, what additional supports will be needed?
5. What are the person's social skills strengths and weaknesses?
6. What skills will be needed for productive employment?
7. What types of supports will he or she require to live independently? Or what type of living arrangement will be needed?

The levels of required support needed for an individual diagnosed with ID should be discussed in the summary and recommendations sections as well. The AAIDD developed a classification system based on the amount of supports needed by the client (Schalock et al., 2010). The four levels of support include intermittent, limited, extensive, and pervasive. Depending on the functioning of the individual and the severity level of the ID diagnosis, the support may be as simple as brief targeted interventions such as social support (intermittent) or as extensive as continuous, daily life support (pervasive) in all aspects of their life (Carr & O'Reilly, 2016). While intermittent support is brief, limited support is more constant but only in certain situations (e.g., entering a new environment). Extensive support is a continuous support, but not life dependent, such as pervasive support with the hope that the individual will become more independent over time (Sigafoos, Lancioni, Singh, & O'Reilly, 2017). Any changes in support needed should also be discussed. While ID is a lifelong condition, the amount and types of support needed may change over time. When explaining the changes, clinicians should be careful to be sensitive to hopeful questions (e.g., eventually living independently or becoming more functionally independent) and would be well advised to temper feedback with an individual client's strengths as well as weaknesses. The amount of the support may wax and wane, but the severity of the diagnosis will not.

Once the data is gathered, the clinician should determine what is beneficial to be included in the report to address the main concerns. The major findings should be included as well as diagnostic trends that are applicable to the area of concern (e.g., does the client have developmental delays across all areas of life?). Background information should be consolidated to relevant items instead of including every word spoken in session. For people referred for possible ID, it is important to thoroughly examine adaptive functioning, achievement levels, skill levels (e.g., motor skills, language skills), behavioral concerns, functions of behavior, and possible comorbid disorders. By analyzing the data, the report will be able to integrate assessment results with information about the client. Crnic (1988) discusses a list of points to consider when determining what information to integrate in the report:

1. Is there significant test scatter across skills areas?
2. How do the results compare with previous assessment?
3. Did changes in the structure of testing (e.g., testing limits or allowing the use of alternating strategies) affect performance?
4. What behavioral factors were problems and what factors were strengths? Did they affect the assessment outcome?
5. Did performance or behavior vary across settings?

Are historical variables (e.g., developmental, medical, behavior) relevant to the client's performance?

Intended Audience

The intended audience of a report will vary depending on a myriad of factors (setting, purpose, etc.), and may not only be the parent/guardian. While the primary referral question will function as the framework of the report, the language used will depend primarily on who the report is written for. Reports written in a concise manner are more likely to be read in full. Writing a report with technical jargon will lead to confusion particularly for the family of the client. For those seeking medical help, especially those being assessed for possible ID, the report may be geared toward physicians who are more interested in reading about the technical or neurological underpinnings. The report may also be written for another psychologist, for example, someone who recommended the evaluation. In a case like this, including more data may be helpful; however, care should be taken as it is typically not good practice to include raw data in the actual report. An authorization to release information should be used in order to deliver data to other psychologists. Data are ordinarily not provided to non-psychologists or those inexperienced in their interpretation.

For reports meant to be used in school settings, tailoring the report to school interventions is ideal. It is important to note that schools offer different interventions and not all schools will offer the same services. Therefore, the examiner should enquire about the applicable resources available to the client to ensure the recommendations made are feasible. Different audiences will evaluate reports in wildly different manners and should be written as such.

One should also be careful of the language used to report a diagnosis of ID. Clinicians should use "people first" language (i.e., a person with an intellectual disability instead of an intellectually disabled person), as an individual's diagnosis does not define them. This can be even more significant to a family who is just learning about the diagnosis of ID. It is best practice to be sensitive to the reaction and feelings of a client and their family especially regarding diagnoses. Using "people first" language can also teach the client and family that while there might be developmental delays, there are strengths and positive attributes that make up the person. Because of the stigma surrounding ID (and unfortunately most other mental health diagnoses as well), correct terminology should be used. Intellectual disability was previously called "mental retardation," which has since been deemed offensive. Handen (2007) stated that this should be explained since the family may come across this label among other agencies. Some families may have never come across the labels "intellectual disability" or "mental retardation" even after having assessments with similar findings; however, the terms should be explained (Handen, 2007). Careful consideration should be taken when discussing the diagnosis.

The feedback session is an ideal opportunity to explain the scope and implications of the diagnosis of ID to the client and/or family, especially if the report is written for a different intended audience. The success of a feedback session can be based on how well the clinician probed for the initial referral question. Being on the same page about concerns can promote a productive discussion about the findings and the implications. While it is relevant to explore the scope of a diagnosis of ID, the strengths of the client should be stressed, leaving the session with a positive note. Intervention areas and services available should also be discussed to ward off any feelings of helplessness or stress. The client or advocate needs to understand that ID is a lifelong diagnosis and not something that will go away or be fixed; however, there are multiple resources available. In a case where a person with ID does not have family or an advocate there to comprehend the scope of the diagnosis, the discovery should be explained using the appropriate language if appropriate. The intellectual level of discussion should be based on the level of functioning of the client so that they leave comprehending what ID means and what resources can be of help.

In some ways, one of the most difficult feedbacks to conduct are with the family, advocates, and/or an individual with an ID. It is important that the client and/or their advocate understand what a diagnosis of ID means. One way to achieve this goal is to discuss the report in detail. The results found in the assessment can be discussed by going over strengths and weaknesses in certain areas such as the subscales of the IQ assessment or the adaptive behavior assessment. Providing figures or visual aids to understand the test scores (e.g., bell curves) can also help get the point across in less technical terms. Bell curves are based on statistical analysis and cannot perfectly fit every demographic. The bell curve figure should be used as a general illustration to make explanations more comprehensible but is not meant to be the actual data of the results section or representative of all populations.

By dividing up the information into tangible data, the individual can better understand what equates delays. This also provides the opportunity to discuss what qualifies someone for accommodations or programs that can benefit the client with ID. Sometimes the news of a diagnosis of ID can leave families feeling overwhelmed and unable to comprehend the implications during the feedback session. By providing them with a written report and feedback, family members have another chance to react to the news and possibly contact the clinician later with additional questions. Clinicians should always offer another chance to discuss findings or answer any questions to ward off confusion (Handen, 2007).

Confidentiality

Ensuring client confidentiality should be a priority when creating a psychoeducational report. The rights of those with ID can change quite drastically with severity levels. Whether the client has the legal or mental capacity to uphold their own legal standings does not determine confidentiality; however, it can determine who can be provided the confidential information. Under the Health Insurance Portability and Accountability Act and various state and federal laws (seek your own counsel for advice and applicable law), private health care information remains confidential, and privacy laws are to be upheld by health providers (and their business associates) including clinicians conducting psychological evaluations.

Shared information should be kept to a minimum by only providing the minimal details that is relevant to the purpose of the disclosure (Office of Civil Rights, 2017). For example, if a client was seeking services for ID through a government agency, providing the diagnosis would be relevant, but providing the client's religious affiliation would not be relevant. Due to the possibility of the client's consent to release the report to other agencies, the report should be written with only applicable details pertaining to or defending the diagnosis of ID or any other comorbid disorder. Psychologists should only include in written and oral reports information pertinent to the purpose of the communication (American Psychological Association, 2017).

Providing too many details on the families' life can also be a breach in confidentiality. The report is centered on the client, which should include family history; however, the report should not reveal confidential information on specific family members. For example, the report should include family history of previous psychological diagnoses but should likely not state, "Her sister, Jane, was diagnosed with schizophrenia." By divulging details of someone else's diagnosis, confidentiality has been broken for a person who is not even a client.

An authorization form should be used to obtain or release information to and from others for the sole purposes of receiving information to write the report or release the report to other agencies for services. The authorization form is a specific consent form that details what information is being released or obtained and to who. One of the main reasons a client with ID may seek an evaluation may be to provide various agencies a legal document detailing their diagnosis. The report should be written so that there is no violation of privacy when the report is released (Office of Civil Rights, 2017). Confidentiality and privacy laws are mostly governed at the state level. Any confusion about content of the report breaching confidentiality or when or to whom information should be shared should be directed to appropriate legal counsel in the state under which the evaluation is being conducted.

Safeguarding the Data and the Report

Once the evaluation is complete and the report is generated, the priority shifts to safeguarding the data. Confidentiality should not end once the report is finished and the client is no longer seen. Confidentiality of data and reports not only covers how records are kept but also who owns and has access to data, where the data are stored, how the data are protected, how long the data should be kept, and when the data can be destroyed (Cooper, 2016).

Release of raw data and psychological test materials affects the reliability and validity of the test procedures and results and also often has overlooked entanglements with copyright violations (e.g., making copies of protocols). Currently, federal courts and approximately 20 states promote the protection of psychological tests while some states also enact a nondisclosure privilege and duty to safeguard test materials and raw data from disclosure (Kaufmann, 2009). With the current shift from paper to electronic sources of record keeping comes new guidelines. HIPAA guidelines state that the health provider must maintain reasonable and appropriate administrative, technical, and physical safeguards when storing private health information, which would include raw data, test materials, and reports (HIPAA, 1996). The Department of Health and Human Services (HHS) provided new security standards in 2003, stating that psychologists who transmit private health information electronically take security precautions to prevent a breach in data and conduct risk analyses (for details contact your legal representation).

In 2007, the American Psychological Association produced record-keeping guidelines (see https://www.apa.org/practice/guidelines/record-keeping.aspx). Guideline 3 details confidentiality, stating that practitioners should be aware of the current regulatory and legal requirements regarding client records. Guideline 6 explains the security measures that should be established for practitioners with client records. If client paper records are created, they must be stored in a cabinet with a lock and key. The same can be said with electronic records which should also be properly stored. Records should be stored in a location where they are protected from damage (e.g., fire, water, mold, insects). Guideline 9 goes in detail on how to store electronic records stating that practitioners should be careful with the use of e-mail and other communication tools due to the possibility of breach of confidentiality. Electronic records should be protected via passwords, firewalls, data encryption, and authentication (Lustgarten, 2015). Standard 6.02 of the code of ethics establishes that in any form, record creation and storage must be confidential. Moreover, if a practitioner must use shared information, the minimum amount of information needed should only be used (APA, 2017). The completed report should be stored under lock and key to prevent tampering or stealing of sensitive information and should only be distributed under the client's authorization. Even then, only pertinent information should be shared with authorized agencies.

There are a number of extra steps that can be taken to further protect confidential records. Lee (2013) suggested creating a threat model to asses each client's associated risk. The *Electronic Frontier Foundation* (2014) suggested asking five questions in developing a threat model:

1. What do you want to protect?
2. Who do you want to protect it from?
3. How likely is it that you will need to protect it?
4. How bad are the consequences if you fail?
5. How much trouble are you willing to go through to try and prevent those consequences?

Stronger protections can also be applied by encrypting all electronic files so that getting to the client's record entails multiple encryptions. For example, a file storing device can be encrypted as well as the documents contained on the device. Storing the information on a file system that can be locked in either a lockbox or cabinet can further protect client information. There are ethical guidelines that must be followed if a breach in security for client records occurs. These guidelines overall are constantly evolving and so consultation with competent legal counsel is a must.

The APA Ethics Code states that informed consent must include the practices of storing and protecting client data and reports. Clients and legal guardians should be notified of how the information is stored (e.g., paper or electronic) and steps taken to protect confidentiality (Devereaux & Gottlieb, 2012). By not informing clients before services begin, practitioners are left with the possibility of monetary and disciplinary consequences (Lustgarten, 2015). Clients should also be notified during informed consent about retention of records. APA Ethics Code suggests retaining full records until 7 years after the last date of service for adults or until 3 years after a minor reaches the age of majority, whichever is later. When conducting evaluations for clients with a diagnosis of ID, the retention time of reports should be heavily weighed. Since this disorder is a lifelong diagnosis, the report may be needed for a longer period of time than that of a different diagnosis.

Client records of an assessment for ID include sensitive information discovered in interviews, behavioral observations, and test administration. All pieces of client information should be safeguarded by the practitioner to protect the client from harm. The APA Ethics Code and relevant state laws should be the guidelines followed when storing and protecting client records, and any confusion or questions should be resolved with knowledgeable legal counsel.

Conclusion

While writing a psychological report may seem like an overwhelming task, staying organized and concise can be the key to accomplishing the job. The importance of a psychological report with an ID diagnosis can be monumental considering the disorder is a lifelong disability. Establishing the groundwork during assessment to ensure the relevant information is covered removes the doubt of the diagnosis in the report. A detailed report indicating the diagnostic criteria the client meets (or does not meet) is valuable to the client and their family in getting services and accommodations. Concrete, feasible recommendations, some of which that can be started while waiting for more intensive services, are essential to the report. Writing a valid, comprehensive, integrated report that answers the initial referral question while simultaneously addressing any additional problems (e.g., comorbid disorders) will have the most positive impact on the client and their family.

Agencies and Professions in the Provision of Care

Karen L. Nankervis and Maria V. Vassos

Background

With the move away from institutionalisation to community participation, inclusion, human rights, and person-centred supports, the need for systems and services to meet the needs and aspirations of people with intellectual disability (ID) and their families is essential. However, supporting people with ID who are described as having complex needs is often regarded as challenging to systems, services and individuals, leading to difficulties in having those needs met effectively. Supporting people with ID and complex needs requires multiple safeguards as well as service coordination between multiple agencies and service systems. This chapter provides an overview of the issues associated with complex needs for people with ID, and best practices in supporting them.

What Is Meant by Complex Needs?

There is inconsistent understanding of what is meant by "complex needs" and it is often used to describe people with ID who have additional needs (Cooper & Ward, 2011) or multiple needs that span issues, services and systems (Rankin & Regan, 2004). *Complex needs* is a term described by Rankin and Regan (2004) as:

> *"A framework for understanding multiple, interlocking needs that span health and social issues. People with complex needs may have to negotiate a number of issues in their life, for example learning disability, mental health problems, substance abuse. They may also be living in deprived circumstances and lack access to suitable housing or meaningful daily activity. As this framework suggests, there is no generic complex needs case. Each individual with complex needs has a unique interaction between their health and social needs and requires a personalised response from services."* (p.i)

Accordingly, there is no universal understanding or definition of the term complex needs. For instance, a person may have complex *disability support* needs that are associated with impairment, such as having profound intellectual and multiple disabilities. In other cases, a person may have complex needs that are associated with having needs that span services and systems, not just disability services. As proposed by Rankin and Regan (2004) complexity of need can involve multiple and interlocking problems that have

J. L. Matson (ed.), *Handbook of Intellectual Disabilities*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-030-20843-1_13

depth (severity of need) and/or *breadth* (range of need). Thus, complexity of need can arise from: (1) the severity of impairment and disability for the individual and/or (2) needs that require system and sector coordination due to multiple needs (such as co-morbidity), circumstances (abuse, neglect, trauma), or complex situations (such as inadequate appropriate accommodation). Table 13.1 presents some examples of the depth and breadth of complex needs for people with ID.

However having breadth or depth of need alone may not be complex. While some people with ID have severe and pervasive disability support needs, or multiple needs that span organisational boundaries, where adequate, appropriate and coordinated services and supports are readily available meeting those needs may not be complex. A person's support needs can also become complex unpredictably especially where crisis arises such as carers' or services unexpectedly no longer able to provide care or where challenging behaviour results in placement breakdown, leading to potential homelessness or inappropriate accommodation. Thus, complexity of need is associated with any difficulties in having those needs met. Such difficulties include the timely availability of required supports and services or systems that are able to work together in a responsive and integrated fashion.

Table 13.1 Examples of complex needs associated with severity of need (depth) or range of need (breadth)

Severity (depth)	Range (breadth)
Intense and pervasive level of support needs associated with profound intellectual and multiple disabilities	Residing in inappropriate accommodation such as young people in residential aged care, long stay hospital settings or precarious and unstable accommodation
ID and high physical, and/or medical needs	Multiple, socio-economic disadvantage and social isolation
ID and challenging behaviour	Social exclusion with few opportunities for engagement in meaningful activities
Multiple and co-occurring disabilities and conditions	Co-existing conditions with ID such as mental health, alcohol, and/or drug misuse
Mild to moderate ID and a history of offending (forensic disability)	A background of trauma or neglect
Children with ID in out of home care with high physical disability or extreme challenging behaviours	

Service and System Responses and Outcomes for People with Intellectual Disability and Complex Needs

While the vision for people with complex needs is the same as for everyone—inclusion and participation, independent living and paid work, people with ID and complex needs often experience lower levels of quality of life, adverse life outcomes, and social isolation. They are disadvantaged in health, housing, independent living and employment (Cooper & Ward, 2011) and there is an overrepresentation of children with disabilities in child protection systems (Hill, 2012) with a contributing factor being increased likelihood of being abused and neglected (Horner-Johnson & Drum, 2006; Spencer et al., 2005).

Rankin and Regan (2004) state that those with the greatest (most complex) needs are at greatest risk of getting the least services. Also, that where care systems fail to recognise the interconnected nature of people's complex needs, they fall through the gaps between services. For people with complex needs there can be a lack of supports coordination, fragmentation of services, and poor information flow at government and local service level (Rosengard, Laing, Ridley, & Hunter, 2007). Accordingly, service systems and processes need to ensure that complex needs are met in an integrated fashion.

There are a number of factors that contribute to poor outcomes for people with ID and complex needs (Collings, Dew, & Dowse, 2016; Mansell & Beadle-Brown, 2012 ; Rosengard et al., 2007). These include:

- People with complex needs and their families/carers being daunted by complex service systems that span numerous agencies and are difficult to navigate, know what is available and how to go about gaining access (Mansell & Beadle-Brown, 2012; Rosengard et al., 2007). Gaps in required services and supports can occur where there is a lack of collaboration and integration by services and systems or inability to meet complex needs such as co-occurring mental health and intellectual disability. Other gaps and challenges people with ID and complex needs face arise where services and systems are too inflexible to respond to a breadth and depth of needs (Collings et al., 2016) and have administrative or bureaucratic barriers that must be crossed.

- Not being able to access the services or ending up in inappropriate services due to the nature of the person complex needs. Complex needs associated with severe disability, co-occurring mental health problems, autism and/or extremely challenging behaviours can lead to higher levels of out of area placement, associated with higher costs, lack of choice and control, social isolation and difficulties in transitioning back to their community of origin (Mansell & Beadle-Brown, 2012; Pritchard & Roy, 2006; Rosengard et al., 2007). People with complex needs are more often in long-stay hospital settings, "stuck" due to a lack of supported housing that meets their needs, level of risk and level of support required to live in the community (Sergeant & Brown, 2004). Additionally, they can find themselves in group accommodation where there is incompatibility between co-residents including resident to resident physical and verbal assault resulting in people with ID reporting that they feel unsafe in their home environment (Gatfield, 2016).
- Barriers to accessing required services and systems due to inflexible service criteria that may use ID or challenging behaviour as exclusion criteria (Mansell & Beadle-Brown, 2012; Rosengard et al., 2007) or have obscure or inconsistent entry criteria. Fragmented and siloed service systems that lack coordination and integration limit the person's ability to receive coordinated service provision and have their range of needs met (Mansell & Beadle-Brown, 2012; Rosengard et al., 2007).
- Resource constraints that prevent early and proactive supports, leading to crisis driven responses. Examples of such resource constraints include lack of respite care or short breaks for families or early intervention for younger children with challenging behaviour (Mansell & Beadle-Brown, 2012; Rosengard et al., 2007).

As can be seen, services and systems are critical to the quality of life outcomes for people with ID and complex needs. Therefore disability agencies and professions in the provision of supports to people with complex needs must be able to assist people with ID and their support networks to negotiate service systems to ensure needs are met and human rights are safeguarded.

Special Case: Family Crisis Resulting from Poor Service Response

While caring for a person with ID (regardless of age) can be a rewarding experience for parents and families (e.g.Corman, 2009 ; Grant, Ramcharan, McGrath, Nolan, & Keady, 1998 ; Hastings, Beck, & Hill, 2005), it can also be challenging for a multitude of reasons including the restrictions placed on the family's opportunities for social engagement (e.g.Burton-Smith, McVilly, Yazbeck, Parmenter, & Tsutsui, 2009 ; Edwards, Higgins, & Zmijewski, 2007), and the long-term impact on the physical and/or mental health of parents in particular (e.g.Burke, Patton, & Taylor, 2016 ; Burton, Lethbridge, & Phipps, 2008 ; Emerson, Robertson, & Wood, 2004 ; Miodrag & Hodapp, 2010). Consequently, some parents and families can experience a "crisis of caring" resulting in a request for a disability service to take over the day-to-day care of their family member with ID (*out-of-home care*).

Typically families requiring out-of-home care for their child with ID will go on to a waitlist for accommodation services in their jurisdiction. When a placement becomes available, the family usually works in collaboration with the service provider to implement planned transition to the accommodation arrangements.

However, there are instances where families seek immediate, unplanned emergency out-of-home care for their family member with ID as a result of family crisis. In these cases, the family member is often placed in temporary, emergency accommodation until the family agrees to resume the caring role, or an accommodation service is sourced if the family is unwilling to provide care on a continual basis.

Illustrative Case Study

Sam, a 12-year-old boy with autism and Down syndrome, lives at home with his mother. His mother wants him to continue to live at home; however, she needs assistance due to Sam's high levels of challenging behaviours. In-home supports are funded as well as some clinical services, including speech therapy to increase his communication skills. However his aggression has been escalating and Sam's mother does not believe that she can keep her other children safe from harm. While Sam has been supported in the family home by a disability service provider, that provider withdrew involvement due to assaults of workers and a lack of behaviour assessments or supports in place. Despite considerable efforts, a new service provider could not be engaged. A serious incident where Sam injured his mother led to the police being called and Sam being removed from the family home. Sam's mother refused to have him return home and crisis meetings were called by the government agency to find emergency accommodation. Sam lived in a number of short-term respite accommodation houses for 6 months until a longer term, more stable accommodation placement could be found.

Multiple studies have been conducted to investigate the reasons why families have sought out-of-home care for a family member with ID, with only a handful of studies specifically focusing on families who have sought unplanned, emergency out-of-home care during a period of family crisis. There is a noticeable overlap in the reasons reported by families who sought planned out-of-home care, and the families who sought immediate, emergency out-of-home care, with three groupings evident across the identified reasons. The first grouping relates to the *family member* with ID, who typically presents with complex needs due to severe disability, limited communication, challenging behaviour, and/or health problems (e.g.Ellem, Wilson, & Chenoweth, 2016 ; Essex, Seltzer, & Krauss, 1997 ; Grey, Griffith, Totsika, & Hastings, 2015 ; Llewellyn, Dunn, Fante, Turnbull, & Grace, 1999 ; McConkey, Nixon, Donaghy, & Mulhern, 2004 ; Nankervis, Rosewarne, & Vassos, 2011). The second grouping specifically relates to the *parent and other family members*, with parent inability to cope with the parenting role (e.g.Alborz, 2003 ; Mirfin-Veitch, Bray, & Ross, 2003 ; Victorian Equal Opportunity and Human Rights Commission [VEOHRC], 2012), poor parent health and/or mental health (e.g.Duvdevany & Vudinsky, 2005 ; Ellem et al., 2016 ; Nankervis et al., 2011), parental concern for their other children (e.g.Hostyn & Maes, 2007 ; Llewellyn, McConnell, Thompson, & Whybrow, 2005 ; VEOHRC, 2012), family conflict (e.g.Ellem et al., 2016 ; Hostyn & Maes, 2007 ; Llewellyn et al., 2005 ; McConkey et al., 2004 ; Nankervis et al., 2011), and financial strain (e.g.Chui & Hung, 2006 ; Ellem et al., 2016) cited as reasons leading to the decision to seek out-of-home care (or emergency out-of-home care).

The last grouping specifically relates to the *supports available* to the family to upkeep the caring role. Within this grouping, what is evident is that families who have sought out-of-home care (or emergency out-of-home care) are *reliant* on formal services available through the disability service system in order to cope with the caring role, mainly as a result of social isolation or a lack of social supports available to the family (e.g.Hostyn & Maes, 2007 ; Mirfin-Veitch et al., 2003 ; Nankervis et al., 2011). Because of this overreliance on formal supports (especially respite care), these families report significant unmet need for services, which then influences their ability to cope with the caring role on a long-term basis (e.g.Ellem et al., 2016 ; Llewellyn et al., 2005 ; McConkey, McConaghie, Barr, & Roberts, 2006 ; Mirfin-Veitch et al., 2003 ; VEOHRC, 2012). In addition, many families who have sought out-of-home care (or emergency out-of-home care) indicated that the services made available to them were of poor quality in their opinion (e.g. poor support practices in use, poor staff), resulting in more stress for the family as opposed to a sense of relief and assistance (e.g.Mirfin-Veitch et al., 2003 ; VEOHRC, 2012).

Coupled together, the known reasons for families to seek out-of-home care (or emergency out-of-home care) paint a picture of families who are experiencing many stressors, demands and hardships related to providing not only for the family member with ID, but the entire family. However, it should be noted that not all families caring for people with ID who have high support needs will seek out-of-home care. This is where formal service delivery and access to supports is crucial to families, and cannot be underestimated. Resilience is a notion widely discussed in the psychology research literature, with *parental resilience* recently defined by Gavidia-Payne, Denny, Davis, Francis, and Jackson (2015) as a parent's capacity to deliver quality parenting and care to their children despite adverse circumstances within the family. Gavidia-Payne et al. (2015) identify many protective and risk factors that are associated with parental resilience, with social connectedness being a crucial protective factor for the family (i.e. parental resilience is associated with greater levels of support). Also, resources such as social support and access to effective formal services allow a family to maintain their desired family social system, and if these resources are limited, family crisis can ensue (McCubbin & Patterson, 1983), Given the above, when it comes to conceptualising family crisis within the disability service system, the role of the service system and the supports available to a family cannot be neglected.

So what can agencies and professionals do to prevent family crisis? Recommendations from the research literature around the early identification of parents at-risk of seeking emergency out-of-home care (Nankervis et al., 2011; VEOHRC, 2012) have merit. Specifically, the VEOHRC (2012) advocate that systems must be put in place to accurately *identify* families at-risk of seeking emergency out-of-home care, with a focus on providing coordinated, early intervention supports to prevent these families from reaching a stage where they feel that crisis-driven, out-of-home care is their only viable option to cope. These recommendations for future practice were endorsed by parents who had sought emergency out-of-home care in the past (Vassos, 2017). Early identification of families at risk of crisis constitutes a proactive and prevention-based approach to ensure assessment of need processes that inform service allocation and support planning.

The Role of Agencies and Professions in the Provision of Care to People with ID Who Have Complex Needs

Systems, agencies and professionals are critical in supporting families and ensuring that people with ID's high and complex needs are appropriately met. The challenges in accessing the supports and services required must be addressed to avoid poor outcomes such as social isolation and poor quality of life. This necessitates an understanding of the depth and breadth of a person's needs and the implementation of a carefully targeted approach that understands and addresses the interaction between those needs and those that span systems (Rankin & Regan, 2004). An integrated approach to understanding complex needs and spans systems and processes enables the early identification of supports and interventions required to prevent crisis or other adverse outcomes.

The essential elements for such an integrated and coordinated approach to meeting complex needs are listed below (Carnaby & Pawlyn, 2009; Hudson, Dearey, & Glendinning, 2004; Rankin & Regan, 2004; Rosengard et al., 2007), and will be discussed further in this section:

- Understanding the needs of the person, especially their complexity.
- Access to information and advice.
- User and carer empowerment and co-design.
- Single point entry and access to required supports.
- Coordinated service delivery.
- Integrated systems.
- A proactive and preventative approach.
- Monitoring and measuring outcomes.

Understanding the Needs of the Person

In order to understand the person, a comprehensive, person-centred approach is essential, as well as understanding what constitutes complexity for the individual and their support network. An understanding of the whole person needs to be at all stages of service delivery and requires an exploration of the breadth, depth and interaction between needs (Rankin & Regan, 2004). By understanding the person and the basis of their complex needs, services can be tailored to the person, their circumstances and their needs. This requires comprehensive needs assessment that considers the whole person, and enables a person-centred approach where services are designed around the person rather than the person "fitting in" with the services that are on offer (Hudson et al., 2004; Rankin & Regan, 2004; Rosengard et al., 2007). Service planning and delivery should be designed to meet the needs of the person, not those of the service or system.

Access to Information and Advice

In order for people with ID to have their needs met, they need to be aware of what is available to them, both disability specific and mainstream. Commonly there is a lack of accessible information for people who have complex needs, and they have low awareness of what is available (Rosengard et al., 2007). Therefore information and advice for people with ID and their families must be accessible and understandable (e.g. written in Easy English, using plain language; translated into other languages), as well as readily available.

User and Carer Empowerment and Co-design

With human rights generally, and the UN Convention on the Rights of Persons with Disabilities (2006) specifically, giving primacy to a person's will and preferences must be actively supported (Carney, 2015). The best outcomes are where the person with ID is involved in planning their supports recognising and building on their strengths as well as those of their support network. As such, users of social services need to be recognised as co-producers of their own care (Rankin & Regan, 2004), and the experts about their own lives (Hudson et al., 2004). Involving people with ID and their carers at all levels of service planning, development and delivery as well as facilitating access to advocacy as required recognises the contribution the person with ID can make, and views them as the experts (Rosengard et al., 2007).

For people with complex needs and ID, choice, control and decision-making are important; however, due to the complexity of their needs (including severity on ID), decisions about the person's life may be undertaken by others, often under formal arrangements for substitute decision-making such as guardianship. Supporting a person with ID to participate in decision-making includes involving them right at the start; avoiding a tokenistic approach; allocating the necessary time, resources and commitment; and being clear about what exact decisions can be made (Hudson et al., 2004).

There is a growing focus on supported decision-making in response to overreliance on formal systems of substitute decision-making (Jameson et al., 2015). Supported decision-making aims to empower people with cognitive impairments, including ID, by recognising that they are the decision-maker, but are provided support for decision-making from one or more others from their network of support, giving them the assistance they need (Kohn, Blumenthal, & Campbell, 2012). This support is individualised to the person (Jameson et al., 2015) and may involve explaining issues and options in ways that are understandable to the person, or interpreting the individual's words or behaviours to identify preferences (Kohn et al., 2012). People with ID who exercise greater self-determination and have more control over their lives have greater independence and quality of life (Jameson et al., 2015). A reciprocal model emphasises the contribution that can, or could be made by the people in receipt of services and support (Hudson et al., 2004), recognising them as valued persons who have valued social roles. A person's level of participation in decision-making can range from being provided with information about decisions to be made, services and supports available, through to the individual having the authority and ability to make decisions for themselves (Hudson et al., 2004).

Single Point Entry and Access to Required Supports

Navigating complex and fragmented service systems is a significant barrier to people having their complex needs met. Users of service systems should be able to access the entire system of support through a single point of entry (Rankin & Regan, 2004). Single point entry can involve the ability to access appropriate services to meet different needs, information about available services (Rosengard et al., 2007) without the need to identify and then have contact with multiple agencies. Additionally, multiple legitimate routes to a variety of services from a variety of sectors that reflects diverse needs and circumstances are required (Hudson et al., 2004).

Coordinated Service Delivery

For a person with ID and complex needs in the context of service fragmentation, the roles of "service navigator" (Rankin & Regan, 2004; Rosengard et al., 2007) or "systems wranglers" (Madden, Fortune, Collings, & Madden, 2014) are needed to assist the person with ID and their family to identify needs and goals, plan their supports, and coordinate access to the required supports and services. Such a role needs to have knowledge of both specialist and mainstream services, as well as knowledge of specific issues, such as dual disability (Madden et al., 2014; Rankin & Regan, 2004). Case management is used to address situations where a person has complex needs and a single service response will not be adequate (Gursansky, Kennedy, & Camilleri, 2012). An essential element is a skilled coordinator, working across sectors and services, who is an active negotiator who understands the needs of the person who acts as the central point of linking services and other sectors (Madden et al., 2014).

Integrated Systems

An integrated systems approach is based on a holistic view of the person and a comprehensive, whole system model where all relevant services are involved in joint processes for information sharing (with the person's/family's permission) to prevent service users having to repeat information, facilitate pathways through services (Rosengard et al., 2007). Joined up and integrated service systems do more than just share information. They serve to enhance the supports provided by each other as well. Joint working is essential in order to have a "whole systems" approach (Hudson et al., 2004) rather than partnerships that are ad hoc or fragmented. In an integrated system working relationships are built around shared service user goals rather than organisational frameworks and existing systems (Hudson et al., 2004).

A Proactive and Preventative Approach

Early and proactive supports to meet identified needs and prevent escalation and crisis is essential. This implies identification and provision of supports and services to meet the needs of adults and children with ID in a timely manner rather than crisis driven responses. For example, children with intellectual disability are at increased risk of developing emotional and behavioural difficulties at an early age and carers experience stress related to the behaviours of the child (Gore, Hastings, & Brady, 2014; Nankervis et al., 2011). An early, preventative approach to providing behaviour supports, including parent education, can have a positive impact on the child's behaviour as well as carer stress and coping (Hudson et al., 2003). Without an early intervention approach, emotional and behavioural difficulties will persist over time into adulthood (Gore et al., 2014).

Additional to early interventions, timely and proactive identification of a person with ID as having complex needs and the provision supports is required. Systems, agencies and personnel need to reconsider approaches that prioritise access by urgency of need (crisis-driven) to ensure that reasonable and necessary supports are provided in a timely manner.

Monitoring and Measuring Outcomes

Continuous monitoring of how services are being provided and the outcomes for the person is critical so that progress in meeting their needs can be monitored and acted upon. Monitoring enables the identification of difficulties and barriers, identifying what is working well and achieving desired outcomes, which is essential to informing any reassessment of the person's needs and objectives. Monitoring the implementation of planned actions avoids implementation gaps that lead to poor outcomes, such as inappropriate accommodation or homelessness.

Monitoring should also focus on outcomes that are meaningful for the individual, be measured and the tools and ways of measuring should be individualised to the person's needs and goals (Carnaby & Pawlyn, 2009; Rosengard et al., 2007).

Hudson et al. (2004) draw on the evidence of the outcomes that service users contribute to a good quality of life as:

(a) Being healthy.
(b) Staying safe.
(c) Enjoying and achieving, including feeling valued and having access to social contact and company.
(d) Making a positive contribution.
(e) Economic well-being.

Of course, the role of agencies and professions in the provision of integrated and effective supports for people with ID who have complex needs is dependent on the skills, knowledge and experiences of the staff involved. The next section of this chapter will concentrate on the required competencies for the professions involved in service provision to people with ID and complex needs.

Professional Competencies

All professionals involved in planning and service delivery for people with ID who have complex needs require training to ensure that they are able to recognise and relate effectively to people with complex needs and their families, and assist them in navigating systems of services and supports available (Rankin & Regan, 2004). Given this, the concept of professional competence is fundamental to any discussion regarding service quality in the disability service sector, and will receive extensive focus.

In 1999, Hoffman stated there are three main approaches when it comes to defining *competencies:* (1) *observable competence,* (2) *standard of performance,* and (3) *underlying attributes*. In the first notion of observable performance—one must be able to witness performance on a task in order to attribute if someone can competently complete the desired task. The second approach is to conceptualise competency as a standard, i.e. a minimum standard of performance a person need to demonstrate in order to be deemed competent to complete the desired task. The third and last approach is to conceptualise competency in terms of a person's underlying attributes, i.e. the knowledge, skills or abilities that allow competent performance on the desired task. Hoffman also indicated that the approach to competency adopted will depend on context and requirements. When exploring the notion of professional competencies in the disability service system, the second and/or third conceptualisations will be focused on specifically.

When it comes to supporting people with complex needs, three professionals working in the disability service system have key roles to play to ensure quality service for people with ID—disability support workers, behaviour support practitioners, and case managers. The essential competencies associated with these three work roles, starting with disability support workers is discussed further.

Disability Support Workers

With regard to disability support workers, also referred to as disability support professionals, consistent conceptualisation of worker competency is difficult due to the variability of this role. Generally speaking, the role of a disability support worker is to ensure that support plans related to client personal care, health, behaviour, community access, and other relevant needs are effectively implemented on a consistent basis (Bogenschutz, Hewitt, Nord, & Hepperlen, 2014; Hewitt & Larson, 2007; Iacono, 2010). This may involve varying levels of direct care/support, ranging from supporting clients to complete daily living tasks to the best of their ability, to undertaking daily living tasks for their clients. Additionally, disability support workers can also be employed within various service settings such as supported accommodation, day programs and respite services, or within the clients' home. Given the heterogeneity of the intellectual disability population and the various service options available, the disability support worker role is diverse, with individual work duties and tasks typically determined by the worker's place of employment and the support needs of their clients (Bogenschutz et al., 2014). Given this, defining a universal framework for support worker competency may be difficult.

However, some researchers have attempted to piece together an all-encompassing set of competencies related to the disability support worker role. In line with Hoffman's (1999) third conceptualisation of competency, Taylor, Bradley, and Warren (1996) focused on understanding the skills, knowledge, abilities and personal characteristics that disability support workers require in order to effectively perform their role. Taylor et al. (1996) conducted focus groups with support workers working within various support services, and identified 144 relevant skills, knowledge and abilities within twelve competency areas (see Table 13.2). These competency areas are also reflected in a more recent competency analysis conducted by the National Disability Authority (2018) (see Table 13.2 also). The National Disability Authority (2018) reviewed ten competency frameworks regarding the disability support worker role from various countries, and uncovered 18 common competency areas. Eight of Taylor et al.'s (1996) competency areas were directly comparable with competencies reported by the National Disability Authority (2018). In comparison to Taylor et al. (1996), the National Disability Authority (2018) emphasised additional competencies related to staff behaviour (e.g. ethical practice, respect, resilience, safety and cultural awareness/practice, innovation) and specific work tasks (e.g. focus on client health/wellness, providing specific clinical support, working from a person-centred practice perspective, focusing on quality improvement). While the National Disability Authority (2018) mentioned staff behaviours as specific areas of competency, Taylor et al. (1996)

Table 13.2 Disability support worker competency areas (National Disability Authority, 2018; Taylor et al., 1996)

Taylor et al. (1996)	National Disability Authority (2018)
• Communication skills (to engage with clients)	• Communication (to engage with clients)
• Participant empowerment (to support decision-making, choice) • Advocacy (knowledge of issues facing people with a disability, skills to facilitate advocacy)	• Empowerment and advocacy (promoting clients to advocate for themselves, and supporting client advocacy)
• Assessment skills (in order to identify client needs)	• Evaluation, observation and assessment (regarding client need and support)
• Education, training and self-development (to maintain skills, knowledge and abilities)	• Education, training and self-development (to maintain skills, knowledge and abilities)
• Community living skills and supports (support to build client skills around independent living)	• Community living skills and supports (appropriate assistance to support clients to engage in meaningful activities and other services)
• Community and service networking (skills to facilitate service use, knowledge of services and supports available to clients)	• Community inclusion and networking (knowledge of services and supports available to clients, supporting client inclusion in the community and within their family and social networks)
• Crisis intervention (e.g. problem solving skills, conflict resolution skills)	• Crisis prevention and intervention
• Facilitation of services (i.e. creating support plans, implementing them)	• Planning and organisation (to promote partnerships, access to services for clients, and effective work practices)
• Vocational, educational and career support (to enable employment and participation in educational courses)	• Professionalism and ethics (ensuring all practice is considered ethical and professional)
• Organisational participation (i.e. knowledge of their service, participation in the processes of the service)	• Specific clinical support (related to behaviour support, mental illness and other clinical issues)
• Documentation (completion of)	• Health and wellness (supporting clients to maintain good health)
	• Quality (focus on service improvement, and evaluating quality of care provided to clients)
	• Person-centred practice (providing supports in line with this framework)
	• Safety (ensuring that the environment around the client is safe and predictable, and using safe work practices at all times)
	• Resilience, positive attitude and openness to change
	• Cultural (values and respects diversity, and supports clients in accordance to cultural customs and beliefs)
	• Respect, dignity and privacy (regarding their clients)
	• Innovation, creativity and problem solving (to ensure positive experiences for clients)

identified these behaviours as *ideal* support worker characteristics.

Further work in developing a universal competency framework for the disability support worker role is needed, based on the views of people with ID themselves. When asked to discuss the qualities of an effective support worker, people with ID place more emphasis on support worker skills and characteristics related to *interpersonal interaction* with clients, whereas service managers emphasise skills and characteristics that allow the worker to effectively complete their work duties (Dodevska & Vassos, 2013; Hatton, Wigham, & Craig, 2009).

Behaviour Support Practitioners

Behaviour support practitioners specialise in providing support to people with ID who exhibit challenging behaviour. According to Emerson (2001), challenging behaviours include behaviours that threaten the quality of life and/or the safety of a person with ID, or others who support the person (e.g. family members, support staff). Examples of such behaviours include self-injurious behaviours and aggressive or destructive behaviours. Behaviour support practitioners work in accordance to the principles of positive behaviour support. Positive behaviour support has its developmental roots in person-centred practice and the normalisation, social role valorisation and inclusion movements, while also intersecting the principles of applied behaviour analysis (Carr et al., 2002). Behaviour support practitioners work with people with ID, their families and their disability support workers to develop and implement a coordinated evidence-based intervention strategy that aims to enhance the person's quality of life while also minimising their challenging behaviour by addressing the function of that behaviour (Carr et al., 2002). Intervention approaches adopted in positive behaviour support include functional behavioural assessment, skill development using behavioural principles, and systematic environmental change.

Often behaviour support practitioners working with people with ID are trained in a discipline other than positive behaviour support, such as psychology, social work, nursing, occupational therapy or speech pathology. These professions will often have competency standards for registration to practice within the discipline. Because of this, behaviour support practitioners are likely assessed for competency based on the frameworks outlined by their relevant registration body, as opposed to a specific competency framework related to competently implementing positive behaviour support. Nevertheless, documenting competency to provide behaviour support services is starting to gain some traction within the disability service system, with the Positive Behaviour Support Coalition (2015) in the United Kingdom introducing a competence framework for providing best practice positive behaviour support services. In addition, to align with the introduction of the National Disability Insurance Scheme (NDIS) in Australia, the NDIS Quality and Safeguards Commission (2018) has introduced a national Behaviour Support Competency Framework. The competency framework of the Positive Behaviour Support Coalition will now be discussed in some detail.

The Positive Behaviour Support Coalition (2015) framework focuses on informing what knowledge behaviour support practitioners need to know, and the tasks/duties they will need to implement in order to deliver best practice positive behaviour support. The framework is divided into three main sections that describe specific competencies that need to be achieved by behaviour support practitioners, disability support workers and supervisor/management staff. The first section of the framework relates to *creating high quality care and support environments*, the second section relates to *functional, contextual and skills-based assessment*, and the last section of the framework relates to *developing and implementing a behaviour support plan*. Table 13.3 presents the summarised Positive Behaviour Support Coalition (2015) competency framework, with the detailed framework (not shown) breaking down each individual component in the framework into knowledge and work tasks/duties relevant to the three workers. The Positive Behaviour Support Coalition (2015) indicate that their framework can be used to support the development of a whole organisation approach to positive behaviour support, to develop curriculums related to training staff in positive behaviour support, and to support staff recruitment.

It can be expected that by undertaking competent practices that ensure the implementation of evidence-based, person-centred positive behaviour support plans, by behaviour support practitioners, in conjunction with the client and their supports, will result in positive outcomes. These outcomes include (1) enhanced quality of life for the person with ID, including active participation in meaningful daily life activities, (2) increased development of skills and positive behaviours

Table 13.3 The summarised Positive Behaviour Support Coalition (2015) competency framework

Creating high quality care and support environments	Functional, contextual and skills-based assessment	Developing and implementing a behaviour support plan (BSP)
• Ensuring that services are values led • Knowing the person • Matching support with each person's capabilities and with goals and outcomes that are personally important to them • Establishing clear roles and effective team work • Supporting communication • Supporting choice • Supporting physical and mental health • Supporting relationships with family, friends and wider community. • Supporting safe, consistent and predictable environments • Supporting high levels of participation in meaningful activity • Knowing and understanding relevant legislation • A commitment to behaviour skills training	• Working in partnership with stakeholders • Assessing match between the person and their environment and mediator analysis • Knowing the health of the person • Understanding the principles of behaviour (the four term contingency); understanding the function of behaviour • Supporting data driven decision-making • Assessing the function of a person's behaviour • Assessing a person's skills and understanding their abilities • Assessing a person's preferences and understanding what motivates them	• Understanding the rationale of a BSP and its uses • Synthesising data to create an overview of a person's skills and needs • Constructing a model that explains the functions of a person's challenging behaviour and how those are maintained • Devising and implementing multi-element evidence-based support strategies based on the overview and model (antecedent strategies, alternative behaviours, increasing skill and communication, systems change and contextual interventions) • Devising and implementing a least restrictive crisis management strategy (arousal curve, reactive strategies) • Developing the plan; outlining responsibilities and timeframes • Monitoring the delivery of the BSP (procedural/treatment fidelity/integrity) • Evaluating the effectiveness of the BSP • The BSP as a live document

that are functionally equivalent and replace the challenging behaviours, (3) reduction and elimination of the use of restrictive practices (such as chemical, physical or mechanical restraint, seclusion and containment), and (4) reduction of risk for the person and their supports, including decreasing risk of placement breakdown.

Case Managers

As previously discussed in this chapter, people with ID and complex needs are likely to require support from case managers to assist them in identifying and gaining access to required services and supports. People with ID and complex needs often require high intensity case management from case managers who have specialist skills and competencies (Cambridge, 2008).

The Case Management Society of America (CMSA;, 2016, p. 11) defines case management as "a collaborative process of assessment, planning, facilitation, care coordination, evaluation and advocacy for options and services to meet an individual's and family's comprehensive health needs through communication and available resources to promote patient safety, quality of care, and cost effective outcomes". The CMSA definition is an internationally recognised definition, with other case management professional bodies using this definition as the basis of their definition of the role, for example the Case Management Society United Kingdom (CMSUK;, 2015). Case management competency frameworks that are specific to people with ID and complex needs are scarce, and for that reason the more generic but widely recognised and adopted case management competencies of the CMSA (2016) and CMSUK (2015) will be the focus of this section. These frameworks are summarised in Table 13.4.

In line with Hoffman's (1999) second conceptualisation of competency as a set of minimum standards for workers, the CMSA (2016)

Table 13.4 A summary of the CMSA (2016) and CMSUK (2015) competency standards for case managers

CMSA (2016)	CMSUK (2015)
Client selection process—Screening referrals to identify those who will benefit most from case management	Professional practice—Engaging in regular supervision of practice, practicing autonomously and within professional boundaries, self-awareness and reflective practice, and continuing professional development regarding evidence-based practice
Client assessment—The completion of a thorough, person-centred assessment that takes into account the cultural and communication needs of the client and any other relevant stakeholders	Ethical conduct—Knowledge of relevant ethical codes of conduct, practicing ethically and with integrity, advocating on behalf of clients where appropriate, implementing procedures to adequately deal with client complaints, and working in accordance to relevant legislation
Care needs and opportunities identification—The identification of client care needs that would benefit from case management intervention	Communication—Providing information to clients and relevant stakeholders, employing appropriate communication strategies, developing rapport with clients and relevant stakeholders, and building skills to deal with difficult conversations or negotiations
Planning—In collaboration with the client and other relevant stakeholders, work to identify intervention goals and document them within the client's case management plan	Assessment—Using different methods to gather relevant information, applying relevant assessment measures for the client, and sharing (confidentially) knowledge and information for the benefit of others
Monitoring—Ongoing assessment of the client's response to their case management interventions	Goal setting—Identifying SMART goals, setting objectives to support the achievement of goals, and measuring outcomes relevant to the goals
Outcomes—Positive health and well-being outcomes are maximised as a result of case management intervention	Planning and prioritising—Evaluating different forms of information to identify issues and draw conclusions, organising information to support goal planning, identifying client priorities for intervention, producing case management plans relevant to the client's priorities and goals, demonstrating creativity and innovation to create the best possible plan for the client, and problem solving when faced with challenges
Closure—Undertake relevant procedures to close off case management services when appropriate	Implementing plans—Appropriate delivery of interventions, ensuring continuity in intervention, and coordinating activities in support of the client's objectives
Facilitation, coordination and collaboration—With clients and relevant stakeholders in order to achieve client goals and positive client outcomes	Monitoring and evaluation—Monitoring client progress to achieve goals, identifying effectiveness of interventions using appropriate measures, and applying continuous improvement principles (regular monitoring, etc.)
Qualifications—Maintaining certification to practice within a health or human services discipline or in the absence of a need for certification, evidence of qualification in a relevant health or human services discipline with a relevant fieldwork component as part of the qualification	Record keeping—Maintaining objective and accurate records, ensuring confidentiality and usability of information, presenting information in clear and concise reports
Legal—Adherence to all relevant legislation when providing case management services to clients	Management—Use appropriate referral avenues, engage in teamwork to support clients, assess and manage any client risks, managing resources appropriately and managing client expectation, and ensuring all support provided abides by organisational policy
Ethics—Ensuring all practice is ethical and adheres to ethical code of conduct governing the case manager's discipline of practice	Leadership—Making effective decisions, acting in a leadership capacity, and work in accordance to the principles of evidence-based practice in an effort to shape case management practice
Advocacy—Advocate on behalf of the client where appropriate	
Cultural competence—Maintain awareness of, and be responsive the cultural and communication needs of each client	
Resource management and stewardship—Integrating factors related to quality, safety, access, and cost-effectiveness when supporting clients	
Professional responsibilities and scholarship—Ongoing professional development to maintain knowledge and competency, and working in accordance to the principles of evidence-based practice	

and CMSUK (2015) competency frameworks provide a set of standards for case managers, with both frameworks also making explicit statements regarding how a case manager can demonstrate that they meet each standard. For example, regarding the CMSA's (2016) *monitoring* standard, case manager can demonstrate their competency by: (1) documenting their efforts to collaborate with their clients and relevant stakeholders to review client progress, (2) initiating changes to the proposed case management interventions in response to any changes to a client's circumstances, and (3) undertaking and documenting care plans reviews, and making efforts to ensure that updated intervention plans are acceptable to the client and relevant stakeholders. Comparing the two frameworks, there is overlap in content, implying that competency standards for case managers may have some universality. Of interest, competence in the areas of *assessment* of client need, *goal setting* and *outcome measurement*, intervention *planning* and ongoing *monitoring*, effective client *collaboration* and *communication*, and *ethical/professional conduct* are stressed by both frameworks.

In summary, the available evidence and information regarding professional competency for three key professionals who support people with ID who have complex needs is lacking. This is concerning given that staff competency plays a crucial role in ensuring service quality within any human service organisation. Researchers and policy makers need to prioritise the development, validation and evaluation of universal competency frameworks for key professionals working in the disability service system. This is especially the case when working with people who have complex needs as this cohort has a higher likelihood of adverse outcomes. Given that many countries are implementing significant changes to how disability services are provided to people with a disability, this task takes on extra importance as a method of ensuring consistent and effective staff practice to ensure high quality disability services that are focused on outcomes for individuals.

Concluding Remarks

Meeting complex needs for people with ID can be challenging. However these challenges can be overcome if services and systems work in ways that ensure integrated and coordinated service provision that meets human rights, provides safeguards, and improves quality of life. Often complexity of need is not associated with the individual or the need itself. Complexity arises where the right supports are not available or accessible, where service systems are fragmented and difficult to navigate, or where access to services is only prioritised where there is imminent crisis.

This chapter has highlighted the need for the early identification of families who are supporting children with ID and complex needs and are at risk of requiring out-of-home placement due to stress and inability to continue to care for their child. Such early identification enables the early and timely provision of the supports required to prevent escalation of the depth of the needs of the child and supports the family's ability to continue to care for their child in the family home.

Also discussed has been the essential elements required to be in place for social service systems, service provision agencies and professionals for best practices in providing care for people with ID who have complex needs. Having in place competent systems, agencies and professionals that understand an individual's complex needs will enable responses that result in positive outcomes that are meaningful and individualised to the person with ID and their support network.

Informed Consent

14

Eileen Carey and Ruth Ryan

Values governing the need for informed consent 'promote and protect a person's well-being' and 'respect a person's self-determination' (Buchanan & Brock, 1990). Realising these values has proven to be problematic for people with intellectual disabilities, and those who support them, and as such, are a central focus of this chapter. While a vital component of supporting people with intellectual disabilities to make informed choices in their living, evidence suggests that informed consent means different things in different contexts and settings, variably practiced and rarely achieving the theoretical ideal. This chapter sheds light on and contributes to the theoretical and practical discourses of seeking, obtaining and facilitating informed consent for persons living with intellectual disability. Guided by the United Nations Convention on the Rights of Persons with Disabilities (UNCRPD) (2006) reasoning on 'rights' and 'disability' this chapter relates the notion of informed consent and activities of consenting with particular relevance to the application of CRPD's Article 12 (Arnardóttir & Quinn, 2009; Werner et al., 2012).

The chapter firstly traces the history of consent theory from pre-modernist, modernist and post-modernist perspectives. The evolving nature of informed consent is addressed and changing perspectives described noting the significance of evolving concepts of autonomy and self-determination specifically as relating to intellectual disability. Firstly historical reflections signify how deprivation and infringement of rights occurred (Kayess & French, 2008; Stein, 2007) often due to the absence of safeguards to insure that consent was informed rather than being coerced (Iacono & Carling-Jenkins, 2012). Secondly, aligned with the rise of bioethics, the endorsement of autonomy and self-determination of intellectually disabled individuals is demonstrated which aims to challenge readers to think of informed consent as more than personal rights but as augmenting inclusion in society. Thirdly, supported by two figures (Figs. 14.2 and 14.3) the principal processes and interactions of informed consent are presented which recognise both the simplicity and the multifactorial nature of informed consent communications, which require active involvement of those involved. Ultimately, this chapter demonstrates the enablement of intellectually disabled people to provide informed consent in all matters related to their life choices, and especially so for such examples as, receipt or use of a service, an intervention, or participation in research.

Historical Developments of Consent

Despite the fact that numerous people from theology, law, anthropology, philosophy, medicine, nursing, psychology, sociology and psychiatry have debated the political, legal, ethical and moral issues and processes of consent, compared to many other areas in scientific enquiry, consent continues to be an evasive concept as no unifying theory exists. An overarching view of informed consent has been restricted. It is a widespread and varied phenomenon and despite extensive research and debate, remains deeply puzzling. In a capsulated review of consent theory, the literature abounds with studies representing theoretical perspectives that have influenced the study of informed consent, shaping and reshaping societies' understandings.

It is beyond the scope of this chapter to explore every theory or every writer; therefore, it is limited to works and writers taken as indicative of a particular era, and have influenced Western and Christian cultures. Three epochs of pre-modernism, modernism and post-modernism are utilised to provide a framework to debate the various discourses of consent. These three epochs produce three very different ways of understanding consent. More importantly, as the rise of consent theory has been diffuse, haphazard and a very slow process, it would be absurd to champion specific dates. To some extent these epochs overlap and it is the dominant philosophical system of the time and associated belief system as opposed to chronological time that is emphasised. The discourses presented highlight the different perspectives that prevailed and the manner in which permissions, prohibitions and alliances have been constructed based on each discourse. Table 14.1 provides an overarching framework, which has been conceptualised to guide some of the discussion in this chapter. Discussion of the various discourses lends insights into modern-day consent modes held by cultural institutions medicine, nursing and research.

Table 14.1 An overview of the discourses on consent

Pre-modernist discourses	Modernist discourses	Post-modernist discourses
A source of harmony	A source of liberalism	A legal-political concept
A source of conformity	A source of obligation	An ethical-legal concept
Control vs. autonomy	A question of morals	A basic human right
	An acknowledgement of rights	A communicative interaction

Pre-modernist

The pre-modern epoch extends from approximately the beginnings of western civilisation, in ancient Greece, through to the beginning of modernity in the early fifteenth century. The primary epistemology of pre-modernism emphasised the use of mythical thinking and myths to explain and interpret the world by the first civilisations of ancient Mesopotamia and Egypt. In exploring pre-modern discourses, including reference to consent in ancient Greece and consent codes of practice described by theologians with the Christian church, an enabling understanding of consent is conceptualised as 'a source of harmony' and 'a source of conformity' identifying informed consent as an ethic of subjection to religious authority and social order.

In this era, many writers spoke in terms of hierarchy and consensus, unity and subordination where social order required one unified hierarchy, with such matters involving counselling of the rulers and consent by the ruled (Herzog, 1989). Early pre-modern history therefore offers a concept of 'tacit consent', which is not necessarily verbalised, explicit or formalised. Regarded as implicit, 'tacit consent' denotes the tranquil and serene adhesion of the community to any determination presented as such, to a specific form of action, which was perfectly integrated within the customs and habits of that community and thus legitimated by norms and tradition' (Nerves 2004). The state of things was generally seen as unchanging, and the social order was strictly enforced. Consent evoked a common sense of feeling confirmed by habit or tradition rather than being understood as an individual prerogative, nor as the expression of the exercise of any (Fletcher 1983). Influenced by an enmeshment of religious and political activity, cultural and societal habit and tradition dominated routine choice. In other words, 'consent' referred to what was in conformity (what agrees) with the customs and habits of that community without being requested or granted explicitly or formally (Fletcher 1983). Such practices greatly reduced opportunities for understanding individual will and preference.

It was the Greeks who instigated ideas of political freedom, whereby thinkers, such as Plato and Aristotle developed ideas of statehood noting attributes such as the ability to reason and to exercise intelligence as being distinctively human. At the beginning of the tenth century, as the Church began expanding and secular kingdoms arose in supremacy, both church and kingdom struggled with issues of power over ultimate authority. The end of this era depicted the emergence of *rivals* to consent such as freedom and liberalism which still dominate consent discussions to the present day.

Modernist

The Modern era extends from approximately the early fifteenth century to the middle of the twentieth century. Modernism is known as the Age of Enlightenment, which emphasised a belief in human progress through rationality and the methods of science (Rolfe, 2006). The Age of Faith gave way to the Age of Reason. Discourses within this era focused efforts to rationalise behaviour on a scientific footing. Enmeshed in the generation of scientific knowledge and understanding and of new perspectives consent theory developed. Such perspectives began a change in focus from mythical beliefs, religious supremacy and moral constraints to concepts of liberty, freedom, obligations, morals and eventually rights.

The major theorists in this era Locke, Kant and Montesquieu presented discourses of consent which implied normative assumptions in that individuals behave according to the norms of the societies in which they live. In contrast to the pre-modernist control and conformity thinking around consent this paradigm shift marked the cornerstone of modern liberalism viewing society as a collection of free individuals (Herzog, 1989). Early modern theorists clearly supposed that individuals had basic normative powers over themselves before they entered into social contracts, which brought questions of political obligation to the fore. In the early stages of this era the main thrust of discourses surrounding consent focused on liberalism and obligation versus issues of morality and rights. Arguing that individuals were rational and freethinkers challenged previous mythical beliefs, religious supremacy and moral limitations. But due to nature that such individuals were living in societies which were governed by religious and political authority which determined social order these discourses of the modernist era became entangled in controversy. The main debate being that when individuals have the power to bind themselves by exercising the normative power, then the upshot of the social contract becomes obligation.

Kant challenged Locke's theory of natural law and natural rights emphasising morality as a general term for an individuals or a society's standards of conduct, both actual and ideal, and of the character traits that determine whether people are considered 'good' or 'bad' (Levine, 2008). In its simplest formulation, an act that is moral brings more good consequences than bad ones. This gave rise to a consideration of how morals and ethics impact consent. Kant believed that because of the constitution of the mind of an individual, they presuppose a relationship of cause and effect in all experiences with the objects of this world.

Kant (1795) claimed that consent was not fundamental to a social contract view but rather that the inner voice of individuals, the conscience, was the source of morality, which informed individuals of what was right and commanded them to do their duty. Often called deontological, this approach has been increasingly called Kantian, because of its origins in the theory of Immanuel Kant (1724–1804) (Beauchamp, Walters, Kahn, & Mastroianni, 2008).

The conceptualisation of consent in this era introduced notions of rights and the role consent plays in determining and enacting the legitimate ends that governments can pursue. Since Governments existed by the consent of the people in order to protect the rights of the people and promote the public good, governments that failed to do so could be resisted and replaced with new governments. Montesquieu (1689–1755) alleged the study of political and social behaviour not to be an exercise in abstract thought, but rather to be undertaken in relationship to geographic, economic, and historic conditions. Montesquieu claimed that such conditions, along with customs, habits, religions and institutions, gave each nation a particular character, and therefore each society required constitutional forms and laws that reflected and supported the character of its inhabitants. The consequences reflected in this paradigm shift in the change of thinking about liberalism as individual rights taking precedent over collective rights has major implications for adults with intellectual disabilities (discussed in section-rise of bioethics). Modern theorists' contribution to consent theory primarily insisted consent be deliberate, voluntary arising from self, all-be-it either individual or group consent.

Post-modernist

In the context of consent, post-modern theorists challenged previous discursive constructions of consent and questioned the taken for granted assumptions that were used as a basis for knowledge construction. Post-modernism adopted a critical approach to all knowledge, highlighting the inter-relationship between truth, knowledge and power (Kaye, 2007). Post-modernists rejected many of the principles of the scientific revolution arguing that society is characterised by differences as opposed to commonalities. Rather than trying to find a common theory or narrative to guide all actions, post-modernist theorists developed and consolidated consent by integrating it within a coherent and unitary system, which acknowledged historical and social contributions while integrating legal, political, moral and ethical principles grounded in appropriate communicative transactions.

Post-modernists argued consent to be a complex process founded in historical and cultural social constructions. The focus of these theorists was on deconstructing concepts that had been used to construct consent theory and to develop new approaches to informed consent. The outset of the post-modernist era coined the term ‘informed consent’ as a legislative concept that marked the beginning of an explosion of discourses and the production of a variety of modes of informed consent, which became instruments in the surveillance, regulation and control in maintaining human rights. Major theorists exploring consent in the initial part of this era were Ramsey (1930), Jonas (1969), Veatch (1972) and Fletcher (1978). Further developments are reflected in seminal works of Beauchamp and Childress (1979), Fadan and Beauchamp (1986), Beauchamp and Childress (2001), Berg, Appelbaum, Lidz, and Parker (2001) and Manson and O’Neill (2007). Informed consent began to be viewed as an ongoing process, a safeguard of personal statute, with communicative interaction as being recognised as one of the most critical elements involved.

The key contribution of the post-modernists era is the manner in which legal, political and ethical standards focused on respect for individual autonomy and inalienable rights. In other words, ‘informed consent’ theory was borne out of respect for individual autonomy, paralleled with the rise of the bioethical movement and debates around issues of gaining consent particularly relevant to minority groups such as people with intellectual disabilities. This focus served to promote a person’s right to self-determination, often happening within the context of the need for safeguards and complex communicative transactions within the decision-making process. Some of these pertinent issues are highlighted in the following sections.

Rise of Bioethics and Informed Consent

Noting historical developments of informed consent, it is clear to see how the expansion of informed consent practices and regulations have occurred in tandem with the broader evolution of society, noting bioethics and ethical participation of human subjects in research as significant movements in which the discourse of informed consent has given rise to contentious debate. Bioethics is integral to these considerations because it examines the ethical, legal and social issues of advances in bioscience in a number of disciplinary domains, namely ageing and end of life, clinical ethics, life sciences, disparities in health and healthcare and disability.

A notable abuse of humanity reflected in modernist times refers to the eugenics era, a movement purporting to 'improve the genetic composition of the human race'. Given the extent of the subject area, the brief outline of it here is inevitably illustrative rather than comprehensive. Basically, between the years of 1907 onto 1957 the eugenics campaign sought to promote a genetic purity which was guided by a White supremacist colonial project designed to maintain the purity, superiority, and health of the default, that being the White race (Llyes, 2018). Psychological and intellectual assessments played an essential and powerful player in this eugenic project (Winston, 1998) with new ways of classifying people, through a brief consideration of an essential psychological concept, 'the normal distribution', culminating in a statistical visual organising tool for populations (Hacking, 1995). And in rounding up the very tail of the normal distribution of population level intelligence quotient (IQ) scores, psychologists classified many people as feebleminded, imbeciles, idiots, and institutionalised. And for those who fell within this remit, many were subjected to atrocities such as forced sterilisations and inhumane institutionalisations.

Forced Sterilisations (Early 1900s)

Advancing this ideology of the eugenics perspective, societies' obligation was to prevent those considered 'feebleminded' from procreating so as to prevent 'them' from 'continuing their kind'. In the early 1900s the United States of America was the first country to undertake sterilisation for eugenic purposes, unleashing a global wave of forced sterilisations across many countries including Canada, Australia, Germany, Belgium, Scandinavia, Japan, China, India, Taiwan and South Africa. And by 1963 over 60,000 people in the USA had been sterilised without their consent (Roy, Roy, & Roy, 2012). However, Universal Human Rights have subsequently driven agendas to uphold the rights of people, by proclaiming that the necessity for each individual to provide informed consent on such decisions. More recently in 2014, in conjunction with a number of organisations the World Health Organization issued a joint statement: 'Eliminating forced, coercive and otherwise involuntary sterilization, An interagency statement' (WHO, 2014) which references the involuntary sterilisation of a number of specific population groups including women with intellectual disabilities.

The Vipeholm Sugar Trial (Sweden 1947–1955)

At the beginning of the twentieth century, Vipeholm, in Lund Sweden, was the only state hospital which catered for the needs of approximately 800 individuals who were intellectually disabled, classified at that time as the 'uneducable mentally deficient'. During this time, 'tooth decay' had become increasingly prevalent in the Swedish population. In order to establish an effective preventative public health strategy, the government commissioned the Folktandvåren (Public Dental Service) and Medical Board to establish an interdisciplinary team at Vipeholm to identify the cause of dental caries.

In 1947 progressing the Vipeholm Dental Caries Study, adding sugar to the basic (standard) diet of 436 patients in various controlled formats over the course of each day resulted in 2125 new dental caries been induced by the end of the study in 1953. Findings from this study have advanced our understanding related to oral health, and considered the most significant contributions to the entire dental literature as it:

> *'…definitively established that the more frequently sugar is consumed, the greater the risk, and that sugar consumed between meals has a much greater caries potential than when consumed during a meal'* (Zero, 2004)

However, ethical issues were not discussed formally either before or during the study and none of the patients involved in the study had given their informed consent (Zero, 2004). Subsequently, legislation was introduced which prevented the use of Vipeholm patients as research subjects (Zero, 2004). Similar inhumane treatment of children with intellectual disabilities was evidenced in the Willowbrook studies.

The Willowbrook Study (United States of America 1963–1966)

In the United States of America, the Willowbrook Study reflects a significant case of advance in medicine (Krugman, 1986). In this period of 1963–1966 over 700 children at the 'Willowbrook State School' were involved in a 'successful' experiment that discovered a vaccination for hepatitis under the principal investigator Dr. Saul Krugman. Krugman states that parents were informed that their children were likely to have only a sub-clinical infection followed by immunity to the particular hepatitis virus, and only children with parents who gave informed consent were included. The research subjects were all children deliberately infected with the hepatitis virus. Critics of this research differ in opinion, related to unethical or questionably ethical procedures involving risks to the health and consent which portrayed cognitive privileges in dehumanising individuals with intellectual disabilities (Carlson, 2009) and questions related to the concept of 'informed consent' (Iacono & Carling-Jenkins, 2012).

Children's diets consisted of extracts of stools from infected individuals, while others were administered injections of more purified virus preparations. For example, coercion and pressure have been identified as concerns for parents of children with intellectual disabilities, a notable case in the early 1970s, the 'Willowbrook State School for Children with Mental Retardation' (Klotz, 2004, Carlson, 2009, Iacono & Carling-Jenkins, 2012).

However, if consent obtained through coercion or parents feared losing their children's placements in the school, the principle of voluntariness of consent had been violated. Moreover, due to crowding and long wait lists for admission to the school, minimal home supports, and available rooms for children on the experimental wing, thus influencing the decision of some parents who did not have the resources to care for their children (Iacono & Carling-Jenkins, 2012). Krugman re-visits the ethics of this research in his 1986 paper recognising '*the accomplishments of the research to be well documented in the medical literature*' arguing that the development of a vaccine would outweigh the anticipated 'minor harms' to these children (Krugman, 1986). It is clear to see how the polarisation of risks and benefits of informed consent gives rise to many debates and controversial considerations in health services and research.

Ethical Considerations for Human Experimentation and Research

In efforts to protect the rights of people from abuse, the first international code of ethics, The Nuremberg Code, was established in 1949. The central declaration of The Nuremberg Code (1949) was that the voluntary consent of every human subject would be obtained prior to research being undertaken (Beauchamp et al., 2008). In 1964 The Declaration of Helsinki advocated prior review of research protocols by an '*independent committee*', as well as making explicit provision for participation in research by legally incompetent persons. Early history of research ethics policy focused on the risks and on preventing subjects from being exposed to unacceptable or exploitive levels of risk (Fadan & Beauchamp, 1986).

The Belmont Report (1978) later outlined what was considered the three most important ethical principles (respect for persons, beneficence, and justice) that should govern the conduct of research with human beings. And the 1994 National Institute of Health (NIH, 1994) guidelines ensured that research inclusion gained momentum over research exclusion. Therefore, the presumption about research participation flipped from exclusion (protection from risk) to inclusion (enabling autonomous choice about participation).

More recently, legal and international human rights framework emphasise the capacity of the intellectually disabled for social, physical, emotional and intellectual development, and in doing so, concepts of autonomy and independence have become central features (UNCRPD, 2006). Furthermore, in Article 31 of The United Nations Convention on the Rights of Persons with Disabilities (2006) researchers are now required to include representative populations of minority groups unless there are special reasons for excluding them. Published ethical guidelines for conducting research with people with Intellectual Disabilities has now come to the fore Lai et al. (2006). While various philosophies in relation to research ethics are now widely debated, Biggs (2010) accepts that no single theory or principle can be adopted as a guiding philosophy for researchers or research ethics committees (RECs). Biggs proclaims that REC decision-making needs to balance various approaches to arrive at a consensus decision. Conversely, McDonald et al. (2009) have argued that blanket prohibitions imposed by Institutional Research Boards may actually limit the autonomy and self-determination of intellectually disabled individuals and thereby increase their marginalisation in society.

Evolving Definitions of Informed Consent

The concept of informed consent has been described as evolving over centuries by different schools of thought. The changing definitions of informed consent have reflected changing attitudes to how best to seek, obtain, and maintain consent when engaging people, especially those regarded as being vulnerable. Generally legal, political, moral, regulatory, philosophical, medical, and psychological literature favour components of informed consent to include: (1) disclosure; (2) understanding (3) voluntariness; (4) competence and (5) consent. For example, Appelbaum (2007) conceptualised consent as encompassing four components, which include the ability to: (1) understand relevant information; (2) appreciate the consequences of the information for one’s own situation; (3) reason about the available options; and (4) communicate a choice. And specifically with regard to people with intellectual disabilities, Dye, Hare, and Hendy (2007) identified three main components of informed consent as: (1) possessing sufficient information relevant to the decision to be made; (2) having the capacity to make a decision and to understand the consequences of the decision; and (3) making the decision voluntarily and free from coercion. While focus shifted to consent capacity as being the determining issue in obtaining informed consent, defining it as ‘ability to understand information relevant to making an informed, voluntary decision’ (National Institutes of Health (NIH), 2009), the need to regard informed consent as a ‘respectful relationship’, and as a ‘process’ rather than a one-off event placed more onus on advocates for facilitating resources to enhance informed consent experiences, especially for those with intellectual disabilities (DHSSPS, 2003). And more recently, the boundaries of what exactly constitutes ‘informed consent’ have been broadened by specifically constructing the concept from an ethics of care perspective, created in notions of relational autonomy-in-informed consent (RIAC), which when placed within the remit of care ethics attracts global perspectives so as to enrich current ideas of bioethics principles of autonomy and informed consent (Osuji, 2018). Figure 14.1 presents a Venn diagram showing the multiple overlapping purposes of informed consent (Hall, Prochazka, & Fink, 2012).

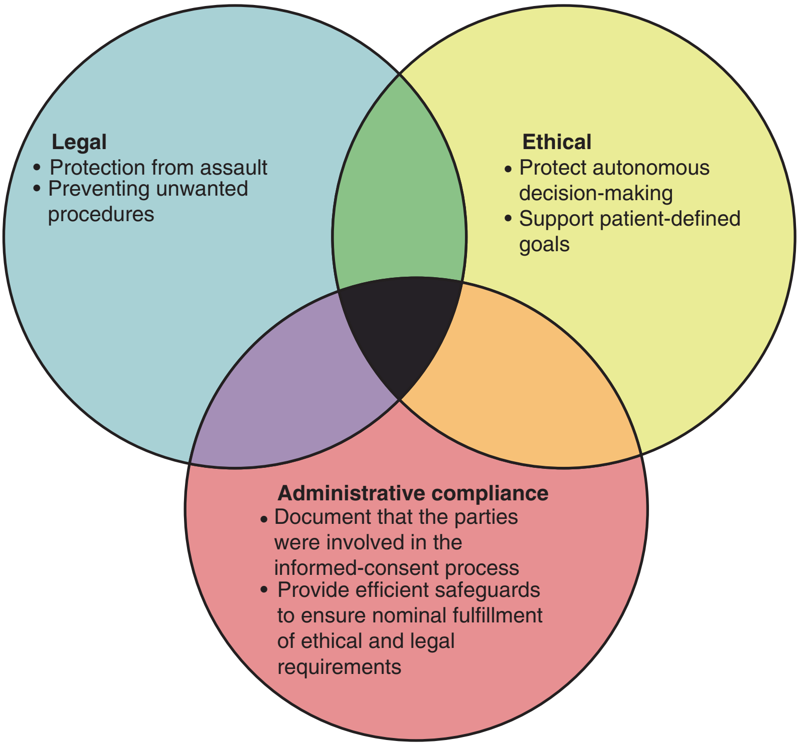

Fig. 14.1 Purposes of informed consent

Informed Consent Approaches

In asserting post-modernist theorists views of consent the following paragraphs and figures explicate the authors understanding of how informed consent can foster the autonomy and freedom of intellectually disabled people to make an informed decision. Infusing values of self-determination and choice can be challenging when people experience complex communication needs, impaired social interaction and limited experience of choice in addition to difficulty making informed choices for themselves (Bigby, Fyffe, & Ozanne, 2007), but not impossible. The following approaches Fig. 14.2: ‘Gaining Informed Consent: A Process’, and Fig. 14.3: ‘Informed Consent Gaining: An Interactive Cycle’ illustrate this perspective.

Gaining Informed Consent: A Process

The following Fig. 14.2 presents the standard ‘Gaining Informed Consent: A Process’, which portrays disclosure; understanding; voluntariness; competence and consent.

This framework has evolved from the initial focus whereby consent conveyed by an individual has been sought and obtained in culturally and linguistically appropriate language. Additionally, where written agreement has been utilised, integral in the act of signing and the existence of the signature is the credibility of the above-mentioned components of informed consent. Generally, the onus of proof of capacity has not been on the person seeking consent but rather on the consenting individual. In this standardised approach to gaining informed consent; the assimilation of and processing of information; the

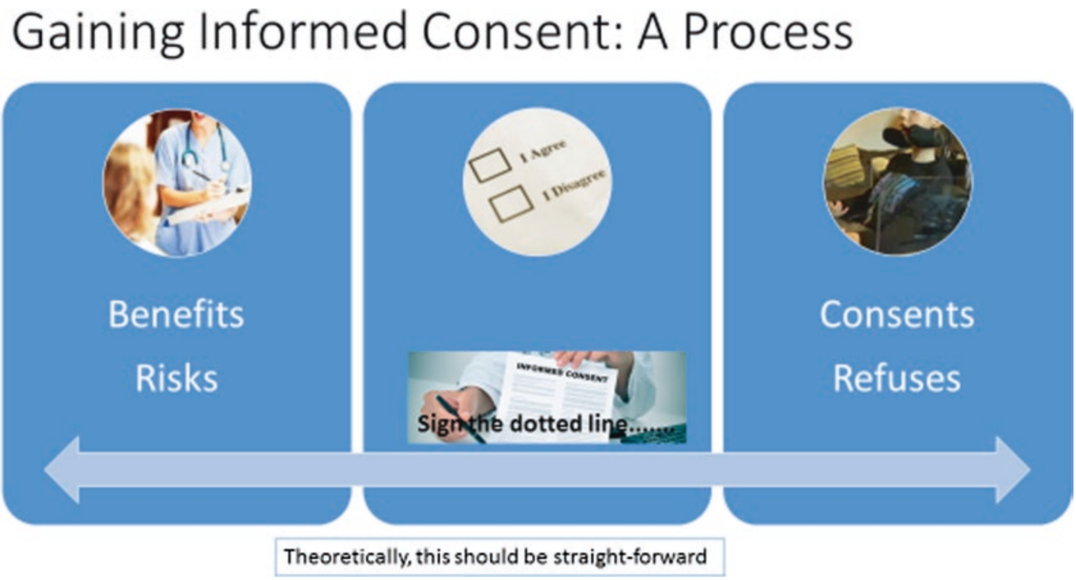

Fig. 14.2 Gaining informed consent: a process

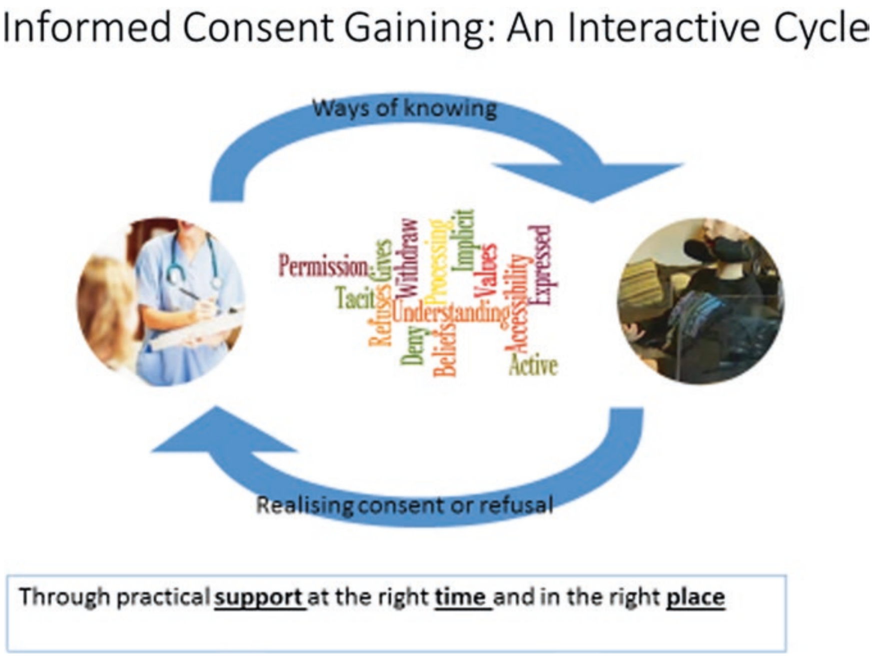

Fig. 14.3 Informed consent gaining: an interactive cycle

making of a judgement and the communication of a voluntary decision demonstrates the embodiment of theories of cognition and rational decision-making. Cautionary notes indicate such emphasis has rendered many people with disabilities, especially those with intellectual disabilities, disadvantaged in terms of communicating and explaining personal choices in these cognitive and rational domains. Particularly for those with moderate, severe and profound intellectual disability, the process of informed consent has traditionally been guided mainly by a status approach,[1] which determined that these individuals, by the nature of having an intellectual disability, did not have (legal) capacity. These people, subsequent to being deemed to lack capacity, were subjected to the enactment of guardianship laws. Reflective of individual and society responses to protecting those regarded as being vulnerable the introduction of guardianship laws aimed to demonstrate responsibility towards people at different periods in their lives, placing many people within custodial remits. And when rolled out in practical situations for people with intellectual disability, guardianship laws by the very nature of excluding them from matters of disclosure, voluntariness and choice rendered many unable to engage in the process of informed consent. Opportunities to make or engage in life choices was severely restricted for those who found themselves segregated by custodial care provisions. There is little doubt that the status approach obliterated the human rights of many people to engage and participate not only in having choices and making decisions for themselves as individuals but also in contributing to group and wider society decisions, erroneous thoughts in light of newer understandings of how this minority group of people can participate in making life choices.

Informed Consent Gaining: An Interactive Cycle

The 'interactional' perspective in Fig. 14.3 asserts the importance in developing meaningful relational interactions in time and over time to enhance mechanisms to develop engagement in disclosure (alternative and augmentative communication strategies); understanding (trust and relational); voluntariness (checking for signs of assent and dissent; comfort zones); competence (at ease to make a decision-with required supports) and consent (acceptance or refusal).

By gaining informed consent from people with intellectual disabilities, a 'respectful relationship', rather than a one-off event, is advocated enhancing interactions over a period of time. The impetus for this challenge reflects the beliefs in maximising human potential and services required to meet individual needs and outcomes while avoiding emphasis on limitations to understanding disability.

Underpinning these beliefs the value of communication displayed in 'Informed Consent Gaining—An Interactive Cycle' aims to present how meaningful and trustful relationships inherent within informed consent, placing emphasis on human potential, guided by a supports based approach. This philosophy aligns with the assumptions and understandings of the UNCRPD (2006) Handbook for Parliamentarians on the Convention which describes support in decision-making as:

> '*Those assisting a person may communicate the individual's intentions to others or help him/her understand the choices at hand. They may help others to realise that a person with significant disabilities is also a person with a history, interest and aims in life, and is someone capable of exercising his/her legal capacity*' pp.X

This interactive cyclical nature of seeking, obtaining, maintaining consent and/or respecting refusals or withdrawals to consent is underpinned by two principles, (a) *ways of knowing* people and (b) *maximising human potential*.

Ways of Knowing

A fundamental aspect of consent gaining interactions is that it challenges the '*ways of knowing*' people, from a pathological model where persons were perceived as objects or 'labels' in contrast to people with the potential to flourish as masters of their own lives, ability to self-determine, with a life plan and pathway, a life story or narrative (Bach & Kerzner, 2010; Barnes & Mercer, 2010; Department of Health, 2009; HSE, 2011; Lashewicz, Mitchell, Salami, & Samantha, 2014). In illuminating '*ways of knowing*' the practical implementation of supports, needs to take cognisance of individual values and principles that recognise contributions within communities.

---

[1] Status approach determining that capacity related to intellectual functioning and IQ singularly

With the right support, people with intellectual disabilities can exercise their right to make decisions and consent to life choices of their choosing. Willingness of support persons not only to listen to the person but to hear what the person is inferring via signs and expressions, recognising their individual and often unique mechanisms of communication. This lies at the heart of knowing the person. For this to be achieved personal supporters, support networks and/or circles of support should understand a person's life history, individual needs, routines, preferences and forms of communication. The value of familiarity and trust within any support for people with intellectual disabilities must be acknowledged since it evolves around supporters' willingness to develop connections, establish and sustain meaningful interactions (de Haas & Ryan, 2016).

Maximising Human Potential

The second principle of consent gaining interactions is that it must no longer consider intellectual disability as an absolute invariant trait of the person. Disability as a concept is viewed as a social–ecological construct exemplifying the interaction between the person and his or her environment. Therefore communications must focus on the role that meaningful interactions play in enhancing human functioning, self-worth and subjective well-being, so '*maximising human potential*'. Therefore when making a presumption that every person has the right to make decisions and be supported to exercise these rights (ACT, 2015; MCA, 2005), a movement beyond rational and cognitive theories therefore underpins the informed consent process, requiring recognition of affective theories (Cifor, 2016), which minimises the risk of 'absorbing the other'.

Expressing the changing understanding that intellectual disability needs to be recognised beyond an inherent pathological disorder to a more inclusive social ecological functioning, aids in reforming not only systems of support that people living with intellectual disabilities require but also the paradigm shift in medical, legal and familial understandings of delivering the practical functional supports required. In light of decisions to be made, taking cognisance of the timing of these decisions, people with intellectual disability should be supported to provide informed consent via a functional approach to decision-making in order to successfully engage in either or both of the above mentioned approaches.

Being Active Agents within Informed Consent

The following paragraphs demonstrate how people with intellectual disabilities can be supported to be active agents central to decision-making when providing informed consent. The aim being to diminish notions that people with intellectual disabilities are non-progressive and hold perpetually undeveloped cognitive capacities. Maximising decision-making capacity, supported decision-making models and circles of support demonstrate how people can be supported to be active agents within informed consent.

Maximising Decision-Making Capacity

It is now widely recognised that many individuals with intellectual disabilities are capable of providing informed consent with minimal, if any support. For others consent processes need to be tailored to maximise decision-making capabilities. Meaningful interactions need to be incorporated in order to provide support to individuals at the time the decision is to be made, taking cognisance of disclosure (of the procedure, expectations, benefits, risks); understanding (interpretation of information); voluntariness (having a choice, autonomy, self-determination, lack of coercion); competence (ability to make a decision-with required supports) and consent (acceptance or refusal).

For a person to be able to exercise decision-making capacity and make informed decisions, supported in a social and political environment, which recognises and promotes the value of autonomy allowing it to flourish is required (Atkinson, 2007). The terms autonomy and self-determination are sometimes used interchangeably but distinguishing between the two is helpful in relation to understanding 'informed consent'. Atkinson (2007) describes the difference between these terms as follows:

> *Autonomy is the capacity for self-government and self-determination: the ability to choose for oneself. (…/…) Self-determination requires an individual to have the capacity to formulate and carry out plans, desires and policies of their own devising. Self-government further requires the individual to take account of their own rules and values in making these choices* (Atkinson, 2007)

In maximising decision-making capacity, a recognition of the inherent values and respect for humanity in promoting autonomy and self-determination of all people, post-modernists move beyond the status approach of whether a person has capacity or does not have capacity, to acknowledging the wide range of applicability attributable to the moving statuses and functional approaches[2] to maximising capacity. The ability to understand the nature and consequences of a decision, when communicated in appropriate and respectful means, in the context of available choices, at the time the decision is to be made, with supports and accommodation ensures that a person is in a position to exercise their legal capacity.

As post-modernist perspectives of consent are adopted, and the philosophy and understanding of the United Nations Convention on the Rights of People with Disabilities the following definition of legal capacity supporting informed consent is fitting:

> *'Legal capacity to me is a continuum that connects with everything needed to enable the person to flourish—a right to make decisions and have them respected, a place to one's own, a life in the community connected to friends, acquaintances and social capital, whether in public or private settings. Personhood is broader than just capacity—and these broader connections serve to augment capacity in a virtuous circle'* (Quinn, 2011)

Therefore, this perspective flips the traditional belief that disabled people lack capacity to a belief in the unique ability of each person to express capacity by the nature of being a person. These changing beliefs represent a move in social processes from intellectually disabled people perceived as not having abilities, to favouring moving statuses and functional perspectives to viewing capacity as developing decision-making capability to self-determinate.

Supported Decision-Making Models

Supported decision-making models are now recognised as enablers to the implementation of practices facilitating people, especially those with intellectual disabilities, to provide informed consent when making life choices. The following addresses two prominent models of supported decision-making (SDM). Two models describing SDM, 'Maximising Decision-Making Abilities' (Bach & Kerzner, 2010) and 'Enabling Conditions' (Flynn & Arstein-Kerslake, 2014a), are conducive to the implementation of informed consent practices. From a Canadian perspective Bach and Kerzner (2010) conceptualise SDM as a process with outcomes, viewing SDM as:

> *'occurring when an individual with cognitive challenges is the ultimate decision-maker but is provided support from one or more persons who explain issues to the individual and, where necessary, interpret the individual's words and behaviour to determine his or her preferences through three different decision-making statuses'* (Bach & Kerzner, 2010)

The three statuses, (1) legally independent status, (2) supported decision-making status, and (3) facilitated decision-making status, are now presented.

Figure 14.4 demonstrates how providing meaningful supports and accommodations sufficient to the disabled person's unique needs and anticipated outcomes, over time, assists the disabled person in maximising their decision-making capability to exercise their legal capacity. This supports and accommodations approach significantly contrasts with the custodial nature of pervious historical approaches. Within this framework Bach and Kerzner identify decision-

---

[2] Functional approach

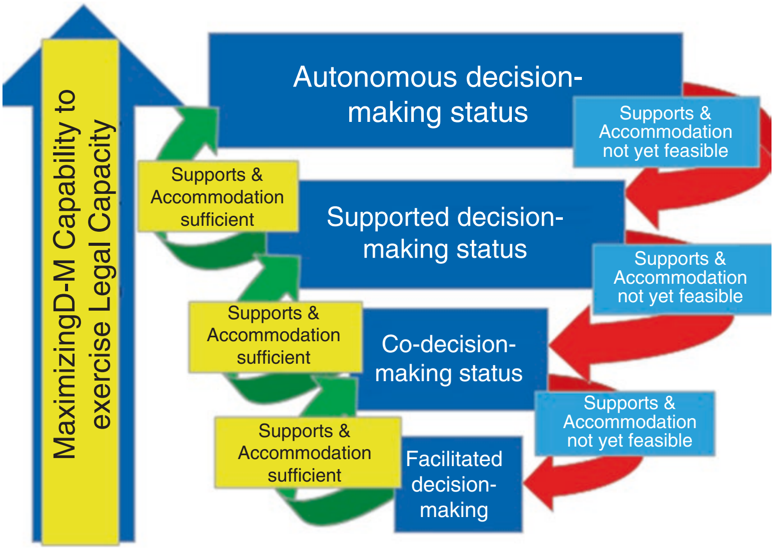

Fig. 14.4 'Maximising decision-making capacity' Bach and Kerzner (2010). This approach to 'decision-making capacity' advocated by Bach and Kerzner (2010) focuses on what accommodations and supports a person requires to manage the decision-making process in a way that maximises their decision-making capacity and thus exercise legal capacity

making statuses, which aim to be consistent with the person's identity. In general, while conceptualising distinct 'statuses' they acknowledge movement between legally independent and supported can be made, depending on the decision in question and the time the decision is made. The conceptualisation of SDM purported by Bach and Kerzner (2010) as a process with outcomes underpins decision-making capability has underpinnings in decision-making capability and seen as a relationship between decision-making abilities, decision-making supports and accommodations, and decision-making status. People move between statuses as abilities, supports and accommodations evolve reflected in Fig. 14.4.

The first autonomous decision-making status, familiar to most people, automatically recognises the person's capability to make decisions, by him/herself or with assistance, to understand and appreciate the relevant information, and the reasonably foreseeable consequences of, making a decision, therefore, exerting will and preference and exercising legal capacity. The first point on Bach and Kerzner continuum is the autonomous legal independent decision-making status, where an individual has the ability to make decisions on his/her own and is recognised as such. This may require reasonable accommodation to assist the decision-making process. One example of this would be ensuring that information relating to the decision is made available in a format which the person can understand (Goldbart & Caton, 2010), giving the person plenty of time to come to a decision, and enabling the use of informal support where the person can consult those closest to them in making the decision (The Office of the Public Advocate, 2014). This point reflects the ways in which most people make decisions by consulting others, while being free to accept or reject their advice.

In the supported decision-making status and co-decision-making status, a support person is appointed by the person with a disability, or by an administrative tribunal or court. This occurs specifically within a meaningful relationship between the person with a disability and his/her support person. The individual is provided with assistance in decision-making in any and all areas desired. This assistance can take the form of a circle of support, whereby the person chooses a number of trusted individuals to assist in the decision-making process (Atherton & Gates, 2007). These should be people who know the individual well, and can help interpret the person's will and preferences and communicate these intentions to third parties (Schalick, Westbrook, & Young, 2012), who are obliged to accept the decision as a valid one. The state should have a role in providing opportunities for support, enabling support

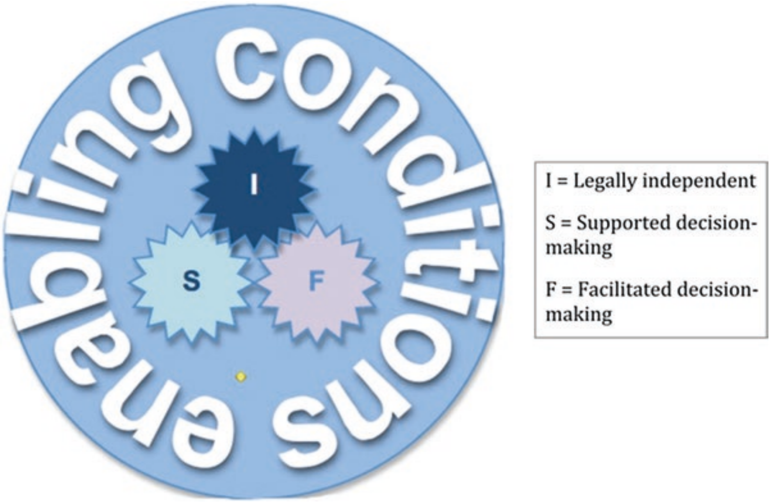

Fig. 14.5 Support model (Flynn & Arstein-Kerslake, 2014a). This model builds on the work of Bach and Kerzner (2010) and acknowledges the enabling conditions a person needs moving between the different statues of decision-making

agreements to be formalised and ensuring that decisions made through this mechanism are respected by third parties (Bach & Kerzner, 2010). Therefore, support person credibility to interpret the disabled person's will or intention, consistent with their personal identity becomes characteristic of supported decision-making, to exercise legal capacity.

In the final facilitated decision-making status a facilitator is appointed by administrative tribunal or advanced planning document (i.e., power of attorney). This decision-making status is applied as a last resort, where there is no circle of support or other person who could reasonably interpret the will and preferences of the individual. In this case, an appointed facilitator takes decisions on behalf of the individual, but does so with the will and preferences of the individual at the centre of the decision-making process and in the manner which best augments the person's autonomy and decision-making capability (Bach & Kerzner, 2010).

The benefits of Bach and Kerzner model is that is focuses understanding on the mechanism of SDM through 'decision-making capacity' when realising how accommodations and supports a person requires to manage the decision-making process in a way that maximises their decision-making capacity and thus exercise legal capacity, given their unique decision-making abilities. Building on the work of Bach and Kerzner (2010); Flynn and Arstein-Kerslake (2014c) purpose the 'Support Model' to SDM presented in Fig. 14.5.

Flynn and Arstein-Kerslake (2014a) SDM 'Support Model' image represents the overarching support model of legal capacity. The cogs in the centre of the circle represent the three statuses of decision-making: legally independent, supported and facilitated as previously outlined by Bach and Kerzner (2010). The major difference in the models relates to the area surrounding these statuses 'the enabling conditions' which include advocacy, reasonable accommodation, accessible information and communication, recognition of different forms of expression, advance planning tools, and so on.

The first principle of Flynn and Arstein-Kerslake model is that every person enjoys legal capacity regardless of his/her level of decision-making ability a principle of Article 12 UNCRPD, and each person should empowered to exercise his/her legal capacity through the expression of will and preference. Second, this requires the abolition of any assessment of decision-making ability (capacity assessment) which, if undertaken, may result in the loss of legal capacity. Any assessment which takes place in a support model of legal capacity should be centred on the support that is needed in decision-making to augment an individual's existing strengths, rather than the deficits of the individual (Flynn &

Arstein-Kerslake, 2014c). The facilitator's role is to imagine what the person's will and preferences might be and to make the decision on this basis. This distinguishes facilitated decision-making from substitute decision-making (Flynn & Arstein-Kerslake, 2014b).

Both models, Bach and Kerzner (2010) and Flynn and Arstein-Kerslake (2014a) are reflective of changing times, emphasising important aspects of the collaborative and relational aspects underpinning SDM in enabling a person to provide informed consent. The models require the abolition of substitute decision-making which subjects the will of an individual to the dominance of another's will or notion of what is in her 'best interest'. This does not prevent a representative from making a decision for another person who is not expressing her will and preferences in a way which anyone can interpret, rather, it requires representatives making such decisions to do so in a way which attempts to draw out the imagined will and preferences of the person (Flynn & Arstein-Kerslake, 2014c).

Recognising that many life choices can be complex, difficult to understand and challenging for some people, the following paragraphs introduce the concepts of circles of support providing for discussion of key elements required to support decision and enable a person provide informed consent.

Circles of Support

Popularity of circles of support in practice are emerging partly due to the philosophy and ideology surrounding the approach, perceived outcomes related to guidance (Macadam & Savitch, 2015), tangible resources and practical assistance (Lay & Kirk, 2011) and emotional support (Kaye-Beall, 2016). Circles of support originally designed to target social isolation and emotional loneliness have more recently been used as a support to intellectually disabled people to be autonomous in the decisions they make. Every circle is different because of the uniqueness of the individual at the centre of the circle and the uniqueness of the contribution of each circle member; therefore, it is important to recognise that one method will not suit all people who require support to make decisions, as everyone is different and will need different supports at different times (Browning et al., 2014).

Understanding person centeredness and circles of support contribute to understanding the ***ideology*** of SDM by facilitating individuals independence in decision-making, legal capacity and avoid having their right to control their decisions taken over by substitute decision-makers through co-production approaches. Perhaps worth noting however, even though a rights based approach to service provision is espoused, freedom and choices in identified service strategies to support this framework are currently more likely to revert support persons to charitable models and a dependency approach to support. For example, with family numbers reducing and family members more geographically dispersed, there is a need to look at natural support systems within local communities and this has been described as 'Circle of Friends' or 'Voluntary Workers' and 'Host Families'. These are generally unpaid and sustainability is challenging. These circles emulate principles similar to that of the social model of disability which recommends person-centred approaches of support to be achievable through assistance of local volunteers and often professional supporters, additional to paid workers (Lay & Kirk, 2011).

Circles have been given a variety of names and follow different models such as 'Self-Directed Support Corporations' and 'Circles of Support and Accountability' and are similar to methods of organising like 'Family Group Conferencing' (Neill & Sanderson, 2012). Therefore, the importance of basing care and support in addition to habitation practices and educational supports on substantial scientific evidence for practical, moral and legal reasons is acknowledged. Inclusion of evidence based practices contribute to the discussion of informed consent and intellectual disability. There is however a dearth of research and empirical literature in relation to circles of support notably in the areas of sustainability, productivity and cost effectiveness.

Trusting and Respectful Relationships in Gaining Informed Consent

Trusting and respectful relationships are pivotal constructs in the optimisation of autonomy pertaining to the life choices of people with intellectual disability. Yet consensus in the literature reveals that by the very nature of the label of intellectual disability, this population group are regarded as vulnerable (Parker, 2012; Parley, 2010) and subsequently their personal choices variably acknowledged and respected. The word 'vulnerable' is now widely used in health and social care, but its precise definition remains elusive, partly because of its universality and dynamism in that everyone becomes or feels vulnerable to a greater or lesser extent at different times in their lives (Pritchard, 2001; Rogers, 1997). Little, Paul, Jordens, and Sayers (2000): 495) identifies vulnerability as 'susceptibility to any kind of harm, whether physical, moral or spiritual, at the hands of an agent or agency' explicating the concept of vulnerability beyond the inherent disposition of an individual to (a) the role an external agent or agents, 9b) the notion of harm (either purposive or unintentional) and (c) the widening of the types of harm and safety beyond physical.

When vulnerability is recognised as being inherently human, perhaps a flaw with post-modernist conceptions of informed consent relate to the elevation of individualism at the expense of considering important relational and environmental considerations. This elevation of individualism minimises the interdependent nature of being and is perhaps not reflective of the experiences articulated by many intellectually disabled people. This chapter opened with the statement that values governing the need for informed consent 'promote and protect a person's well-being' and 'respect a person's self-determination' (Buchanan & Brock, 1990). Perspectives of both intellectually disabled people and those who support them should be established determining what exactly family, circles of support, citizenship, friendship and/or professional assistance looks like and how they work to ensure honesty, transparency and clarity when determining roles and functions. Therefore, the authors recognise how informed consent is based on the premises that all persons:

- Have decision-making abilities and make decisions.
- Require varying levels of support at different times.
- Receive appropriate communication to inform understanding.
- Experience trustful and respectful interactions.
- Have equal legal rights.

Building on the above premises, safeguards in post-modernist times especially for people with intellectual disability, provide that those who support this group of individuals are obliged to identify and act on the persons will and preference and to accept their determinations as valid decisions. It is the states' responsibility to ensure legal mechanisms are in place so as to explicate this will and preference. In the context of informed consent, the following sections present practical examples of access and participation in research and healthcare relevant to the lives of people with intellectual disabilities.

Informed Consent Gaining and Research Participation

As previously discussed, research was often undertaken about people with intellectual disabilities, rather than being inclusive of them, and often without their consent; therefore, such research participation was without safeguards (Taua, Neville, & Hepworth, 2014). Understandably, in the past number of years ethical regulation of health and social research has increased considerably (Wiles, 2013). Various international and national ethics guidance have now proliferated policies and procedures which enshrine the concept of 'informed consent' as the principal code to be adhered to protect the individual patient or healthy volunteer subject from possible exploitation and harm conceptually linking to discourses of human rights and autonomy. Particular challenges can present to researchers seeking to access population groups such as people with intellectual disability who are regarded to be some of the most vulnerable or marginalised in society, and researchers must ensure rigorous ethical safeguards are in place (Carey, 2010; Ramcharan, 2006). These people regarded to be vulnerable are entitled to participate in research while having their interests safeguarded (Smith, 2008).

Iacono (2006) describes the dilemma between the intentions of an ethical committee of protecting people with intellectual disabilities from potential harm when participating in research while guaranteeing them the autonomy to make their own decisions as they participate in research. Gilbert (2004) discusses the groups of people who may be involved and the influences they may have when research is undertaken in the field of intellectual disabilities. Diversity and complexity of lay and professional groups and individuals, along with knowledge, attitudes and power relationships are issues identified which can be influencing factors in research access and participation by people with intellectual disabilities. A prime example is provided by Carey and Griffiths (2017) who report that adults with intellectual disability were required to undergo physical and mental health assessments in order to be deemed to be fit to participate in a research study. These authors raised the question as to whether this was a reflection of principles of beneficence and non-maleficence or an act of discrimination?

Once ethical approval has been obtained potential participants with intellectual disability are often conscripted to research participation through intermediaries, such as their family, support workers, social workers, friends, unpaid carers or doctors (Nicholson et al., 2013). Formal gatekeepers are officially appointed within services whereas informal gatekeepers are people known to the person and who can influence the person's decision-making about research participation. For the duration of many research projects those who fulfil the role of formal gatekeeper are often managers nominated by organisations. Such gatekeepers are those people who control access to either participants or data (Gerrish & Lacey, 2007). Enlisting managers as gatekeepers can facilitate the research process and promote the best communication practices between the researcher, the participants and where necessary, families, about the nature and procedures associated with the research (Carey, 2010).

Conversely, undertaking such dual roles of gatekeeper and manager may also result in issues of power impacting the research, as gatekeepers have been regarded as people who can either help or hinder research depending upon their personal beliefs (McDonald & Kidney, 2012). Lee (1993) found that in some research, frequent attempts were made by gatekeepers to frustrate and circumscribe the studies, while in other research projects, gatekeepers had preconceived expectations of the appropriate methodology and refused access to the study population. Carey and Griffiths (2017) recommend to those proposing to recruit and undertake research with people with intellectual disabilities to consider:

- *The need to build and maintain trusting relationships with relevant formal and informal gatekeepers.*
- *To set time aside to understand the attitudes and concerns gatekeepers may have with regard to a research study, principally how it may impact on the potential participants with an intellectual disability, support persons and the service involved and to work to alleviate such concerns.*
- *To set time aside to get to know and understand potential research participants.*
- *To engage in reasonable accommodations to support decision-making with and for adults with intellectual disabilities so that they can make decisions about participating in research.*
- *Ensure the person understands what they need to do to participate, how the research actually applies to them.*
- *Endorse the activity of ongoing consent by ensuring the each participant is appropriately informed in a timely manner and where necessary offered reminders and repetitions of the processes involved while being vigilant and observant for signs of assent and dissent.*

- *Affording time for participants to process and assimilate information regarding the nature and procedures associated with the research study and their associated feelings and thoughts.*

Carey and Griffiths (2017) advocate the benefits of familiarity in enhancing research experiences for researchers, gatekeepers and people with intellectual disability. Familiarity of the ways of knowing the person can illuminate routine ways the person communicates, for example, how do they express how they want to opt in or opt out of ordinary life choices. By understanding the ways of knowing of the person the researcher can tailor the appropriateness of information sharing to the identified timely and decision-specific needs of the person. If researchers are to engage meaningful interactions with potential participants in order to identify their will and preferences and to gain informed consent then researchers need to spend time understanding their ways of knowing as expressed by these individuals themselves, an element which must be factored into ethics applications. Currently this is challenging as researchers have limited access to such groups prior to gaining their informed consent. Many researchers are not identifying frameworks which assist those undertaking research with people with intellectual disability who do not have time spent with the person prior to undertaking the research. For example, Taua et al. (2014) describes a qualitative research study undertaken in New Zealand. Taua et al. (2014) included individuals with a dual disability (intellectual disability and mental health issues). The overarching aims of the study were to understand what people with a dual disability and carers experienced during the time of an inpatient admission to a mental health service. University ethics approval granted in Australia and multi-region ethical approval granted by a national ethics committee in New Zealand. Making minor adaptations and additions to those originally developed by Dougall and Fiske (2008, pp. 73–75), Taua et al. (2014) presented a framework for researchers to follow during the consent gathering process taking cognisance of the following:

- *Communicate slowly and clearly, quiet location with minimal interruptions.*
- *Concepts and questions introduced one point at a time.*
- *Use an appropriate level of language for each individual.*
- *Provide a written copy of the key points (use colour where possible).*
- *Combine words and pictures wherever possible.*
- *If possible, encourage the person to take their own notes so they can check back with you.*
- *Explore other ways of providing information if written and/or verbal information do not work (*e.g. *video, audio, pictorial).*
- *Use diagrams and flowcharts wherever possible (at least have several different formats prepared).*
- *Ask the person to repeat back frequently to confirm understanding.*
- *Utilise a support person/translator, as necessary.*
- *Allow enough time.*

Furthermore, for researcher perusal these author provided a list of reflective questions:

- *Did I provide all the information needed?*
- *Could the information be presented in a way that is easier to understand (*e.g. *visual aids, or with simpler language)?*
- *Have I fully explored all the different methods of communication?*
- *Did I ensure the right supports/people were in place in order to prevent coercion?*
- *Have I explained all the risks and benefits?*
- *Did I allow enough time for questions?*
- *Did I check back frequently enough?*
- *Was the environment appropriate/conducive?*
- *Have I documented the consent process thoroughly?*

Taua et al. (2014) recognise how the basic frameworks for seeking informed consent from potential participants should not differ dramatically for any person, as there is a level of risk for all participants in research. It is critical, however, that researchers recognise the higher levels of vulnerabilities in the intellectually disabled population, especially those with a dual diagnosis and ensure that their recruitment processes are rigorous and respectful. Research with people with intellectual disability should maximise the benefits of the research and minimise the risks, and those who are to conduct the research should be competent to do so, and if needed, be appropriately supervised. Researchers must not only be vigilant in listening to the communications of their research participants but they must hear what they are saying. Researchers must ensure that their research approaches can be flexible enough to concur with changing needs of research participants.

Informed Consent Gaining and Healthcare

In terms of the prevalence of health conditions, individuals with an intellectual disability have poorer health than others (Emerson, 2009). Entitled to be treated with dignity, respect, honesty and be involved in decisions about their health and well-being, it is well known that people with intellectual disabilities experience challenges in this regard (Krugman, 1986; Resch et al., 2010). Specifically healthcare access and healthcare participation arise as prominent issues of vulnerability for this population group (Philips, 2016; Wark et al., 2017). For those supporting people with intellectual disabilities there is a necessity to place more attention on care needs, access to healthcare, preventive care and health promotion (Lafferty, O'Sullivan, O'Mahoney, Taggart, & van Bavel, 2016; Sheerin, 2011).

Wark et al. (2017) sought to understand informed consent when supporting individuals ageing with intellectual disability to participate in developing their own health and support programs. Indeed, challenges in the provision of oral healthcare to people with intellectual disability have been acknowledged as physical dexterity, impaired sensory functioning, communication and behavioural problems (Knibb, 2010). And notably, in the provision of healthcare, the presence of cognitive disorders have traditionally been synonymous with critical impairment of decision-making abilities. Subsequently, a long-standing culture of paternalistic practices have existed and for some people remain evident, especially so when those providing services to people with intellectual disabilities have limited experience of intellectual disability.

The following demonstrates how the attitudes and practices of healthcare professionals can impact the informed consent experience of people with intellectual disabilities. In aiming to identify the main approaches adopted by dentists in a French study, Camoin, Dany, Tardieu, Ruquet, and Coz (2018) found a 'reassuring attitude' to be the main approach that ensued when treating an anxious child with intellectual disability. Four topics were discussed, first contact with the patient, information, attitude towards the patient and outcome from the practitioner's viewpoint. The coding procedure used thematic content analysis. In all twelve dentist participant's, eight women and four men (mean age = 42.5), three had an exclusively hospital practice, three had a private practice, and six practiced in both settings. Regarding experience, four practitioners had less than 5 years' experience, six practitioners had over 15 years' experience, and two practitioners had between 5 and 15 years' experience. All practitioners interviewed declared that they informed the patient about what was happening, from the start and throughout the session. This information was conveyed by various means (verbal and non-verbal communication) and various approaches (distraction, tell-show-do, transitional object). Different communicational strategies used were:

- ***Tone of voice***: *'I mainly use a soft and empathetic tone', 'my voice is calm, composed and even' (male, more than 15 years' experience, private practice).*
- ***Tell-show-do***: *'I show the patient the mirror, I make them touch it with their fingers, and then together we put it in the patient's mouth' (female, more than 15 years' experience, private practice); 'I always show the patient the*

instruments and let the patient touch them before I put them in their mouth' (*female, less than 5 years' experience, both private and hospital practice).*
- ***Use of a transitional object*** *(cuddly toy): 'If the patient brings a cuddly toy, it can also be used to show that the mirror is harmless' (female, between 5 and 15 years' experience, private practice).*
- ***Distraction****: 'Did you have a good holiday?' (female, between 5 and 15 years' experience, both private and hospital practice). 'I tell him a story to distract him, with a knight or a princess for example' (male, between 5 and 15 years' experience, hospital practice).*

These strategies demonstrate a variety of approaches and various mechanisms promoting relations between practitioners and children with intellectual disabilities. Worryingly, the practitioners within the study reported that if an ethical dilemma arose, and the patient refused care or had to be restrained, ethical values of patient autonomy would be sacrificed, under the realms of beneficence and non-maleficence, when clinical decisions were made.

Similarly, Goldsmith, Skirton, and Webb (2008) conducted an integrative literature review examining how consent was obtained from people with intellectual disabilities for healthcare interventions. Time limits set were publication between January 1990 and March 2007, encompassing 17 years of research with adult populations. The data reflected the opportunities and processes that intellectually disabled people demonstrated within consent to research, consent to treatment or (indirectly) consent to taking medication, while some data reflected hypothetical vignettes and some 'real-life' situations. Overall, the integrative review findings highlight the negative attitudinal responses as a main barrier to obtaining informed consent by healthcare staff. Several of the included studies reported that staff assumed that individuals with intellectual disabilities were unable to consent to treatment, and one study demonstrated that staff were unaware of guidelines relating to consent. Not surprisingly, assumptions of staff in this review demonstrate the prominent attitude of the status approach, all or nothing attitude to gaining informed consent. The review recommends a functional approach to assessing capacity for the purpose of obtaining informed consent recognising the complexity and nature of the decision need to be taken into account (Goldsmith et al., 2008).

Therefore, whether or not capacity to consent is achieved depends on the effort to 'tailor' the relevant information to the abilities and needs of the individual concerned. A significant point raised in this integrative review recognises how professionals are obliged to comply with their country's legal requirements; in practice, however, this may cause problems due to the time needed to maximise the potential for capacity in many people with intellectual disabilities. Future research into informed consent in people with intellectual disabilities is needed using real-life situations which are more likely to be familiar to the participants than hypothetical vignettes.

In 2013, further developing the theme of gaining informed consent with real-life situations, Goldsmith, Woodward, Jackson, and Skirton (2013) conducted a primary qualitative study using an ethnographic approach. People with intellectual disabilities were eligible for this study if they were aged 18 years or over, able to consent to participate in research, not affected by acute physical health problems, and not currently under the care of the local mental health team. The final inclusion criterion was the requirement for a routine blood test (e.g. for monitoring blood sugar control) within a few months of recruitment.

Participants' age ranged from 27 to 65 (mean 45). Half (50%) lived in a shared house (supported living), with the remainder either living at home with parents, living independently with support, or living along with informal family support. Participants with severe or profound intellectual disabilities were excluded, and this limits the transferability of the findings. Twelve of the 14 participants were single.

Observations and interviews formed the methods of data generation. Six participants were observed having one blood test, the observation period ranged from 3 to 6 min. All participants observed having the blood test were due to have blood tests as part of their routine medical care. All six participants were well known to the health professionals who performed the blood test. Health professionals included phlebotomists, healthcare assistants and registered general nurses. One semi-structured interview was conducted with 14 participants lasting between 12 and 35 min. All participants were offered the opportunity to bring a supporter to the interview and ten did so.

Consultations and interviews were video- and audio-recorded to ensure accurate transcription and enable observation of non-verbal behaviour. Data analysis was approached in an inductive way, considered appropriate for an exploratory, descriptive study guided by Braun and Clarke frameworks (Braun & Clarke, 2006). In all, the researchers identified six key themes; the patient in the healthcare context, information and knowledge, the consent process, behavioural characteristics, strategies and coping mechanisms, and 'the self'. Significantly, researchers noted that the consent process did not appear to be fully followed in any of the consultations observed in the taking of blood. In some cases, adequate information was provided. However, in the majority of cases, the health professional did not check that the participant understood the information given; this is an essential requirement for informed consent.

Goldsmith et al. (2013) reiterate the strength of their 2008 findings adding how personal qualities and experiences may influence the consent process; factors such as a person's place of residence, previous health experience and opportunities to make their own life choices all contribute to the individual's ability to consent to healthcare interventions.

In this study, the health professionals knew all participants described as 'experienced' patients. This may have led the health professionals to make assumptions concerning consent. As this study was conducted in the UK Goldsmith et al. (2013) noted that these assumptions would not be sufficient to fulfil the requirements of the Mental Capacity Act (2005), as it is the responsibility of the person carrying out the procedure to ensure that valid consent is in place at the time and this should include provision of relevant information. The right to self-determination and the right to full disclosure are major components on which informed consent is based (Grove, Burns, & Gray, 2014; Polit & Beck, 2004).

In addition, in the Goldsmith et al. (2013) study, there are two points worth highlightening (1) people with intellectual disability lack experience in decision-making, and the affect this has on their functional capacities with regard to informed consent and (2) clearly expressed their information needs with regard to their healthcare; they required clear, accessible information, with any verbal explanations being simple and without jargon.

Most notable, in Goldsmith 2013 from the 2008 study is the change in attitude of staff, in the belief that people with intellectual disabilities seek information and consent to healthcare procedures. These studies demonstrate the need to ensure there is greater awareness of increasing opportunities for effective communication to ensure that intellectually disabled people have choice, are in control and active in decision-making regarding their life choices. Nevertheless, even with the global and philosophical impetus of supporting decision-making, particularly with the implementation of the UNCRPD, current research reports continue to highlight challenges of implementing such moral and ethical principles.

Conclusion

Over the years consent theorists' have and continue to strive to illuminate and develop both the simplicities and intricacies of informed consent. An overview of historical contexts of consent theory, the impact of the bioethics and the evolving definitions informed consent lead to a current representations of informed consent both as a process and as an interactive cycle.

This chapter has presented informed consent as a dynamic, contextually driven, respectful approach to viewing people with intellectual disability primarily as decision-makers, inextricably linking informed consent with supported decision-making and rights.

This chapter presented a new way of thinking about informed consent and the role of communication and interaction. Figures 14.2 and 14.3 present an understanding of the components of informed consent asserting the importance in developing meaningful relational interactions in time and overtime to enhance mechanisms developing engagement in disclosure, understanding, voluntariness, competence and consent.

Building on such premises, the authors acknowledge the need for safeguards ongoing process and maximising human potential in supporting people with intellectual disability to identify and act on their will and preference.

Recommendations

There is a need for persons with intellectual disabilities, policy makers, legislators, service providers and supporters, to recognise how processes and interactions of informed consent maximises human potential.

People with intellectual disabilities need to have meaningful involvement at all levels in all aspects of decision-making and informed consent which affects their life choices.

- Persons with intellectual disabilities be included in education, research and philosophical debates exploring what informed consent means to them in their lives.
- Perspectives of both intellectually disabled people and those who support them to be established determining what exactly family, circles of support, citizenship, friendship and/or professional assistance looks like and how they work to ensure honesty, transparency and clarity when determining roles and functions in supporting people to make informed decisions.

As policy and legislation continues to develop in response to the needs of people with disabilities progress needs to be monitored and evaluated from the perspectives of all stakeholders. To continue driving the human rights agenda, building on the work of the UNCRPD to enable people with intellectual disabilities to take their rightful place in society as active citizens.

Service providers ensure that reasonable accommodations are afforded to people with intellectual disabilities so that they are equal members of their society.

In maximising decision-making support services need to ensure that meaningful interactions are incorporated in practices central to successful processes and interactions.

There is an onus to ensure explicit structures and procedures are utilised to enable the person to make decisions.

Individuals who support persons with intellectual disabilities must engage trustful relationships, aiming to support the person to explicate their will and preference to maximise human potential in decision-making. And when necessary ensure the availability and delivery of information about reasonable accommodations to enable the person in providing informed consent.

Research Priorities and Protections

15

Susana Gavidia-Payne and Mervyn Jackson

Introduction

Research can be simply defined as the establishment of a (new) knowledge base through the systematic application of agreed upon protocols. Approaches to research depend upon epistemologies, which vary considerably and require adaptation to specific questions as applied to particular populations. However, the creation of scientific knowledge should always follow ethical (or moral) principles. These principles govern the behaviour of researchers during all stages of the research process. They involve: the framing of research questions that benefit the target population; deciding upon a representative sample; ensuring participants have given informed consent (including the right to withdraw and protection from harm); using materials/test instruments that will generate reliable and valid knowledge; and, ensure responsible reporting of findings that lead to benefits for participants, the target population and the community/society as a whole. However, ever since research on humans began, problems with the ethical conduct of medical and behavioural researchers have continued. A clear example is highlighted by Beecher's (1966) paper on "Ethics and clinical research" (Jones, Grady, & Lederer, 2016). In his review of contemporary medical research, Beecher compiled a set of 50 empirical studies funded by US, Canadian or European Union Government agencies and published in leading medical journals (including the New England Journal of Medicine) that breached current ethical guidelines. While not specifically focusing on research involving people with intellectual disability, Beecher (1966) hoped that drawing attention to ethical problems would be sufficient for future researchers to address these issues (Jones et al., 2016). However, Jones et al. (2016) concluded that 50 years later, with ethical values changing over time, there is little consensus on what counts as ethical research; many conflicting interests in determining what is acceptable, ethical research still remain. The purpose of this chapter is to address the extra complexity of applying ethical principles to research involving people with intellectual disability, and the issues that continue to be posed for their participation in research that is ethical and significant to improve their quality of life. This chapter will review the history of abuse in the field, with a focus on ethical dilemmas emanating from past and contemporary research studies, including the implementation of safeguards used to protect people with intellectual disability. As research efforts are essential for improving the quality of life of people with intellectual disabilities, this chapter will discuss the prioritization of research themes in line with their level of acceptability.

The presentation of ethical dilemmas, conceptualized as those problematic situations where two or more principles or values conflict and more than one principle applies while there are good reasons to support mutually inconsistent courses of action (Kalvemark, Hoglund, Hanssona, Westerholmb, & Arnetza, 2004), has pervaded the history of human research. A classic illustration can be found in the series of social psychological studies carried out by Milgram in the 1960s where he suspended the participants' right to withdraw from experiments. To study obedience, Milgram developed a research paradigm where he placed subjects in a moral dilemma: Harm a fellow participant or defy the experimenter and withdraw from the experiment (Gridley, et al., 2017). To test defiance/obedience, Milgram provided the experimenter with standard prompts to be given to reluctant subjects ("the experiment requires you to continue, the next word is…"). This prevented subjects from terminating the experiment even though they clearly did not want to continue. The resolution of ethical dilemmas in research varies depending upon the dilemma and the experimental context. While the solution to some ethical dilemmas in research involves choosing the greater good/lesser evil solution, other ethical dilemmas are best resolved by case-based reasoning (Leake, 2001). Case-based reasoning can be applied to research involving people with intellectual disability where research has relied primarily on resolving the unique features arising from their diversity. In this way, Carlson (2013) has raised a number of ethical dilemmas associated with research involving people with an intellectual disability. These include: inclusion (and risk of exploitation) of people with intellectual disability vs. the exclusion (and discrimination) of people with an intellectual disability; the importance of informed consent vs. the inherent difficulty of obtaining informed consent; and the research focus on curing and preventing intellectual disability vs. affirming the right and quality of life of people with an intellectual disability to inhabit a shared world with people without disability.

Ethical dilemmas become more prominent as the *intellectual disability* classification (American Psychiatric Association, 2013) casts a wide net, encompassing individuals with a broad range of abilities and disabilities This complicates efforts to make generalizations about people with an intellectual disability as a single uniform group (Carlson, 2013). Hence, ethical considerations have to be adapted and qualified for each unique individual who is being considered as a research participant. The common characteristics of intellectual disability require that researchers need to carefully consider the challenges of working with this population, and with their participation, their various ethical issues that can arise. These may include: the capacity of the participant to make an independent informed decision to fully participate; the ability of the research team to simplify complex information (including research designs that involve placebos and no treatment controls); the manner in which this information is communicated (verbal, visual, etc.); the awareness that people with an intellectual disability may lack the experience of making independent decisions on their own behalf; the avoidance of any coercion or undue influence by researchers or other non-research people (parents, guardians) who may be involved directly (surrogate) or indirectly in decision-making; determining the risks/harm and benefits to the individual participant and not just the benefits to the research team or society; and, the continual monitoring through the whole research process to detect any discomfort/distress (resistance) that may directly or indirectly be displayed by the research participant indicating that they may no longer wish to participate (Bailey et al., 2014; Calveley, 2012; Iacono & Carling-Jenkins, 2012; Williams & Moore, 2011). This challenge is central as Carlson (2013) reported on a survey of clinical trials involving people with an intellectual disability on the US National Institute's registry. The survey revealed hundreds of studies involving participants with a variety of intellectual disability conditions (from broad designations of intellectual disability to specific conditions such as Down syndrome) using a wide variety of designs (random control trials, drug trials, genetic research and behavioural observations) into a variety of topics (including the nature and aetiology of disability to the impact of disability on various health conditions). With a wide variety of studies on a diverse population of people with intellectual disability, it is essential that all possible ethical concerns are explored and resolved.

Historical Context

There have been a number of remarkable reports on studies in which people with an intellectual disability have been subjected to unethical practices. These include (but not limited to) the following: World War II medical research; drug trials using live polio viruses; the failure to treat syphilis by the Tuskegee Institute; the purposeful infection of hepatitis at Willowbrook Sate Institution; and the use of children with intellectual disability in radioactive experiments. One of the most historically salient studies occurred during World War II in Nazi Germany, medical researchers completed many experiments on participants (including people with intellectual disability) without their consent and without any safeguards for their protection from harm (Annas & Grodin, 1992; Berg, 1996; Freedman, 2001). These medical researchers were put on trial after the war and as a consequence of these deliberations, the judges issued the Nuremberg Code of medical ethics, addressed further below. In another study in 1950, researchers reported feeding the live polio virus to 20 children with "mental retardation" at the Letchworth Village in New York State. The researchers did not request permission from the New York State Department of health (they later reported they believed the request would be denied) and there was no record in the original report of parental permission being sought or granted (Smith & Mitchell, 2001).

Originally called the Tuskegee study of untreated syphilis in the Negro male, this experiment began in 1932 by the US Public Health Service and the Tuskegee Institute, lasting for 40 years, and only terminated by a journalist whistle-blower (Dawson, 2008); it is considered one of the most unethical studies in history. The study comprised 600 participants (399 who had syphilis) and while promised free health treatment, none were treated even after the effective penicillin therapy became widely available. Participants were adult black males who were poor, had little education, were from rural areas, and many who were likely to be classified as having an intellectual disability.

Another infamous study took place at the Willowbrook State School (located on Staten Island, New York), which was a state supported institute housing children with an intellectual disability. In the first decade of operation (1950s) the institution become over-crowded and had frequent outbreaks of hepatitis. In order to understand the transmission and progress of this infectious disease, healthy children from Willowbrook were injected with various strains of hepatitis (Angell, 1992; Beecher, 1966; Krugman & Shapiro, 1971; Krugman, Ward, Giles, Bodansky, & Jacobs, 1959). While parents gave consent, later inquiries into this research found that they were not adequately informed about the risks/harm of these medical experiments (Freedman, 2001; Grodin & Glantz, 1994). Also at the level of state facilities, the (US) President's Advisory Committee on Human Radiation Experiments reported on a series of experiments using institutionalized children (with intellectual disability) at the Fernald and Wrentham Schools (West, 1998). The researchers exposed residents to radiation to investigate its effects on the human body's mineral absorption. While parents provided consent, they were not informed that the research involved ingestion of radioactive material (Advisory Committee, 1995: Freedman, 2001). Interestingly, the inquiry found that these experiments were conducted to the ethical standards of the day, but still violated the human rights of the participants (West, 1998). The direct result of each of these ethical abuses led to key inquiries with reports that helped frame current ethical guidelines into research involving people with intellectual disability.

Responses to Historical Events

In response to these ethical violations by researchers, a series of inquires reacted and responded by developing codes and guidelines for ethical researchers. These included the Nuremberg Code (Nuremberg Code, 1949); the Helsinki report (Declaration of Helsinki, 1964); the Belmont code (Belmont Report, 1978); and, the Common Rule. After World War II, a series of trials (known as the "Doctors' trial") were administered to hold German medical researchers accountable for conducting unethical medical procedures on prisoners (no informed consent, no voluntary participation, and no protection from harm). On advice from expert medical advisors to the prosecution, the three judges published a 10-point Nuremberg code of medical ethics. It included ethical principles such as need for informed consent; the absence of coercion; the principles of maleficence and benefice; properly formulated research paradigms; properly trained, qualified staff; and the participants' right to withdraw if they felt physically and mentally unable to continue. While the Nuremberg code was not officially adopted as law by any nation, it has been considered to be one of the most important documents in the history of clinical research ethics. It directly influenced the establishment of the Declaration of Helsinki and subsequent national regulations on research conduct in many nations including the USA, Canada, UK and Australia. Strict adherence to the Nuremberg Code could exclude the participation of many people with an intellectual disability from any scientific research, since the code clearly establishes that the voluntary and full informed consent of the human subject is absolutely essential (Glidden, 2008; Nuremberg Code, 1949). The powerful influence of researchers and parents/guardians, and the limited experience and understanding of participants with intellectual disability pose severe barriers to provide voluntary, informed consent (Berg, 1996: Clements, Rapley, & Cummins, 1999; Dalton & McVilly, 2004; Iacono, 2006; Weisstub & Arboleda-Flórez, 1997). While it must be recognized that some people may not be able to give informed consent, every effort should be made to ensure ethical practices are developed so that people with an intellectual disability will not be excluded from research (McCarthy, 1998).

The Declaration of Helsinki was developed by the World Medical Association and is a set of ethical principles regarding human experimentation. The declaration is morally binding on medical practitioners and its obligations override any national or local laws or regulations. The basic principles include: respect for the individual (participant); their right to self-determination; their right to make informed decisions; their right to fully participate or withdraw consent at any time; participant welfare must take precedence over the interests of science and society; and ethical considerations override national laws and regulations. There have been seven revisions (latest 2013) but many of the later revisions have been controversial and many nations (including USA and European Union) only recognise changes up to and including the third revision (1989) in their national legislation. The benefits of requiring researchers to follow internationally endorsed ethical standards such as the Declaration of Helsinki are evident. However, the Declaration of Helsinki states that some research populations are vulnerable and need special attention. Although vulnerability was never defined and there has been a tendency that the concern to protect vulnerable populations (for example, people with an intellectual disability) may lead gate keepers (ethics committees) preventing their inclusion in research studies. It is important that the protection of the rights of people with an intellectual disability is enhanced to the extent that it allows them to be ethically included in relevant research (Dalton & McVilly, 2004; Iacono, 2006).

In the USA, the Belmont Report (1978) summarizes ethical principles and guidelines for research involving human subjects and was created by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. Three core principles are identified: respect for persons (participants); beneficence; and social justice. The three primary areas of application are: Informed consent; assessments of risks and benefits; and, subject/

participant selection. In the USA, the Federal Policy for the Protection of Human Subjects (known as the "Common Rule") is based on the fundamental principles of the Belmont Report. However, community-based participatory researchers have criticized the Belmont Report because it is general in nature and does not take into account individual differences (including people with intellectual disability) (Shore, 2006).

The Nuremberg code (1949) and the Declaration of Helsinki (1964) form the basis for the ethical guidelines developed by various national government bodies including: National Institutes of Health (USA); National Health Service (UK); Medical Research Council (Canada); and, the National Health and Medical Research Council (Australia) (Iacono, 2006). However, these documents do not specifically address research involving people with an intellectual disability (Yan & Minur, 2004). Each document has separate sections for inclusion of people with an intellectual disability in research protocols, but none of the codes are sufficiently detailed to provide adequate guidelines to ensure the ethical inclusion of people with an intellectual disability in research. It must be noted that the rationale for these codes was in response to mainstream ethical dilemmas at the time and were not aimed to address the needs of specific populations such as people with an intellectual disability (Beecher, 1959; Curran, 1982; Musto, 1999; Perley, Fluss, Bankowski, & Simon, 1992; Yan & Minur, 2004).

Contemporary Ethical Dilemmas Involving People with Intellectual Disability

It has been widely acknowledged that people with intellectual disability played a very small to no role in decisions affecting their lives (Bailey et al., 2014; Freedman, 2001) with often incorrect assumptions about their cognitive capacity and functional competencies. It is then unsurprising that having a say about their participation in research endeavours may have also been considered problematic if not challenging to themselves, researchers and community alike, more particularly in the implementation of outcome-based research and genetic testing and therapy (Freedman, 2001). Investigations have then been fraught with difficulties, where consent, decision-making and risks and benefits of research participation of people with an intellectual disability have been amplified (Carlson, 2013; Iacono, 2006). The last 20 years, however, has seen an emphasis on self-determination, empowerment and self-advocacy by people with intellectual disability, all of which have brought to a head further dilemmas about whether, how and when people with an intellectual disability can become active research participants (Freedman, 2001; Stalker, 1998). While recent research has yielded further light in understanding these contentions from the perspectives of researchers and research participants with an intellectual disability (McDonald, 2012; Watchman, 2016), three issues remain complex and debatable, namely, decision-making, informed consent, and active participation in research endeavours. It must be noted that these ethical aspects of the research enterprise are closely interconnected in their execution, but for purposes of clarity, they will be treated separately in the present chapter.

Decision-Making

The process of decision-making is typically conceptualized as encompassing four components: (1) understanding relevant information; (2) appreciating a given situation and its consequences; (3) reasoning about available options; and (4) communicating a choice (Appelbaum, 2007). These features have been inextricably linked with the assessment of cognitive competence or capacity which may render an individual impaired and unable to understand information and act on the various available options. It is impairment associated with body function and structure as described in the International Classification of Functioning, Disability and Health [ICF; World Health Organization (WHO), 2013], that has been generally assumed to be the main barrier for people with an intellectual disability to make decisions about participating in research processes. This proposition is debatable considering that people with an intellectual disability do not constitute a homogenous group, and that intellectual disability is characterized by elements beyond cognitive impairment and affective states. As recognized by the ICF (WHO, 2013), it is possible that other experiences of a personal, social and environmental character such as lack of information and support, prior history in decision-making to participate research and some gate-keeping (McDonald, Conroy, Olick, and The Project ETHICS Expert Panel, 2017a) may be responsible for the limited participation of people with intellectual disability in research endeavours. This situation has given way to proposing forms of decision-making such as surrogate (Freedman, 2001), supportive (Iacono, 2006) to more actively participatory (Stack & McDonald, 2018). The latter has been favoured as more thoroughly serving the needs of people with an intellectual disability for inclusion, choice and participation as shown by McDonald, Conroy, Olick, and The Project ETHICS Expert Panel (2017b). The authors examined the perspectives of adults with intellectual disability, family members, researchers, disability service providers, and Institutional Review members about the perceived harmfulness of decision-making processes leading to research participation. All stakeholders agreed that surrogate decision-making was comparatively more harmful than other forms of decision-making. The authors concluded that the 'assent' expressed by people with intellectual disability in terms of their desires and thoughts should be a significant factor to be considered in the decision-making process to participate in research activities.

Variation in 'decisional capacities' for types of research has also emerged as a key point to consider beyond legal or other imperatives (Bailey et al., 2014). In their examination of parental ratings of decisional tasks of adults with Fragile X to participate in clinical trials, Bailey et al. (2014) reported great variability in decisional abilities, with 29% of adult males rated as not being able to complete decisional tasks as portrayed in a series of vignettes. Older people with Fragile X, whose parents were more willing for their child to participate in research studies, were predictors of greater participation in research. Recent studies also suggest that people with intellectual disability can and want to enact their preferences about participating in research with certain characteristics above others. They wish to make decisions about their participation, especially in research that involves positive social interactions, increased agency and confidentiality (McDonald et al., 2017a). It is then possible that a number of factors may be influencing the decisional capacity to participate in research, ranging from individual to more contextual in nature. Consensus on what constitutes an appropriate threshold for decisional capacity for varying types of research (Bailey et al., 2014; Freedman, 2001) is yet to be reached. Further research in this area can assist in providing a framework for 'degrees' of levels of participation in different types and aspects of research studies (e.g. medical vs. social research) according to the decision-making characteristics of people with intellectual disability. This may be a useful approach for ethics review boards to address not only ethical requirements and place appropriate safeguards in place, but also to be in line with the claims of people with intellectual disability for independence and autonomy.

Consent

Consent to participate in research has been inextricably linked to the notion of cognitive capacity or competency of people with intellectual disability, generating questions about whose responsibility it is to determine such capacity to provide informed consent (Iacono, 2006). While acknowledging that tensions and dilemmas around this issue continue to exist (Morgan, Cuskelly, & Moni, 2014), it is assumed that the right for autonomy and self-determination of people with intellectual disability is central to consenting to research participation. The question then arises, how would this look in practice? The operationalization of the process of consent can assist in teasing out how people with disability engage with consent provision. Specifically, this may mean ascertaining how people with intellectual disability vary in the extent to which they understand the information provided; appreciate different options and their consequences (risks and benefits), and are able to communicate a choice (Appelbaum, 2007). Horner-Johnson and Bailey (2013) tested these notions by examining the answers of people with intellectual disability to questions about key aspects of the consent process associated with a health promotion study. It was revealed that while more than half of participants correctly answered all of the questions, the remaining could not, with identifying potential risks of being in the study proving the most challenging. Horner-Johnson and Bailey concluded that many people with intellectual disabilities can provide their own consent to participate in low risk studies. However, the authors also raised the question of whether consent to participate in research studies is truly informed and understood as it has been argued elsewhere (Flory & Emanuel, 2004). A number of characteristics and elements of research studies, such as level of risk, design and topic, may be influencing the extent to which people with intellectual disability understand information that allows them to provide consent to participation in research events. Conceptualizing and operationalizing informed consent as a process, as opposed to a ‘one-off’ event, may be a more effective way of increasing its effectiveness.

The use of intervention strategies to improve understanding of informed consent has received some attention in the literature, particularly in regards to participation in clinical trials. Flory and Emanuel (2004) conducted a review of 30 studies covering 42 clinical trials which utilized interventions to improve consent understanding in various groups of hospital patients with a range of medical diagnoses, some of whom presented with cognitive impairment. In those studies, limited improvement in understanding using multimedia interventions and enhanced consent forms, and significant improvement through extended interactions between research staff and participants were reported. Participants with lower educational attainment and mental illness also showed lower understanding of the consent process. Similarly, in a recent review of audio-visual presentation of information for informed consent for participation in clinical trials with populations of children and people deemed not to be competent to give consent, Synnot, Ryan, Prictor, Fetherstonhaugh, and Parker (2014) found low quality evidence of the effect of such interventions on enhancing the information consent process.

It has then been proposed that in order to promote the understanding of informed consent, it may be necessary to utilise different tools according to an assessment of the functional characteristics of people with disability as well as the features of the research study. Horner-Johnson and Bailey (2013) suggest to diversifying the demands on consenting depending on the level of risk of the study, with lower risk studies requiring only some evidence of understanding as a sign for an individual to provide consent. Some authors assert (Bailey et al., 2014; Flory & Emanuel, 2004) that one-to-one encounters which are flexible and extended in their discussion of the study, while at the same time responding to the specific needs (emotional or otherwise) of participants, are most promising in facilitating understanding of consenting to research. More than action in itself, this premise implies that the provision of consent be conceptualized as a relational process so appropriate strategies are developed with deliberate attempts for environmental and contextual changes to facilitate consent (Bailey et al., 2014; Carlson, 2013; McDonald et al., 2017a).

Participation

Historically, the research participation of people with intellectual disability has been characterized by harm and abuse, a fact that inevitably turned the pendulum towards a view that rendered them vulnerable and in need of protection. This paternalistic premise, however, has been challenged by more contemporary efforts of people with intellectual disability for inclusion, self-determination and autonomy, with calls for their increased research participation (Nuwagaba & Rule, 2015). In discussing the risks of inclusion and exclusion of people with intellectual disability in research, Carlson (2013) maintains that researchers need to engage with critical disability perspectives, whereby common assumptions about what constitutes research involvement are challenged, and informed by careful deliberations about the interactions and power dynamics among people with disability, family members, researchers and ethics review boards. It follows that the various factors that can affect the research participation of people with intellectual disability, are similar to those influencing the process of consent, and therefore need to be evaluated in the 'real world'. This issue was examined by Cleaver, Ouellette-Kuntz, and Sakar (2010) who reported that greater research participation was associated with researcher's direct access to participants and where data collection procedures were non-invasive. These findings indicate, as has been suggested elsewhere (Nuwagaba & Rule, 2015), that diminished research participation may have more to do with contextual and cultural issues instead of the inherent characteristics of people with intellectual disability.

Risks, Benefits and Protections Associated with Participation

The inclusion and participation of people with intellectual disability in research events implies a weighing up of associated risks and benefits. Their identification, however, has been suggested to be a value-laden and contested process (Carlson, 2013). The diversity of views of key stakeholders such as families, researchers, ethics review boards, children and adults with intellectual disability themselves add complexity to the assessment of risks and benefits. Risk assessments in particular, despite requirements of ethical review board assessments, are not straight forward (Carlson, 2013; Iacono, 2006; Nuwagaba & Rule, 2015) as they are often at odds with the desires of people with intellectual disability to participate in research (McDonald, 2012). Within the context of a participatory research paradigm, Morgan et al. (2014) experienced unanticipated tensions and ethical dilemmas about conceptualizations of intellectual disability, role of the researchers, transparency, equality, and changes to original ethics agreements. Morgan et al.'s (2014) reflections highlight the unforeseen risks posed to both participants and researchers as they embark in the research process as well as the possibility that such risks can have detrimental effects on the well-being of all concerned.

Benefits of research participation, on the other hand, have strong support in the literature from a number of perspectives. First, participation of people with intellectual disability in research activities endorses their rights, dignity and autonomy, considering their inclusion a matter of justice (McDonald et al., 2016). Second, it adds value to the research process, providing enriched perspectives, as alternatives to the more academic and often considered rigid views of researchers (McDonald et al., 2016; Woelders, Abma, Visser, & Schipper, 2015). Third, research participation of people with intellectual disability contributes to their feeling valued and empowered, providing opportunities to demonstrate their abilities, learning from the research experience, and helping others (McDonald et al., 2016). Fourth, their representation, particularly in health research, is necessary to improve outcomes and ameliorate the influence of risk factors such as chronic conditions and poverty (Rios, Magasi, Novak, & Harniss, 2016). All these benefits can be achieved when characterization of the research process is effectively inclusive and collaborative, and where people with intellectual disability are considered research team members as opposed to research subjects (Woelders et al., 2015).

Discussion about the protection of people with intellectual disability when participating in research events has inevitably raised the notion of vulnerability. This concept is generally used as the main premise to protect them against risk, and offering of guarantees of well-being during their research participation. Safeguards against potential risks are crucial in this context, and informed consent has generally been the tool through which protections have been enforced by ethical review boards. This regulatory process, however, has been called into question (Iacono, 2006; McDonald et al., 2016); Nuwagaba & Rule, 2015) as decisions based on perceived risk, benefits and safety will vary according to whom is defining them, and may not necessarily represent the views of the community, including people with intellectual disability. For example, people with intellectual disability see 'gatekeeping' as more harmful than family members and ethical review board members (McDonald et al., 2017b).

Recent evidence also indicates that perceptions of safety converge and diverge on a number of fronts, while people with intellectual disability concur with others on focal safeguards for decision-making, they do not on issues of recruitment. Specifically, they perceive to be in greatest safety when recruited by somebody they trust, and when researchers ensure participants' own decision-making (McDonald et al., 2016). It can then be argued that people with intellectual disability may not necessarily feel they are in a vulnerable position, and that they are capable of making decisions about their participation in research on their own right. Researchers could support demystifying the issue of vulnerability by educating ethical review boards and others in the community, as well as introducing modifications to certain elements of the research process to ensure safety in keeping with ethical principles. Ethical and methodological dilemmas can be best navigated with flexibility in data collection and communication methods with people with intellectual disability (Watchman, 2016). On a similar vein, ethical review boards could promote disability ethical procedures that are disability friendly and contextualized (Carlson, 2013; Nuwagaba & Rule, 2015).

Moving Forward: Research Priorities

Consensus exists regarding the need to include people with intellectual disability in research, upholding ethical principles for their safe participation, as well as maintaining academic rigour in conducting research. The scientific community has been urged to take an increased role in providing creative solutions for the inclusion of people with intellectual disability, their families and communities, and effectively addressing decision-making, consent process and research design issues (Dalton & McVilly 2004; Iacono & Carling-Jenkins, 2012; Northway, 2014). To this end, the establishment of partnerships among researchers and people with intellectual disability, and creation of protocols are all laudable aims to have (Carlson, 2013). Importantly, however, advancing the work in this area also necessitates a continued focus on 'researching research processes' and the establishment of priorities within these. The current strengths and gaps observed in the current state of the field begets the formulation of research directions that translate available knowledge into practical outcomes that address the ethical dilemmas that have plagued the field, as well as methodologies that can progress our understanding and knowledge about the meaningful inclusion people with intellectual disability in research activities (Watchman, 2016).

Contemporary literature as a whole identifies various research themes and policy work around ethical conduct in researching with people with intellectual disability. They include: promoting understanding of the ethical issues of decisional capacity, informed consent, and actual participation among people with intellectual disability; qualities of the research process to maximize participation, including the researcher's role; characteristics of research methodologies; the role of key stakeholders in supporting safe and meaningful participation; and themes not deemed suitable to be researched. First, working with people with intellectual disability to support their understanding of key ethical matters related to the research process (i.e. decisional capacity, provision of consent, actual participation) through the development of validated assessment and intervention support models has been identified as an important research target (Bailey et al., 2014; McDonald et al. 2017a, 2017b). Bailey et al. (2014) suggests that while these issues have been addressed with other populations, limited work has been done with people with intellectual disability whose experiences may be largely different and varied relative to people without disabilities. Limited opportunities for decision-making given their life circumstances have precluded them from exercising competencies, typically involving problem-solving, evaluation of risks and benefits, and consent to research participation. The usefulness and ethical integrity of some models of support for decision-making to participate in research studies above others also need to be evaluated (McDonald et al., 2017a). Further looking beyond the disability type, and instead focussing on the analysis of the various components of decision-making to participate in research, is necessary. In this regard, testing the use of new technologies, visual media, augmentative communication devices and so forth can generate evidence about factors that can potentially influence the ethical aspects of participation, as well as their usefulness in supporting models that promote understanding of risk and benefits of research participation in actual practice (McDonald et al., 2017b; Synnot et al., 2014).

Second, the qualities of the research enterprise that can be adapted to ensure the participation of people with intellectual disability can be posed as another research priority. As the planner, designer, implementer, analyst and interpreter of findings, the role of the researcher is crucial to the establishment of a research context that is conducive to maximizing the contribution of people with intellectual disability. The shift towards modifying elements of the research process may mean the adoption of research models that may not necessarily be consistent with academic control and institutional demands, and which may also pose some challenges for researchers. Furthermore, Woelders et al. (2015) argues that researchers need to move beyond the notion that they are the only authority in adjudicating 'validity', as we know it, to the research process. Investigation of views about the role of the researcher as an advocate and educator with ethical academic boards, policy-makers and other community stakeholders can also provide further impetus for policy re-development regarding the safe participation of people with intellectual disability (McDonald, Schwartz, Gibbons, & Olick, 2015). At a more 'micro' level, conversational and interpersonal encounters between researchers, participants and key stakeholders, that are characterized as respectful, positive, empathetic, and over a period of time have support in the literature (Carey & Griffiths, 2017; Carlson, 2013; McDonald, 2012; McDonald et al., 2016). Eliciting their views in the form of values, preferences, and concerns is central to supporting significant contributions by people with intellectual disability to the research process. They want to contribute to research and indicate the particular ways they want to do so, including the accommodations that need to be made such as in how research aims are communicated, the clarity of verbalizations used, to the settings where research interviews are conducted, and compensation for participation if appropriate (McDonald, 2012). Bigby, Frawley, and Ramcharan (2014) argue that there is more than one way to do inclusive and participatory research with people with intellectual disability while cautioning us against making universal and rigid prescriptions about its meaning for different groups and stakeholders. Despite these understandings, the evidence base for a model of support for inclusive and ethical research that encompasses all these qualities is yet to be developed. Such a model can offer the foundations to set ethical standards for optimal research processes from the outset, ranging from the conceptualization of a study and formulation of research questions, to the selection and implementation of methodologies to the dissemination of findings.

Third, some research methodologies may be more conducive to the meaningful participation of people with intellectual disability beyond the ethical considerations involved. Qualitative research designs, including participatory research models (Beighton et al., 2017; McDonald, 2012) as well as those following a grounded theory approach (Carey & Griffiths, 2017) have been reported to promote their active research participation. Interviews using open-ended questioning and delivered on a one-to-one basis offer the added benefit of capturing any risks associated with research participation while strengthening the richness of findings, especially when it comes to working with children and young people (Lewis

& Porter, 2004). Participatory action research designs may convey more accurately the nuanced expressions of people with intellectual disability, their thoughts, feelings and behaviours (Inglis & Cook, 2011). Comparative studies of specific costs and benefits of quantitative and qualitative research designs in terms of funding, time, labour intensity, and stakeholder involvement would also add to this evidence-base. Research quality can also be improved with further investigation into emerging research models that actively promote the empowerment of people with intellectual disability such as the community-based participatory approach (Stack & McDonald, 2018). Notions of 'co-creation' and 'co-design' of knowledge using modern technology (e.g. online communities) can also be examined to determine their usefulness for further collaboration and inclusion in research of people with intellectual disability (Amann & Rubinell, 2017).

Fourth, the role of key stakeholders in supporting safe and meaningful participation is fundamental to the inclusion of people with intellectual disability in research undertakings. Particular consideration should be given to already documented findings about the differential perceptions of key stakeholders, and the 'gatekeeping' that can occur in the name of protection against harm (McDonald et al., 2016). In the case of children with intellectual disability, the evaluation of parental views about the risks they encountered and benefits that they and their children may gain from research participation is also critical in informing the design of more relevant and valued research studies. Bailey et al. (2014) adds that research into parental perceptions of children's participation throws further light into the specific role parents may wish to play as advocates in research conceptualization, design and dissemination. It would also be important to canvass the perspectives of service providers and other care staff as sources of support for research participation, and their specific role and contribution in the development and implementation of research studies. Apart from investigations by McDonald and colleagues, little attention has been devoted to this area. Last but not least is the role of ethical review boards as key stakeholders in safeguarding people with intellectual disability. Much has been written about the labelling of people with an intellectual disability as a homogeneous and vulnerable group in need of protection, a view commonly held by ethical review boards. Yet, evidence indicates that stringent ethical requirements have failed to safeguard them effectively, and in fact have added greater complexity for researchers and people with intellectual disability to fully participate in research activities (Iacono & Carling-Jenkins, 2012). The role that researchers can play in educating ethical review boards about intellectual disability, and the reported alternatives to meaningfully involve them in research deserves attention as a possible research and policy development focus.

Fifth, several research themes, generally in the realm of investigations of interventions with people with intellectual disability, are considered to be too dangerous to be researched. Illustrations of interventions in this category shown to be associated with possible harm include chelation therapy (Mitka, 2008; Sinha, Silove, & Williams, 2006), and facilitated communication (Committee on Children with Disabilities, 1998). Interventions (and the research behind it) that may lead to further discrimination and promote categorization, stigma and exclusion have long been judged as deleterious to improving the well-being and quality of life of people with intellectual disability, and considered ethically questionable. For example, should the use of comparative groups (e.g. people with intellectual and disability and their counterparts without a disability) be an acceptable research methodology given its potential to characterize one group 'better' than the other? Ultimately, in making decisions related to the topics to investigate, good research practice demands that not only attention be given to the evidence-base behind such interventions, but also the values that guide those practices (Stoneman, 2009). In this way, the development and evaluation of a system with thresholds along the continuum of acceptability-non acceptability in research practices with children and adults with intellectual disability can be argued to be a research priority. This can assist in preventing the conduct of research that is to this day, still unacceptable and unethical (see ProPublica Illinois, Cohen, 2018). This task may demand more than just the stipulation of intervention procedures that are acceptable/non acceptable because of the possibility of dangerous outcomes. It should also include the operationalization of all possible components of the research enterprise, possible risks, and concomitant adjustments that support the ethical integrity of the study, and hence the inclusion of people with intellectual disability.

In summary, several lines of research have been identified that address questions with the aim of achieving the ethical research inclusion and participation of people with intellectual disability. The range of possible issues to investigate is ample; some are associated with the effective implementation of protections in research practice, while others relate to factors that facilitate or hinder inclusion of people with intellectual disability while maintaining adequate ethical safeguards. The knowledge basis on which to increase evidence that supports this objective already exists (e.g. Dalton & McVilly, 2004; Inglis & Cook, 2011; McDonald et al., 2015) and is well-placed to begin the development of systematic models of interventions and supports that can inform researchers, policy makers, people with intellectual disability and their communities.

Conclusion

Research experiences of people with intellectual disability in the past were characterized by abuse and stigmatization. As a result, they have endured marginalization in terms of inclusion in research activities. It is recognized that a balance must be reached where ethical research integrity is upheld while at the same time academic rigour is maintained in the conduct of research. This state of affairs still continues to offer a number of dilemmas where various stakeholders have a role to play beyond the person with intellectual disability. Central to this predicament is the relationship between researchers and people with intellectual disability, whereby collaborative, strength-based interactions must prevail. Along these lines, researchers need to ensure that their studies are carefully planned, while allowing for time to recruit and collect data rigorously in a sensitive and respectful manner. However, this, in addition to the demands on researchers to meet peer-reviewed publication quotas and dissemination (which could be considered essentially academic concerns), may not necessarily be consistent with promising models, which espouse the empowering qualities of research studies that may ultimately facilitate the research participation of people with intellectual disability. Researchers have similarly an important role to play in advocating for the increased research inclusion of people with intellectual disability in such a way that notions of vulnerability and risk are debated as a function of growing evidence in favour of their rights and wishes. The research priorities earlier proposed constitute only some of several potential research avenues that can be pursued. It is argued that collaborating with, including and enabling people with intellectual disability with knowledge, resources, and adaptations during the implementation of research can ultimately minimise and even prevent the use of unethical procedures.

Restraint and Seclusion

16

Timothy R. Vollmer, Meghan A. Deshais, and Eliana M. Pizarro

Introduction

For the purposes of this discussion, *Restraint* is defined as physically holding or securing an individual, either for a brief time period to interrupt severe problem behavior or for an extended period of time using physical holds or mechanical devices to prevent dangerous behavior (Vollmer et al., 2011). *Seclusion* is defined as isolating an individual from others to interrupt problem behavior that places others at risk of harm (Vollmer et al.). It is recognized that not all professions or organizations use these terms in the same way, but some guiding and defining characteristics are necessary to present a fruitful discussion. Deviations from such usage will be pointed out as we discuss various position statements and regulations.

Historically, restraint and seclusion were used as methods to either protect individuals from harming themselves or others, or in some cases to punish harmful behavior (Metzner et al., 2007). In more recent times, restraint and seclusion are usually viewed primarily as protective measures designed to keep an individual from doing harm to self or others. It is recognized that restraint and seclusion can at times serve a punishing function (i.e., decrease the probability of the future occurrence of behavior), but that is not usually the primary purpose of contemporary usage. Though the ethical position of most professionals in autism and intellectual disabilities is that these procedures may be necessary at times, it is the role of the professional to protect individuals from misuse of restraint and seclusion. In this chapter we will provide some historical perspective on the use of restraint and seclusion, sample some position statements from various professional organizations that seem to confirm this ethical stance, and examine some state regulations. Finally, we will outline best practices as gleaned from the literature.

History

During the eighteenth and nineteenth centuries, acute and long-term psychiatric hospitals emerged and flourished in Europe and the United States. Throughout this period, institutionalization of individuals with mental illness, intellectual disabilities, or both was regarded as a humane practice that prevented those individuals from posing a danger to themselves or others. Institutionalization became so widespread that overcrowding became a significant concern (Colaizzi, 2005). Restraint and seclusion procedures were routinely used by staff to physically manage patients and as treatments for challenging

behavior (Steinert et al., 2010). Following some controversial debate over the use of these procedures, the American Psychiatric Association (formerly known as the Association of Medical Superintendents of American Institutions for the Insane; AMSAII) was developed in 1844. They asserted a collective decision to permit the use of restraint in American institutions (Colaizzi, 2005).

Although some doctors, such as French psychiatrist Philippe Pinel, advocated for the use of less intrusive strategies to treat and manage individuals with mental illness, the use of seclusion and physical, mechanical, or chemical restraint (i.e., use of medication that slows behavior in a general manner) was widespread and largely unregulated. In the mid-nineteenth century, John Connolly, a superintendent at a large asylum in Great Britain, developed and popularized the use of padded seclusion rooms as an alternative to restraint (Colaizzi, 2005). Connolly was a major proponent of the "non-restraint" movement, urging that psychiatric patients could receive therapeutic treatment in the absence of (mechanical) restraint.

Not much is known about the history of restraint practices in educational settings. We do know, however, that procedures that involve the removal of students from learning opportunities have been in practice for decades. Some examples include sending students home from school, in-school suspension, and various forms of time-out (including seclusion). Ryan, Peterson, Tetreault, and Van Der Hagan (2008) found that students have been secluded in empty rooms, specially designed time-out booths, closets, and refrigerator boxes.

Throughout the twentieth century, concerns about the conditions in psychiatric hospitals frequently arose in public discourse. Many of the debates about inhumane treatment focused largely around seclusion and restraint practices. For example, in 1998, the Hartford Courant published a series of articles revealing that over a 10-year span, 142 individuals died as a result of restraint or seclusion in psychiatric hospitals, facilities for individuals with disabilities, and group homes in the United States (Weiss, Altimari, Blint, & Megan, 1998). Children under the age of 17 accounted for over 26% of the deaths and the disturbing details in the articles sparked public outrage. Despite the fact that most professionals are generally in agreement that less restrictive procedures should be used primarily, investigations by the US Department of Justice revealed sustained inappropriate use of seclusion and restraint (U.S. Department of Education, 2012), and a period of great scrutiny and regulation of these procedures emerged (Weiss et al., 1998). Over the past 20 years, restraint and seclusion have remained controversial topics at the forefront of much debate. Numerous position statements have been disseminated, wherein the misuse of restrictive procedures and their negative effects have been well established. Sturmey (2009) urged researchers for a "call to action" for more research, acknowledging that while the literature has demonstrated that the excessive use of restrictive procedures is undesirable, we have not yet developed a strong body of literature exemplifying how we can effectively eliminate these procedures.

In response to the controversy and risk surrounding the use of restraint and seclusion, these procedures are among the most highly regulated in psychiatric treatment settings. Numerous organizations have developed policies to regulate the use of these procedures. Due to the potentially severe risk to the patient, some individuals even advocate for the total elimination of these procedures. However, failing to use restraint and seclusion in emergency situations could also result in adverse outcomes, either to the patient themselves or to others in their environment (Recupero, Price, Garvey, Daly, & Xavier, 2011). Below we discuss samples of the position statements of various organizations on the use of restraint and seclusion in clinical settings.

The Emergence of Position Statements

The Association of Professional Behavior Analysts (APBA) represents the interests of credentialed practitioners of applied behavior analysis.

It is the position of the APBA that advances in behavior analytic assessments and interventions have greatly suppressed the need for restraint and seclusion procedures. They acknowledge that in some cases, however, the severity of behavior may necessitate more restrictive intervention to minimize the risk of harm. Instances in which the use of restraint and seclusion are deemed essential, the APBA outlines a few critical stipulations. First, restraint and seclusion should only be used once less restrictive procedures have failed, or have been determined to be unsafe or insufficient. Second, the APBA states that restraint and seclusion procedures are not designed to be used in isolation. Rather, they should be used simply as a component of a comprehensive behavior plan. Finally, when restraint and seclusion are used, they should be carefully monitored by a supervising behavior analyst and only implemented by individuals specifically trained in implementation of the procedures (APBA, 2010).

The Association for Behavior Analysis International (ABAI) has been the primary organization of the field of behavior analysis since 1974 (representing not only practitioners, but behavioral scientists and theoreticians). ABAI's position on restraint and seclusion functions under three guiding principles: (1) the welfare of the individual served is the highest priority, (2) individuals have a right to choose, and (3) the principle of least restrictiveness. Given these principles, ABAI condemns the *unnecessary* or *inappropriate* use of intrusive measures such as restraint and seclusion. Similar to APBA, they acknowledge there may be instances in which the use of restraint or seclusion is unavoidable. In these cases, they stress the need for oversight and design by a licensed professional. Additionally, a Behavior Intervention Plan (BIP) that includes the use of restraint must be consistent with the current literature base, derived from a functional assessment, include reinforcement-based procedures, and be objectively monitored through data analysis. In regard to seclusion, ABAI states that when used within the context of a BIP, seclusion can function as a protective measure, as well as to facilitate the acquisition of appropriate behavior. While ABAI approves of a predetermined timeout or safety intervention procedure involving seclusion, it must ultimately serve as an evidence-based component of a comprehensive BIP (Vollmer et al., 2011).

The American Psychiatric Association (APA) supports intervention design that minimizes the use of restraint and seclusion. When restrictive procedures are deemed necessary, they should be implemented by trained individuals. In addition to providing guidelines for reactive procedures, APA also outlines proactive measures to prevent the need for seclusion and restraint. Following each instance of seclusion and restraint, a debriefing should be held during which research and clinical information is discussed to determine best practice procedures. Additionally, they support programs to educate practitioners on the minimal and safe use of these restrictive procedures as well as maintaining updated information on the use of pharmacological interventions that may prevent the need for seclusion and restraint (APA, 2003).

The American Academy of Pediatrics (AAP) acknowledges that "restraint" can be considered both chemical and physical. However, their position statement focused solely on the use of physical restraint, specifically for children or adolescents in the acute care setting. They also distinguish between restraint, and mechanisms typically used during transport or medical procedures. Devices used to protect the patient, to support the patient in a specific position, or to assist in the maintenance of normal body functions are not considered restraint interventions in the view of AAP. They note that beyond these customarily used procedures, restraint may sometimes be necessary for severe behavior to keep the individual from injuring themselves or others. When restraint is required under these circumstances, AAP notes specific procedures for safe application, documentation, reassessment, as well as criteria that such a restrictive procedure should only be used after consideration of alternative methods. AAP makes additional notice that verbal interventions and "therapeutic holding" have been used for children and adolescents in psychiatric facilities to avoid the use of restraint or seclusion. AAP defines therapeutic holding as the "physical restraint of a child by at least two people to assist the child who has lost control of behavior to regain control of strong emotions" (AAP, 1997).

The largest professional membership organization committed to psychiatric-mental health nursing is the American Psychiatric Nurses Association (APNA). In a statement on the topic of restraint and seclusion, they express a commitment to the reduction and ultimate elimination of these restrictive procedures. APNA advocates for further development of empirically based practices for the management and (ideally) complete prevention of behavioral emergencies. While complete elimination of such procedures may seem like a daunting task, APNA is committed to working toward that goal via collaboration with other disciplines and professionals. Until that time, however, they state a few critical specifications should restraint and seclusion be deemed necessary. First, these restrictive procedures should only be used (a) when less restrictive measures have failed and (b) for the minimal time necessary to ensure the safety of both the individual and others in their immediate environment. Additionally, they affirm that individuals who are restrained must be permitted to move as much as possible while still maintaining the safety of others. To ensure their safety, the individual must be monitored continuously throughout implementation of the procedure. The APNA also comments on intent, urging that restraint or seclusion should never be used as a means of convenience, punishment, or coercion (APNA, Updated 2014).

The Cochrane Library is a collection of independent, high-quality evidence to help inform healthcare decision-making. Of a search yielding 2155 citations, no controlled RCT studies evaluating the use of seclusion and restraint were identified. Given the lack of controlled research studies evaluating the effectiveness of these procedures, Cochrane Library states that no official recommendation can be made in regard to the effectiveness, benefit, or harmfulness of seclusion or restraint. However, they do note some qualitative data that suggest these procedures may have serious adverse effects (Fisher, 1994). Although the data are minimal, it is their view that until further analysis is completed, the clinical use of these procedures should be minimized. Until further empirical evidence is gathered, Cochrane Library expressed a need for identifying alternative techniques to replace these restrictive procedures (Sailas & Fenton, 2000).

Restraint and seclusion are of critical concern across a multitude of practitioners and their respective disciplines. The National Association of Psychiatric Healthy Systems (NAPHS) collaborated with the APA, the APNA, with support from the American Hospital Association to compile recommendations to the Board of Trustees of the APA. Among these recommendations, four priority areas were targeted for reform. One of these high-priority areas consisted of seclusion and restraint. The organizations acknowledge that, when used properly, restraint and seclusion can function as injury-sparing and even life-saving measures. Within this compilation, they provide detailed information on specific case studies in which restraint or seclusion may have resulted in unnecessary harm to the individual. They then provide a few regulations surrounding implementation of these procedures. Most notably, they specify that a debriefing should follow each episode of seclusion or restraint. The debriefing should include an assessment of the factors leading to the use of these techniques, steps to reduce their need in the future, and the clinical impact of the intervention on the patient (NAPHS, 2003).

While many groups described above have taken a more neutral position, offering guidelines and parameters for the use of such procedures, some organizations have taken a firm stance on one side or the other. For example, the Autism National Committee (AUTOCOM) has taken a position of complete opposition to the use of physical restraint or seclusion. They believe that these procedures are in direct violation of the civil and human rights of individuals with disabilities. AUTOCOM feels that physical restraint is simply evidence of treatment failure, and should not be used under any circumstance (1999). We will return to this point shortly, in an effort to point out that this position may be extreme and potentially impossible to adopt as policy (see section under "summary: best practices"). Along similar lines, The Autism Society supports legislation on the federal regulation of restraint, and that restraint only be used in situations of imminent danger and always implemented by trained individuals. Conversely, the American Association of School Administrators (AASA) released a statement in strong opposition of this sentiment. AASA argues that restraint and seclusion are sometimes necessary to maintain safety in public schools. Without the option of these procedures during emergency situations, some students would not be able to sustain placement in public school settings (Pudelski, 2012).

In a recently published article, Scheuermann, Peterson, Ryan, and Billingsley (2015) used nonfictional case examples to provoke discussion surrounding the professional use of seclusion and restraint. Although some previous reports described circumstances in which seclusion or restraint were misused, Pudelski (2012) argues that the acts committed by those wrongful individuals are not representative of the majority of personnel that utilize seclusion or restraint procedures in schools. However, Scheuermann et al. (2015) stress that those violations should not be so easily dismissed as isolated events, but rather, as an indication of a more severe foundational issue that warrants exploration. Six categories of professional and ethical concerns surrounding the use of restraint or seclusion were identified. These were: (a) potential for death or injury, (b) failure to use the least intrusive intervention and evidence-based practices, (c) inappropriate restrictions on liberty and access to education, (d) programming failures, (e) disproportionate use with certain minority groups, and (f) insufficient training, supervision, and monitoring. In conclusion, the authors acknowledge that although various professionals have differences of opinion, all seek to maximize the benefits of intervention while minimizing the risk to our clients (or students). With that said, they felt that a call-to-action is necessary both on the individual and group level to maximize the "beneficence" to clients. Legislation concerning the use of restraint and seclusion with individuals with disabilities ranges from nonexistent to comprehensive across various levels of the U.S. government. At federal, state, and local levels, there are laws, guidelines, and policies about the use of these procedures in schools, healthcare facilities, and correctional facilities. However, laws, guidelines, and policy documents do not carry the same weight with respect to adoption, implementation, and adherence by individual institutions (Butler, 2016). Laws, of course, are established via the legislative process and are enforced by the judicial system; thus, violations are subject to legal ramifications. Conversely, guidelines and policy documents are merely recommendations (Butler, 2016). There is no legal recourse if individual institutions (schools, healthcare facilities, correctional facilities) choose to develop policies and practices that do not align with federal or state guidelines or policy recommendations.

Guidelines in Educational Settings

According to the U.S. Department of Education's Office for Civil Rights (OCR), students with disabilities make up 12% of the public education student population but account for 67% of the students exposed to restraint or seclusion procedures (OCR, 2016). In 2016, the DOE published a "Dear Colleague Letter" suggesting that the differential rates of restraint and seclusion used on children with disabilities relative to children without disabilities in schools might constitute discrimination and a violation of Section 504 of the Rehabilitation Act of 1973 and Title II of the Americans with Disabilities Act of 1990 (ADA). Over the past decade, there have been a number of high profile allegations of abuse surrounding restraint and seclusion of children in public schools, including a government-issued report in 2009. Taken together, it is not surprising that there has been a recent push to establish standards for the use of restraint and seclusion in schools.

Federal

At the time of this publication, there is no federal legislation concerning the use of restraint or seclusion in public schools (U.S. Department of Education, 2017). From here forward, the term public schools will be used to refer to educational placements that receive federal, state, or local funding, or some combination (elementary, middle, and high schools, special education schools, charter schools, residential schools). Since 2010, several legislative bills have been introduced to the U.S. Congress. One bill, "Keeping All Students Safe Act" seeks to establish federal laws governing the use of restraint and seclusion in public schools. The bill has undergone a series of revisions and has been introduced to the U.S. House of Representatives and U.S. Senate multiple times, but no versions of the bill have been enacted.

In the most recent version, introduced to the 114th House of Representatives, the bill directs the U.S. Department of Education (DOE) to establish minimum standards about the use of restraint and seclusion in public schools (H.R. 927, 114th Cong., 2015a). Notable sections of the bill include: (a) prohibiting mechanical and chemical restraint, (b) banning restraint that restricts a student's breathing, (c) barring the use of restraint and seclusion under any circumstances except when a student poses an imminent danger of injury to themselves and others, (d) requiring Local Educational Agencies (LEAs) to ensure that school personnel undergo state-approved crisis intervention training, (e) prohibiting restraint and seclusion from being written into a student's education/safety/behavior plan, (f) mandating that schools notify parents in a timely manner if their child is restrained or secluded at school, and (g) directing the DOE to conduct a national assessment of the Act's effectiveness. The bill also authorizes the delivery of federal grant money to LEAs that demonstrate adherence to the items outlined in the bill, collect data on restraint and seclusion, and utilize school-wide positive behavior interventions. At the time of this publication, Keeping Students Safe has not been introduced to the current (115th) U.S. Congress.

In 2015, President Barack Obama passed the "Every Student Succeeds Act" (a reauthorization of the Elementary and Secondary Education Act). Every Student Succeeds calls for a reduction in "the use of aversive behavior interventions that compromise student health and safety" (S. 1177, 114th Cong., 2015b). However, the term "aversive behavior interventions" is not defined. Thus, although this terminology could be interpreted as including restraint and seclusion procedures, this act merely calls for a reduction in aversive behavioral procedures and does not explicitly regulate or prohibit the use of restraint or seclusion in public schools.

Perhaps in lieu of federal legislation, the DOE issued a Resource Document in 2012 outlining 15 guiding principles that LEAs should use when developing restraint and seclusion policies (DOE, 2012). The 15 guiding principles can be found in the bulleted listing below. Although the publication of the Resource Document appears to have influenced the laws and guidelines in some states (Freeman & Sugai, 2013), there is no legal recourse at the federal level if states fail to adhere to the guiding principles:

- Every effort should be made to prevent the need for the use of restraint and for the use of seclusion.
- Schools should never use mechanical restraints to restrict a child's freedom of movement, and schools should never use a drug or medication to control behavior or restrict freedom of movement (except as authorized by a licensed physician or other qualified health professional).
- Physical restraint or seclusion should not be used except in situations where the child's behavior poses imminent danger of serious physical harm to self or others and other interventions are ineffective; in cases where restraint and seclusion are used, they should be discontinued as soon as imminent danger of serious physical harm to self or others has dissipated.

- Policies restricting the use of restraint and seclusion should apply to all children, not just children with disabilities.
- Any behavioral intervention must be consistent with the child's rights to be treated with dignity and free from abuse.
- Restraint or seclusion should never be used as punishment or discipline (e.g., placing in seclusion for out-of-seat behavior), as a means of coercion or retaliation, or as a convenience.
- Restraint or seclusion should never be used in a manner that restricts a child's breathing or harms the child.
- The use of restraint or seclusion, particularly when there is repeated use for an individual child, multiple uses within the same classroom, or multiple uses by the same individual, should trigger a review and, if appropriate, revision of strategies currently in place to address dangerous behavior; if positive behavioral strategies are not in place, staff should consider developing them.
- Behavioral strategies to address dangerous behavior that results in the use of restraint or seclusion should address the underlying cause or purpose of the dangerous behavior.
- Teachers and other personnel should be trained regularly on the appropriate use of effective alternatives to physical restraint and seclusion, such as positive behavioral interventions and supports and, only for cases involving imminent danger of serious physical harm, on the safe use of physical restraint and seclusion.
- Every instance in which restraint or seclusion is used should be carefully and continuously visually monitored to ensure the appropriateness of its use and safety of the child, other children, teachers, and other personnel.
- Parents should be informed of the policies on restraint and seclusion at their child's school or other educational setting, as well as applicable Federal, State, or local laws.
- Parents should be notified as soon as possible following each instance in which restraint or seclusion is used with their child.
- Policies regarding the use of restraint and seclusion should be reviewed regularly and updated as appropriate.
- Policies regarding the use of restraint and seclusion should provide that each incident involving the use of restraint or seclusion be documented in writing and provided for the collection of specific data that would enable teachers, staff, and other personnel to understand and implement the preceding principles.

State

At the state level, the laws, guidelines, and policies related to restraint and seclusion practices vary. In 2009, the U.S. Government Accountability Office (GAO) published a report on restraint and seclusion in schools. The report contained a review of federal and state legislation concerning the use of restraint and seclusion in educational settings. In addition, the GAO report examined 10 cases of restraint and seclusion of school-aged children that resulted in a criminal conviction, a finding of liability, or a large financial settlement. Almost all of the children in these cases were diagnosed with an intellectual or developmental disability. The accounts of these cases contained within the GAO report contain graphic descriptions and disturbing allegations. For example, in 2002, a 14-year-old boy in a Texas public school died as a result of his trunk being compressed after being placed in a prone restraint by a special education teacher almost twice his size because the student refused to remain seated. At the time of the GAO report, 19 states had no legislation related to the use of seclusions or restraints in schools (GAO, 2009).

Since the publication of that report, 30 states have made changes to their laws or policy documents (Freeman & Sugai, 2013). By 2017, 38 states had legislation and 45 states had policy documents regarding restraint and seclusion (Marx & Baker, 2017). At present time, there are no state laws or policy documents that altogether prohibit the use of restraint with students with (or without) disabilities in schools. However, there are five states that explicitly prohibit the use of seclusion with students with disabilities (Butler, 2016). There are four states that do not have any laws or policy documents on restraint and seclusion in schools (Idaho, North Dakota, New Jersey, and South Dakota; Butler, 2016).

In their analysis of state laws and policy documents, Freeman and Sugai (2013) found four general trends in terms of content. One trend was the focus on preventive strategies. This included strategies such as de-escalation training, the use of functional behavior assessments, and schoolwide positive behavior intervention and supports. For example, in Rhode Island, all school staff must attend annual training on de-escalation strategies. Staff members who are identified as authorized to assist in restraint and crisis situations must also receive advanced training (Rhode Island Department of Elementary and Secondary Education, 2002).

Another trend identified by Freeman and Sugai was the establishment of procedural parameters for restraint and seclusion. In state laws and policy documents, procedural parameters are often preceded by definitions of what constitutes restraint and seclusion. Generally speaking, physical restraint is defined as restricting the physical movement of a student and seclusion is defined as placing a student in an area where they are physically prevented from leaving. Although many of the definitions are similar across states, differences in phrasing can have implications for practice and data collection in a given state. For example, in Colorado, restraint does not include instances in which a student is held for less than 4 min or brief holding of a student by one adult for the purposes of calming or comforting the student (Colorado State Board of Education, 2009). This definition leaves room for subjective interpretation. In other words, a student in Colorado could be physically held by an adult for periods of time longer than 5 min as long as the adult's intention is to calm the child. The definitions of seclusion in state laws and policy documents are often distinguished from time-out procedures. However, depending on the state, the distinction between seclusion and time-out is not always clear.

Two other trends that emerged during their analysis are parental and state notification regarding instances of restraint and seclusion and debriefing staff and students following each instance. Thirty-two states require parents to be notified when their child is restrained or secluded at school (Freeman & Sugai, 2013). Most states have established time frames for notification. For example, in Massachusetts, teachers must inform the student's parents within 1 day or send a written report within 3 days (Massachusetts Department of Elementary and Secondary Education, 2014). In terms of reporting rates of restraint and seclusion to the state, 25 states currently collect data at the state-level for students with disabilities (Butler, 2016).

Freeman and Sugai (2013) outlined three specific procedural parameters in their discussion of trends in state laws and policy documents. The first is the use of restraint or seclusion for punishment. According to Butler (2016), 23 states have laws or policy documents that indicate that restraint and seclusion procedures should only be used in emergency situations in which a student is at risk of physically harming themselves or others. Other states, such as Montana, permit the use of restraint if a student is threatening to damage school property (DOE, 2017). Many state laws and policy documents explicitly state that these procedures should be discontinued when the emergency ends and should not be used for the purposes of punishing students. The second procedural parameter is the use of prone restraints. Prone restraints are physical restraints in which an individual is immobilized on the floor in a face down position. Research has demonstrated that some prone restraint positions produce restriction of lung function (Parkes & Carson, 2008). Given this finding and the number of high profile cases in which students have died during or following prone restraints, the use of prone restraints in schools has been explicitly (by name) or implicitly (by definition/description) banned by 33 states (Butler, 2016). The third procedural parameter is the establishment of time limits for restraint and seclusion. Freeman and

Sugai (2013) found that the time limits for restraint or seclusion found in state laws and policy documents ranged across states but most states limited these procedures to 30 min to 1 h, with a stipulation that an administrator must authorize additional time.

In 2017, Marx and Baker reviewed the legislation and policy documents for each state and examined their alignment with the 15 guiding principles outlined in the Resource Document published by the DOE (DOE, 2012). For state laws, they found adherence or partial adherence to the principles ranged from 3 to 32 states, depending on the principle. For state policies, they found that adherence or partial adherence to the principles ranged from 4 to 38 states. Both state laws and policies were most likely to be aligned with Principle 3 (physical restraint must only be used when a student poses a danger to themselves or others) and least likely to be aligned with Principle 14 (policies are reviewed regularly and updated, data need to be collected and analyzed based on subgroups, settings, staff, etc.).

Noneducational Settings

Healthcare Facilities

The Code of Federal Regulations regarding restraint and seclusion are outlined in the Center for Medicare and Medicaid Services (CMS) State Operations Manual (Department of Health & Human Services, 2008). Any hospital, healthcare facility, residential, non-medical, or community-based facility that serves adults or children and that receives federal, state, or local funding must abide by these regulations. In other words, to continue receiving public funding, they must maintain the Conditions for Participation outlined in the manual. Facilities are routinely surveyed to ensure that conditions are being met. The CMS manual states, “All patients have the right to be free from restraint or seclusion, of any form, imposed as a means of coercion, discipline, convenience, or retaliation by staff. Restraint or seclusion may only be imposed to ensure the immediate physical safety of the patient, a staff member, or others and must be discontinued at the earliest possible time” (Department of Health & Human Services, 2008). Physical, mechanical, and chemical restraint are all included in the definition of restraint. The CMS manual also states that restraint and seclusion can only be ordered by a physician or other licensed independent practitioner who is authorized by the state. Standing orders and orders for restraint or seclusion on an as-needed basis are prohibited. Patients must be monitored continuously during periods of restraint or seclusion and patients must be examined face-to-face by an authorized physician or nurse within 1 h of the beginning of the procedure. An additional face-to-face assessment by the ordering physician must be conducted if a restraint lasts longer than 1 h for a patient under 10 years old, 2 h for a patient aged 10–18 years old, or 4 h for patients older than 18 (Masters, 2017). CMS mandates that staff be trained in the implementation of restraint and seclusion and requires all healthcare facilities to report deaths associated with the use of these procedures. State laws governing restraint and seclusion vary from state to state. In cases in which state laws are more stringent than federal laws, the state laws supersede federal laws.

The Joint Commission for hospital accreditation has also published regulations on restraint and seclusion. Technically, the Joint Commission is not a part of or affiliated with the federal government; it is an independent nonprofit organization. However, in the realm of healthcare, their accreditation is considered important. The 2017 Joint Commission standards are in the bulleted listing below.

- Uses restraint or seclusion only when it can be clinically justified or when warranted by patient behavior that threatens the physical safety of the patient, staff, or others.
- Uses restraint or seclusion safely.
- Initiates restraint or seclusion based on an individual order.
- Monitors patients who are restrained or secluded.
- Has written policies and procedures that guide the use of restraint or seclusion.
- Evaluates and reevaluates the patient who is restrained or secluded.

- Continually monitors patients who are simultaneously restrained and secluded.
- Documents the use of restraint or seclusion.
- Trains staff to safely implement the use of restraint or seclusion.

Correctional Facilities

According to the U.S. Department of Justice, approximately 2 in 10 prisoners and 3 in 10 jail inmates report having a cognitive disability (U.S. Department of Justice, 2015). Currently, there are no federal laws or guidelines regarding restraint or seclusion in public correctional facilities specific to inmates diagnosed with an intellectual disability. However, there are two laws that are potentially applicable in certain circumstances. First, the eighth Amendment stipulates that the government may not inflict cruel and unusual punishment on U.S. citizens (U.S. Const. amend. VIII). Second, the ADA prohibits discrimination against individuals with disabilities by public entities. In other words, individuals with intellectual disabilities who are sentenced to public correctional facilities are entitled to the protections outlined in the ADA, including "reasonable accommodation" for their needs and access to the services available to inmates without disabilities. A recent investigation by the United States Department of Justice Civil Rights Division reported that a state correctional facility in Pennsylvania exposed half of the prisoners diagnosed with an intellectual disability to three or more continuous months of solitary confinement. This practice was deemed a violation of the eighth amendment and the ADA.

In 2007, a Task Force commissioned by the APA issued a Resource Document on the use of restraint and seclusion in correctional mental health (Metzner et al., 2007). The Resource Document reported that correctional facilities use restraint (physical and mechanical) and seclusion as mental health interventions as well as for custody or disciplinary purposes. The Resource Document also noted that rules about restraint and seclusion outlined by the CMS manual do little to regulate the use of these procedures in correctional facilities because so few of them participate in Medicare or Medicaid. Correctional facilities usually seek accreditation from the American Correctional Association (ACA) and the Commission on Accreditation for Corrections (CAC). Both bodies require correctional facilities to have policies for the use of restraint but there are no specific guidelines regarding monitoring, time limits, and documentation (Champion, 2007). The Task Force concluded that correctional mental health facilities have not developed guidelines or procedures that are consistent with community practice. Additionally, the Resource Document suggested that the regulations outlined in the CMS manual should be used as a basis for developing national standards of care for the use of seclusion and restraint in correction facilities (Champion, 2007).

Summary and Best Practices

A simple "thought" problem will demonstrate that nearly all would agree that seclusion or restraint is sometimes necessary. Suppose that an able-bodied adult teacher is walking through a school hallway and a student shouts, "I have a gun and I am going to shoot!" The teacher sees that the student does in fact have a gun, and the student has begun to fire in the direction of other students by pulling the trigger. Probably most anyone would agree that the teacher should restrain the student in whatever way possible if the opportunity to do so should arise. Now suppose the student is not just any student, but is a student known to have an intellectual ability. Should the teacher refrain from restraining due to the disability? Now further suppose that there is no gun, but a student with a disability has just hurt a student and is running toward another student with a closed fist. The point is not to take a position that is pro-seclusion or pro-restraint, but rather to take the position that has been adopted by most entities concerned with abuses of seclusion and restraint: there are times when it is likely necessary or at least safest to use these approaches. Given this likelihood, most entities have chosen to identify best practices in the use of seclusion and restraint.

Seclusion and restraint should be reserved for cases when a person is posing immediate harm to themselves or others. The procedures should only be used if it is determined that other strategies, such as de-escalation, are ineffective. Staff in facilities and schools should be trained in the use of state or locally approved crisis prevention strategies. If seclusion or restraint is used, the procedures should be carefully monitored by professional staff, and the parents or guardians of the individual should be notified as immediately as possible. If use of these procedures is repeated (i.e., used more than once), future planning should occur and treatment strategies should be adopted and documented based on a functional assessment of the student's behavior. Such a treatment plan should be approved by relevant care providers and especially by parents or guardians. The treatment plan should include strategies for increasing alternative and safe behavior through positive reinforcement and other less intrusive strategies, and decisions about efficacy should be determined by careful monitoring of plan implementation and outcome data for behavior of concern.

It also seems important to further distinguish seclusion from timeout. Seclusion should never be considered a treatment strategy, it is reserved for protection of or from the individual. However, research on timeout shows that periods of restricted access to positive reinforcement can be effective at very short intervals (such as 2 min) and without isolating the individual (e.g., Donaldson, Vollmer, Yakich, & Van Camp, 2013). Thus, whereas timeout could be an acceptable component of a behavioral intervention plan, which would presumably also include reinforcement for alternative behavior, seclusion is not an acceptable treatment component. It is a protection strategy.

To conclude, seclusion and restraint will remain controversial because both procedures are at times misused. Such misuse occurs on a continuum from ignorance, to negligence, to abuse. It stands to reason that such misuses must stop, and that is the purpose of the many position statements, proposed regulations, and standards of use. However, to ignore that the procedures will be used in dangerous circumstances is to in fact set the occasion for terrible misuse. Haphazard use of seclusion and restraint should be avoided at all costs. Understanding implementation of seclusion and restraint should be a priority for staff and care provider training at all levels of care for individuals with intellectual disabilities.

Monitoring Drug Side-Effects

17

Gerda M. de Kuijper, Arne Risselada,
and Rianne van Dijken

Introduction

People with intellectual disabilities are one of the most heavily medicated population in society. This phenomenon is likely related to the frequently presence of comorbid ill-health conditions (Cooper et al., 2015). The prevalence of ill-health conditions in people with intellectual disability varies between populations and is highest in people living in institutional settings. Also, the nature of ill-health conditions may vary. In general, people with mild intellectual disability are more vulnerable for ill-health conditions associated with cardiovascular disorders like obesity and diabetes. People with severe intellectual disability more often suffer from ill-health conditions associated with brain dysfunction like epilepsy and cerebral palsy. Besides, a high proportion of people with intellectual disability suffer from gastrointestinal conditions like constipation and gastroesophageal reflux disorder. Mental ill-health conditions, including autism spectrum disorder and challenging behavior, are prevalent in approximately 40% of people with intellectual disability (Cooper, Smiley, Morrison, Williamson, & Allan, 2007; Smiley et al., 2007). The increased health risks in people with intellectual disability are probably related to life style factors, e.g., unhealthy diets, lack of exercises and sedentary life styles, and genetic conditions, e.g., increased risk for obesity and mood disorder in Down syndrome, for hearing loss and psychosis in Velo-cardio-fascial syndrome, and for sleep disorders and self-injurious behavior in Smith-Magenis syndrome.

In people with intellectual disability, the medication use is high and polypharmacy is common. Polypharmacy is defined as the use of more than five pharmaceutical agents simultaneously. Haider, Ansari, Vaughan, Matters, and Emerson (2014) found in a population-based study of people with intellectual disability in Victoria, Australia, that 76% of adults >18 year used one or more prescribed medicines and in 21% there was polypharmacy (Haider et al., 2014). O'Dwyer et al. (2016) studied a population of older adults (40–90 years) and found a percentage of 90% medication use and of 32% polypharmacy (O'Dwyer, Peklar, McCallion, McCarron, & Henman, 2016). In a population of children and adolescents aged 4–18 year Tobi et al. found that 22% used chronic medication of whom 47% used two or more drugs (Tobi et al., 2005).

The prevalence of drug use in these school-aged children increased with severity of intellectual disability. All studies showed that the most frequently prescribed classes of drugs were psychotropic drugs and antiepileptic drugs. Also, laxatives and drugs for peptic ulcer diseases were frequently prescribed as well as analgesics. Anticholinergic medication was prescribed in 16%, mainly in those with polypharmacy (O'Dwyer, Peklar, et al., 2016).

Polypharmacy may have negative consequences like increased health care costs and health risks (Maher, Hanlon, & Hajjar, 2014). Especially people with intellectual disability who live independently or who receive support to a small extend are prone to medication non-adherence or inappropriate storage of their medication. This may lead to lack of treatments effects or even life-threatening situations, e.g., in case of insulin storage outside a fridge resulting in a hyperglycemic coma. Also drug interactions may lead to decreased effects of pharmaceutical agents; however these interactions may also lead to increased effects. Drug interactions may occur when one or more pharmaceutical agents are administered concurrently resulting in reactions between the drugs. These reactions may influence the absorption or the excretion of the drug, and/or the availability of drug receptors. As a consequence these interactions may increase the risks for the occurrence of drug-induced adverse events. These may be serious and life threatening also, as was shown in studies of the occurrence of adverse events and reasons for health care visits and hospitalization (Maher et al., 2014; Warle-van Herwaarden et al., 2012). Moreover, adverse events may reduce the quality of life of people with intellectual disability (Brandt, Lahr, & May, 2015; Ramerman, Hoekstra, & de Kuijper, 2018a; Scheifes et al., 2016). People with intellectual disability are more vulnerable for the occurrence of drug-induced side-effects, especially for side-effects of psychotropic drugs, including antiepileptic drugs (de Kuijper et al., 2013; de Winter, Bastiaanse, Hilgenkamp, Evenhuis, & Echteld, 2012; Matson & Mahan, 2010; Scheifes, Walraven, et al., 2016; Sheehan et al., 2017), because of the frequent presence of comorbid disorders and the risk of drug interactions in case of multiple drug use. The recognition of drug-induced side-effects is often hampered, on the one hand by patient-related factors like communication problems and reduced capacity to adequately cooperate in assessments, on the other hand by staff-related factors like lack of knowledge on psychotropic drug side-effects (de Kuijper & van der Putten, 2017; Donley, Chan, & Webber, 2012).

In this chapter information on drug-induced side-effects of the most frequently prescribed classes of drugs in people with intellectual disability is provided, with an emphasis on side-effects of psychotropic drugs. Also, information on the monitoring of side-effects, including guideline recommendations on instruments and monitoring schedules which can facilitate the assessment of psychotropic drugs' side-effects, is presented. The role of the different disciplines involved with pharmaceutical care in people with intellectual disability, i.e., clinicians, pharmacists, and nurses regarding the monitoring and management of side-effects will be briefly outlined. Finally, a tool which is useful in evaluating effects of drug-use and management of side-effects will be discussed.

Side-Effects of Drugs: Definition and Precautions

Drug-induced adverse events, otherwise named side-effects of drugs, are defined as any harmful, undesirable effect of drugs. Three types of side-effects can be distinguished related to the origin of occurrence. There are two types of patient-related side-effects. Both are drug dose independent. The first type is thought to be caused by allergic or disturbed immunological responses. Examples are skin rashes and lowering of blood platelets or leucocytes. The other type of patient-related side-effect is an increased risk for specific comorbid disorders, e.g., increased risk for cardiovascular disorder in case of use of NSAID analgesics. The frequency of both types of side-effects is low and their existence mostly becomes yet clear when the drug in question is used on a large scale. The third type of side-effect is drug dependent. This type of side-effect is often dose dependent and related to the pharmaceutical effect of the drug in question. It is mostly discovered in clinical trials before the drug in question is licensed and registered by pharmaceutical and health care authorities. After a licensed registration all the available information on side-effects should be included in the medication leaflet.

Drugs are cleared from the body in different ways, i.e., metabolization by the liver and excretion in urine or feces. In case of compromised renal or liver function the dosage of the drug should be lowered to minimize the chance for potential dose dependent side-effects. Furthermore, for several metabolizing enzymes in the liver (e.g., CYP2D6 and CYP2C19) there are known genetic variances influencing their metabolic capacity that result in altered elimination half-lives of drugs and therefore different plasma levels. Based on their genetic makeup patients can be classified as poor, intermediate, extensive, or ultrarapid metabolizers (Berm, Risselada, Mulder, Hak, & Wilffert, 2013).

In case of rapid metabolizers higher doses than normal are needed to treat the patient, whereas in poor metabolizers much lower doses are needed to achieve the same result. Intermediate and extensive metabolizers can often be dosed as normal. Especially in case of psychotropic drugs (e.g., antidepressants and antipsychotics) and cytotoxic drugs there is a lot of evidence supporting the benefits of genotyping (Swen et al., 2011). However, given the relative lack of experience of most physicians with genotyping in daily clinical practice it is advisable to consult an expert beforehand, to maximize the potential benefits of genotyping.

Drug metabolizing and/or drug clearance problems of patients increase the risk of dose dependent side-effects and drug interactions. Therefore, in case of difficulties in history taking, which will often be the case in people with intellectual disability, a laboratory examination on potential liver and renal dysfunction and genotyping of metabolizing enzymes may be needed before prescribing the drug. Also, monitoring of drug plasma levels during drug use is warranted in case of drug clearance problems and altered metabolization.

Side-Effects by Drug Classes

As was described in the introduction section, psychotropic drugs, antiepileptic drugs, laxatives, proton pump inhibitors, antacids, analgesics, and anticholinergic medication are the most frequently prescribed drug classes in people with intellectual disability. Although in this chapter the focus is on side-effects of psychotropic drugs, some information on the other drug classes is also given.

In people with intellectual disability there is often comorbidity of mental disorders, epilepsy and gastrointestinal disorders, and therefore polypharmacy consisting of drugs used to treat these disorders is common. Moreover, agents from these drug classes are also prescribed to reduce the burden caused by side-effects of psychotropic drugs.

Antiepileptic Drugs

There are different types of antiepileptic drugs, and these agents are licensed for different indications. Main reasons for use are seizure disorders, neuropathic pain, migraine, and last but not least for bipolar and mood disorders.

Common side-effects of all types of antiepileptics are sleepiness, fatigue, and weight gain.

Laxatives

Laxatives, e.g., macrogol or lactulose are most often prescribed for long-term prevention of constipation in people with cerebral palsy or otherwise disturbed autonomic bowel function. Laxatives are also often prescribed as co-medication to prevent constipation caused by other drugs, e.g., psychotropic drugs and iron supplements.

Common side-effects are inherent to their function: abdominal cramps, flatulence, and diarrhea.

Proton Pump Inhibitors and Antacids

These agents are prescribed to reduce heartburn and the risk of gastroesophageal disorders. Especially people with severe intellectual disability are in need for this type of medication.

Furthermore, these agents are often prescribed as co-medication to reduce the risk of peptic ulcers when patients are treated with NSAID's (e.g., diclofenac, ibuprofen, naproxen). Side-effects of proton pump inhibitors and antacids are rare, but may include headache and nausea. Long-term use may cause anemia due to a decrease in absorption of iron. Furthermore, the decrease of acidity in the stomach may increase the risk for respiratory tract infections, especially in case of aspiration of stomach content which is relatively common in people who are more severely disabled.

Analgesics

Chronic use of analgesics is most common in people with multiple disabilities, who may also have mental or behavioral problems. NSAID's and paracetamol are commonly prescribed.

Use of NSAID's is associated with gastrointestinal complaints and with increased risks for peptic ulcer and stomach bleeding.

Anticholinergic Agents

These drugs are prescribed to reduce symptoms of Parkinson disease such as muscle stiffness and brady- and hypokinesia. Other indications are asthma and bladder dysfunction, and reduction of antipsychotic drug-induced parkinsonism.

Side effects of these agents and drug interactions are common. Side-effects are, among others, constipation, dizziness, sleepiness, headache, dry mouth and dry eyes, and bladder dysfunction/urinary retention. Especially older people and people with intellectual disability are vulnerable to these side effects and prescription of anticholinergic medication in these populations should preferably be avoided.

Side-Effects of Psychotropic Drugs

Psychotropic drugs are prescribed for a wide range of mental disorders and psychiatric and behavioral symptoms. Most are registered and licensed for specific indications, sometimes extended to specific symptoms. An example of the latter is the antipsychotic drug risperidone which is licensed for the treatment of psychosis and for the short-term treatment of aggressive or irritable behavior. Psychotropic drugs are also often prescribed off-label (outside licensed indications) where evidence for their effectiveness and safety may be scarce. In people with intellectual disability the off-label use of psychotropic drugs, especially of antipsychotics, is high (de Kuijper & Hoekstra, 2017; Haw & Stubbs, 2005; Sheehan et al., 2015).

Psychotropic drugs act by modulating the availability of neurotransmitters by stimulating or inhibiting their release, or enhancing or blocking the function of their receptors on neurological cell membranes. Neurotransmitters are biochemical agents, which are produced by neurons and bind on neurotransmitter receptors located at the cell membrane of other neurons. Brain functions are based on coordinated activities of neurons via neuronal pathways of neuronal axons and neurotransmitters. There are different types of neurotransmitters, e.g., dopamine, serotonin, histamine, (nor) adrenalin, glutamine, acetylcholine, and gamma-aminobutyric acid, each with its own receptor. Neurotransmitter receptors are located on neurons of neuronal pathways in the central nervous system (the brain), but also on neurons of peripheral neuronal pathways. Psychotropic drugs exert their actions by modulating specific neurons of neuronal pathways in the central nervous system. Apart from hopefully achieving the desired result like decrease of symptoms of mental disorders this may also lead to part of the side-effects caused by these medications. Examples are parkinsonism caused by antipsychotic drugs and tremors caused by antidepressants. Besides these side-effects caused by modulation of the central nervous system, psychotropic-induced side-effects also occur by modulation of the peripheral nervous system. Examples of the latter are for instance constipation and urinary retention caused by anticholinergic properties of various antipsychotic and antidepressant drugs.

Side-effects of psychotic drugs are very common and often harmful to health and may therefore reduce the quality of life (de Kuijper et al., 2013; Koch et al., 2015; Ramerman, Hoekstra, & de Kuijper, 2018b; Young, Taylor, & Lawrie, 2014). When prescribing psychotropic drugs clinicians ought to discuss the advantages and disadvantages of treatment with the client, caregivers, and representatives. In case of serious mental illness the potential benefits will be clear, but in case of off-label prescriptions pros and cons should be carefully balanced.

Side-effects of psychotropic drugs can be distinguished in metabolic, neurological, and hormonal side-effects. Furthermore, there are sexual side-effects, which probably are caused by neurological as well as by hormonal effects of psychotropic drugs, and a category miscellaneous, e.g., skin rashes. Side-effects of the latter category are mostly patient-related, occur infrequently and cannot be explained by the pharmaceutical drug-properties. This type of side-effects will not be discussed in this chapter.

- Metabolic side-effects are weight gain, increase in abdominal fat mass, unfavorable changes in plasma lipids, and disturbed glucose metabolism with increased risks for diabetes. Most of these side-effects are associated with the use of second generation antipsychotic drugs, also commonly described as atypical antipsychotic drugs, and increase the risks for the presence of the so-called metabolic syndrome, which in turn increases the risk for cardiovascular disorders.
- Neurological side-effects; an overview of the different kinds of these side-effects is presented in Table 17.1.

Motor side-effects of psychotropic drugs, so-called extrapyramidal symptoms, may occur shortly after the first administration of the drug, e.g., acute dystonia, or after long-term use, e.g., tardive dyskinesia and tardive akathisia. The occurrence of tardive dyskinesia is sometimes related to dose changes or discontinuation of the drug and may persist after the use of the drug has been stopped. Motor side-effects are associated with the use of antipsychotics, and especially in case of multiple psychotropic drug use, long-term use and older age a substantial part of patients will develop tardive dyskinesia and/or akathisia.

Table 17.1 Neurological side-effects of psychotropic drugs

Motor side-effects	Dystonia[a]	Dyskinesia[b]	Parkinsonism[c]	Akathisia[d]
Autonomic side-effects	Gastrointestinal side-effects; drooling, obstipation, abdominal pain	Cardiovascular side-effects; tachy/bradycardia, blood pressure dysregulation	Bladder function; incontinence, urine retention	Blurred vision, disturbed sexual function, temperature dysregulation
Sensory side-effects	Hypo/hyperpathy of the skin	Tingling of fingers, hands or feet	Abnormal taste or smell	Tinnitus
Cognitive/psychological side-effects	Sedation, sleepiness, dizziness	Disturbed mood and/or sleep	Affect and cognitive flattening	Loss of appetite/increased appetite

[a] Dystonia: painful, persistent muscle cramps
[b] Dyskinesia: involuntary movements of face, eyelids, mouth, and tongue, of hands and fingers, and of ankles and feet
[c] Parkinsonism: muscle stiffness, tremor, brady- and hypokinesia
[d] Akathisia: feelings of- or motor restlessness

- Hormonal side-effects are caused by drug-induced increased release of the lacto trophic hormone prolactin. In turn, this hormone may suppress the release of the sex hormones estrogen and testosterone. Effects are disturbed menstrual cycle, loss of libido, and reduction of muscles. Secondary effects are loss of bone mass and feelings of fatigue and loss of energy.
- Sexual side-effects of psychotropic drugs may be underestimated or ignored by clinicians, in particular in people with intellectual disability. Therefore, we will extend on this theme below.

It is well known that psychotropic drugs can contribute to sexual dysfunction or sexual problems (Bella & Shamloul, 2014). Sexual dysfunction can be defined as any reduction in desire or libido, diminished arousal, a decline in the frequency of intercourse, or an undesirable delay in or inability to achieve orgasm. In the general population sexual dysfunction is rarely reported spontaneously, leading to underestimation of its prevalence. In studies, using structured interviews or questionnaires, it has been shown that 16–60% of patients using oral antipsychotics experience sexual dysfunction (de Boer, Castelein, Wiersma, Schoevers, & Knegtering, 2015). However even though this is well known there are hardly any studies available when it comes to people with an intellectual disability. People with an intellectual disability have limited verbal communication abilities which results in an inability to report adequately sexual side-effects of medication. For example the inability to achieve orgasm can result in excessive masturbation. Possibly, this behavior may be interpreted as an increase in maladaptive behavior, which in turn may lead to dosage increases or additional prescriptions of psychotropic drugs.

The pharmacological mechanisms of antipsychotic-induced sexual dysfunction are not yet fully understood. Dopamine antagonism, α1-antagonism and prolactin elevation are likely to be involved. Most antipsychotics are potent postsynaptic dopamine antagonists and can cause elevation of prolactin. Dopamine is involved in experiencing motivation and rewards, including sexual motivation (desire) and probably also sexual reward. While dopamine antagonists decrease levels of dopaminergic output, prolactin levels are increased (de Boer et al., 2015). Antipsychotic-induced hyperprolactinemia has been associated with a number of side effects including galactorrhea, menstrual disturbances, amenorrhea, decreased libido, and erectile dysfunction (de Boer et al., 2015; Lambert, Farmer, & Brahm, 2013). Furthermore, histamine receptor antagonism and hormonal changes could also be involved (Bella & Shamloul, 2014).

Table 17.2 shows the main effects of antipsychotics on sexual functioning.

Treatment with antidepressant drugs is also associated with significant rates of sexual dysfunction. The pharmacological mechanisms are largely unknown. A hypothesis is that SSRI's reduce dopaminergic transmission via serotonin receptors in the mesolimbic area, thereby reduc-

Table 17.2 Effect of antipsychotics on sexual functioning[a]

	Effects on sexual response
D2 agonism	Increased sexual desire (anticipation of reward)
D2 antagonism	Decreased sexual desire and activity, erection and ejaculation
5-HT2 agonism	Delay of orgasm
5-HT1a agonism	Activation of sexual behavior, facilitation of orgasm
5-HT2a and 5-HT2c antagonism	Probable stimulation of sexual behavior
α1 antagonism	Central effect: Decrease of erection and ejaculation. Decrease of lubrication peripheral effect: May have a stimulating effect on erection
α2 antagonism	Stimulation of erection
H1 antagonism	Sedation causing indirect effect on sexual performance
M1 antagonism	Decreased erection and lubrication

[a] Adapted from De Boer, Castelein, Wiersma, Schoevers & Knegtering, The facts about sexual (Dys)function in schizophrenia: an overview of clinically relevant findings, Schizophrenia Bulletin 2015: 674–686

ing the dopaminergic stimulating effect on sexual desire and orgasm (Bella & Shamloul, 2014).

In section "Psychotropic drugs' side-effects by subclasses" information per specific subclass of psychotropic drugs will be provided.

Assessment of Psychotropic Drugs' Side-Effects

The assessment of the presence and severity of drug-induced side-effects in people with intellectual disability may be difficult. In this population there are often limitations in self-reporting of subjective symptoms, and in adequately cooperating in physical examinations and blood sampling because of motor or behavioral problems.

In people with intellectual disability, regular methods for physical examinations of blood pressure, body weight and length, and waist circumference will mostly suffice; however in people with multiple disabilities adapted methods may be needed. Also, blood and urine sampling for assessment of metabolic and hormonal side-effect will mostly be quite possible. In case of urine incontinence catheter sampling may be done. Measurements of bone density may be needed for assessments of osteoporosis caused by drug-induced bone loss. Here, also adapted methods may be needed.

Neurological side-effects are generally assessed by taking history and observation of the patient, and a brief physical examination, which is aimed to identify symptoms of parkinsonism, dystonia, dyskinesia, and akathisia. Also examination of heart rate and heart rhythm, and of blood pressure are needed to assess cardiovascular autonomic side-effects. Sometimes Electro Cardio Gram (ECG) laboratory is necessary in case of suspected heart rhythm disorder or use of certain types of psychotropic drugs, which are known to cause disturbed heart rhythms. Cognitive, psychological, and autonomic side-effects are generally assessed with help of questionnaires and self-report instruments.

In people with intellectual disability assessment of neurological side-effects may be hampered, because of underlying motor disabilities or dyspraxia, and patients' limitations in self-report of autonomic, psychological, and cognitive side-effects. Observations in daily life of clients by support professionals and interviews of clients along with help of caregivers, or in case of non-verbal clients, interviews with proxies will be needed for taking history of potential subjective symptoms of side-effects. There are a number of instruments which are specifically developed or adapted for use in patients with intellectual disability. One of these is the Matson Evaluation of Side-effects scale (MEDS) (Matson et al., 1998; Matson & Cervantes, 2013), a comprehensive scale covering all types of psychotropic drugs-induced side-effects. It is an informant-based scale, which should be completed by a high graduated nurse based on the medical record, own observations and by interviewing the client's caregiver. It consists of nine subscales on bodily functions or anatomic regions, including four scales for neurological side-effects, i.e., Central Nervous System (CNS)-General (G), CNS-Dystonia (D), CNS-Parkinsonism/Dyskinesia P/D, CNS-Behavioral/Akathisia (BA), and covers all types of side-effects. It is a widely used scale, but its use may be limited in countries where there is lack of high graduated nurses in health care systems for people with intellectual disability.

In general, in most countries there is lack of adapted scales to assess neurological side-effects in people with intellectual disability. Yet, there are some scales which may be suitable for people with intellectual disability. For the assessment of autonomic side-effects the Scale Outcomes Parkinson disease-Autonomic symptoms (SCOPA-AUT) (Visser, Marinus, Stiggelbout, & Van Hilten, 2004) may be a useful instrument when slightly adapted by adding questions on urine and fecal continence. It was used in research projects on discontinuation of antipsychotics (de Kuijper, Evenhuis, Minderaa, & Hoekstra, 2014). The Epworth Sleepiness Scale may be used for assessment of drug-induced sedation (Ramerman et al., 2018b) and the Antipsychotics and Sexual Functioning Questionnaire (ASFQ) for the assessment of sexual side-effects (de Boer et al., 2013). However, all these scales are self-report

Table 17.3 Reliable[a] instruments for assessment of the presence and severity of drug-induced extrapyramidal symptoms

instruments and therefore should preferably be completed by the main caregiver along with the client or client‘s family.

To assess drug-induced extrapyramidal symptoms there are a lot of instruments and scales available. There are also a number of instruments which are specifically developed or validated for use in patients with intellectual disability. Table 17.3 shows instruments for assessments of dystonia, dyskinesia, parkinsonism, and akathisia for use in the general population and for use in people with intellectual disability. There are single- and multi-instruments, developed for measurement of a single kind of extrapyramidal symptom or instruments covering all kind of extrapyramidal symptoms respectively.

In intellectual disability practice the AIMS, DISCUS, UPDRS, BARS, and ARMS are widely used. As a multi-instrument the SHRS may be an alternative, however, for assessments of dyskinesia addition of the DISCUS or AIMS is possibly needed.

The reliability of instruments for use in the general population as well as for use in the intellectually disabled population may be less well when assessments are based on judgments of less well trained health care professionals. The latter was shown in a recent study on agreements of main caregivers and physicians in the presence and severity of dyskinesia, akathisia, and parkinsonism in their patients. There were hardly any correlations between the informant-based three neurological subscales CNS-D, CNS-PD, and CNS-BA of the MEDS and assessments of physicians with help of the AIMS, DISCUS, and BARS (de Kuijper & Hoekstra, 2016).

It is very important that support professionals and other staff members, who are working with people with intellectual disability and mental or behavioral disorders, are well educated and trained in the effects of psychotropic drug use in people with intellectual disability. Staff ought to have some knowledge on storage and administration of medication, as well as on registered indications, desired effects and adverse events of psychotropic drugs. They should have knowledge on reasons for prescription and know of the precautions which are needed, in particular in case of off-label use. However, studies have shown support professionals lack sufficient knowledge and they indicated that they were in need for education and training on this issue (de Kuijper & van der Putten, 2017; Donley et al., 2012).

In people with intellectual disability a major problem is the identification and assessment of dyskinesia and akathisia, since these symptoms may be held for behavioral symptoms. This is especially so when psychotropic drugs are prescribed for challenging behavior, e.g., dyskinesia may be mistaken for hyperactivity and akathisia for restlessness. Here, training and education off support professionals, nurses and physicians in both effects of psychotropic drug use, as well as in management of challenging behavior and symptoms of mental disorders should be a priority.

Videotaping of observations and of physical examinations directed towards identification and assessment of extrapyramidal symptoms may be used to enhance the intra-rater and inter-rater reliability of these symptoms.

A promising future direction may be the use of Telemedicine. An example is videoconferencing of patients and clinicians, when the patient is in his own environment, which may aid to better diagnostics of extrapyramidal symptoms. Videotaping of observations and of the physical examinations directed towards extrapyramidal symptoms may aid in more reliable assessments of clinicians. Software programs may be used to compare clinical comparisons over time (Shore et al., 2015). Furthermore, the use of electronic devices for measurements of bradykinesia and akathisia may be promising (Mentzel et al., 2016; Mentzel et al., 2016; Poyurovsky et al., 2000). Actually, a research project is running, investigating the applicability in people with intellectual disability (Beumer & Maes-Festen, 2017).

Assessment of Sexual Side-Effects

Several studies have shown that sexual dysfunction is one of the most distressing side effects of psychotropic drugs and a major cause of poor quality of life (Bella & Shamloul, 2014). As we know this, what does this mean for people with an intellectual disability. What do we know and how can we recognize sexual dysfunction? There are no studies which describe the epidemiology, impact, and treatment of sexual dysfunction among persons with an intellectual disability. Yet, some recent studies have shown that sexuality is an important issue for people with intellectual disability (Brown & McCann, 2018; Gil-Llario, Morell-Mengual, Ballester-Arnal, & Diaz-Rodriguez, 2018). Inappropriate sexual behavior among persons with an intellectual disability is quite common with the incidence ranging from 15 to 33%. However, this may be more attributable to socially inappropriate behavior than to serious assaults (Thom, Grudzinskas Jr, & Saleh, 2017). The studies investigating sexuality issues in men and women with mild and moderate intellectual disability had shown that the majority of clients had some knowledge and had received education on sexuality, although this may be incomplete. Furthermore, a majority had sexual feelings and fantasies, and had sexual relationships with another person. The most frequent sexual behaviors and practices were masturbation, kissing and petting, vaginal intercourse and oral sex. Yet, just 41% reported they had sufficient sexual satisfaction (Brown & McCann, 2018; Gil-Llario et al., 2018). In clinical practice in institutional settings it is known that a considerable part of women experience pain during intercourse, are in need for education on sexual behavior and skills, and have no understanding of their own sexual needs and desires. Also, in men there is lack of adequate knowledge and skills and there is often report of excessive or inappropriate masturbation, inappropriate touching and/ or touching others and erection problems. Furthermore, men report that they are often dissatisfied with their partner or lack a partner. So, we may conclude that sexual side-effects of psychotropic drugs are likely to be an important issue in people with intellectual disability.

Adults with intellectual disability tend to have limited verbal communication abilities. This results in their inability to express a subjective experience of adverse drug reactions and side-effects of medication (Lambert et al., 2013). An important goal in clinically assessing sexual side effects of psychotropic drugs in people with an intellectual disability is therefore to recognize sexual dysfunction. Psychological, social, symptom, and medication-related aspects of sexual performance should be disentangled. Therefore, investing in the relationship between patient and clinician tends to be worthwhile. Furthermore, clinicians should strive to establish and maintain a good relationship with family members and/or staff and caregiver. Obviously, if applicable, clinicians must obtain the permission of clients prior to discussing their sexual problems with any other person than the client him/herself. It is important to explain the cause of their sexual problems to the client and also to understand the influence of sexuality on the individual's overall quality of life in order to try to find a solution and to assess the need for additional therapy. Treatment alternatives should be discussed and considered. Lowering the dose, switching to an antipsychotic with less detrimental effects on sexual functioning, or prescribing additional medication, e.g., a dopamine agonist, aripiprazole, or phosphodiesterase-5-inhibitor, are the main treatment options (de Boer et al., 2015). Clinicians should be aware that people with a mild or borderline intellectual disability might stop their medication use when they don't understand the possibilities to decrease the sexual side effects and the consequences of stopping their medication. Stories and explanation in simple language and pictures may enable people with an intellectual disability to understand the nature and causes of their sexual problems.

There are a number of instruments available for the assessments of sexual side-effects (de Boer, Castelein, Wiersma, Schoevers, & Knegtering, 2014). Unfortunately, these questionnaires are not specifically designed for people with intellectual disability and because most are self-report instruments their usefulness may be limited in people with intellectual disability. However, since the ASFQ has been designed for people with cognitive and concentration problems (de Boer et al., 2013), this questionnaire may be also suitable for people with intellectual disabilities. Furthermore, in a recent study in people with intellectual disability, a questionnaire, evaluating sexual behavior, preventive behavior and knowledge, and experience of sexual abuse, has been used (Gil-Llario et al., 2018). It may be worthwhile to investigate whether this questionnaire is useful in assessments of psychotropic drugs' sexual side-effects in people with intellectual disability.

In contrast to people with mild or borderline intellectual disability, recognizing sexual side effects in people with a severe or profound intellectual disability may be more difficult, due to their limited communication abilities. Inappropriate touching and/or approaching others may be a sign of sexual dysfunction as well as excessive masturbation. Clinicians may try to lower the dose or taper off the drugs which likely cause the sexual side-effects, in order to investigate whether the sexual problems are caused by the drug in question. In case of considerable risks that psychiatric symptoms might increase or re-emerge when the drug dose is lowered, other causes should be excluded first.

Psychotropic Drugs' Side-Effects by Subclasses

Antipsychotic Drugs

Antipsychotic drugs primarily achieve their therapeutic efficacy in psychotic disorders by blocking dopaminergic and serotonergic receptors. Apart from their antagonistic properties for dopamine and serotonergic receptors, these drugs may also have antihistaminergic, anticholinergic, and antiadrenergic effects. Antipsychotic drugs may be divided in three generations (Table 17.4), with the second and third generation also often being referred to as atypical due to their lower antidopaminergic activity compared to the first generation antipsychotic drugs and their antiserotonergic properties.

Although there are substantial differences in pharmacological mode of action, research has shown that there are only small differences in antipsychotic efficacy (Leucht et al., 2013). Only clozapine appears to be more effective than the

Table 17.4 Three generations of antipsychotic drugs and their properties

Generation	Predominant mode of action	Important antipsychotic drugs in this group
First generation	Antidopaminergic (D_2), except for clozapine Antiadrenergic Anticholinergic (some)	Haloperidol, pipamperone, pimozid, zuclopentixole, clozapine
Second generation	Antidopaminergic Antiserotonergic Antihistaminergic Antiadrenergic Anticholinergic	Olanzapine, risperidone, paliperidone, quetiapine
Third generation	Partial antagonism for D_2-receptor (ca. 80% inhibition, 20% activation) Partial antagonism for serotonergic 5HT1A/ Antiserotonergic (5HT2A) Antihistaminergic (higher doses) Antiadrenergic (higher doses)	Aripiprazole, brexpiprazole

other antipsychotic drugs, specifically in treatment resistant schizophrenia. When differences in efficacy are small, side-effects and comorbidities become important characteristics in choosing between antipsychotic drugs.

Based on experience and cost often first generation antipsychotics and risperidone are chosen first. These drugs primarily exert their action by strongly inhibiting dopaminergic receptors, and therefore also often cause side-effects associated with this: affective flattening, extrapyramidal symptoms, and hyperprolactinemia. When these side-effects occur a dosage reduction should be the first step, since these side-effects are dose dependent. If the side-effects persist, or dosage reduction is not possible without losing therapeutic benefit, a switch towards an antipsychotic drug with less antidopaminergic action is warranted, e.g., clozapine, quetiapine, olanzapine or aripiprazole. The second generation antipsychotic drugs are less antidopaminergic than the first generation antipsychotic drugs, apart from risperidone and paliperidone, but have strong antiserotonergic and antihistaminergic properties. Antipsychotic drugs with strong antihistaminergic properties (e.g., olanzapine, quetiapine, clozapine) are strongly sedative. This may be beneficial when a patient also suffers from a sleeping disorder, but increases the chance for falling incidents. Antipsychotic drugs with strong antiserotonergic properties (e.g., olanzapine, quetiapine, clozapine) decrease feelings of satiety during eating and lower the metabolic rate. Combined with the often present antihistaminergic action of these antipsychotic drugs this causes weight gain, and potentially diabetes and/or the metabolic syndrome. When a patient is underweight these side-effects may be beneficial, but more often weight gain is a harmful side-effect, since it increase the risk for diabetes, hypertension and several forms of cancer.

The third generation antipsychotic drugs currently consists of aripiprazole, but a new antipsychotic drug in this class is on its way, brexpiprazole. These antipsychotic drugs primarily have a partial antagonistic action on dopaminergic (D2) and serotonergic (5HT1A) receptors, and are therefore also sometimes called dopaminergic and serotonergic modulators. Antipsychotic drugs in this generation have a more favorable profile regarding side-effects, since they less frequently cause extrapyramidal and metabolic side-effects. They are considerably more expensive than the other antipsychotic drugs however and frequently cause akathisia.

Many antipsychotic drugs (e.g., olanzapine, quetiapine, and clozapine) have strong anticholinergic properties, and often give rise to anticholinergic side-effects like constipation, urinary retention, dry mouth (and associated periodontitis), and cognitive problems. These side-effects are almost always harmful to the patient.

All antipsychotic drugs also increase the risk of a stroke, especially in the first 3 months, and most give rise to QTc prolongation, which increases the risk of a ventricular arrhythmia and cardiac mortality (Chen et al., 2017; Hsu et al., 2017). Some antipsychotics, especially clozapine and to a lesser extent quetiapine and olanzapine, also increase the risk of an epileptic seizure (mostly myoclonic) (Alper, Schwartz, Kolts, & Khan, 2007).

Antidepressant Drugs

Most antidepressants exert their action by increasing serotonin and/or noradrenalin levels in the synaptic cleft, the small space between two adjacent neurons. Based on their mechanism of action or chemical structure antidepressant drugs are often divided into several groups (Table 17.5).

SSRI's

The drugs belonging to the SSRI's hardly differ in their mechanism of action, and therefore also cause the same side-effects: tremors, excessive sweating, nausea and vomiting, diarrhea, sleeping disorders, restless legs, and sexual dysfunction (mostly impairment of libido and ejaculation). Paroxetine is somewhat anticholinergic and may therefore cause constipation more often than other SSRI's.

SNRI's

The SNRI's duloxetine and venlafaxine inhibit both the reuptake of serotonin and noradrenalin. Since this includes the same pharmacologic action as SSRI's these drugs can also cause the same side-effects. Their noradrenergic action however adds some side-effects like agitation, hypertension, and tachycardia. This may be undesirable in most patients, but when a patient also experiences neuropathic pain, which benefits from a noradrenergic action, duloxetine may be a desirable drug.

TCA's

The various tricyclic antidepressant drugs differ more with regard to their mechanism of action. All TCA's inhibit the reuptake of serotonin and noradrenalin, but some are predominantly serotonergic (imipramine, clomipramine) whereas others are predominantly noradrenergic (nortriptyline). Amitriptyline inhibits both the reuptake of serotonin and noradrenalin equally. Since TCA's exert the same mechanism of action as the SSRI's and or SNRI's, they can also cause the same side-effects as those groups. However, TCA's also have strong antihistaminergic and anticholinergic properties and are more cardiotoxic due to an inhibition of electrical conduction in the atrioventricular node which can result in a cardiac arrest when an overdose is taken. Their antihistaminergic properties result in weight gain and sedation, whereas their anticholinergic properties result in constipation, urinary retention, dry mouth, and cognitive problems among others. Although harmful in many patients, some

Table 17.5 Overview of antidepressants and their mechanism of action

Group	Mechanism of action	Important antidepressants in this group
Selective serotonin reuptake inhibitors (SSRI's)	Inhibit reuptake of serotonin	Paroxetine, fluoxetine, sertraline, citalopram, escitalopram, fluvoxamine
Serotonin and noradrenalin reuptake inhibitors (SNRI's)	Inhibit reuptake of serotonin and noradrenalin	Venlafaxine, duloxetine
Tricyclic antidepressants (TCA's)	Inhibit reuptake of serotonin and/or noradrenalin Antihistaminergic Anticholinergic	Amitriptyline, nortriptyline, clomipramine, imipramine
MAO-inhibitors	Inhibit mono-amine oxidase (which breaks down dopamine, serotonin and noradrenalin)	Tranylcypromine, phenelzine, moclobemide
Miscellaneous	Divers. Most have an impact on serotonergic, dopaminergic or noradrenergic receptors	Bupropion, mirtazapine, trazodone, agomelatine.

patients may benefit from these side-effects. As an example, bed wetting can be treated with amitriptyline or clomipramine, and neuropathic pain or sleeping disorders can also benefit from amitriptyline. Nortriptyline is the least anticholinergic TCA and is therefore often the drug of choice when a TCA is indicated.

MAO-Inhibitors

MAO-inhibitors are sometimes used in treatment resistant depression, and consist of two irreversible MAO_A and MAO_B inhibitors (phenelzine and tranylcypromine) and one reversible MAO_A-inhibitor (moclobemid). Inhibition of MAO, which is an enzyme responsible for the degradation of serotonin, dopamine and noradrenaline can result in a variety of side-effects. The most-important side-effects of these drugs are orthostatic hypotension, nausea and vomiting, and sexual dysfunction. When an irreversible MAO-inhibitor is used a diet excluding tyramine, an amino acid that can be found in some wines and cheese among others, becomes very important because ingestion of tyramine can result in a hypertensive crisis in these patients. The same goes for use of inotropic drugs like isoprenalin, adrenalin, xylomethazoline, dopamine and noradrenalin. Tranylcypromine has a dexamphetamine like effect, which can cause hypertension shortly after a dose is ingested, resulting in headache.

Miscellaneous

Antidepressants belonging to the miscellaneous group differ greatly in their mechanism of action and therefore also in associated side-effects. The two most commonly used drugs in this group are bupropion and mirtazapine. Bupropion inhibits the reuptake of dopamine. Side-effects include nausea and vomiting, convulsions, and tremors, but the dopaminergic action of bupropion might be of benefit in patients with Attention Deficit Hyperactivity Disorder (ADHD). Mirtazapine has strong antihistaminergic and antiserotonergic properties resulting in sedation and weight gain. This mechanism of action might be of added value in people with depression who also suffer from sleeping disorders. Mirtazapine can sometimes be added (in low dose) to treatment with SSRI's or SNRI's to treat sexual dysfunction and sleeping disorders caused by the SSRI or SNRI.

Trazodone acts as a serotonin antagonist in low dosages, but inhibits reuptake of serotonin when higher dosages are used. In low dosages trazodone is used to prevent drug-induced sleeping disorders (e.g., MAO-inhibitors).

Agomelatin is an antidepressant that stimulates melatonin receptors and blocks a specific serotonergic receptor. It might have some benefit in treatment of depression with concomitant sleeping disorders, but is known to cause serious side-effects, specifically hepatic failure.

Psychostimulants

There are several psychostimulants that can be used to treat ADD and ADHD. The most commonly used stimulants are methylphenidate, dexamphetamine, atomoxetine, clonidine, and bupropion. Methylphenidate and dexamphetamine stimulate the central nervous system by inhibiting the reuptake of noradrenaline and dopamine and stimulating the release of these two neurotransmitters. Side-effects include loss of appetite, weight loss, hypertension, and nausea and vomiting.

Atomoxetine is a selective noradrenalin reuptake inhibitor causing associated side-effects like hypertension, tachycardia, loss of appetite, and weight loss. Bupropion inhibits the reuptake of dopamine, and also causes side-effects like nausea and vomiting, convulsions, and loss of appetite.

Growth retardation can occur during the use of stimulants as a result of the loss of appetite and weight loss.

Clonidine acts as an adrenergic-alpha2a-agonist and therefore has a very different mode of action. Its main side-effects include sedation and hypotension, and is not associated with growth retardation.

Mood Stabilizers

The most commonly used mood stabilizers are lithium, sodium valproate, carbamazepine, lamotrigine, and the antipsychotic drugs. These drugs are used to treat severe and ongoing periodic mood swings that are symptoms of bipolar disorder. Sodium valproate, carbamazepine, and lamotrigine are also used as antiepileptic drugs.

Lithium is the keystone in treating bipolar disorder, since lithium is an effective treatment for both the manic and depressive states and reduces the suicide risk. Lithium may however cause several serious side-effects, including weight gain, tremors, cognitive and concentration problems, polyuria, nephrogenic diabetes insipidus, and thyroid dysfunction. Long-term use of lithium may also cause a decrease in renal function.

Sodium valproate is also frequently used as a mood stabilizer and may cause side-effects including polycystic ovarium syndrome, liver toxicity, hematologic problems, elevated ammonia levels, and weight gain.

Carbamazepine is less frequently used as a mood stabilizer due to the multiple drug interactions carbamazepine causes and its anticholinergic properties. Its side-effects include sedation, liver toxicity, gamma-GT elevation, hematologic problems, Stephen Johnson syndrome, and hyponatremia.

Lamotrigine is used mainly to treat depressive episodes, since it lacks efficacy in treating mania. Lamotrigine is often well tolerated but frequently causes skin disorders, especially when dose accumulation is rapid. It may also rarely cause Stephen Johnson Syndrome and toxic epidermal necrosis which are life-threatening conditions that are comparable to third degree burns.

The antipsychotic drugs are most effective in treating mania. Their side-effects have been described in the previous section.

Anxiolytic Drugs

Drugs used to treat anxiety include the aforementioned SSRI's, benzodiazepines (e.g., oxazepam, diazepam, lorazepam), buspirone, and propranolol.

Benzodiazepines are drugs with strong sedative properties that may therefore have a negative impact on response time and cognition, cause affective flattening, and increase the risk of falling. In people with intellectual disability benzodiazepines may cause paradoxical reactions including agitation.

Buspirone is less sedative than benzodiazepines. Buspiron acts as a partial serotonin agonist and may cause side-effects including dizziness and headaches.

Propranolol is a non-selective beta antagonist which is mainly used as an anxiolytic drug when there is sympathetic over-activity and in aggressive outbreaks. Caution is warranted in patient suffering from asthma or COPD since propranolol may impair the efficacy of bronchodilators used in those patients. Side-effects include bradycardia, sleeping disorders, nightmares, fatigue, and cold hands and feet.

Hypnotics

Benzodiazepines used as a hypnotic drug include nitrazepam, temazepam, midazolam, zolpidem, and zopiclon. Their side-effects are the same as the other benzodiazepines.

Melatonin and promethazine may also be used as hypnotic drugs. Melatonin is frequently used as a hypnotic/chronobiotic when there are circadian problems and rarely causes side-effects. Promethazine may be used when benzodiazepines aren't effective and has strong antihistaminergic and anticholinergic properties. Side-effects include sedation, dizziness, confusion, constipation, urinary retention, and dry mouth.

Low dosages of the antidepressant mirtazapine (3–15 mg) or the antipsychotic quetiapine (12.5–50 mg) are also used to treat sleeping disorders. However, since the metabolic side-effects of these drugs are largely independent of the dosage monitoring for these potential side-effects is necessary.

Monitoring of Psychotropic Drugs' Side-Effects

There are a number of guidelines on the prescribing of psychotropic drugs in people with intellectual disability. Examples are the NICE guideline "Psychotropic medicines in people with learning disabilities whose behaviour challenges," which includes an algorithm for the review, reduction or stopping of psychotropic drugs (nice.org.uk/guidance/ktt19, January 2017), the guideline of The Royal College of Psychiatrists (UK, April 2016) "Psychotropic drug prescribing for people with intellectual disability, mental health problems and or behaviours that challenge: practice guidelines "(http://www.rcpsych.ac.uk/pdf/FR_ID_09_for_website.pdf) and a paper in the journal "Australian Prescriber" (Trollor, Salomon, & Franklin, 2016). Also, guidelines on this issue exist in other countries, adapted to own health care systems and language. All guidelines recommend evaluating on reasons for (ongoing prescription) effects and safety of the prescribed drugs.

Before a pharmaceutical treatment is started an assessment of baseline health condition, including use of prescribed and of "over the counter" medication is needed and symptoms of potential side-effects should be examined. Baseline blood pressure, heart rate, body weight, body mass index, and laboratory parameters should be noted. In people with intellectual disability the presence and severity of minor neurological deficits, e.g., developmental coordination disorder, mild forms of dyspraxia or cerebral palsy and symptoms of Parkinson's disease should be noted, since these symptoms may be mistaken for extrapyramidal symptoms.

The monitoring of psychotropic drugs differs between psychotropic drug subclasses.

Below you will find monitoring schedules of the two most frequently prescribed psychotropic drugs subclasses in people with intellectual disability, i.e., antipsychotic drugs and antidepressants. For the monitoring of mood stabilizers we refer to national professionals guidelines of psychiatrists; a guideline on the prescribing of psychotropic drugs, including monitoring schedules, of the Dutch Association of Intellectual Disability Physicians (NVAVG) is also available (nvavg.nl/voorschrijven-van-psychofarmaca/; bijlage 9.5d-9.5 g, December 2016).

It is important to realize that all of these monitoring schedules are based on expert opinions and are generated in multidisciplinary groups. There are no studies comparing multiple monitoring schedules with regard to harms and benefits. Therefore it is important to weigh the potential benefits of wanting to know if certain side-effects occur against the harm it may cause for each individual patient. Since collection of blood can be stressful for the patient monitoring for side-effects should be noninvasive whenever possible. When the potential benefits of blood monitoring outweigh the potential harm it is important to also have a baseline measurement before the drug is started. A baseline measurement may help in determining which drug is best suited (e.g., when sodium is already low carbamazepine may not be the best choice) and also helps in identifying whether the recently started drug is to blame for a certain change in blood value.

Antipsychotics

The monitoring schedule for antipsychotics, as shown in Table 17.6, was specifically designed for patients with intellectual disability (de Leon, Greenlee, Barber, Sabaawi, & Singh, 2009). Monitoring is largely noninvasive, apart from measurements focused on metabolic side-effects (glucose and lipid levels) and prolactin. Baseline measurements are more elaborate.

Antidepressants

The monitoring schedule for antidepressants, as shown in Table 17.7, was not specifically designed for patients with intellectual disability. Monitoring is largely noninvasive, apart from measurements of glucose levels, renal function, and electrolyte levels. The latter is mainly relevant for diagnosing a drug-induced hyponatremia otherwise known as Syndrome for Inappropriate ADH release (SIADH), which mostly occurs in the first few weeks of treatment. An ECG may be necessary in case of relevant cardiac comorbidities or risk factors for QTc prolongation when TCA's (e.g., nortriptyline and amitriptyline) are used (Table 17.8).

Management of Side-Effects of Psychotropic Drugs

When side-effects occur, regardless of what type of drug causes it, the first step towards preventing or treating the side-effect should be to determine

Table 17.6 Monitoring for side-effects when using antipsychotic drugs (excl. clozapine)[a]

	Baseline	*t* = 1 month	*t* = 2 months	*t* = 3 months	*t* = 6 months	*t* = 12 months	Half-yearly	Yearly

[b] Only at the start of treatment and after significant dosage alterations in patients with risk factors for cardiac problems including QTc prolongation (table x), otherwise on indication

whether or not that specific side effect is dose dependent. If the side effect is dose dependent, and most of them are, or when there is uncertainty whether or not it is dose dependent the first action should be to lower the dose of that drug. If lowering the dose does not solve the problem or is not possible without losing efficacy, then the second step should be to see whether an alternative treatment is possible with a different psychotropic drug that may be equally effective, but is less likely to cause the same side effect. For example, if side-effects like parkinsonism are caused by an antipsychotic drug with strong antidopaminergic activity (e.g., risperidone) a switch towards an antipsychotic drug with less antidopaminergic activity (e.g., aripiprazole or quetiapine) may solve the problem. If none of these actions are possible, then addition of other drugs to treat the side-effects is warranted. Otherwise the risk for polypharmacy increases, with more and more drugs being added to treat the side-effects of other drugs. The treatment of four side-effects with a high prevalence in people with intellectual disability caused by psychotropic drugs will be discussed; constipation, extrapyramidal symptoms, sexual dysfunction and weight gain.

Table 17.8 Risk factors for QTc prolongation[a]

Alcoholism
Change in nutrition (anorexia nervosa, starvation, malnutrition)
Bradycardia (<50 strokes/min)
Cerebrovascular problems (intracranial and subarachnoïdal bleeding, stroke, intracranial trauma)
Congenital long QT-syndrome
Diabetes mellitus
High age
Electrolyte problems (hypokalemia, hypomagnesaemia, hypocalcaemia)
Female sex
Heart failure (cardiomyopathy)
Hypertension
Hypoglycemia
Hypothermia
Thyroid insufficiency
Myocardial infarction or ischemia
Obesity

Constipation

Constipation is often caused by drugs with anticholinergic properties, like most antipsychotic drugs, tricyclic antidepressants, and promethazine. A recent study used the Anticholinergic Burden Scale (ABS) to compute a cumulative score of drugs to determine an individual's anticholinergic burden in older people with intellectual disability (O'Dwyer, Maidment, et al., 2016). Drugs with no anticholinergic effects score 0, drugs with possible anticholinergic effects score 1 and drugs with definite cognitive anticholinergic effects score 2 or 3. In these older patients 42% had an ACB score of 1–4, 29% had an ACB score ≥ 5, and 29% had an ACB score of 0. So overall, around 71% of the older population with intellectual disability had at least one drug with anticholinergic properties, of which antipsychotics were the dominant group. Antipsychotics comprised 35% of the total cumulative ACB score, followed by anticholinergics (16%, e.g., biperidene) most of which were probably added to treat extrapyramidal symptoms caused by the same antipsychotic drug. Antidepressant drugs with anticholinergic properties (e.g., TCA's) were also used regularly (9.4% of the ACB-3 drugs used in this population).

Apart from daytime drowsiness which was significantly associated with a higher ACB score, a greater proportion of those with a higher anticholinergic burden were chronically constipated (27% ACB ≥ 5 vs. 8% ACB 0) and frequently used two or more concurrent laxatives (29% ACB ≥ 5 vs. 5% ACB 0).

Regarding the use of psychotropic drugs with anticholinergic properties, the first step should be to see if treatment with that drug is still needed or if a switch is possible towards an alternative with less or no anticholinergic properties like some first and third generation antipsychotic drugs, risperidone, SNRI's, and SSRI's.

If switching is not possible or constipation persists treatment towards treating constipation should be started. The basic treatment of every form of constipation consists of non-medical interventions focused on adequate intake of fluids and fiber and increasing physical activity. Laxatives are used if those interventions are insufficient to resolve the constipation.

Laxatives are generally divided into four groups, depending on the way they work; bulk-forming laxatives (also known as fiber supplements, e.g., psyllium fibers), osmotic laxatives (e.g., lactulose, macrogols, magnesiumhydroxide, and phosphate enemas), stimulant laxatives (e.g., bisacodyl, senna), and fecal softeners (e.g., paraffin).

The stimulant laxatives and paraffin are less suited for chronic use, because the constant irritation of the colonic mucosa by the stimulant laxatives may result in a megacolon, and paraffin may cause anal irritation. The other types of laxatives can be used chronically, but there are some practical issues to consider. Lactulose may cause flatulence which may cause stomach and intestinal discomfort. Bulk-forming laxatives have to be combined with adequate intake of fluids to prevent bezoar formation. Therefore in most practices macrogols are used as laxatives for chronic use, since these less frequently cause flatulence and require less fluid intake.

To monitor a patients fecal pattern and determine constipation in an early stage a Bristol stool chart (https://commons.wikimedia.org/wiki/

File:BristolStoolChart.png) with type 1 and type 2 being indicative for constipation.

Extrapyramidal Symptoms

Extrapyramidal symptoms (EPS) are drug-induced movement disorders that include acute and tardive symptoms. The symptoms include dystonia, akathisia (including restless legs syndrome and bruxism), parkinsonism, bradykinesia, tremors, and tardive dyskinesia. EPS are frequently caused by antipsychotic drugs, but can also be caused by serotonin reuptake inhibitors and sodium valproate.

EPS are a dose-dependent side effect, so again, reduction of the dose should be the first potential step in preventing EPS. If a dose reduction is not possible without losing efficacy a switch towards a more favorable psychotropic drug may be warranted. Regarding antipsychotic drugs, a choice can be made towards less antidopaminergic antipsychotic drugs like clozapine, quetiapine, olanzapine, and aripiprazole. When EPS occur during use of SSRI's a switch towards an antidepressant that does not inhibit the reuptake of serotonin is advisable, like nortriptyline, mirtazapine, or bupropion. EPS during use of sodium valproate may be less easy to switch away from, since a switch to lithium may also result in tremors as a side-effect of lithium, and a switch to carbamazepine often results in unwanted drug interactions. Mood stabilizers that may be a suitable alternative regarding EPS are lamotrigine, olanzapine, aripiprazole, or quetiapine.

EPS can be treated by starting anticholinergic drugs like biperidene, but these drugs cause anticholinergic side-effects that are troublesome in this population. Moreover, use of biperidene may increase the severity of dyskinesia. If this option is chosen extra attention towards anticholinergic side-effects is warranted.

When a patients suffers from a sleeping disorder caused by restless legs syndrome or bruxism (frequently caused by SSRI's) dopaminergic agents (e.g., pramipexole) can be used to treat these problems. In patients who are prone to psychosis adding a dopaminergic agent is not absolutely contraindicated, but caution is advised and a lower starting dose of the dopaminergic agent should be considered.

Sexual Dysfunction

Many psychotropic drugs can cause sexual dysfunction. This may sometimes be a desirable side effect since 15–33% of the population with ID show inappropriate sexual behavior (Thom et al., 2017), but often is not. Sexual dysfunction may consist of a diminished libido, erectile dysfunction and premature or delayed ejaculation and is often caused by antipsychotic and antidepressant drugs.

Antipsychotic drugs with antidopaminergic properties and antidepressants that inhibit serotonin reuptake (e.g., SNRI's, SSRI's, TCA's) increase prolactin levels, which in turn causes a reduction in estrogen and testosterone levels leading to a diminished libido. Switching to antipsychotic drugs with less antidopaminergic activity (e.g., quetiapine, clozapine, aripiprazole) or antidepressants that don't inhibit the reuptake of serotonin (e.g., nortriptyline, mirtazapine, bupropion) may solve the problem. Addition of a low dose of bupropion, when antidepressants are the cause of the sexual dysfunction, is also possible since this reduces elevated prolactin levels (Pereira, Arias-Carrion, Machado, Nardi, & Silva, 2014).

Although erectile dysfunction may also be caused by a diminished libido it is often associated with anticholinergic drugs. Switching to a comparative drug with less or no anticholinergic action may improve the erectile dysfunction. Addition of a phosphodiesterase-5-inhibitor (e.g., sildenafil, tadalafin) may also improve the erectile dysfunction.

Ejaculation problems are often associated with noradrenergic actions of psychotropic drugs. Drugs with a noradrenergic stimulating action (e.g., the noradrenalin reuptake inhibitors atomoxetine and nortriptyline) may cause a premature or even a spontaneous ejaculation, whereas drugs with anti-noradrenergic properties (e.g., antipsychotics, TCA's) may cause a delayed ejaculation. Dose reduction when possible or switching to a psychotropic drug with a different noradrenergic profile may solve the problem.

Table 17.9 Antipsychotic-induced weight gain (mean) in first 10 weeks of treatment

Antipsychotic	Weight gain (kg)
Clozapine	4.45
Olanzapine	4.15
Thioridazine	3.19
Sertindole	2.92
Chloorpromazine	2.58
Risperidone	2.10
Quetiapine	2.18
Sulpiride	1.90
Haloperidol	1.08
Aripiprazol	0.71
Bromperidol	0.50
Fluphenazine	0.43
Ziprasidone	0.04
Placebo	−0.74

Adapted from: Allison DB, Mentore JL, Heo M, et al. Antipsychotic-induced weight gain: a comprehensive research synthesis. Am. J. Psychiatry 1999;156:1686–1696

Weight Gain

Weight gain can be caused by some antidepressant drugs (e.g., TCA's and mirtazapine), but is most frequently caused by antipsychotic drugs. Weight gain can occur during use of any antipsychotic drug, but is more severe with second generation antipsychotics, especially clozapine and olanzapine (Table 17.9), since they have a higher affinity for receptors associated with weight gain (e.g., muscarin, histamine, serotonin) .

Weight gain is most clearly visible during the first 3 months of treatment with antipsychotics, after which a new plateau is reached. However, weight gain can endure for years during treatment with olanzapine or clozapine. Apart from the increased risk of comorbidities associated with weight gain, patients also consider weight gain as one of the most disturbing adverse events and an important reason for non-adherence to therapy (Hugenholtz et al., 2005).

Increased awareness for weight gain, and other metabolic adverse effects caused by antipsychotic drugs, lead in 2008 to the development of the first Dutch (Cahn, Ramlal & Bruggeman, 2008) protocol for routine somatic screening and treatment procedures in patients with schizophrenia in order to prevent long-term complications like cardiovascular disease and diabetes.

The cornerstone in treatment of drug-induced weight gain are life style interventions, including diets and promoting physical exercise. If those options are not possible or effective, then switching to a comparable drug with a more favorable metabolic profile is advisable (e.g., SNRI's/SSRI's instead of mirtazapine or TCA's, or aripiprazole instead of other antipsychotic drugs).

If switching to a more favorable drug is also not possible, then additional pharmacotherapy with a low dose of the antidiabetic drug metformin or the antiepileptic drug topiramate may be effective in achieving weight loss (Chen et al., 2013; Mahmood, Booker, Huang, & Coleman, 2013).

Multidisciplinary Care in Monitoring and Management of Psychotropic Drugs' Side-Effects

As outlined above the monitoring and management of side- effects of psychotropic drugs on physical health and mental functioning is a multifaceted, sometimes complicated process. For good quality pharmaceutical care a multidisciplinary approach is required, wherein the role and responsibilities of each discipline involved is clear. Where physicians and pharmacists are responsible for the prescription, delivery and quality of drugs, nurses are responsible for the administration. Furthermore, main caregivers, nurses, and/or support professionals are responsible for daily care and observation of behavioral and physical symptoms, possibly due to side-effects of drugs. In mental health care for people with intellectual disability the psychologist and/or behavioral scientist will mostly be responsible for the care plan of the client, including the assessment and management of challenging behavior and symptoms of mental disorders. It will be clear that when it comes to the monitoring and management of side-effects of psychotropic drugs, cooperation of all disciplines is required.

The past decade the role of specialized intellectual disability nurses, although not clearly defined, has become more prominent. Nurses are the main contacts of families and representatives, and they feel they have responsibilities towards clients with regard to advocacy and health promotion, assessment and case management, behavioral interventions, safety and risk management, communication and medication administration, and to take a leading role in the multidisciplinary team (Doody, Slevin, & Taggart, 2018; Taua, Hepworth, & Neville, 2012). In case nurses are educated and trained in specialized intellectual disability care, they may also take a role and share responsibilities with physicians in the monitoring of side-effects of psychotropic drugs provided that they have sufficient knowledge of effects of psychotropic drug and of alternative treatments of mental and behavioral disorders (Jenkins, 2000). However, studies have shown that support professionals' and nurses' knowledge was insufficient and that they were in need for education on this issue (de Kuijper & van der Putten, 2017; Donley et al., 2012).

The psychologist and behavioral scientist are very important disciplines with regard to the monitoring of effects of psychotropic drugs on clients' behavior and the management of side-effects. Especially in case of discontinuation of off-label use they have to look for alternative treatments and to support the team with regard to the management of clients' challenging behaviors. Also, when life style interventions are needed in case of overweight or risk of cardiovascular disorders due to metabolic side-effects, they have important roles regarding changes in the care plan and supporting the client and team to change behavioral patterns concerning food intake and exercises. Furthermore, their help will be needed in the management of sexual side-effects, when clients may be frustrated and display irritable or aggressive behavior.

In most guidelines on psychotropic drug use regular monitoring and a multidisciplinary approach is advised. However, the adherence to guidelines may be poor due to insufficient implementation (Ramerman, de Kuijper & Hoekstra, 2017; Ramerman et al., 2018a). Among others, changes in organizational policies are needed to facilitate professionals in offering the required quality of care.

A Tool for Customized Pharmaceutical Care

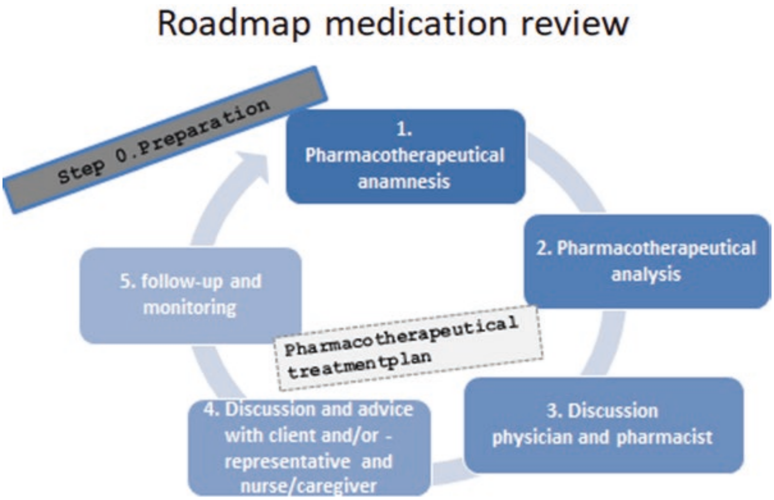
Although reduction of unnecessary use of medication should always been sought, many people with intellectual disability will have need for chronic medication use, including psychotropic drugs. Here, a good quality multidisciplinary evaluation of the medication use on indication, effects and side-effects of all prescribed drugs is needed. Disciplines who take part in such a medication review are the pharmacist, physician, nurse, and the support professional of the person with intellectual disability who is on chronic medication use. The review includes an interview with the patient and/or the patient-representative or main caregiver by the nurse, physician, and/or pharmacist. Preferably the medication review is in addition to an annual health check of the patient or is at least preceded by an evaluation and monitoring of the psychotropic drug use of the patient.

STRIP, a Systematic Tool to Reduce Inappropriate Prescribing, is a systematic method for reviewing medication prescribing, which may be very useful for customized pharmaceutical care in people with intellectual disability. The method includes a cycle of five steps, preceded by an assessment of the patient's health condition by studying the medical and pharmaceutical record, taking history and/or a physical examination (Fig. 17.1).

Step 1 can be carried out by the pharmacist, physician or specialized high graduated nurse. Step 2 is carried out by the pharmacist. Besides the pharmacist and physician, other disciplines involved in reviewing patients medication use (Step 3) may be the psychologist, support professional and nurse of the client. In step 4, discussion with the client and/or his representative and main caregiver, a psychologist should also be involved in case of psychotropic drug use. Step 5 is part of the regular monitoring of the medication use. After 1, 2, or 3 years, the cycle of five steps should be repeated.

The STRIP has been developed for use in elderly health care, but it is also a promising tool for application in intellectual disability health

Fig. 17.1 STRIP method



care (Scheifes, Egberts, Stolker, Nijman, & Heerdink, 2016; Zaal et al., 2016). The tool is targeted towards the identification of prescription errors and other drug-related problems. These are defined as:

1. Undertreatment, i.e., the missing of necessary medication for treatment or reduction of risk for side-effects caused by use of certain kinds of medication. An example is the need for prescription of an antacid agent to reduce the risk of stomach bleeding when the patient also uses an NSAID for treatment of pain.
2. Lack of effectiveness,
3. Overtreatment, e.g., there is no clear reasons for prescription (anymore).
4. The presence or risk of side-effects.
5. Clinically relevant contra-indications for medication, e.g., antipsychotic drugs in case of severe and untreatable seizures, or interactions between two or more agents.
6. Insufficient dosage (related to the indication for prescription).
7. Administration problems, e.g., the patients cannot swallow tablets or through probe.

When the prescription errors and drug-related problems are identified, the pharmacist will talk with the patient and the physician to discuss the errors and problems and will give advices for interventions to overcome the drug-related errors and problems. In intellectual disability medical practice, these interventions are not always implemented. This may be related to objections by patients, patient-representatives, caregivers, or other staff members, but also to organizational factors. In the study of Zaal et al. (2016), which took place in living facilities of service providers, after 6 months just 16% of advised interventions were implemented. In the study of Scheifes, Walraven, et al. (2016), which took place in a treatment facility for people with mild intellectual disabilities, almost 60% of advised interventions were implemented.

In many countries health care systems may be limited to allow for application of the STRIP method or even to apply for regular evaluations of (psychotropic) drug use in people with intellectual disability.

Yet, the quality of medication evaluations can be improved by cooperation of health care professionals affiliated to different health care systems within countries. Policy makers, health care insurances, intellectual disability service providers, and mental health care systems should facilitate the deployment of high graduated and specialized nurses, knowledge exchange and cooperation between pharmacists, physicians and nurses. In this way, good quality pharmaceutical care may be possible, at least to some degree, for people with intellectual disability in middle and lower income countries too.

Conclusions

To guarantee good quality pharmaceutical care in people with intellectual disability who use psychotropic drugs, a multidisciplinary approach is required: physicians, pharmacists, and main caregivers cooperate in medication reviews; physicians, pharmacists, main caregivers, and psychologists cooperate in observation and management of side-effects; physicians, nurses, and main caregivers cooperate in the monitoring of side-effects. However, nurses as well as support professionals should have sufficient skills and competence to reliably observe and monitor the side-effects. For this they should be educated in their vocational and specialist training. Also, there is need for validation and development of reliable instruments for assessments of neurological side-effects including sexual side-effects. The implementation of guidelines in the monitoring of psychotropic drug use should be enhanced by training of physicians and clinicians and changes in organizational policies.

Part V

Causes and Risk Factors of Intellectual Disabilities

The Effects of Genetic Disorders on Language

18

Natalia Freitas Rossi and Célia Maria Giacheti

Analyzing the effects of genetic disorders on language is like putting together the pieces of a big puzzle or like moving—most of the time—in uncharted waters. This analogy that represents the challenges that researchers have to face while approaching the issue is due to a set of factors that can influence language development; genetic influence is one of the factors in this context.

It represents the past and present views of the nature vs. nurture debate. Fortunately, due to advances in interdisciplinary studies using molecular genetics and brain imaging techniques, this issue is currently better understood.

Language From a Neurobiological Perspective and Its Evolution

The evolution of communication and language systems among different species can be approached from a number of different perspectives, ranging from a biological to an anthropological point of view. The fundamental question of how genetic and environment factors work together is still open, but a little better understood now. The open-ended complex questions regarding the gene-brain-language interaction have stimulated the nature vs. nurture debate.

Biological and environment factors have received different weights among theoretical models to explain language acquisition and its developmental trajectory. However, both factors are recognized as part of this process, even if the theoretical models seem to indicate either one or the other as the driving factor. On the one hand, we have those who defend the theory that language evolution results from interplay between genetic and brain modifications; this theory reinforces Chomsky's assumption that language is fundamentally a biological structure. On the other hand, this assumption is too simple to explain human language acquisition, and it has been suggested that human language acquisition is the result of a long process of cultural evolution (Chater & Christiansen, 2010; Christiansen & Kirby, 2003).

In fact, the evolution of the complex communication system is the result of a long biological and cultural process that makes humans unique; this evolution was a turning point that made *Homo sapiens* a symbolic species. The evolution of symbolic language (gestures, spoken, and written symbols) over thousands of years provided substantial evolutionary advantage from monkeys to other primitive hominids and finally to humans, in the Darwinian process of natural selection. Due to its complexity, coevolution of the brain and human language seems to be a plausible hypothesis (Deacon, 1998).

J. L. Matson (ed.), *Handbook of Intellectual Disabilities*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-030-20843-1_18

The evolutionary approach toward language development takes into consideration multiple factors involved in communication, from vocal anatomical structural modifications to the evolution of social cognition. So far, the following questions regarding the emergence and evolution of speech and language in the human species remain unanswered: did the brain evolve to accommodate the evolution of language and the complexity of social relations, or were language and social relations more complex changes as a result of genetic influences and brain structural modifications, or is this all a reflection of coevolution?

The coevolution hypothesis argues that the need to communicate may have led humans to change their communication strategy from simple to more complex forms. Human communication requires sophisticated capabilities that involve more than nonlinguistic communication skills (e.g., facial expression, gestures); it requires a grammar system domain and the ability to deal with the idiosyncrasies of language and its discontinuities (Deacon, 1998).

It is known that genetic changes with respect to the evolution of the brain occurred with no major genome-wide changes; this may seem paradoxical with regard to language evolution. In fact, what is seen in the primate-specific lineage is that new genes are recruited during the early development of the brain, which indicates that new genes have an important function during the development of the human fetal brain (Zhang, Landback, Vibranovski, & Long, 2011).

Social behavior is shaped by a combination of motivation, emotion, and communication skills, which leads a species to move from a rigid eusocial behavior to constructing representations of the relations between oneself and others, and to use those representations flexibly to guide social behavior (Adolphs, 2001).

Prosocial motivation is a well-known, remarkable aspect of the human communication system. It is based on fundamentally cooperative intentions, and this makes human communication skills different from those of other primates (Tomasello, 2010). Prosocial motivation and caregiving behaviors (inhibiting aggression, and facilitating affective communication and cooperation between members of a similar social group) is driven by empathy, which is not exclusive to humans, but certainly a hallmark of humans. Empathy is supported by the neurobiological architecture, including the brainstem, amygdala, anterior cingulate cortex, hypothalamus, striatum, insula, and orbitofrontal cortex, as well as the autonomic nervous system and neuroendocrine processes (Decety, Bartal, Uzefovsky, & Knafo-Noam, 2016).

Despite the evolution in communication systems among humans from primitive modalities to highly sophisticated social interactions in current times, including communication via internet modalities (Yeger, 2015), the ability to match the emotional state of another (empathy) and to understand the other person's mental state (theory of mind) still remains crucial in everyday interactions (Goldstein & Winner, 2012); together these two social cognitive domains with language probably formed an evolutionary cycle, wherein, advances in one fed advances in the other. It is unclear what human cognition (social or otherwise) would be like without the powerful cultural augmentation that language provides.

Evolution of the temporal and frontal regions of the brain is of significance because these brain areas support the evolution of the mechanisms of comprehension and production of spoken language, as well as social cognition that brought to our species, an important adaption for living in a society (Poeppel, 2014). In terms of maturation, it is well known that the frontal cortex is a late-developing region of the neocortex (Fuster, 2002). The frontal lobe is responsible for sophisticated spoken language organization in the form of a narrative discourse (Friend & Bates, 2014), executive functions, and social cognition (Miller & Cummings, 2017; Yeh, Tsai, Tsai, Lo, & Wang, 2017). It is highly unlikely that the sophisticated cognitive and communication system of humans with complex language capacities is only due to the large brain size in our species, in part, because the size of the human brain is not so different from that of chimpanzees. Nevertheless, in spite of similarities, there are important differences in behavior and social skills between humans and chimpanzees. Changes at the protein level with evolution of regulatory networks (Zhang et al., 2011), a more complex organization and distribution pattern of neurons and glial cells, and changes in gene expression seem to be reasonable explanations for the more complex brain function in humans (Verendeev & Sherwood, 2017).

This is in agreement with the perspective of an evolutionary advancement that favors brain connectivity rather than size itself. For example, the neural circuit involving the inferior frontal lobe and the posterior superior temporal cortex via a dorsally located fiber tract was a crucial evolutionary advancement toward the development of the uniquely human capability of language (Friederici, 2017).

While it is known that communication involves more than linguistic skills (phonology, semantics, syntax, and pragmatics), for many years, the ontogeny of the brain as well as the cortical language network have been constructed based on different models not only to comprehend the evolution of language in the primate brain, but also to better understand the course of maturation of speech and language areas in the brain and their developmental trajectories (Skeide & Friederici, 2016).

Language, cognition, and motor control are lateralized to the left hemisphere of the brain, possibly due to a genetic predisposition for hemispheric specialization during cognitive, linguistic, and brain development (Karmiloff-Smith, 1992). Localization of neural processing of language has been shown in functional magnetic resonance imaging and electroencephalography studies, wherein more diffuse and bilateral activation patterns with regard to language processing are seen in children, but at the same areas of the brain as those of adults (Holland et al., 2007).

Understanding the changes in brain functioning in the typical and deviant language developmental context has significant implications on developmental theories and in understanding how language is represented in the brain along the maturational trajectory (Rossi, 2016). It is well known that pathological conditions contribute significantly not only in understanding brain evolution, but also in comprehending brain functioning, and supporting significant advances in neuroscience (de Sousa & Cunha, 2012). However, adult models of high-order cognitive function correlations (e.g., language) cannot explain deviations in language development in children; thus, models that can clarify the neurobiological mechanisms from a developmental perspective are lacking (Friederici, 2006; Karmiloff-Smith, 1997; Karmiloff-Smith, 2018).

In this context, speech and language in neurodevelopmental disorders with a known genetic cause, as well as others with complex genetic etiology, are not understood enough. It would be useful to identify the critical gene for brain development with regard to language, understand the gene-brain-language relationship, and to define the neurodevelopmental phenotype, including the language phenotype, and its association with neurocognitive and behavioral patterns. Furthermore, by studying genetic disorders and their impact on language development, we are contributing to the nature-nurture debate and theories concerning the development of language.

Defining the Language Phenotype in Genetic Disorders

A genetic disorder is defined as a disease caused by alterations in one or more genes. Genetic disorders in humans are classified as chromosomal disorders, monogenic conditions (typical Mendelian heritance), multifactorial or polygenic disorders, and mitochondrial disorders. Chromosomal disorders could be due to missing chromosomes (deletion) or gaining extra segments or an entire chromosome (duplication). Single-gene diseases (monogenic) have a typical Mendelian inheritance pattern (dominant or recessive) in the autosomal or sex chromosome. On the other hand, multifactorial disorders have a complex interaction between genes (polygenic) and the environment, and finally, mitochondrial disorders are a small part of genetic disorders (Baty, Carey, & McMahon, 2010).

Online Mendelian Inheritance in Man (OMIM) is a database of all known Mendelian disorders and over 15,000 currently identified genes; it is a genuine representation of the advances in genetic disorders. OMIM was created in 1985 by a collaboration between the National Library of Medicine and the William H. Welch Medical Library at Johns Hopkins University and made publicly available on the internet since 1987. In 1995, OMIM was developed for the World Wide Web by the National Center for Biotechnology Information (NCBI). OMIM is authored and edited at the McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, under the direction of Dr. Ada Hamosh.

One of the important challenges faced by OMIM is how best to catalog multifactorial disorders and phenotypes, especially with epigenetic mechanisms bringing complex phenotypes and genotypes into focus, in addition to the need for a large cohort of subjects. The cataloging system was suggested by McKusick in McKusick, 2007; however, it is still valid in recent times and can be extended to the context of the language phenotype, especially since a growing body of genetic studies has emerged over the last few years providing a more comprehensive view of the genetic map and the genes involved in the language evolution process, as well as its disorders.

Studying the role of genetic influence in the context of language disorders requires a comprehensive approach taking into account a set of factors; low scores on language performance (standardized tests and naturalistic language sampling) is one of these factors. Research needs to be focused on whether the language disorder is accompanied by other developmental difficulties, so that a distinction can be made between children whose language difficulties can be attributed to a known cause and those with unexpected, unexplained language problems, and also whether there are any associated significant environmental factors (low socioeconomic status or low educational level in the family).

Therefore, for the purposes of diagnosis and intervention in patients with language impairment, speech-language pathologists and other professionals have to take into account the family history as a fundamental part of the medical history investigation and to identify any history of speech and language difficulties and comorbidities across the generations. In the course of the clinical and academic routine, we teach speech-language students to construct the family pedigree using a standardized nomenclature (Bennett, French, Resta, & Doyle, 2008). A practical application of pedigree elaboration in our laboratory routine has been its benefit in identifying the genetic risks for language disorders and formulating an intervention plan in the early stages of language development. In this context, a 2-year-old late-talking child with a positive family history of speech or language impairments and with no obvious cause that could explain the language acquisition problems might require language follow-up to distinguish between a persistent language difficulty (disorder) and a transient language difficulty (normal course, but delayed).

Basically, experimental designs in studies evaluating spoken language development in genetic disorders have to consider five language domains (phonology, morphology, syntax, semantics, and pragmatics) across two processes (receptive and expressive) with different levels of organization and complexity (words, sentences, and narratives).

A didactic description of each component was provided by Hoff (2013). The phonology domain constitutes the sound system of language, while the system of combining units of meaning is morphology and the system of combining words into sentences is syntax. The content domain of words and associated knowledge constitutes the lexicon, and finally, how to use language to communicate is part of the pragmatic and sociolinguistic development.

It is useful for researchers and students of language development, to make distinctions among the sub components of language (Hoff, 2013). The vast majority of studies regarding language development and related disorders have focused on the receptive or expressive language process. Most of the time, these two language processes and the language components (phonology, semantic, syntactic, and pragmatic) have been described separately, depending on the major objective of the research.

Language assessment usually includes a set of standardized measures to allow a relatively objective and reliable assessment of the language component, and more qualitative observations with naturalistic language sampling (e.g., conversation and narration) to capture the functional aspects of communication that are not always picked up on formal assessment. Understanding the development of different language sub components with regard to the receptive and expressive processes and its interaction with the cognitive developmental profile (neurocognition and social cognition), as well as with behavioral and personality traits is the accurate way to understand the nature of language problems and describe the language phenotype of genetic disorders.

Language phenotype delineation is challenging since it is influenced by critical genes involved in brain development and by environmental factors. Therefore, the association between genetic disorders and language development necessarily refers us to a research context where a focus on interdisciplinary mechanisms is necessary to understand the different mechanisms involved in communication, as well as the characterization of these manifestations (Giacheti & Rossi, 2012).

It is well known that understanding the genetic influences of a complex genetic trait affecting behavior, cognition, and language at the molecular level is not possible without a very well characterized phenotype (Giacheti & Rossi, 2012; Mervis & Robinson, 2005). The key role of genetics in language development is complex and surrounded by controversies; therefore, a clear specification of the target phenotype is necessary (Hauser et al., 2014), which in turn requires consensus on the terminology used to describe it. The only way to understand the nature of the impairment and, in turn, depict a language phenotype is to have differentiating terminologies with clear meanings (Bishop, 2014).

First, let us make a distinction among the concepts with regard to speech, language, and communication. According to Bishop, Snowling, Thompson, and Greenhalgh (2016), "speech," "language," and "communication" are not interchangeable and the distinction among these terms and their meanings is the starting point of this research topic. Language is the comprehension and use of words and sentences to convey ideas and information. The different modalities of language are spoken, written, and sign; speech is part of the spoken language modality. Speech refers to the production of vocal sounds, a process that involves both motor (articulatory) and linguistic skills. Language and speech are both facets of communication, which encompasses the broader set of nonverbal and verbal means of conveying information and emotions (Bishop, 2017).

The terminological debate over language impairment in children is a current and necessary movement, which has important implications on genetic advances in the study of child language problems (Bishop, 2014; Bishop et al., 2016; Reilly, Bishop, & Tomblin, 2014). The debate related to the pros and cons of developmental language disorder as a primary manifestation or as part of a medical condition that may co-occur with other deficits in other developmental domains, such motor or intellectual impairment, is not a new phenomenon; however, there is a growing consensus among researchers regarding the use of a neurobiological approach to language and its disorders. Therefore, if the aim is to identify genetic specificities and neural correlates in typical and atypical developmental trajectories, it is necessary—not to say mandatory—to know the distinctions between language disorders (conditions or symptoms).

The key point of this problematic question has been explored in the studies by Dorothy Bishop and depicted in two studies published by an international group of experts, the CATALISE panel (Bishop et al., 2016; Bishop et al., 2017), created to discuss consensus on diagnostic terminology for language disorders in children. Based on the results of the project, the group has recommended the following terms: "Developmental Language Disorders (DLD)" for children with language difficulties not associated with a biomedical condition, and "Language Disorder," when associated with a biomedical condition (e.g., genetic syndromes, hearing loss, intellectual impairment, or autism spectrum disorders [ASD]).

Regarding terminology, the trend in literature seems to favor the use of DLD to refer to primary language disorders or specific language impairment, and will be used in this chapter as well. However, this is not the position in the 5th edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) (APA, 2013). In effect, in DSM-5, the term "Language Disorder," which is part of the Communication Disorder diagnostic category, is supported by four criteria, including: (1) persistent difficulties across modalities (spoken, written, sign language) with deficits in both language process comprehension and production; (2) functional language deficits due to language abilities below the chronological age; (3) manifestation of symptoms in the first years of life; and (4) difficulties not explained by intellectual impairment or medical condition. This fourth criterion drives us to DLD, but the position is not clear. There is no terminology distinction in DSM-5, which has motivated the continuing debate on this issue (Bishop, 2014).

ASD might be a good analogy with regard to the DLD debate, from the perspective of describing the phenotype. ASD is one of the neurodevelopmental disorders in DSM-5 (APA, 2013), and the diagnostic criteria include persistent deficits in social communication and social interaction in multiple contexts, and restricted and repetitive patterns of behavior. Symptoms are present early, although they may not be fully apparent. The identified symptoms cause clinically significant impairment in social, occupational, or other important areas of functioning. The specifier "associated with any known medical or genetic condition or environmental factor" should be used when the person has a known genetic disease (e.g., Rett syndrome, Fragile X syndrome, Down syndrome) or a history of environmental exposure (e.g., valproic acid, fetal alcohol syndrome, very low birth weight).

Therefore, researchers need to answer important questions while describing a phenotype, for example: is studying ASD manifestations as part of a genetic disorder with a well-known genetic etiology like Fragile X syndrome commensurate to studying the ASD phenotype? Dilemmas like this have to be considered in the study design so that researchers can identify the susceptibility genes for a developmental phenotype, and describe the natural history of the condition.

This issue is beyond just an academic question, as the researcher observes the actual phenomena, which puts it in a different perspective. Moreover, different genetic mechanisms need to be considered, even if the language manifestation is similar (Bishop et al., 2016).

Insights from Language Phenotypes in Down Syndrome, Fragile X Syndrome, and Williams Syndrome

Because language development is a complex process that depends on both neurobiological and social factors, the acquisition and development of language is an important developmental parameter that is susceptible to intervening factors (internal and external), which drive the developmental path of language and may manifest as deviant language development that could persist in some children throughout their lives (Bishop, 2014).

Individuals who exhibit persistent and early-onset developmental impairment are part of the diagnostic category of the DSM-5 (APA, 2013) "Neurodevelopmental Disorders." This diagnosis is attributed to individuals who present impairments in one or more domains of development (e.g., motor, intellectual, social cognition, behavioral, and language) when compared to their peers of the same age and gender in the same linguistic and social culture. This group includes cases with intellectual disability, communication disorders (language, speech, fluency, and communication disorders), autism spectrum disorder, attention deficit hyperactivity disorder, specific learning disorders, motor disorders, and other neurodevelopmental disorders (DSM-5; APA, 2013).

With regard to neurodevelopmental disorders, it is estimated that approximately 10 to 15% of the children born alive have a deviant neurodevelopmental trajectory, and 30 to 40% of these cases are associated with a known genetic etiology, such as chromosomal and genetic alterations, which result in deviant cerebral development, right from conception. The remaining cases are due to an interaction between genetic predisposition and environmental factors, such as biological events or chemicals with neurotoxic effects (e.g., alcohol consumption during pregnancy or maternal viral infections) (Andersen, 2003), which impact brain development in different ways depending on the developmental stage at which the event occurred and the epigenetic mechanisms (Grandjean & Landrigan, 2014; Rice & Barone Jr, 2000; Rodenhiser & Mann, 2006).

Certainly, a well-defined genetic condition in terms of genetic etiology might be a good neurobiological model to explore other complex conditions. Research into phenotype-genotype correlations in neurodevelopmental disorders has contributed to our knowledge regarding the contribution of genetic and neurobiological factors to variations in typical and atypical development (Järvinen-Pasley et al., 2008).

However, the results reported over the years have shown that impairments in different developmental domains manifest differently in each clinical group. A possible explanation for this is the existence of different etiopathological mechanisms that determine the neurofunctional differences that contribute to the expression of different neurodevelopmental phenotypes, including language (Knowland & Thomas, 2011; Luyster, Seery, Talbott, & Tager-Flusberg, 2011). Differences with regard to neurodevelopmental phenotypes are important considering their implications in the intervention methods used in these individuals (Bishop & Rutter, 2008; Mervis & Robinson, 2005; Rossi & Giacheti, 2017).

Studies that have focused on the delineation of neurodevelopmental phenotypes and their specificities taking into account the main developmental domains (e.g., motor, intellectual, social, behavioral, and cognitive) have gained importance over the years. In this regard, some neurodevelopmental disorders have been more systematically investigated, which was justified by Bishop (2010) based on some factors: (1) population frequency, which explains the large number of studies on individuals with Down syndrome; (2) a biological model to discuss and sustain theoretical models that contributes to the understanding of the neurobiological processes of language and related functions, as in the case of Williams syndrome; (3) conditions with a suggested genetic basis that have not yet been confirmed, such as ASD and primary language developmental disorders, and finally (4) the impact on public health, which justifies the interest in the study of the fetal alcohol spectrum disorders.

Cross-syndrome comparison of developmental domains is a very useful methodology to delineate neurodevelopmental phenotypes, and to identify overlaps or specifications of a deviant neurodevelopmental phenotype (Camp, Karmiloff-Smith, Thomas, & Farran, 2016). However, there are few studies exploring cross-language comparisons between genetic disorders in comparison with those describing language disorders in a specific clinical group.

The most frequent cross-syndrome studies of language and its disorders with well-known genetic etiologies have been conducted with Down syndrome (OMIM # 190685) (Johns Hopkins University, 2018a), Williams syndrome (OMIM # 194050) (Johns Hopkins University, 2018b), and Fragile X syndrome (OMIM #300624) (Johns Hopkins University, 2018c). Down syndrome and Fragile X syndrome are the most common genetic causes of intellectual disability. Down syndrome occurs in approximately 1 in 700 live births and Fragile X syndrome in approximately 1 in 4000 males and 1 in 8000 females (Baty et al., 2010). Williams syndrome is considered a rare genetic disorder occurring in approximately 1 in 7500 live births (Strømme, Bjømstad, & Ramstad, 2002).

The genetic bases of these conditions are quite different. Down syndrome is a classic chromosomal disorder caused by complete or partial triplication of chromosome 21, while Fragile X syndrome is a single-gene disorder caused by an expansion mutation of the trinucleotide (CGG) in the promoter region of the FMR1 gene, and Williams syndrome is a chromosomal microdeletion at 7q11.23 (Goldstein & Reynolds, 2010).

In terms of general cognitive functioning, individuals with Down syndrome, Fragile X syndrome (Abbeduto et al., 2001), and Williams syndrome show similar performance in standardized tests, ranging from mild to moderate intellectual impairment (Martens, Wilson, & Reutens, 2008). Age-associated decline is a particular characteristic of Down syndrome, which makes this genetic condition an optimum model for studying the genetic basis of Alzheimer-type dementia (Grieco, Pulsifer, Seligsohn, Skotko, & Schwartz, 2015; Potter, 2016).

The presence of intellectual disability in all these three genetic conditions invariably results in language disorder. In the face of intellectual disability, mixed receptive and expressive deficits in language are expected, although overall, it is seen that there is greater difficulty with expressive than with receptive language abilities (Rice, Warren, & Betz, 2005). Individuals with these three genetic disorders have problems in comprehension, which affect their capabilities to perceive and correct breakdowns in communication during spoken language production (Martin et al., 2017).

The expressive language abilities of individuals with Williams syndrome have been highlighted as fluent and well-articulated speech with an effective phonological working memory, which is responsible for facilitating the retention and manipulation of verbal information (Bellugi, Wang, & Jernigan, 1994; Vicari, Bellucci, & Carlesimo, 2006), and also, for favoring the syntactic domain of language (Jarrold, Baddeley, Hewes, & Phillips, 2001; Volterra, Caselli, Capirci, Tonucci, & Vicari, 2003); this is opposite to the trait seen in Down syndrome and fragile X syndrome.

Compared to individuals with Williams syndrome, morphosyntax and phonology are weak domains in individuals with Down syndrome and fragile X syndrome. However, this is a more prominent characteristic in Down syndrome compared to fragile X syndrome. As suggested by Abbeduto, Brady, and Kover (2007), the expressive language of individuals with fragile X syndrome shows more variation with regard to these language domains.

While children with Williams syndrome exhibit the most intelligible speech at the beginning of spoken language development using spoken language as the main communicative resource, children with Down syndrome show significant speech intelligibility problems, leading to prolonged use of gestures as a communicative resource. The use of representational gestures in children with Down syndrome and fragile X syndrome is controversial among researchers. Interventions promoting parental input into representational gestures have been suggested as an additional opportunity for language development in children with Down syndrome, and have been considered to have a predictive value with regard to vocabulary development Dimitrova, Özçalışkan, & Adamson, 2016; Lorang, Sterling, & Schroeder, 2018). On the other hand, the use of representational gestures in early developmental stages in children with Fragile X syndrome seems to be not effective due to the impact of autistic symptoms (Flenthrope & Brady, 2010; Rague, Caravella, Tonnsen, Klusek, & Roberts, 2018). The regulatory function of language seems to have greater positive predictive value in language development in Fragile X syndrome than gestures (Hahn, 2016).

One of the hypotheses explaining expressive language difficulties due to speech intelligibility problems in Down syndrome is weakness in the phonological working memory (Dodd & Thompson, 2001) and impairment of motor speech skills, with typical manifestations of childhood apraxia of speech (CAS), which include impairments in precision and consistency of speech movements (Kumin, 2006). The motor speech disorder associated with Down syndrome seems to be complex, involving single speech movements to sequential movements, and causes diadochokinetic deficits (Rupela, Velleman, & Andrianopoulos, 2016). Similarly, persistent speech production deficits and motor speech disorders are very common in children with Fragile X syndrome (Shriberg, Strand, & Mabie, 2016; Spinelli, Rocha, Giacheti, & Richieri-Costa, 1995; Zingerevich et al., 2009). Regarding Williams syndrome, these deficits seen in Down and Fragile X syndrome are not a main characteristic; however, Krishnan, Bergström, Alcock, Dick, and Karmiloff-Smith (2015) described a surprising oromotor praxis deficit in a study of individuals with Williams syndrome.

The other common evidence that supports spoken language deficits in Down syndrome is the higher prevalence of disfluencies in these patients (Eggers & Van Eerdenbrugh, 2018). In a comparative study conducted by our research team (Giacheti, Medina, & Rossi, 2010), individuals with Down syndrome showed a higher percentage of stuttering disfluencies (blocking, repetition of sound), whereas, individuals with Williams syndrome showed typical disfluencies related to linguistic formulation difficulties (hesitation and a silent pause between sentences), which suggests that this is an important aspect that differentiates the phenotypic expression related to fluency of speech between these two genetic syndromes. In fact, in a subsequent study we showed that the type of disfluencies presented in a language sample of individuals with Williams syndrome were important indicators of difficulties in elaboration and organization of the oral narrative, and therefore were possibly associated with language processing rather than speech processing (Rossi, Sampaio, Gonçalves, & Giacheti, 2011).

Regarding comorbidities and their implications in the language phenotype of genetic disorders, behavioral problems (hyperactivity and attention deficit symptoms, anxiety, and social interaction issues among others) and psychopathological manifestations (autistic symptoms) are commonly described in genetic syndromes. There is strong evidence that autism-like symptoms are associated with lower cognitive functioning in all three genetic disorders, namely, Down syndrome (Channell et al., 2015), Fragile X syndrome (McDuffie, Thurman, Hagerman, & Abbeduto, 2015), and Williams syndrome (Rossi & Giacheti, 2017; Royston et al., 2018).

Since individuals with Williams syndrome are hypersociable and not reserved with strangers (Gosch & Pankau, 1997; Mervis et al., 2000), this syndrome is considered an exciting model for social neuroscience, and is considered a unique phenotype that reflects the dimensions of prosocial behavior (Järvinen, Korenberg, & Bellugi, 2013). The social cognition phenotype of Williams syndrome has been described to be the opposite of that of autism (Couture et al., 2010) and to that of Fragile X syndrome. Fragile X syndrome is considered the most studied genetic model for ASD, as many of the typical autistic manifestations are part of the fragile X syndrome phenotype (Budimirovic, Protic, & Toma, 2017).

Repetitive and stereotyped behaviors are heterogeneous, and are usually described in many genetic disorders such as Fragile X syndrome, Prader-Willi syndrome, Smith-Magenis syndrome, and Algelman's syndrome (Riby & Hancock, 2008; Whitehouse & Lewis, 2015). The neurobiology of repetitive behavior is still under investigation, but there is strong evidence that it may result from corticostriatal circuit dysfunction (Langen, Durston, Kas, van Engeland, & Staal, 2011).

Repetitive and restrictive behaviors occur differently between and within genetic conditions; however, there is some level of deficit in social interaction and social communication in all these syndromes (Klein-Tasman, van der Fluit, & Mervis, 2018; Riby & Hancock, 2008). This is because many of these repetitive characteristics affect spoken language (e.g., echolalia, repetitive questions, conversational topic perseveration), which, in turn, has an impact on the functional use of language.

A set of studies conducted in our laboratory (Rossi, Moretti-Ferreira, & Giacheti; Rossi & Giacheti, 2017) are examples of how repetitive and restrictive behaviors occur in different ways within a genetic condition, and even more, how the simultaneous occurrence of these behaviors with other speech-language characteristics and behavioral problems might be important for describing sub-phenotypes in genetic disorders. However, we observed that both echolalia and perseverative speech were restrictive and repetitive behaviors that were observed in the speech of individuals with Williams syndrome; these behaviors had different impacts on communication performance. Echolalia is more restrictive than being just repetitive in a topic of conversation (perseverating on a topic) or using clichés.

Using clichés with exaggerated prosody and talkative behavior contributes to an apparent superior socio-communicative domain in Williams syndrome, contrary to echolalia. Furthermore, curiously, our study on individuals with Williams syndrome also showed opposite speech–language and behavioral traits, including monotone intonation and shyness, which represent the exact opposite of the Williams syndrome phenotype. Shy participants show lower speech rates in narration and have monotone intonation, which are similar to the fragile X syndrome phenotype.

Taking into account the overall advances with regard to our understanding of the three syndromes, Williams syndrome is without doubt the most fascinating genetic condition that has genuinely changed our understanding of language over the years. Though it is a rare disease, Williams syndrome has been investigated extensively as a neurobiological model of modularity with regard to the hypothesis of dissociation between verbal and nonverbal skills; this has been a milestone in relation to cognitive and language studies (Brock, 2007).

The hypothesis of superiority of auditory and verbal performance over visual-spatial deficits with relatively good language in spite of general cognitive deficits (Udwin & Yule, 1990) is currently discussed with caution.

For years, the language performance of individuals with Williams syndrome was supported by the static adult neuropsychological model that explained the language development in these individuals as parts intact and parts impaired (Karmiloff-Smith, 1997; Karmiloff-Smith, Brown, Grice, & Paterson, 2003). Certainly, the developmental perspective brought about a new approach with regard to language and cognition in Williams syndrome and suggested that it was a different developmental trajectory from that seen in typical development (Karmiloff-Smith et al., 2003; Laing et al., 2002; Mervis & Becerra, 2007). The intact language paradigm has been broken in view of the concept of different developmental trajectories with strengths and weaknesses in language abilities (Karmiloff-Smith et al., 2003). In these individuals, the interests in social-communication interactions and skills in using prosody to capture the attention of the audience (Gonçalves et al., 2010; Losh, Bellugi, & Reilly, 2000; Reilly, Losh, Bellugi, & Wulfeck, 2004) contrast with the pragmatic language impairment, inappropriate turn-taking and initiation of the turn, difficulties in maintaining the topic of conversation (Laws & Bishop, 2004; Philofsky, Fidler, & Hepburn, 2007; Rossi, Moretti-Ferreira, & Giacheti, 2007), and macrostructural deficits in narrative, with significant coherence deficits (Diez-Itza, Martínez, Pérez, & Fernández-Urquiza, 2018; Gonçalves et al., 2010; Reilly et al., 2004).

A cross-cultural study conducted in our laboratory with international collaboration investigated the oral narrative performance of individuals with Williams syndrome from Brazil, Portugal, and Spain. Narration was analyzed taking into account macrostructural elements (scenario, theme, plot, challenges, and resolution) and its organization. The results confirmed that these individuals have difficulty in organizing the global structure of a story, which leads to important pragmatic narrative deficits, regardless of their cultural background (Rossi, Garayzábal-Heinze, Sampaio, Gonçalves, & Giacheti, 2015). It appears that the major narrative problem in Williams syndrome occurs at the macrostructural level of narration (Diez-Itza et al., 2018; Gonçalves et al., 2010; Reilly et al., 2004; Rossi et al., 2015); this is in contrast to the impairment seen in Down syndrome and fragile X syndrome, which manifest mainly as significant impairments in phonology and in the syntactic structures of sentences (Finestack, Palmer, & Abbeduto, 2012).

However, our experience with Williams syndrome has shown that problems related to microstructures are also to be expected, since there are difficulties with the use of cohesive elements (Garayzábal Heinze, Prieto, Sampaio, & Gonçalves, 2007), and lowering of lexical diversity and sentence structure complexity in individuals with lower general cognitive functioning, and mainly with comorbidities such as autism-like symptoms.

Narrative intervention studies in genetic disorders are rare. A study conducted by Diez-Itza et al. (2018) in individuals with Williams syndrome reported both microstructural and macrostructural improvements. Therefore, considering that pragmatic narrative skills are weak overall in neurodevelopmental disorders, narrative assessment may be helpful in understanding the language phenotypes in genetic disorders, and in planning the necessary interventions.

The Role of Genetics in Spoken Language and its Disorders

Over the years, the critical neural elements and genes that are involved in spoken language have been described by studying some communication disorders such as DLDs, speech sound disorders, and fluency disorders.

DLD is a neurodevelopmental disorder that is not accompanied by intellectual disabilities, global developmental delays, hearing or other sensory impairment, motor dysfunction, or other mental disorders or medical conditions that can justify the child's language development as below that expected for the chronological age (Bishop & Hayiou-Thomas, 2008).

Children with DLD have significant difficulties in acquiring and developing language skills despite normal general cognitive abilities; these children have a gap between their verbal and nonverbal IQs (lower verbal IQ). Difficulties in lexical acquisition with speech delays are common manifestations reported by parents in the two first years of the children's lives (Bishop, 2006). These difficulties, including morphosyntactic deficits (which is considered a hallmark of the DLD phenotype), persist until the later years (Conti-Ramsden, Ullman, & Lum, 2015).

Theories of language organization and development have been proposed to explain the nature of the language problems in DLD. Among the different theoretical hypotheses to explain DLD, one is based on morphosyntactic deficits, with impairments in grammatical inflections and poor comprehension of sentences due to the complexity of the syntactic structure. Another perspective is based on weak phonological short-term memory with difficulty repeating nonwords (Leonard, 2014); this has been considered by some researchers as a strong diagnostic marker of this condition. Furthermore, performance with regard to nonword repetition is a useful measure of the heritable phenotype in DLD (Girbau, 2016; Newbury, Bishop, & Monaco, 2005).

The heterogeneity of the DLD phenotype might be represented by the multiple loci associated with this disorder (Bishop & Snowling, 2004). Currently, there are five loci associated with DLD documented in the OMIM database: 16q (OMIM # 606711, SLI1) (Johns Hopkins University, 2018d), 19q (OMIM # 606712, SLI2) (Johns Hopkins University, 2018e), 13q21 (OMIM # 607134, SLI3) (Johns Hopkins University, 2018f), 7q35-36 (OMIM # 612514, SLI4) (Johns Hopkins University, 2018g), and SLI5 (OMIM # 615432) (Johns Hopkins University, 2018h) caused by a mutation in the TM4SF20 gene on chromosome 2q36.

It is interesting to note that the forkhead box protein P2 (FOXP2) region is not listed among the DLD loci. The FOXP2 frenzy and media attention have overestimated FOXP2 as the "language gene." However, since the time when the FOXP2 gene was first described as the "language gene," there has been an increasing body of evidence arguing that this gene has low contribution to susceptibility to DLD (Newbury et al., 2002).

Fisher, Vargha-Khadem, Watkins, Monaco, and Pembrey (1998) described a three-generation pedigree with a severe speech and language disorder (the KE family) with an autosomal dominant monogenic trait and, indicated the 7q31 chromosome region to be responsible for the speech and language disorder. This was followed by a study by Lai, Fisher, Hurst, Vargha-Khadem, and Monaco (2001), which reported a point mutation in the FOXP2 gene in the KE family members. Many studies have been conducted since then to analyze and comprehend the role of FOXP2 in speech and language and its functions in the brain, since the primary neurobiological deficit was an open question.

The evolutionary history of the human FOXP2 gene indicates that it is biologically important. The FOXP2 gene located on chromosome 7q31 (OMIM # 605317) (Johns Hopkins

University, 2018i) is highly conserved in humans; the human gene differs at three amino-acid positions from its orthologue in the mouse and at two amino-acid positions in chimpanzees. Fixation of the allele in the human species is supposed to have occurred during the last 200,000 years, which gave humans a huge adaptive advantage (Enard et al., 2002). The forkhead box (Fox) family of transcription factors are genes that have implications in the developmental process, from organogenesis to speech acquisition (Hannenhalli & Kaestner, 2009).

In fact, mutation in the highly conserved genes has a huge impact on basic human functions, as they are involved in human developmental processes, such as spoken language. However, it would be naive to think that a complex symbolic system, such as the language system, would be controlled by only one gene. Moreover, there was a more important question related to the discovery of the FOXP2 gene mutation in the KE family: What was the nature of communication deficits in the KE family from the perspective of language development and diagnosis? Thus, this leads us to other important questions with regard to the debate on terminologies and taxonomies: What was, in fact, the KE family's speech-language diagnosis? Would it be a language disorder or a speech sound disorder?

Certainly, receptive language deficits in relation to the significant difficulties faced by KE family members to use syntactic rules must be the main reason that instigated the debate as to whether KE family members represented a language disorder or a speech sound disorder. It was not clear if the linguistic impairments in the KE family members were secondary manifestations of motor planning and sequencing deficits or if they arose simultaneously (Lai, Gerrelli, Monaco, Fisher, & Copp, 2003).

FOXP2 gene expression has been linked to neuronal circuits underlying the regulation of motor control and sensory-motor integration, which are considered critical to the development of the speech and language neural system, and therefore, FOXP2 is considered a central, but not unique, gene related to impairments in the movement sequence involved in producing speech and procedural learning (Lai et al., 2003).

Nowadays, there seems to be a consensus that the most overt feature of the KE family's phenotype is oromotor praxis deficit, which, in turn, is named "childhood apraxia of speech (CAS). CAS is a common term used by the American Speech-Language-Hearing Association (ASHA), which defines CAS as a speech sound disorder with deficits in the precision and consistency of speech movements in the absence of neuromuscular deficits. The main characteristics include errors in speech sound production and prosody due to impairment in planning and/or programming spatiotemporal parameters of movement sequences (ASHA, 2007).

Finally, taking into account DSM-5 (APA, 2013), the KE family diagnosis could be classified into the class of "speech sound disorder," which is defined as persistent difficulty in producing speech that interferes with speech intelligibility or prevents verbal communication of messages. The condition causes limitations in effective communication, which interferes with social participation, academic success, or professional performance, individually or in combination. The onset of symptoms occurs early in the developmental period and the speech difficulties are not attributable to congenital or acquired conditions, such as cerebral palsy, palatine cleft, deafness or hearing loss, traumatic brain injury, or any other cause. According to DSM-5 (APA, 2013), it is called "verbal dyspraxia" if motor coordination impairments are a particular characteristic.

The term "CAS" is also used as an alternative to "Speech-Language Disorder 1" in the OMIM database (OMIM # 602081, SPCH1) (Johns Hopkins University, 2018j), associated with FOXP2 disruption in the 7q31.1 chromosomal region. Further, the term "Speech Sound Disorder" in the OMIM database (Johns Hopkins University, 2018k) has the strongest linkage with the 3p12-q13 chromosomal region, which is also a locus linked to reading disability (dyslexia).

Quite apart from the research on the KE family and the FOXP2 gene, literature on CAS suggests concomitant language deficits as possible manifestations, which lead to difficulties in making an early diagnosis or including it in the differential diagnosis.

Differentiating CAS from other types of speech sound disorders or from DLD is challenging in children less than 3 years old. This is because children with severe speech sound disorders (with or without motor impairment) or with language disorders coexisting with articulation or phonology deficits frequently have a restricted expressive language or even more frequently, unintelligible speech, which most of the time is a limitation with regard to characterization, and consequently, identification of the nature of the deficit.

Frequently, the CAS phenotype with language impairments is characterized by superior performance in receptive language tasks and low performance in expressive language tasks, which is also a common pattern observed in early DLD (Lewis, Freebairn, Hansen, Iyengar, & Taylor, 2004). However, the receptive language scores of children with DLD are farthest from normative samples compared to scores of children with CAS. Moreover, speech characterized by inconsistency, slow speech rate, disturbed prosody, poorer performance during imitation (Dodd, 2014), and difficulties with diadochokinetic tasks in children with CAS (Fiori et al., 2016) are important parameters that can be help differentiate this condition from other speech sound disorders and DLD.

It is not surprising that there is evidence of linguistic and motor planning difficulties in CAS. There is a large overlapping network involving the temporal, frontal, and parietal areas that are involved in both language and praxis skills (Roby-Brami, Hermsdörfer, Roy, & Jacobs, 2012).

Speech sound disorder is a challenging diagnostic category due to the heterogeneous symptomatology (perceptual deficits, working memory impairments, speech motor control deficits) and the different subgroups of the condition are characterized by different manifestations (Dodd, 2014). According to Carrigg, Parry, Baker, Shriberg, and Ballard (2016), one of the major challenges with regard to this diagnostic category is that cognitive and other linguistic components are frequently neglected in speech assessment; therefore, coexisting language impairment may be underestimated, thereby reducing the precision of phenotype and sub-phenotype identification, as well as genetic and neural correlates.

The co-occurrence of speech and language impairment associated with FOXP2 disruption could be explained by the fact that FOXP2 is involved in the regulation of other genes, including the CNTNAP2 gene, which is located on chromosome 7.

Similar to the findings with FOXP2, variation within the CNTNAP2 gene was found among participants with CAS, but not with DLD (Centanni et al., 2015). However, its variants have also been associated with ASD (Rodenas-Cuadrado, Ho, & Vernes, 2014; Ross et al., 2017). Disruption of the CNTNAP2 gene is also associated with fluency disorder (stuttering), as described by our research team (Petrin et al., 2010). In that study, we described the case of a Brazilian boy with a complex neurodevelopmental phenotype with a 10 Mb deletion at 7q33-q35 involving several genes. The boy presented with a set of speech and language difficulties, including stuttering. Our study showed that one or more genes in the 7q33-q35 region may have a causal role in speech motor problems such as stuttering; specifically, partial deletion of CNTNAP2, including a deletion of the binding site for the transcription factor FOXP2, is involved. This case described by our team was a case of persistent stuttering, with poor prognosis even after speech-language intervention.

Stuttering is a childhood fluency disorder characterized by speech breakdown leading to an interruption in the flow of speaking. Typical stuttering manifestations include repetitions (sounds, syllables, words, and phrases), sound prolongations, blocks, interjections, and revisions. These breakdowns in speech also affect the rate and rhythm of speech. Physical tension, negative reactions, secondary behaviors, and avoidance of sounds, words, or speaking situations can co-occur with speech disfluencies (ASHA, 1993).

In DSM-5 (APA, 2013), stuttering is classified into the diagnostic class of neurodevelopmental disorders and the subgroup of communication disorder. The essential characteristics of developmental stuttering include a disturbance in normal fluency with an inappropriate temporal pattern of speech. This disturbance is characterized by frequent repetitions or prolongations of sounds or syllables, and other types of speech disfluencies, including interrupted words, audible or silent blocking, circumlocutions, words produced with excessive physical tension, and repetitions of monosyllabic words. Disturbance in fluency interferes with academic and professional success and social communication. The risk of stuttering among first-degree biological relatives of individuals with a fluency disorder is more than three times greater than the risk in the general population.

The OMIM database lists four loci for familial persistent stuttering: 15q21.2 (OMIM # 184450, STUT1) (Johns Hopkins University, 2018l) with a heterozygous mutation in the AP4E1 gene, 12q24.1 (OMIM # 609261, STUT2) (Johns Hopkins University, 2018m), 3q13.2-q13.33 (OMIM # 614655, STUT3) (Johns Hopkins University, 2018n), and 16q12.1-q23.1 (OMIM # 614668, STUT4) (Johns Hopkins University, 2018o).

This complex and multifaceted developmental fluency disorder can result from genetic and environmental factors, and there is an unfavorable effect on speech fluency if both factors act together (Nogueira, Oliveira, Giacheti, & Moretti-Ferreira, 2015). Regardless of whether there is a familial history of stuttering, factors such as masculine gender, persistent pattern of the fluency disorder, duration over 12 months, stutter disfluency, and negative familial attitudes occurring concomitantly increase the risk of stuttering (Oliveira, Domingues, Juste, Andrade, & Moretti-Ferreira, 2012). Familial stuttering has been classified as persistent and recovered and these subtypes have been put in perspective in genetic studies.

Understanding the developmental trajectory of stuttering and the course to persistence or recovery is necessary to take into account the interactions of stuttering symptoms with other developmental aspects such as temperament, language abilities, and speech motor skills (Smith & Weber, 2016). Beyond genetic influences, a growing body of research has suggested the interplay between cognitive function deficits (working memory), linguistic skills, and poor speech motor coordination as factors underlying persistent developmental stuttering (Yang, Jia, Fox, Siok, & Tan, 2019).

Similar to other communication disorders, the genetic basis of stuttering is heterogeneous and other chromosomal regions seem to be involved in this fluency disorder (2, 3p, 3q, 10, 14, and 16) (Frigerio-Domingues & Drayna, 2017). The exonic regions of FOXP2, CNTNAP2, GNPTAB, GNPTG, and NAGPA genes were sequenced in a study of individuals from North America and Brazil, including a group with familial developmental stuttering and a similar sized-group of neurologically normal controls, and the results showed that FOXP2 and CNTNAP2 genes were not involved in the genesis of familial persistent stuttering. However, mutations were found in the GNPTAB, GNPTG, and NAGPA genes, suggesting that the genetic basis of stuttering differs from that of CAS and DLD (Han et al., 2014). The role of GNPTAB, GNPTG, and NAGPA genes in stuttering have been demonstrated in others studies as well (Kazemi, Estiar, Fazilaty, & Sakhinia, 2018).

Conclusion

The scientific relevance of the language phenotype of neurodevelopmental disorders is supported by the fact that the professional has to deal with the probability that a genetic condition is presenting a certain phenotypic characteristic in the course of its developmental trajectory. It is relevant not only to explore the role of chromosomes and genes in the developmental domains but also to help the speech-language pathologist and other professionals formulate a well-defined intervention plan because of the clinical implications.

Thus, identifying the most prominent deficits in each condition (as exemplified by the descriptions of Down syndrome, fragile X syndrome, and Williams syndrome in this chapter), taking into account the subcomponents of language (phonology, syntax, morphology, semantics, and pragmatics) and its relationship with other specific developmental domains (motor, cognition, and behavioral) has enabled the description of a peculiar phenotype for each one, for example, the intelligible and well-articulated speech with rich prosody resources and clichés associated with a hypersociable personality in individuals with Williams syndrome, which contrasts with the unintelligible speech, agrammatic syntax, and stuttering disfluencies in individuals with Down syndrome and with the shy behavior, increased speech rate, and imprecise articulation of individuals with Fragile X syndrome.

The role of genes in the etiology of speech and language developmental disorders has not been completely determined. A deeper understanding of complex phenomena, such as the gene-brain-language relationship, has emerged from the study of different disciplines. In cases where DLDs and speech language disorders are the primary manifestations, in other words, the phenotype itself, the heterogeneity of manifestations is a huge challenge to molecular studies, in addition to the need for a large number of participants.

The emerging challenges facing the genetic basis of DLDs range from consensus regarding terminology and diagnostic criteria to the need to aggregate powerful technologies (molecular genetics and brain imaging) in order to map not only the susceptible genes, but also the neural circuits that might contribute to the phenotype of complex genetic disorders.

Finally, it is important to make it clear that when we highlight the genetic disorder and its effects on language, it does not mean that the sociocultural context and its influences are being ignored, as language development is a complex phenomenon. However, this chapter did not attempt to encompass the whole width of this issue, or explore the genetics of learning disabilities.

Social and Psychological Stressors

Elizabeth Halstead, Justin Stanley,
and Joanna Greer

Children with IDD are at greater risk for psychopathology than their typically developing peers (de Ruiter, Dekker, Verhulst, & Koot, 2007). Developmental factors and their interaction with an individual's social environment offer a framework for intervention (Kiddle & Dagnan, 2011). In this chapter, stressors are discussed as risk factors for development and exacerbation of emotional and behavioral problems in individuals with IDD. The literature has shown the negative impact of environmental stress factors on individuals with IDD. However, the broader literature, not specific to individuals with IDD, shows although children experience adversity and stress, their mental health and well-being can still be positive (e.g., Alvord & Grados, 2005).

Why some individuals respond better than others to stress has been debated, but one theory is that this variability can be conceptualized as resilience. Resilience is generally seen as a positive construct that can be built upon and improved and encompasses many personal attributes and environmental factors. Rutter has defined resilience as "an interactive concept that is with the combination of serious risk experiences and a relatively positive psychological outcome despite those experiences" (Rutter, 2006, p. 2). Garmezy, Masten, and Tellegen (1984) presented a three-model approach to stress, compensatory, challenge, and protective factor models. Protective factors are defined as having a positive influence on behavior and moderate the relationship between risk and problem behaviors (Jessor, Van Den Bos, Vanderryn, Costa, & Turbin, 1995). Garmezy (1985) organized the protective factors into personality factors, family cohesion, and external support systems.

Resilience is being explored in individuals with IDD and their families, and attributes and skills related to resilience have begun to be identified. A study by Miller (2002) used open-ended questions to determine resilience in students with IDD. Resilience was described as a person experiencing achievement despite others having a low expectation of them. The students identified several attributes which they believed made them resilient, such as identifiable success experiences (having a job), areas of strength (e.g., being good at art/sport), having self-determination, having special friendships and encouraging teachers, and acknowledging the learning disability.

Similarly, Raskind, Goldberg, Higgins, and Herman (1999) found six attributes in individuals with IDD who had been successful: self-awareness, proactivity, perseverance, emotional stability, appropriate goal setting, and the presence and use of effective support systems. Conversely, a lack of self-awareness, reactivity, lack of perseverance, emotional instability, lack of appropriate goal setting and self-directedness, and lack of presence or use of effective support systems led to more negative outcomes. Gilmore, Campbell, Shochet, and Roberts (2013) compared resilience in children with IDD to their typically developing peers (TD), and found children with IDD reported lower levels of tolerance, fewer future goals and higher levels of emotional sensitivity compared to TD peers, though other factors like optimism and self-esteem were reported at a similar level to TD peers.

In addition to building resilience, reviewing potential environmental risk factors and how they could be modified may lead to better outcomes in individuals with IDD (Fletcher, Loschen, Stavrakaki, & First, 2007; Hawkins, Catalano, & Miller, 1992). Dykens (2000) emphasized the need for researchers to go beyond measurement and prevalence studies of psychopathology in children with IDD, and identify the reasons why these children are prone to psychopathology to begin with. More recent research has turned to intervention on this basis of identified risk factors (Fisher, Moskowitz, & Hodapp, 2013; Jacola, Hickey, Howe, Esbensen, & Shear, 2014). Therefore, each section of this chapter considers not only how to reduce risk factors that impact on mental health and well-being, but also how to increase protective factors.

Rutter (1987) proposed resistance to stress is relative; a risk factor in one situation can be a protective factor in another (e.g., social support). Of particular importance is the family environment, reflecting elements such as parental stress, bidirectional relationships between emotional expressions of distress and child behavior problems, and the role of interventions targeting protective factors such as family cohesion and social support. Implications for intervention will be discussed.

Stress and Coping

Perceptions of stress predict current and future symptoms of psychopathology among adults with IDD (Hartley & MacLean Jr, 2005; Hastings, Hatton, Taylor, & Maddison, 2004). Lazarus (1991) describes “stress as harms, threats, and challenges,” the reaction to which depends on “what a person has at stake with an encounter with the environment or in life in general” (Lazarus, 1991, p.1 35) Individuals feel more stress when they perceive a threat to self-esteem or are not confident in their coping abilities (Roe & Gray, 1991).

The literature suggests perceptions of stress may be higher in individuals with IDD. Bramston, Fogarty, and Cummins (1999) found when administering the Lifestress Inventory to individuals with IDD that they reported stressors less than their nondisabled peers. It was found that the IDD group tended to assign higher impact values to the stressors they did report experiencing. In addition, Hatton and Emerson found that individuals with IDD experience stress at a similar, if not greater level to the general population (Hatton & Emerson, 2004). Perceptions of stress may vary based on subtypes of IDD; adults with ASD experience higher levels of perceived stress than their peers with other forms of IDD (Gillott & Standen, 2007).

Coping is related to depression in adults with mild IDD (Hartley & MacLean Jr, 2005). Lunsky (2003) found depressed females with mild IDD used fewer coping strategies than their nondepressed peers. Hartley and MacLean Jr (2005) found that symptoms of depression were related to infrequent use of active coping and later found that a group of IDD participants with depression reported a higher frequency of stressful social interactions than the nondepressed group. Given our knowledge of high prevalence rates of depression in the IDD population, as discussed in Chap. 48, coping mechanisms are likely to be impaired in a considerable proportion of this population. Coping mechanisms are discussed further in Chap. 38.

However, in the context of protective factors buffering risk, coping could be a protective factor in the IDD population as it is a skill that can be developed and positive coping mechanisms have been demonstrated to protect against negative outcomes in the general literature and with parents of children with IDD (Hastings & Brown, 2002; Heiman, 2002; Rutter, 1987; Werner, 2000). Rutter suggested the concept of resilience "focuses attention on coping mechanisms, mental sets, and the operation of personal agency. In other words, it requires a move from a focus on external risks to a focus on how these external risks are dealt with by the individual" (Rutter, 2006, p. 8). Few studies have focused on coping strategies used by individuals with IDD; however, Hartley and McLean Jr (2009) found that use of active coping vs. avoidant coping accounted for a significant portion of the variance in psychological distress experienced by individuals with IDD in stressful social situations. Janssen, Schuengel, and Stolk (2002) found in addition to developing low self-esteem and a general feeling of incompetence, individuals with IDD are at risk of developing learned helplessness, a process they compare to development of learned helplessness in people affected by the demoralizing conditions of chronic poverty (Olson & Schober, 1993). These factors could lead to ineffective coping mechanisms.

A final consideration is that stress measured subjectively can be difficult to assess. Subjective stress is often measured by self-report questionnaires, and as much as reliability can be a matter of concern for the general population (Turner & Wheaton, 1995), this concern may be even greater among the IDD population (Heal & Sigelman, 1995). Bramston, Bostock, and Tehan (1993) acknowledged many stressors individuals with mild ID experience may not be covered in scales like the Lifestress Inventory (Fogarty, Bramston, & Cummins, 1997). However, the Lifestress Inventory has been shown to be internally reliable, and the informant version a suitable parallel instrument (Lunsky & Bramston, 2006). Typically, past researchers have used a combination of qualitative and quantitative methodologies to measure stress, more recently, the Bangor Life Events Schedule for Intellectual Disabilities (BLESID-SR: Hulbert-Williams, Hastings, Crowe, & Pemberton, 2011), has been designed as a measure of significant life events occurring in the life of someone with IDD. In the BLESID-SR an interviewer uses a semi-structured interview to guide the conversation and reflect in the scoring what the individual has said about their life events. The BLESID-SR is available in both a self-report and proxy version. Research exploring caregiver reports of stress and self-reports of stress has suggested that it is important to assess stress from two perspectives when possible (Cummins, 2005).

Life Events

The Impact of Life Events

The connection between life events and mental health problems has been found in the general population (Tennant, 2002). Similar patterns are found in adults with IDD, as life events experienced by this population are associated with emotional disorders, depression, and behavior problems (Esbensen & Benson, 2006; Hastings et al., 2004). Cooper, Smiley, Morrison, Williamson, and Allan (2007) assessed mental health in 1023 adults with intellectual disabilities and found as a significant factor the number of life events experienced in the prior 12-month period. Hulbert-Williams and Hastings (2008) conducted a narrative review of research on exposure to adverse life events as a risk factor for psychological problems and found association of life events with clinically significant depression. Research links experience of life events to behavior difficulties in adults with IDD (Esbensen & Benson, 2006; Hulbert-Williams et al., 2011; Owen et al., 2004). Stress is often associated with negative outcomes in individuals with IDD, including symptoms of mental illness in adults with mild IDD and depression in adults with moderate IDD (Hastings et al., 2004; Lunsky, 2003).

Unfortunately, a gap in the literature concerns the relationship between pre-existing psychological problems in adults with IDD and the susceptibility of this population to trauma and other psychological problems (Hulbert-Williams & Hastings, 2008). Research is needed to investigate further temporal associations between psychological problems and life events (Hulbert-Williams & Hastings, 2008; Kraemer et al., 1997). One study provided tentative evidence that life events may be a risk factor for psychological problems in adults with IDD using a longitudinal approach (Esbensen & Benson, 2006). Additional research is needed into the mechanisms by which experience of adverse events becomes a risk factor for psychological problems, and whether this is mediated by protective factors such as social support.

Major Life Events

The link between major life events (e.g., loss of a spouse, loss of a job, major illness or injury, moving) and the experience of stress and related physical and mental conditions is established in the general population (Harkness & Monroe, 2016). Research has suggested individuals with IDD are more susceptible to psychological distress, and the development of comorbid psychiatric conditions or behavioral problems, after experiencing major life events (Magiati, Tay, & Howlin, 2014). The pattern of increased susceptibility of individuals with IDD to life events begins in childhood. Children with IDD experience a wider range of life events and are reported to experience such events more frequently than children without IDD (Hatton & Emerson, 2004). The discrepancy in risk exposure to adverse life events between individuals with IDD and TD peers continues into adulthood, and may be explained by aspects such as increased dependency on paid and family caregivers, increased negative social interactions, and a relatively restricted social circle compared to nondisabled peers in the same age range (Bramston et al., 1999; Fogarty et al., 1997; Levitas & Gilson, 2001). The greater dependency of adults with IDD on family and paid caregivers is a source of additional risk for major life events, as the loss of a friend or family member may also equate to the loss of a home or a carer (Hollins & Esterhuyzen, 1997; Levitas & Gilson, 2001). Gilrane-McGarry and Taggart (2007) suggest lack of support during bereavement is a major factor in individuals with IDD susceptibility to a complicated grief process, where the failure of grief to resolve over a long time period results in the development of psychopathology including chronic depression.

In retrospective studies, significant major life events and their relationship to mental health crises in those with IDD has been well documented (Ghaziuddin, 1988; Hastings et al., 2004; Hatton & Emerson, 2004). Although the literature shows associations between life event frequency and mental health in individuals with IDD, there is still variability in the psychopathology of individuals with IDD when experiencing life events. One explanation for this may be variation among subgroups. Maag and Reid (2006) found moderators such as gender, age, and ethnicity seem to cause significant variability in depression as an outcome. Taylor, Hatton, Dixon, and Douglas (2004) found significant differences in the rates for particular disorders across gender, age, and residence type. Studies suggest the prevalence of mental disorders may peak at the moderate level of IDD, at least for depression, anxiety, and psychosis (Holden & Gitlesen, 2009; Myrbakk & von Tetzchner, 2008). Psychopathology models in IDD should consider the level of IDD and demographics in the variability of results. There is a need for more differentiation in research regarding gender and severity of disability (Wong, 2003).

Cumulative Life Events

The extent to which a person with IDD is exposed to negative life events is an important factor in development of related mental health problems. Cumulative exposure to life events on the mental health of people with IDD has been studied, with multiple exposure found to correlate with development of affective disorders such as depression (Tsakanikos et al., 2006). Accumulated exposure to life events, and risk factors that are related to cumulative exposure such as poverty and greater presence of physical disability, is linked to poor physical and mental health in this population (Brooks, 2006; Masten, 2001).

What makes a person vulnerable to poor mental health outcomes after a life event will differ based on persons and circumstances (Spini, Hanappi, Bernardi, Oris, & Bickel, 2013). Abravanel and Sinha (2015) conducted a population-based study of 745 adults exposed to cumulative life events, distinguishing between those "at risk" based on pre-morbid mood disorder, and those "never depressed." They found that emotion regulation, assessed using the Difficulties with Emotional Regulation Scale (Gratz & Roemer, 2004), accounted for 50% of the variance in depressive symptomology independent of risk status. Emotion regulation is a complex process drawing on use of cognitive, experiential, and emotion-based strategies to affect the way adverse life events are interpreted across the life course (Garnefski, Kraaij, & Spinhoven, 2001). Relative impoverishment of effective emotion regulation strategies in individuals with IDD compared to their TD peers may begin in childhood and continue throughout the life course (McClure, Hapern, Wolper, & Donahue, 2009) indicating this is a prominent risk factor and suitable for targeting through early intervention. Janssen et al. (2002) argue ineffective attachment models developed by children with IDD are a major risk factor for experience of chronic stress, depression, and problem behaviors during social interactions, persistent through adulthood. This provides one example of how a specific failure in emotion regulation strategies can serve as a risk factor for developing psychopathology during the experience of life adverse events.

Trauma

The development of post-traumatic stress disorder from exposure to life events has been studied in individuals with IDD (Murphy, O'Callaghan, & Clare, 2007) though research is constrained by a lack of ways to measure trauma in this cohort (Wigham, Taylor, & Hatton, 2014). Other than a handful of studies that are largely record reviews concerning sexual and physical assault (see Bowman, Scotti, & Morris, 2010), a dearth of research exists on the types of trauma occurring in the lives of individuals with IDD. Martorell and Tsakanikos (2008) emphasize separating between "non-traumatic" life events and "traumatic" life events may be difficult for this population, as difficulty understanding a stressful situation can lead the person with IDD to experience greater levels of distress than nondisabled peers.

Research suggests a disproportionate number of children with IDD are victims of abuse, with more severely disabled children at greatest risk (Fisher, Hodapp, & Dykens, 2008). There is a tendency for individuals with IDD who have been abused to receive psychiatric diagnosis, such as schizophrenia and depression (e.g., Ryan, 1994). Therefore, it is unclear whether the apparently strong association between trauma and psychiatric disabilities is due to increased risk of abuse in individuals with psychiatric disorders, thus the possibility of a shared etiology between the two.

As in the general population, one of the most prominent consequences of violent victimization in persons with IDD is PTSD. The limited data suggests that, as expected, individuals with disabilities are at increased risk for developing PTSD. For example, Ryan (1994) performed evaluations on 310 consecutive admissions to a team consultation service for persons with IDD and found that 16.5% met criteria for current PTSD. This rate is approximately double the rate of lifetime PTSD in the general population (e.g., Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995).

For example, post-traumatic stress reactions, up to and including the onset of post-traumatic stress disorder, are highly prevalent in adults with IDD when exposed to environmental stressors as well as to abuse, neglect, and violence (Wigham & Emerson, 2015). Adults with IDD experience more traumatic life events compared to the TD population, and have fewer psychological and social resources for dealing with these stressors (Magiati et al., 2014). Adults with IDD frequently "suffer in silence" the higher rate of traumatic life events that they are prone to experience, and have less control over their environment so as to allow them to avoid (whether through internal or external means) reminders of past trauma (Wigham & Emerson, 2015). Staff training on the affective experience of adults with IDD, promoting the idea that they are aware of, and suffer from, life stressors, are needed to address this problem. However, a finding posited by Wigham et al. (2014) is the lack of moderation between social support and significant behavioral disturbances after traumatic life events, which may contribute to the onset of PTSD after experience of trauma. The difficulty people with IDD have in keeping social support may make a difference (Gilrane-McGarry & Taggart, 2007).

Protective factors that mitigate exposure to traumatic life events and adverse psychological outcomes include intelligence, perceived self-efficacy, and optimism, as studied in both disabled and nondisabled children exposed to trauma (Masten, Narayan, Silverman, & Osofsky, 2015) and intellectually disabled children in this situation (Finzi-Dottan & Karu, 2006). Social support is shown in many studies to be protective against adverse effects of trauma (Ozbay et al., 2007) though a distinction has been made between types of support which are more protective, with higher-quality relationships (i.e., allowing for more emotional expression and shared problem-solving) having greater protective qualities (Platt, Keyes, & Koenen, 2014).

Transition

Resilience has been posed as being not a fixed attribute, but as changing with circumstances (Rutter, 1987; Werner, 1989). There are certain points in an individual's life when they may be more vulnerable to stress and this may contribute to changeability in coping and perceptions of stress in individuals with IDD. The transition to adulthood, during which young adults with IDD leave behind the relative structure of the school environment to pursue uncertain employment and residential outcomes, is a period in which many individuals with IDD report being vulnerable to feelings of stress and anxiety (Williams & Heslop, 2005). This is in keeping with Raskind et al. (1999) who theorized the change over time from childhood to adolescence may be due to participants having more power in decision-making concerning their own education at the time.

The transition period is often perceived as a stressful time for young adults with IDD and their families. Many individuals with IDD face poorer outcomes than their TD peers across measures of transition success, such as social relationships, supported and competitive employment, and the ability to live independently (Foley, Dyke, Girdler, Bourke, & Leonard, 2012). Increased rates of psychological distress experienced during transition increases the risk for problem behaviors (Williams & Heslop, 2006). A qualitative interview study of young people with IDD found many young adults with IDD reported subjective feelings of being pressured by parents and teachers to make particular decisions related to their schooling and post-secondary community participation choices, as opposed to feeling free to make their own decisions (Williams & Heslop, 2005). The feeling that one has lost control over decision-making is exacerbated by loss of social networks that occurs when young adults with IDD transition from school environments (Raghavan & Pawson, 2008).

A second stressor faced by young adults with IDD and their families during transition is the unclear pathway of post-secondary supports. Transition-related changes in social roles and lack of supports for families can negatively impact family well-being (Neece, Kraemer, & Blacher, 2009). This combined with loss of social networks can increase problem behaviors during transition (Williams & Heslop, 2006). Williams and Heslop (2006) recommend approaching problem behaviors during transition from the stance of strengthening the individual's social networks. Forte, Jahoda and Dagnan (2011) used a mixed methodology approach to explore resilience in young people with IDD to examine the worries experienced by young people aged 17–20 with IDD during transition into adulthood. Their worries differed significantly in type as well as intensity. Young people with IDD were most worried about making friends, being bullied, and losing people they were dependent upon like parents, vs. TD peers who were most worried about getting a job, not having enough money, and having to make decisions about future choices. The IDD group also reported significantly greater levels of rumination over these worries. Forte, Jahoda, and Dagnan (2011) suggest obtaining insight into these patterns can strength a resilience-based intervention. For example, psychological interventions that target rumination could mitigate development of depression during this period.

Social Environment

Social Competence

The ability to navigate social interactions and benefit from positive aspects of social communication varies in the IDD population. Social competence has been defined as an individual's ability to successfully adapt to his/her social environment (Vaughn & Haager, 1994). Schafer and Semrud-Clikeman (2008) review difficulties that children with IDD experience with social competence.

Individuals with certain IDD diagnoses, such as Down syndrome (DS) and Williams syndrome (WS), are often characterized by having proficient social skills, including empathy and social communication, and in turn enables positive responses to others in distress (Di Nuovo & Buono, 2011). Conversely, individuals with IDD with an autism spectrum disorder (ASD) diagnosis demonstrate more social difficulties than individuals without comorbid ASD. Kau et al. (2004) found greater impact of social communication difficulties on problem behavior, in the case of individuals with Fragile X syndrome (FXS) with comorbid ASD as opposed to individuals with FXS without comorbid ASD. Individuals with Down syndrome (DS) who meet the screening criteria for comorbid ASD report milder social difficulties than children with ASD without any diagnosis of DS (Howlin, Wing & Gould, 1995). Diagnosis type and associated differences in social competence may create differential outcomes when attempting to integrate children with IDD into mainstream classroom settings. For example, integrated with TD peers in mainstream classrooms, children with ASD may be at high risk for social isolation (Locke, Ishijima, Kasari, & London, 2010).

Social difficulties encountered by this population extend beyond difficulties from the increased behavior disorders; also implicated are deficiencies in peer-related social competence. Guralnick (2006) estimates 60–65% of children with IDD fail to use appropriate social strategies during social tasks. Social isolation may be found in children besides the 25% of those with IDD who have behavior problems.

Larkin, Jahoda, MacMahon, and Pert (2012) found correlations between hostile attributional style, and increased experience of social conflict, in young adults with IDD. Increased likeliness of perceiving threat in ambiguous interactions, and a lack of coping strategies for use when faced with social threats, may be responsible for the higher rates of aggressive and affective disorders often observed in adults with IDD (Emerson & Jahoda, 2013).

As social interactions have long been identified as a potential stress factor for individuals with IDD, there is evidence of several interventions aimed at improving social skills for children and adults with IDD as is discussed further in Chap. 38. Szumski, Smogorzewska, Grygiel, and Orlando (2017) identified a significant improvement in the social skills of pre-school children with ASD using a "Play Time / Social Time" intervention designed to develop social skills compared to a problem-solving intervention. A meta-analysis of 55 social intervention skills studies with individuals with ASD (Bellini, Peters, Benner, & Hopf, 2007) found only minimal effect of these interventions; however, they did highlight that the setting of the interventions, such as resource rooms, were frequently inappropriate. In contrast, greater efficacy was observed when interventions took place in classroom / playtime settings. A meta-analysis of 19 studies (Gates, Kang, & Lerner, 2017) found that group social skills interventions led to moderate overall improvements in social competence. The authors also identified a large self-report effect, which they attributed to increased social knowledge, but not perceived changes in the individuals' own social behavior. These effects were found in studies including data from parents, children, observers, and tasks. The same trend was not observed in studies based on teachers' observations. Gates et al. (2017) emphasized that differences in efficacy rates are likely to reflect the variations by reporting sources.

Peer Interactions

Adults with mild IDD report more frequent and severe stress from negative social interactions than from other categories of stress events, and have more difficulty adaptively coping with everyday stressful social situations than other stressful events (e.g., Bramston et al., 1999; Hartley & MacLean Jr, 2005).

Children with IDD experience greater social isolation than TD peers and find it harder to develop positive peer relationships (Guralnick, 2006). Behavior problems are a prominent reason why children with IDD face social isolation (Crnic, Hoffman, Gaze, & Edelbrock, 2004; Guralnick, 2006). Children with IDD whose disabilities heighten the risk of aggression (such as autism spectrum disorder) are more likely to experience social isolation than children with IDD with lower levels of aggression, like Williams syndrome (Odom et al., 2006). Children with IDD with behavior problems and poor social skills are at greater risk of being bullied (Reiter & Lapidot-Lefler, 2007) and engage in bullying themselves (Christensen, Fraynt, Neece, & Baker, 2012).

The social isolation experienced by individuals with IDD often persists into adulthood (Lippold & Burns, 2009). Scott and Havercamp (2014) found a significant number of adults with IDD reported receiving less emotional support from others than nondisabled peers. Adults with IDD are more likely to receive social support from paid caregivers (Amado, 1993). These relationships are not reciprocal and are less likely to buffer against loneliness than other sources of support.

Social stressors such as negative social interactions are linked to physical and mental health problems in adults with IDD, including depression. Nezu, Nezu, Rothenberg, DelliCarpini, and Groag (1995) found associations between symptoms of depression and reported negative social interactions in a study of 107 adults with mild IDD. Hartley and MacLean Jr (2005) found that stress from negative social interactions predicted symptoms of depression in adults with IDD. Lunsky and colleagues also found a correlation between stress from negative social interactions and depressive symptoms; furthermore, continuing stress predicted the persistence of depressive symptoms 6 months later (Lunsky & Benson, 2001; Lunsky & Havercamp, 1999). Bender, Rosenkrans, and Crane (1999) found nonverbal individuals with IDD face a greater risk of suicide and posited that one reason for this may be social isolation.

There is a high prevalence of loneliness reported by adults with IDD. Stancliffe, Wilson, Bigby, Balandin, and Craig (2014) estimate up to 50% of adults with IDD are chronically lonely. Research by Cacioppo and colleagues (Cacioppo & Cacioppo, 2014) suggests loneliness contributes to poorer health through myriad pathways. Other risks for loneliness throughout the lifespan are family ecological variables like childhood attachment styles (Janssen et al., 2002). Adults with IDD, who lack coping resources or social supports to promote resilience during traumatic life events, are at greater risk for suicide (Gilmore & Cuskelly, 2014).

Social Support

It has been established that adults with mild to moderate ID are more vulnerable to stressful social interactions than nondisabled peers, and they report social stressors to have greater negative impact than other life events (Bramston et al., 1999; Fogarty et al., 1997; Hartley & MacLean Jr, 2005). Social support and positive peer interactions can be a protective factor for individuals with IDD as they promote resilience in the face of adverse life events (Bonanno, 2004) and moderate against development of PTSD (Brewin, Andrews, & Valentine, 2000).

A model linking social support to stress-buffering is provided by Cohen and Wills (1985). The buffering effects of social support persist across the lifespan. Rose and Espelage (2012) identify the ways that supportive peer relationships protect children with IDD from experiencing victimization during childhood. However, social support may not always moderate the relationship of trauma and behavioral changes (Wigham et al., 2014). It is likely that the stress-buffering effects of social support is affected by social-cognitive aspects such as whether one perceives such support as positive or negative (Lunsky, 2008).

Interventions to improve social interactions within persons with intellectual disabilities may be most effective in childhood, when social competencies are still developing (Guralnick, 2006). Carter and Hughes (2005) reviewed 26 interventions aimed at improving social interactions between students with IDD and nondisabled peers, and concluded additional research is needed to probe how interventions may have an impact on some but not all aspects of social interaction, such as improving social competence, reducing aggression, or facilitating environmental supports. In a similar light, Amado (1993) considers how to create a conceptual framework for studying interventions for adults with IDD, including bolstering social competencies.

Social Support and the Family

One stress-buffering resource is the availability and/or quality of social support in parents of children with IDD (Ekas, Lickenbrock, & Whitman, 2010; White & Hastings, 2004). Targeting social support can improve aspects of parental well-being including reduced mental health problems (Lovell, Moss, & Wetherell, 2012), reduced spousal problems (White & Hastings, 2004) and greater self-efficacy and coping (Kersh, Hedvat, Hauser-Cram, & Warfield, 2006).

The role of informal support in the reduction of stress in parents of individuals with IDD is widely documented (Robinson, Weiss, Lunsky, & Ouellette-Kuntz, 2016; White & Hastings, 2004). Mothers' ratings of grandparent support in the care of their child are negatively correlated with stress (Hastings, Allen, McDermott, & Still, 2002). Parents' perceptions of the helpfulness of informal sources of support, rather than the number of supports, has the most consistent associations with parental well-being (Zaidman-Zait et al., 2017). There are also changes in the type of support most beneficial with age. Practical support is more associated than emotional support with greater parental well-being in parents of adolescents with ASD (White & Hastings, 2004). By the time a child reaches adolescence, parents might have come to terms with being a parent of a child with an IDD, and need less emotional support.

The role of formal support sources in parental well-being seems to be less clear. Support services for families of children with disabilities more commonly focus on the child's needs (White & Hastings, 2004); therefore parental support needs are often unmet (Freedman & Boyer, 2000). Furthermore, several studies revealed unhelpful relationships and disagreements with professional services, for example, an inability to provide an individualized service adding to stress (Sloper & Turner, 1992).

Family Environment

Parenting Stress

High parenting stress is an important environmental risk variable. It is associated with many undesirable outcomes, including parent depression (Hastings, Daley, Burns, & Beck, 2006), marital conflict (Kersh et al., 2006), poor physical health (Eisenhower, Baker, & Blacher, 2009), less effective parenting (Crnic, Gaze, & Hoffman, 2005), and increased child behavior problems (Baker et al., 2003). Parents of children with IDD typically report more stress than parents of TD children (Baker et al., 2003; Emerson, 2003).

Parenting a child with an IDD is frequently a lifelong responsibility. Robinson et al. (2016) found nearly 50% of family members of individuals with IDD reported more caregiving responsibilities than they could handle, notably if there are more children living at home. Increased burden on parents of individuals with IDD are linked to the severity of symptoms and level of disability (Irazábal et al., 2012). High levels of behavioral support needs are linked to increased parental burden (Al-Krenawi, Graham, & Al Gharaibeh, 2011). This is also evident when the individual with IDD has health complications (Valicenti-McDermott et al., 2015) or a mental health problem (Irazábal et al., 2012). These profiles are reported consistently cross-culturally irrespective of majority / minority ethnicity or the country's level of income (Blacher & McIntyre, 2006; but also see Valicenti-McDermott et al., 2015).

There is a wealth of literature reporting greater deficits in psychosocial functioning and a greater prevalence of psychological distress in parents of children with IDD (Blacher & Hatton, 2007; Hastings, 2016; Singer, 2006). These include psychological distress, anxiety, depression, demoralization, and loss of freedom due to caregiving duties (Robinson et al., 2016). However, a population-based sample found 40% of mothers of children with IDD reported clinically significant emotional problems, whereas 60% did not (Totsika, Hastings, Emerson, Lancaster, & Berridge, 2011). Though the prevalence of parental depression is greater than the general population, evidence suggests most parents of children with IDD do not suffer from clinically significant depression.

Although there is evidence that stress experienced by parents of children with IDD can be chronic, there is marked individual variation in its trajectory over the life course (Glidden & Schoolcraft, 2003). Parents' psychological health and children's developmental health is especially vulnerable during the early years of a child's schooling (Fontil & Petrakos, 2015). Parental concerns include acceptance of their child by new teachers and peers and whether schools can meet the child's learning needs (Hirst, Jervis, Visagie, Sojo, Cavanagh, 2011). There is also evidence of declines in parental psychological well-being with increasing age of the child (Orsmond, Seltzer, Greenberg, & Krauss, 2006), though some research reports decreases in parental stress in adolescence (Woodman, 2014). Young adulthood may be especially challenging due to impending transition from school to work, and cause concerns about the child's future (Lueckling & Fabian, 1997; but see Goff et al., 2016). Social support may reduce during this time (Shattuck, Wagner, Narendorf, Sterzing, & Hensley, 2011).

Another concern is the continued co-residence of the child in the family home, often well past the age when most TD children become independent. Seltzer, Floyd, Song, Greenberg, and Hong (2011) reported a higher rate of co-residence of adults with IDD when their parents were in midlife and in early old age than in a comparison group. An adult child living at home is generally associated with poorer well-being for parents in midlife and early old age, more so in mothers (Pudrovska, 2009). A longitudinal study of 117 families before and after residential relocation (Seltzer, Krauss, Hong, & Orsmond, 2001) found levels of direct caregiving decreased and parents had less frequent contact with residential staff during the first 3 years after the adult child moved from home, resulting positively on parental well-being.

Sociodemographic Variables

Higher education level (Al-Krenawi et al., 2011), higher income (Santiago, Wadsworth, & Stump, 2011), and more effective coping style (Mak & Ho, 2007; Stuart & McGrew, 2009) are factors associated with less parental burden. Families supporting a child with IDD are more likely to be exposed to adverse socioeconomic circumstances (Emerson, 2007; Emerson & Hatton, 2009). They have lower rates of employment, return to employment later after childbirth, and are less likely to work full-time (Parish, Seltzer, Greenberg, & Floyd, 2004), and thus have less financial security later in life.

The relationship of family circumstances to psychopathology in children with IDD appears to be bidirectional. It has been found children with IDD often reside in single-parent, lower-socioeconomic families (Emerson, 2007). Emerson and Hatton (2007) found significant associations between gender, age and eight social variables and the risk of having behavioral disorders as well as hyperkinesis. Emerson and Hatton (2009) found that socioeconomic position moderated associations between child behavior problems and maternal anxiety, depression and self-assessed health.

However, some research suggests that raising a child with IDD contributes to parental stress and depression regardless of the buffering effects of socioeconomic status. Hoare, Harris, Jackson, and Kerley (1998) did not find parental depression to be related to either marital or socioeconomic status (also see Olsson & Hwang, 2001). In contrast, low levels of socioeconomic support along with parents' negative perceptions of their ability to influence their children's behavior are associated with increased stress and depression (Falk, Norris, & Quinn, 2014). Zaidman-Zait, Most, Tarrasch, and Haddad (2018) found during transition, more disadvantaged parents experienced more stress and depression, and their children had lower adaptive behavior and more behavior problems than comparison groups. However, when controlling for between-group differences in family socioeconomic circumstances, poorer well-being among parents of children with disabilities may be attenuated or even eliminated (Emerson, Baines, Allerton, & Welch, 2010; Olsson & Hwang, 2008). As such, socioeconomic status may not serve as a buffer against depression in parents of children with IDD (but also see Stoneman, 2007).

Minority status (Luthar, 1991; Masten, 2011) and racial discrimination (Brooks, 2006) also predict poor outcomes for children and youth. Children of African and Hispanic descent are often disadvantaged due to living in severely distressed neighborhoods with reduced accessibility to social supports, community services, employment opportunities, and high-quality schools. Age of the individual with IDD is important when considering life course vulnerabilities. Raskind et al. (1999) found a reduction in the perceived intensity of stressors from childhood to adolescence, particularly perception of having an IDD. Older women with IDD remain the least studied members of the disability population, and yet they often live well into late adulthood. LeRoy, Walsh, Kulik, and Rooney (2004) found older women with IDD to have limited resources, and social networks; yet they reported that their health was good, though it often limited their activities. Despite their societal limitations, these women reported this is the happiest period of their lives.

Residential placement can have a significant impact on stress and health in adults with IDD. Taggart (2014) found adults with IDD who live in supported residential placements, especially in institution-like settings, are at greater risk of psychopathology than adults who live with family members. Hastings et al. (2004) found people with IDD living in staffed accommodation have significantly more life events. Owen et al. (2004) found participants were exposed to at least three adverse life events the past year, and life event exposure was linked with increased aggressive behavior and greater incidence of emotional disorders.

Adults with IDD often become emotionally as well as practically dependent on the paid support staff assisting them with community access and daily living activities (Lunsky, 2008). When support staff leave due to job changes, or when adults with IDD leave behind support persons with whom they had positive experiences, feelings of bereavement can result (Hartley & MacLean Jr, 2005). Accumulation of multiple stressors combined with an impersonal staff attitude has been found to perpetuate challenging behaviors in people with IDD (Griffith, Hutchinson, & Hastings, 2013).

Family Environment

Along with the established relationship between socioeconomic position within a family, and the health of the child with IDD, there are a number of factors associated with nonoptimal child development (Guralnick, 2005). It is well established that parents of children with IDD show increased stress compared to parents of children without IDD (Emerson, 2003; Hastings & Beck, 2004). Experiencing child behavioral problems with a child with IDD has been shown to be a high risk for poorer health and well-being in cross-sectional research (Baker et al. 2002; Totsika et al., 2013).

However, there has been variability shown in parental well-being and other outcomes as seen similarly in the psychopathology of individuals with IDD. Totsika et al. (2011) found 60% of mothers of children with IDD did not report concerning clinical levels of their emotional problems. Positive outcomes are also established in the literature (e.g., Hastings & Taunt, 2002; Scorgie & Sobsey, 2000). Researchers have explored moderating or mediating factors in the relationship between child behavioral problems and maternal outcomes such as Plant and Sanders (2007) who explored behavioral problems and parental stress, with social support as a moderator. They found social support had a positive effect on this relationship. In addition, Halstead, Ekas, Hastings, and Griffith (2018) found perceived social support functioned as a protective factor, when perceived social support was higher, social support moderated the relationship between child behavioral and emotional problems and maternal outcomes, such as depression and life satisfaction. Social support has been found to be a protective factor between life events and parenting stress and outcomes such as depression, and social isolation (Dunn, Burbine, Bowers, & Tantledd-Dunn, 2001).

Family climate has an impact on child behavioral and emotional problems, including cohesiveness, expressiveness and conflict (Greenberg et al., 2012). Adverse characteristics associated with poorer child mental health include low parental intellectual level (Feldman, 1997), mental illness, particularly depression (Seifer & Dickstein, 2000), and parental neglect or abuse (Barnett, 1997). Guralnick (1998, 2005) suggests family climate risk factors are mediated by nonoptimal patterns of family interaction, such as high levels of expressed emotion and family conflict. Many family interaction patterns are affected by family risk factors, and contribute to poorer outcomes for the child with IDD (e.g., Phelps, Belsky, & Crnic, 1998). Individual risk factors might not exert an adverse impact on child outcomes in the absence of nonoptimal patterns of family interaction, suggesting optimal patterns can protect against the effect of other risk factors (Werner, 1995).

Family Cohesion

Family cohesion relates to positive outcomes for parents and children. Maintaining cohesion may be challenging for families of individuals with IDD (Mitchell, Szczerepa, & Hauser-Cram, 2016), and parents may be at greater risk of relationship breakdown. Research has found somewhat higher divorce rates in parents of individuals with IDD compared with parents of TD children (Hartley et al., 2010). Certain groups may be more susceptible to marital breakdown, such as parents of individuals with ASD (Hartley et al., 2010). Greater depressive symptoms have been found in single mothers of children with IDD (Olsson & Hwang, 2001).

Preventing domestic discord may promote parental mental health in families with children with IDD, as a positive marital relationship can predict lower parenting stress (Benson & Kersh, 2011). The well-being of one parent affects the stress experienced by the other parent (Hastings et al., 2005). This is important for parents of individuals with IDD as they may differ in their perceptions of family life. Studies have found mothers to be more stressed than fathers in having a child with an IDD (Dabrowska & Pisula, 2010; Oelofsen & Richardson, 2006), though this is not a consistent finding (Hastings, 2003; McCarthy, Cuskelly, van Kraayenoord, & Cohen, 2006). Alternatively, parents may differ in their predictors of stress (Hastings, 2003). While parents of children with ASD reported no differences in overall stress, children's problem behaviors and their partner's mental health were predictive of mothers' levels of stress

(Hastings, 2003). However, marital satisfaction positively predicted cohesion for both parents (Mitchell et al., 2016).

Expressed Emotion

Recently, researchers have focused on expressed emotion as an explanatory variable among families of children with disabilities. Expressed emotion is defined by high levels of criticism and/or emotional over-involvement from one family member directed toward another family member with a disability or illness. Expressed emotion is associated with relapse among adults with schizophrenia (Butzlaff & Hooley, 1998) and has been recently examined in families of children with intellectual disabilities (Hastings et al., 2006) as well as autism spectrum disorder (Greenberg, Seltzer, Hong, & Orsmond, 2006).

Research from Hastings et al. (2006) and Greenberg et al. (Greenberg et al., 2006; Greenberg et al., 2012) suggests a bidirectional relationship between child behavior problems and expressed emotion. Hastings et al. (2006) studied mothers of children with IDD at two time points, assessing maternal distress, mental health, expressed emotion, and child behavior problems. Criticism in particular was cross-sectionally, but not longitudinally, related to child externalizing behavior and maternal distress. Greenberg found links between high expressed emotion and maladaptive behavior in autism (Greenberg et al., 2006) and Fragile X syndrome (Greenberg et al., 2012). The latter study also found significant correlations between lack of criticism and fewer behavior problems. Smith et al. (2012) studied behavior problems and disability-related symptoms in adolescents and adults with FXS over a 3-year period, and found an association between maternal warmth, lower levels of symptoms, and higher levels of adaptive behavior. Maternal depression and criticism were associated with more psychological symptoms in individuals with FXS.

However, only examining the negative aspects of the family affective climate may be limiting for understanding the full range of family processes that influence development. Negative and positive well-being, for instance, are not necessarily on the same continuum of mental functioning. There remains a need to examine the positive aspects of emotional expression and other family processes among families with children with autism spectrum disorder.

Family Resilience

Family resilience can be conceptualized as a “renewable power” (Sobotková, 2004), a dynamic property of families’ strengths which allow families to adapt despite stressors. Sobotková (2004) identifies multiple factors that support family resilience: family functioning, stress appraisals, problem-solving skills, coping strategies, and sources of familial durability. Sources of familial durability can be external, such as socioeconomic status or social support networks, or internal, such as mutual value orientation and shared belief systems (Sobotková, 2004).

Several potential resilience factors have been explored, including hope (Lloyd & Hastings, 2009) and self-efficacy (Hastings & Brown, 2002). More recently, a systematic review by Peer and Hillman (2014) suggested that coping style, optimism, and social support may all be factors that influence resilience in parents of children with IDD. Ruiz-Robledillo, De Andrés-García, Pérez-Blasco, González-Bono, and Moya-Albiol (2014) found resilience showed associations with overall general physical and psychological health of caregivers of children with ASD. Research suggests that resilience is associated with mental health, such as anxiety, insomnia, and depression in caregivers (e.g., Tang et al., 2013). The Resilience Scale for Adults (RSA: Friborg, Hjemdal, Rosenvinge, & Martinussen, 2003) has been used in a small population of parents of children with IDD, as part of a comparison between parents of children with IDDs and parents of children with Sanfilippo syndrome (Grant et al., 2013). Parents rated social resources as their highest protective factor, and planned future as their lowest protective factor, both of which are subscales of the RSA.

Resilience research in the IDD field typically uses cross-sectional research. However, Bayat (2007) suggested resilience is a process that can only be shown over time, thus the need for longitudinal studies. One longitudinal study with parents of children with IDD (Gerstein, Crnic, Blacher, & Baker, 2009) studied trajectories of daily parenting stress in parents of young children with IDD, and found factors such as psychological well-being, marital adjustment, and positive relationships affected parenting stress differently in mothers and fathers, and concluded that parents affect each other's resilience. In contrast, Halstead, Griffith, and Hastings (2018) found no longitudinal association between resilience and maternal well-being outcomes, and little evidence of the role of resilience as a protective factor between child behavior problems and maternal well-being. However, they did observe maternal resilience functioned as a compensatory factor, having a significant independent main effect relationship with well-being outcomes in mothers of children with IDD and ASD.

Family Interventions

The Double ABCX model (McCubbin & Patterson, 1983) supports analysis of factors (i.e., protective resources, or risk factors including family discord) related to family adaptation (Saloviita, Itälinna, & Leinonen, 2003). The Double ABCX Model examines stressors that "pile up" post-crisis along with the original stressor (aA), post-crisis resources and those first used to meet the crisis (bB), post-crisis perceptions and those first applied to the crisis (cC) and the overall likelihood of adaptation to future crises on the basis of these developments (Xx).

Multiple components of family intervention programs can contribute to external support of family adaptation. Guralnick (1997, 1998) categorizes these intervention components as resource supports, social supports, and information and services. These components can be adapted to specific family needs to create a successful intervention capable of improving family patterns of interaction. Guralnick (1997, 1998) emphasizes that such interventions are primarily successful when they are delivered consistently with a family's goals, values, priorities and routines.

Mindfulness is typically described as being in the present moment, and responding without judgment to the unfolding of physical, mental, and emotional experiences (Kabat-Zinn, 2003). MBIs may help parents develop non-judgmental ways to focus on their children's behaviors, improving acceptance (de Bruin, Blom, Smit, van Steensel, & Bögels, 2015). Recent research demonstrates the efficacy of MBIs to improve well-being in caregivers of children with IDD (Neece, 2014). For parents of children with IDD, mindfulness is associated with reduced stress and anxiety, and increased positive parent-child interactions (Beer, Ward, & Moar, 2013). Chapters 9 and 42 explore further interventions for parents of children with IDD.

Conclusion

This chapter has reviewed risk and protective factors in the IDD field to date. Our approach considers multiple dimensions over the life course, with particular attention paid to social support, family environment, and individual differences. Moreover, our resilience-based approach has led us to consider how specific factors, such as the family environment, can present as both risk factors and protective factors based on differences in persons and circumstances. We believe that development of problem behaviors and poor mental health outcomes is best understood as a transactional process between the individual and complicated social systems including the family environment, school, and post-secondary outcomes such as residential placement. Exploring the interplay of risk and protective factors during these transactional processes is how best to identify targets for intervention. Continuing research is required to find new ways to promote resilience for people with IDD, and this research should focus on precise identification of risk and protective factors, conceived dynamically as changing over time, and changing in its significance for the individual with IDD based on persons and circumstances.

Environmental Chemical Exposures and Intellectual Disability in Children

David C. Bellinger

Although environmental chemical exposures impair the function of many organ systems, the central nervous system (CNS) is considered to be especially vulnerable, in large part because of the potential life-long consequences of perturbations in its development. Six of the 10 chemicals identified by the WHO as being of greatest public health concern globally are known to adversely affect brain-based functions and their development (air pollution, arsenic, dioxin- and dioxin-like compounds, lead, mercury, pesticides) (http://www.who.int/ipcs/assessment/public_health/chemicals_phc/en/). Emerging data suggests that at least two others (cadmium, fluoride) might do so as well. The goal of this chapter is to describe, in brief, how exposure to an environmental chemical during a critical stage of brain development process might increase a child's risk of an intellectual disability or other developmental disorders. Many of the examples provided involve lead because the body of data available for this chemical is much more extensive than that for any other. Principles derived from the study of lead will generally apply to other chemicals, however.

One reason for the enhanced vulnerability of the developing CNS to exogenous insults is the sheer complexity of the processes it involves, which occur over a protracted period beginning shortly after conception and lasting for at least two decades. Brain development is characterized by an exquisite temporal and spatial choreography of processes that must unfold properly in order to produce an organ consisting of billions of precisely located, highly interconnected, specialized cells. Of course, many factors other than environmental chemicals can interfere with these developmental processes during the prenatal and postnatal years. Examples of such pathogens include viruses (e.g., zika, cytomegalovirus, rubella), bacteria (e.g., syphilis, Neisseria meningitidis), and protozoa (e.g., Toxoplasma gondii, schistosoma).

In the sixteenth century, Paracelsus published what remains the most fundamental dictum of toxicology: "Solely the dose determines that a thing is not a poison." In other words, any chemical can become toxic to biological systems. Because timing is critically important for proper brain development, implying the existence of "critical windows of vulnerability," it is evident that this dictum must be amended to indicate that in addition to dose, the stage of brain development at the time of exposure is an important consideration in determining whether exposure to a chemical is neurotoxic. Nevertheless, Paracelsus' contribution provided the foundation for key toxicological concepts, including as the dose-response relationship and threshold dose. Thus,

in evaluating the extent to which exposure to an environmental chemical poses a public health problem, it is critical to determine whether the doses incurred by members of the general population at critical times in brain development exceed the doses known to cause various forms of harm. The following section briefly describes brain development and identifies chemicals which can have deleterious impact on different aspects of the processes involved.

During prenatal life, the key stages of brain development are primary neurulation (weeks 3–4), development of the forebrain (prosencephalon) (months 2–3), neuronal proliferation (months 3–4), neuronal migration (months 3–5), and neuronal organization (later gestation and continuing postnatally). Myelination begins in mid-pregnancy and continues into young adulthood. The coordination of these complex processes is regulated by myriad signaling pathways that must work properly if an individual is to end up with a species-typical brain. Although minor, inconsequential variations occur among individuals in the fidelity of these processes, some variations can result in abnormalities that have substantial impact on an individual's abilities to carry out brain-based functions. Which aspects of CNS development a chemical perturbs and thus, when exposure is likely to be most deleterious, depends in part on its mechanism of action. Many chemicals affect multiple aspects of brain development. Alcohol, methylmercury, and chlorpyrifos (a pesticide) disturb neural cell proliferation, while methylmercury, alcohol, and X-irradiation affect neural cell migration. Differentiation of neuroblasts is affected by alcohol, nicotine, methylmercury, and lead. The creation of glial cells and subsequent myelination of neurons is affected by endocrine disrupting chemicals, alcohol, and lead. Synaptogenesis is affected by alcohol, polychlorinated biphenyls, triethyltin, and the pesticides parathion and permethrin, while apoptosis (the orderly process of programmed cell death) is affected by lead, alcohol, and methylmercury. Many chemicals affect neurotransmitter systems, including organophosphate pesticides, alcohol, lead, methylmercury, aluminum, and pharmaceutical agents such as some anti-depressants (e.g., selective serotonin reuptake inhibitors).

One reason for the enhanced vulnerability of developing CNS is that the placenta and blood-brain barrier do not fully protect the fetus from exposure to all chemicals. Some, such as lead, passively diffuse across the placenta so that the concentration in fetal blood is approximately the same as in maternal blood (Aylward et al., 2014). In the case of methylmercury, the concentration in fetal blood is approximately 70% greater than in maternal blood (Stern & Smith, 2003), suggesting the possibility that it is actively transported across the placenta. In a nationally representative sample of pregnant U.S. women some chemicals, including polychlorinated biphenyls, organochlorine pesticides, perfluorinated chemicals, phenols (e.g., bisphenol A), polybrominated diphenyl ethers (PBDEs, which are flame retardants), phthalates (plasticizers), polycyclic aromatic hydrocarbons (products of the combustion of organic materials), and perchlorate, were detected in 99–100% of pregnant women (Woodruff, Zota, & Schwartz, 2011).

Moreover, the toxicokinetics of chemicals in the maternal-fetal unit can be complex. For example, in addition to being exposed to whatever lead a woman is exposed to during her pregnancy, the fetus is also exposed to lead to which the woman was exposed in the past. Approximately 90% of the lead in an adult's body is stored in bones. To support the development of a fetus' skeleton, large quantities of calcium are mobilized from maternal bone during pregnancy, especially the third trimester. Lead and calcium share certain key chemical properties, viz., both are divalent cations (valence of +2). As a result, lead is mobilized from maternal bone by the same processes that mobilize calcium. In fact, lead that reflects maternal exposure that pre-dates her pregnancy accounts for a substantial fraction of the lead in a fetus's cord blood (Gulson, Mizon, Korsch, Palmer, & Donnelly, 2003). Cadmium does not cross the placenta, but it can accumulate in it and impair its critical support functions.

In adults, the blood-brain barrier, which consists of tight junctions between the endothelial cells lining cerebral microvessels, prevents larger water-soluble chemicals from entering the brain (Zheng, Aschner, & Ghersi-Egea, 2003). This barrier is not fully developed at birth, however, and studies in nonhuman primates using radioactive tracers demonstrate that many chemicals pass more readily from the circulating blood into the brain in immature animals than in adult animals.

Certain behavioral and physiologic factors also place a developing child at greater risk than an adult to the deleterious effects of chemical exposures (Selevan, Kimmel, & Mendola, 2000). First, certain pathways of exposure are unique to children, including placental transfer and breastfeeding. It is primarily fat-soluble chemicals (e.g., dioxins, PCBs, perfluorinated compounds) that are of concern with regard to passage into breast milk. Certain behaviors that are more common in children than adults bring them into more intimate contact than adults with some chemicals. These include hand-to-mouth activity, oral exploration of objects, and non-nutritive ingestion (i.e., pica). Such behaviors can result in greater exposure to chemicals, such as lead and PBDEs, that might be present in household dust and soil. On a body weight basis, children consume more food and breathe a greater volume of air than do adults, so they tend to experience greater exposures than adults to foodborne and airborne hazards. Children and adults also experience different breathing zones, with children spend more time near the floor, where chemical concentrations in the air might be greater (e.g., after residential pesticide application). Differences between the diets of children and adults can also be important. Because children's relative consumption of fruit juices is typically greater than that of adults, the presence of pesticide residues on these products can pose a greater risk to them than to adults. Certain micronutrient deficiencies, such as iron and calcium, are more common in children and can result in greater fractional absorption of chemicals with which these essential metals share binding sites in the gut. For example, children absorb up to 50% of ingested lead, whereas adults absorb approximately 10%. Finally, some liver detoxification pathways are not fully developed in the early postnatal years. For example, the enzymes that convert lipid-soluble compounds into water-soluble metabolites that can be excreted in the urine are less effective in children, with the result that parent compounds that can damage cellular processes remain present for a longer period following exposure.

Although acute poisonings as a result of a single, high-dose exposure to a chemical can be serious and even fatal, such events are, fortunately, fairly rare. A broader concern is the potential neurological impact of children's chronic, low-dose exposure to chemicals that, in some cases, are nearly ubiquitous in the environment, affecting large numbers of children. The specific concern is that although such exposures might not produce clinical signs of intoxication, they nevertheless adversely impact brain function, increasing a child's risk of reduced intellectual capacities. The following sections discuss in more detail what is known about the effects of particular chemicals or classes of chemicals on children's intellectual development.

Metals

Mercury. Mercury exists in three forms: elemental, inorganic, and organic. The latter forms are considered to be the most important from the standpoint of public health. Ethylmercury was long used as a preservative (as a component of thimerosal) in multi-use vials of vaccines, but its use has largely been discontinued in pediatric formulations because concerns were raised around 2000 about the potential toxicity of the cumulative doses young children received. The following discussion focuses largely on methylmercury.

In the general population, consumption of seafood is the major pathway of exposure to methylmercury. Inorganic mercury that is dispersed into the environment by both natural (e.g., volcanoes, forest fires) and industrial processes (e.g., combustion of fossil fuels) settles into waterbodies where it is bio-transformed (specifically methylated to form methylmercury) by microbes in the sediments. It enters the aquatic food chain and bio-concentrates in tissues as it ascends trophic levels. The concentrations of methylmercury are therefore greatest in long-lived predatory fish (e.g., whales, shark, swordfish, albacore tuna).

Methylmercury provides a striking example of age-dependence of vulnerability to neurotoxicity. Industrial discharge of mercury salts into Minamata Bay in Japan resulted in heavy contamination of the seafood in the region. Children born to women who, during pregnancy, consumed large amounts of this seafood suffered a distinctive constellation of neurologic signs that came to be called, "Congenital Minamata Disease" (CMD) (Harada, 1995). They included growth disturbances, retention of primitive reflexes, sensory impairments, intellectual disability (tenfold increase in risk), cerebral palsy (50-fold increase in risk), and movement and coordination disorders (e.g., cerebellar ataxia, chorea, athetosis, dysarthria). A special hospital was built in Minamata City solely to provide lifelong care for these children, who were unable to function independently. Many of the mothers of children with CMD manifested no symptoms of mercury intoxication or only mild sensory symptoms such as transient parathesias. Neuropathological examination of individuals who were of different ages when their mercury exposure began revealed strikingly different patterns of brain abnormalities (Choi, 1989). In individuals who had already reached adulthood at the onset of exposure, the lesions were highly localized, clustering in the pre- and post-central gyri, the calcarine fissure of the occipital cortex, and the cerebellum. This is consistent with the clinical signs of mercury intoxication in adults, which include movement disorders, tremors, sensory disturbances, and constriction of the visual fields. In individuals exposed throughout gestation, however, lesions were found throughout the brain, with no apparent localization. This is consistent with the global developmental impairments characteristic of patients with CMD. One reason the impacts are diffuse rather than focal in fetuses is that exposure to methylmercury arrests mitotic cells in metaphase, impairing the cytoskeletal proteins (microtubule assemblies) that form the mitotic spindle. As a result, cell proliferation and migration are perturbed, producing widespread abnormalities including heterotopias (islands of cells in the wrong location), reduced cell densities, anomalous cytoarchitecture, disturbance in laminar pattern of cerebral cortex, incomplete myelination, glial proliferation, and limited gyral differentiation.

The devastating neurological effects observed in poisoning episodes such as occurred in Minamata and elsewhere stimulated concern that low-level chronic prenatal exposure to methylmercury has less serious but still deleterious effects on children's brain development. Therefore, numerous studies have been conducted in cohorts from regions in which seafood is an important component of the diet. A large prospective study of children from the Faroe Islands (North Atlantic Ocean) showed that the performance of children on tests of language, attention, and memory, was inversely related to their mothers' mercury exposure during pregnancy (Grandjean et al., 1997). In this cohort, each increase of 1 μg/g (part per million) in the maternal hair-mercury was associated with, on average, a loss of about one-half of an IQ point (Bellanger et al., 2013). Neuropsychological deficits were found at follow-up evaluations of the children at 14 (Debes, Budtz-Jørgensen, Weihe, White, & Grandjean, 2006) and 22 years of age (Debes, Weihe, & Grandjean, 2016), although they were diminished in magnitude. Functional MRI studies of a subset of the cohort showed dose-related alterations in patterns of activation (White et al., 2011). Studies conducted in areas in which local seafood is heavily contaminated by the use of mercury as an amalgamator in artisanal gold mining have found substantial intellectual deficits in the children with the greatest prenatal exposure to methylmercury (Gibb & O'Leary, 2014).

Some large studies of fish-consuming populations have not found significant associations between children's prenatal methylmercury exposure and their later intellectual development (e.g., Davidson et al., 1998). One potential explanation has to do with the pathway or vehicle of exposure. Seafood is a source not only of methylmercury but also a variety of important macronutrients (e.g., protein) and micronutrients (e.g., long-chain polyunsaturated fatty acids such as omega-3, selenium, iron, choline) that promote brain development. Failure to structure statistical analyses in such a way that adjustments are made for the fact that increased intake of these nutrients often accompanies increased intake of methylmercury can obscure the detection of both the toxicity of methylmercury and the benefits of the nutrients, i.e., produce negative confounding (Choi, Cordier, Weihe, & Grandjean, 2008). Analyses that address this issue have shown that by careful selection of the particular species of fish that are consumed, it is possible both to achieve the benefits of these nutrients and minimize exposure to methylmercury, improving the cognitive outcomes of children (e.g., Oken et al., 2005).

Bellinger, O'Leary, Rainis, and Gibb (2016) estimated that the global incidence of methylmercury-associated intellectual disability is approximately 225,000 cases per year. Based on country-specific data on exposure, the incidence rate varied more than 20-fold across different regions of the world. The highest rate of mercury-associated ID was in the low-income region of the Americas (7 cases per 10,000 population) (subregion D in the WHO classification, which includes Bolivia, Ecuador, Guatemala, Haiti, Nicaragua, and Peru). The largest number of cases, however, was estimated to be in countries in the highly populated Western Pacific B region (87,445 cases). This includes all countries in the region except Australia, Brunei Darussalam, Japan, New Zealand, and Singapore. As would be expected, island nations and those in which artisanal gold mining is common tended to have the highest incidence rates, most likely due to the prominence of seafood in the diet. Nearly all of the ID cases associated with methylmercury would be expected to be mild in severity.

Mercury in its elemental form has long been used in dentistry, as dental amalgam, which is used to restore caries, is 50% elemental mercury by weight. These amalgams can release mercury, and individuals with a larger number of such fillings have been shown to have somewhat higher urinary mercury concentrations. The question of whether the concentrations are sufficient to cause neurotoxicity has been controversial. Although there have been numerous case reports and observational studies suggesting that it is, two large trials comparing the neuropsychological and renal outcomes of children with substantial unmet dental needs who were randomized to receive either dental amalgam or composite resin restorations of caries, did not find evidence that children in the composite resin group performed better than the children in the amalgam group in the 5–7 year follow-up period (Bellinger et al., 2006; Lauterbach et al., 2008).

Lead. Lead can produce devastating effects on the developing brain by interfering with myriad processes. Depending on the dose, it increases apoptosis (programmed cell death), excitotoxicity (neuronal damage caused by over-activation of receptors), reduces cellular energy metabolism by impairing mitochondrial function, reduces heme synthesis and the oxygen-carrying capacity of red blood cells, increases oxidative stress and lipid peroxidation thus damaging cell membrane lipids, alters the activity of first and second messenger systems in neurons, receptor densities, and dendritic branching patterns, impairs the development and function of oligodendroglia resulting in abnormal myelin formation, disturbs neurotrophic processes including thyroid transport into brain, and alters the regulation of gene transcription. Severe lead poisoning can cause brain hemorrhage, edema, seizures, and coma. Even children whose lead poisoning is not so severe as to cause such an encephalopathy are left with a variety of residual difficulties. In an early case series, Byers and Lord (1943) demonstrated the error of the view, widespread at the time, that children fully recover from sub-encephalopathic lead poisoning. They observed that, "after recovery from their lead poisoning, these…children made an extremely poor record in competition with their fellows," insofar as, "with one definite and a second possible exception, none of the 20 children succeeded in school" (p.479). They also noted that the children exhibited severe behavioral pathologies, including hyperactivity, reduced impulse control, and aggression (e.g., fire-setting, biting others, stealing supplies, repeatedly dancing on desks, attacking classmates). Other problem behaviors noted included cruelty to animals and lack of response to punishment.

It is now recognized that because lead is so ubiquitous in the environment, intellectual impairment due to excessive exposure is a frequent rather than a rare occurrence. Indeed, some lead can be detected in the blood of virtually everyone. Based on 2015 data, the Institute for Health Metrics and Evaluation estimated that lead exposure accounts for 12.4% of the cases of idiopathic intellectual disability in the world, concentrating in low- and middle-income countries.

Based on the substantial amount of evidence that accrued on lead neurotoxicity over the past few decades, the blood lead concentration considered to be the "upper limit of normal" by bodies such as the World Health Organization and the U.S. Centers for Disease Control and Prevention (CDC) steadily dropped. In the 1960s a value of 60 μg/dL was considered the limit but, at present, because of the apparent absence of a threshold for the appearance of adverse effects on children's cognition and behavior, no level is considered to be "safe." A set of analyses of IQ data collected in seven prospective studies (N = 1333) conducted in several countries provided much of the justification for the present consensus (Lanphear et al., 2005). The motivation for pooling the data from these studies was to increase the precision with which the shape of the dose-effect relationship could be ascertained for blood lead concentrations <10 μg/dL. At the time of these analyses, 10 μg/dL was the U.S. CDC "action" level, at which intervention activities were triggered to reduce a child's lead exposure. The relationships between IQ, measured at age 5–10 years, and various indices of lead exposure were evaluated. A variety of statistical models were compared in terms of goodness-of-fit to the data, adjusting for 10 covariates, such as maternal IQ and home quality. A log-linear model using concurrent blood lead concentration as the exposure biomarker provided the best fit and indicated that an increase in blood lead from 2.4 to 30 μg/dL (the fifth and 95th percentiles of the blood lead distribution in the pooled dataset) was associated with an IQ reduction of 6.9 points. One of the most important findings was that the association was nonlinear, insofar as much of the total reduction, 3.9 points, occurred over the range of 2.4 to 10 μg/dL. The increase from 10 to 20 μg/dL was associated with a further reduction of 1.9 points, and the increase from 20 to 30 μg/dL with an additional reduction of 1.1 points. Although the mechanism(s) by which the proportional loss in IQ are greater at lower than at higher blood lead concentrations remain unknown, similar supra-linear relationships between blood lead and other cognitive outcomes were subsequently reported (e.g., Kordas et al., 2006; Téllez-Rojo et al., 2006).

Epidemiological studies have generally included assessment of other aspects of children's neuropsychological functioning. IQ is an apical measure, integrating children's performance in diverse verbal and nonverbal domains. If the effects of a neurotoxicant are focal, limited to only certain domains, one would expect that tests that focus more narrowly on the vulnerable domains would be more strongly related to lead biomarkers than is IQ. It is somewhat surprising, therefore, that, IQ is more consistently associated with lead biomarkers than is performance on tests that focus on more narrowly defined domains (e.g., memory, language). While this might, in part, be attributable to psychometric differences in the tests used, it might also provide some insight into the mechanism of lead-associated neurotoxicity, suggesting diffuse rather than focal neuronal and/or white matter injury, thereby producing global impairments of higher cortical functioning. It is also possible that the domains most affected vary across studies because of the joint effect of cohort differences in the timing of lead exposure and differences across domains in the timing of greatest susceptibility. The domains vulnerable to lead exposure also depend, to some extent, on cohort characteristics or context specific aspects such as genetic susceptibility, social environment, mixed chemical exposures.

Many studies have reported significant inverse associations, in the general population of children, between lead exposure and success in school, expressed as lower scores on standardized tests, receipt of special education services, grade retention, and failure to complete qualifications (e.g., Amato et al., 2012; Delgado et al., 2017; Fergusson, Horwood, & Lynskey, 1997; Magzamen et al., 2013, 2015; Needleman, Schell, Bellinger, Leviton, & Allred, 1990). In ecologic (i.e., aggregate-level) analyses, Nevin (2009) reported an inverse relationship between preschool blood lead concentrations and SAT scores, lagged by 17 years. Evens et al. (2015) evaluated the relationship between blood lead concentration and performance on the Illinois Standard Achievement Test in a cohort of 47,168 Chicago schoolchildren. Adjusting for covariates, they found dose-dependent reductions, extending below 10 μg/dL, in both reading and math scores, with each 5 μg/dL increase in blood lead associated with an increase of 1.3 in the risk of reading and math scores defined as "failure." A nonlinear dose-response relationship was found for reading failure, with the slope steeper for blood lead concentrations less than 10 μg/dL compared to greater than 10.

In a similar study, Miranda, Kim, Reiter, Galeano, and Maxson (2009) combined a North Carolina blood lead surveillance database with a database containing scores on a reading test given to school children in the state at the end of fourth grade. In the sample of 57,678 children, blood lead concentration ranged from 1 to 16 μg/dL, with a 75th percentile of 6 μg/dL. A significant dose-response effect relationship was found between blood lead and test score, without apparent threshold. Quantile regression analyses indicated that the adverse impact was more pronounced at the lower end of the test score distribution than at the higher end, indicating that the impact of lead is disproportionally greater on children who are already at academic risk than on children who are at low academic risk. This might be attributable to contextual factors that influence a child's resilience or susceptibility to lead exposure, such as nutrition, social environment, and other chemical exposures.

Skerfving, Lofmark, Lundh, Mikoczy, and Stromberg (2015) evaluated the performance of 3176 Swedish children on an examination taken at the end of compulsory schooling (age 16 years) in relation to blood lead concentration measured when the children were in primary school (age 7–12 years). They found an inverse nonlinear association between blood lead concentration (range 0.6 to 16.2 μg/dL, 90th percentile 6 μg/dL) and school performance, with a steeper slope at concentrations below 5 μg/dL than above 5. They estimated that the adverse impact of an increase in blood lead concentration from 2.5 to 5 μg/dL was similar in magnitude to the impact of having a mother with a university versus a primary school education. Surkan et al. (2007) reported that children with a blood lead concentration of 5–10 μg/dL, compared to children with a concentration of 1–2 μg/dL, had significantly lower reading and mathematics scores, even after adjustment for Full-Scale IQ score. This suggests that the achievements of children with greater exposures were not at a level commensurate with their ability.

The effects of lead are persistent as children age, with greater childhood exposure associated with reduced success in life success. In the large Dunedin Multidisciplinary Health and Development Study, Reuben et al. (2017) found that blood lead concentration measured at 11 years of age was inversely related to IQ at age 38 years, even after adjustment for IQ at age 11 years. Furthermore, early lead exposure was inversely related to socioeconomic status at age 38, suggesting that children who were more highly exposed enjoyed lower upward social mobility and, in fact, failed to match the socioeconomic achievements of their parents.

One aspect of lead neurotoxicity that receives little attention is the possible role of early-life exposure to lead as, itself, an effect modifier that increases the adverse impacts of later events and exposures or even normal aging processes. Weiss, Clarkson, and Simon (2002) speculated that if early-life exposure to a neurotoxicant increases the annual rate of neuronal loss by less than 1%, clinical signs of neurodegeneration would appear several years earlier than they would in the absence of such an exposure. Animal studies suggest that lead exposure reduces the ability of rats to weather an unrelated neurological insult in adulthood. Rats exposed to lead early in development but not thereafter were less successful than control rats in recovering function (beam walking, limb placing) after a laser-induced stroke in the somatosensory cortex in adulthood (Schneider & DeKamp, 2007). Early exposure to lead might also influence function in adulthood by altering the speed of aging. Provocative studies in rodents and nonhuman primates suggest that exposure in infancy initiates epigenetic processes, perhaps involving altered patterns of DNA methylation, that result in adult-onset overexpression of proteins involved in neurodegenerative processes characteristic of Alzheimer's Disease (viz., increased deposition of β-amyloid, increased hyper-phosphorylation of tau protein) (Gąssowska et al., 2016).

In the 1970s, the observations of Byers and Lord (1943) regarding the behavioral pathologies were followed up, with case-control and chelation challenge studies suggesting that children diagnosed with hyperactivity had greater lead burdens (e.g., David, Clark, & Voeller, 1972). Subsequent studies indicated that even in children who were neither clinically lead poisoned nor diagnosed with hyperactivity, a greater lead burden was associated with increased distractibility, reduced ability to follow directions, disorganization, daydreaming, and lack of task persistence (e.g., Needleman et al., 1979). A meta-analysis of 33 studies conducted between 1972 and 2010, involving more than 10,000 children, found significant effect sizes linking greater exposure and dimensional measures of both inattentive and hyperactive/impulsive symptoms (Goodlad, Marcus, & Fulton, 2013).

It is now established that increased childhood lead exposure also increased the risk that a child meets diagnostic criteria for ADHD. Using data from NHANES 1999–2002, Braun, Kahn, Froehlich, Auinger, and Lanphear (2006) found that the adjusted odds ratio for parent-reported ADHD among 6–16-year old children with a blood lead concentration in the fifth quintile (>2 μg/dL) was 4.1, compared to children in the first quintile (<0.8 μg/dL). A dose-response relationship was observed, with adjusted odds ratios of 1.1, 2.1, and 2.7 for children in the second quintile, third, and fourth quintiles, respectively. Among the limitations of this study are the absence of a clinician-confirmed diagnosis of ADHD and the fact that data on important covariates, such as family history of ADHD, were not available. A study by Froehlich et al. (2009), using NHANES 2001–2004 data, addressed the first issue. The Diagnostic Interview Schedule for Children, a clinician-administered diagnostic interview based on DSM-IV, was used to confirm a diagnosis of ADHD. Children with a blood lead concentration in the upper tertile (>1.3 μg/dL) were 2.3 times more likely to meet diagnostic criteria than were children with a concentration in the lowest tertile.

This association has been replicated in several subsequent case-control studies (Choi, Kwon, Lim, Lim, & Ha, 2016; Park et al., 2016; Wang et al., 2008). Nigg et al. (2008) clarified possible behavioral mechanisms of the association between lead and ADHD symptoms. Children 8–17 years old who met rigorous criteria for the diagnosis of ADHD had a significantly higher blood lead concentration than controls, even though concentration for all participants ranged only from 0.4 to 3.5 μg/dL, mean of 1.03). A significant relationship was found between blood lead concentration and total ADHD symptoms. In this study, IQ was measured and a Stop task was administered, providing assessments of a child's ability to suppress a prepared response (stop signal reaction time) and variability of reaction time on the "go" trials (response variability, readiness, and control). Mediation analyses suggested that lead exposure might increase a child's risk of ADHD by impairing cognitive control abilities, and that the association between blood lead and IQ was mediated by the association between blood lead and hyperactivity-impulsivity, not vice versa. Nigg et al. (2008) argued that the plausibility of the link between lead and ADHD is supported by the evidence that lead disrupts midbrain dopamine circuitry (striatum and fronto-striatal networks), the same circuitry that is thought to underlie ADHD. Nigg, Nikolas, Knottnerus, Cavanagh, and Friderici (2010) replicated the associations between blood lead concentration and ADHD symptoms in a larger sample, including adjustment for additional covariates, and at even lower blood lead concentrations (range 0.3–2.2 μg/dL).

Several studies in the last decade have suggested that children with greater early-life lead exposure are at increased risk of social pathologies such as criminal activities (e.g., Boutwell et al., 2017; Wright et al., 2008). If this association is true, it seems most likely to reflect a developmental cascade, representing a possible end-state for individuals with reduced intelligence, reduced school success, behavioral impairments such as reduced impulse control and ADHD, executive function deficits such as inability to anticipate consequences or to implement long-term plans, and possible substance abuse (Bellinger, Matthews-Bellinger, & Kordas, 2016). Of course, not all children with excessive early-life lead exposure follow this developmental trajectory, as there are many points along the way at which timely developmental supports might reduce the likelihood that the cascade is fully expressed.

Neuroimaging studies have explored the associations between lead exposure history and brain structure in individuals from the general population. Most of the data are from the Cincinnati Prospective Lead Study in which participants were enrolled prenatally and followed into young adulthood (19–24 years of age). Volumetric imaging revealed significant inverse associations between annual mean blood lead concentration between 3 and 6 years of age and gray matter volume, particularly in the frontal regions of the brain, including the anterior cingulate cortex and the ventrolateral prefrontal cortex, areas usually considered to be related to executive functions, mood regulation, and decision-making (Cecil et al., 2008). On diffusion tensor imaging, reduced fractional anisotropy and axial diffusivity were also associated with greater childhood lead exposure (Brubaker et al., 2009). These findings suggest impaired myelination and reduced axonal integrity in regions that regulate executive functions.

Brain function in adulthood is also inversely related to childhood lead exposure. Proton magnetic resonance spectroscopy studies showed that greater childhood blood lead concentration was associated with reductions in several metabolites, including *N*-acetyl aspartate and creatine and phosphocreatine, in both gray and white matter (Cecil et al., 2011). Functional magnetic resonance (fMRI) imaging showed that during a verb generation task, individuals with greater blood lead concentrations in childhood showed dose-dependent changes in activation pattern in the left frontal cortex and the left middle temporal gyrus (Yuan et al., 2006). In another cohort, individuals with greater lead exposure showed fMRI showed reduced activation in the dorsolateral prefrontal cortex, ventrolateral prefrontal cortex, pre-supplementary motor areas, and inferior parietal cortex on the Wisconsin Card Sorting Test and the n-back task (particularly on trials that imposed the greatest memory load) (Seo et al., 2015). These findings suggest that exposure to lead impairs the fronto-parietal working memory network.

Arsenic

Although arsenic is well known for its acute toxicity, chronically elevated exposure has many effects that would be expected to affect brain function. These effects include increasing oxidative stress, free radicals, and neuronal apoptosis, impaired neurogenesis in the hippocampus and disruption of the expression of the NMDA receptor, disruption of the hypothalamo-pituitary-adrenal axis, reductions in neurotransmitter levels, interference with the expression of thyroid hormone receptor genes, and others (Bellinger, 2013).

The potential consequences of clinical arsenic poisoning became evident from an episode that occurred in Japan in 1955, when milk powder produced by a manufacturer was contaminated with arsenic. Infants who consume formula made from this powder could have had an arsenic intake of as much as 5 milligrams per day, and signs of poisoning appeared after a total intake of approximately 60 milligrams. One-quarter of the infants residing in the prefectures of western Japan were affected. As many as 130 children died, and their brains showed signs of edema, hemorrhage, and white matter degeneration. Those who survived were at an increased risk of epilepsy, severe intellectual disability, and hearing deficit (Dakeishi, Murata, & Grandjean, 2006).

Diverse neuropsychological deficits were still apparent 50 years later, even among those not previously recognized as having any disability (Yorifuji et al., 2016).

For a large number of people in many areas of the world, arsenic naturally occurs at relatively high concentrations in the water used for cooking and drinking. Studies have been conducted in several areas of South Asia (e.g., Bangladesh, West Bengal, Taiwan) to determine whether chronic exposure to elevated, but not acutely toxic, concentrations of arsenic are associated with reduced intellectual capacities of children.

Fluoride

Fluoride differs from most other environmental chemicals in that, in many areas, public health policies insure that most children are exposed to it for its assumed benefit in reducing dental caries. It is added to public water supplies and put in toothpastes and supplements. Because of its addition to water, fluoride also is present in various dietary elements, such as fruit juices, which are commonly consumed by children. A large number of basic neuroscience studies raise concern about the potential effects of excess exposure to developing animals. In some areas of world, however, the concentration of fluoride in groundwater is naturally high enough to cause observable harm (fluorosis). Depending on the dose, the signs range from small white opaque spots on the enamel of teeth to severe pitting and discoloration of teeth, as well as to skeletal fluorosis. According to the CDC, in 1999–2004, nearly 40% of U.S. children 12–15 years of age show signs of at least mild fluorosis, nearly a 100% increase over the rate observed in 1986–1987 (Beltran-Aguilar, Barker, & Dye, 2010). A review of nearly three dozen studies conducted in China, mostly ecologic in design and comparing children from a low-exposure village to a high-exposure village, concluded that they provide suggestive evidence of modest fluoride-associated reductions in children's IQ scores (Choi, Sun, Zhang, & Grandjean, 2012). For several reasons, however, such studies provide only weak evidence. The most important are the fact that only data on external exposure are available (i.e., water fluoride concentration) rather than data on internal exposures (i.e., blood concentrations of fluoride in individual participants or severity of dental fluorosis), and the likelihood that children resident in the villages being compared differ not only in the fluoride concentration in their water supplies, but in also in terms of other factors that might affect the distributions of their IQ scores (e.g., socioeconomic status, access to medical care, quality of schools, etc.). Recently, a few studies that address at least some of these limitations have been conducted. Using dental fluorosis as the metric of exposure in a relatively small pilot study in Sichuan, China, Choi et al. (2015) found negative associations between fluorosis severity, reflecting lifetime exposure, and children's scores on some neuropsychological tests, Khan et al. (2015) found inverse associations between fluorosis severity and IQ scores in Indian children, and Bashash et al. (2017) found inverse associations between children's prenatal fluoride exposure (concentration in maternal urine during pregnancy) and their IQ scores at ages 4 and 6-to-12 years.

Pesticides

All pesticides are neurotoxic by design insofar as they act by targeting the functioning of the insect nervous system. Because the central nervous systems of insects and mammals operate on many of the same principles, the toxicity of these chemicals tends not to be species-selective. There are many different classes of pesticides, differing in their modes of action and in their toxicities. Organochlorine pesticides (e.g., DDT) were developed in the first half of the twentieth century. They are fat soluble, accumulate in the food chain, and persist in the environment for long periods. They act by altering the electrophysiological properties of cell membranes (particularly axons), disturbing sodium and potassium ion exchange. Because of their toxicity and persistence in the environment, their use has largely been banned or restricted in recent decades although their use continues in certain regions of the world.

Pesticides that degrade more rapidly, and therefore have shorter residence times than organochlorines in the environment, were introduced in the mid-twentieth century (e.g., organophosphates, carbamates). The organophosphates were originally developed as nerve gas agents in Germany during WWII. They are generally considered to be less toxic than organochlorines and are widely used on food crops, in homes, parks, schools, and golf courses. Organophosphate pesticides inhibit the activity of acetylcholinesterase, an enzyme that catalyzes the breakdown of the neurotransmitter acetylcholine. However, it is now known that certain OPs have adverse impacts on children's neurodevelopment at doses that do not cause acetylcholinesterase inhibition. They are thought to work by a different mechanism, which might include induction of inflammation, interference with C-reactive protein receptor signaling, insulin resistance, or nuclear transcription factor functioning. Another major class of pesticides, the pyrethroids, were developed in the 1970s. The neonicotinoids were introduced in the 1980s, although controversy quickly arose because they were implicated in colony collapse disorder, involving a massive die-off of workers in a honey bee colony with serious implications for the pollination of food crops.

In the last decades, a substantial number of studies, conducted in both cohorts presumed to have greater pesticide exposures due to the location of their residence and in general population cohorts, have reported that pesticide body burden is inversely related to children's IQ scores. In a group of children living in the agricultural Salinas Valley of California, Bouchard et al. (2011) showed that offspring of mothers with a concentration of the dialkyl phosphate metabolites of OP greater than 50 nmol/L during pregnancy had lower IQ scores at age 7 years than the children of mothers with concentrations less than 50 nmol/L, which corresponds to the mean in U.S. women of reproductive age. In an urban New York City cohort, Rauh et al. (2011) found an inverse association between the concentration of the OP pesticide chlorpyrifos in umbilical cord blood plasma and child IQ and working memory at age 7 years. In this same cohort, morphometric MRI analysis showed dose-related perturbations in the volumes of many regions of the brain (Rauh et al., 2012). Recently, Eskenazi et al. (2018) reported inverse relationships in a rural, agricultural cohort between prenatal exposure to pyrethroid pesticides and children's social-emotional scores at age 1 year and language/expressive communication scores at age 2 years.

Air Pollution

A rapidly developing body of literature on air pollutants indicates that greater exposures are associated with subclinical impacts on children's cognition (Clifford, Lang, Chen, Anstey, & Seaton, 2016). Air pollution is a complex mixture of diverse chemicals, and the composition can vary by site. Components of the mixture include polycyclic aromatic hydrocarbons (which are produced by the incomplete combustion of organic matter), oxides of sulfur, nitrogen, and carbon, ozone, and metals. In the United States, the concentrations of particulate matter have steadily declined in recent years, although the concentration of ozone has increased (www.lung.org/our-initiatives/healthy-air/sota/key-findings). Small particles (smaller than 2.5 micrometers in diameter) are generally considered to be the most hazardous because they can be inhaled and deposited deep in the lung, reaching terminal bronchioles and alveoli.

Approximately 95% of the world's population live in areas where outdoor fine particulate matter (particles less than 2.5 microns in diameter) concentrations (dust or soot particles) exceed the World Health Organization's Air Quality Guideline of 10 μg/m^3, with most areas of Africa, the Middle East, and South Asia exceeding 35 g/m^3 (www.stateofglobalair.org/air). In addition, more than one-third of the world's population is exposed to potentially hazardous indoor air pollution as a result of the combustion of biomass fuels (e.g., wood, dung, peat, crop, wastes) or coal. Because of the closed spaces and the large amount of time spent indoors, especially during the colder months, the indoor concentrations of particulate matter can be as much as 20-fold greater than outdoor concentrations.

It is only in recent years that the impacts of air pollution on the brain have been investigated, and several potential mechanisms have been identified, including oxidative stress/inflammation (viz., elevation of cytokines and reactive oxygen species), altered levels of dopamine and/or glutamate, and changes in synaptic plasticity/structure (Allen et al., 2017). Studies of children and young adults growing up in Mexico City have reported the emergence of exposure-related signs of neurodegeneration, including early stages of the development of neurofibrillary tangles (hyperphosphorylated tau protein) and neuritic plaques (beta-amyloid deposits), with 1 in 4 individuals showing later stages (Braak stages III-V) neurofibrillary tangles by the fourth decade of life (Calderón-Garcidueñas et al., 2018). They also show other abnormalities, including prefrontal white matter hyperintensities, damage to epithelial and endothelial barriers, tight junction and neural autoantibodies (Calderón-Garcidueñas et al., 2016). Studies of a cohort in Spain showed that, even in the absence of morphological changes in brain, greater airborne exposure to elemental carbon and nitrogen dioxide was associated with lower functional connectivity in key brain networks (e.g., the default mode network) as well as altered activation pattern on a sensory task (Pujol et al., 2016). A prospective study conducted in New York City found that greater prenatal exposure to polycyclic aromatic hydrocarbon (PAH) air pollutants was associated with lower IQ at age 5 (Lovasi et al., 2014) and slower processing speed, attention-deficit/hyperactivity disorder symptoms, and externalizing problems at age 7–9 years (Peterson et al., 2015). Morphometric neuroimaging indicated that these effects were mediated by disruptions of white matter in the left hemisphere. Greater postnatal exposure to PAHs was associated with disruptions of white matter in the dorsal prefrontal regions. Several studies suggest an association between various indicators of air pollution and a child's risk of either a diagnosis of an autism spectrum disorder or elements of its phenotype (Weisskopf, Kioumourtzoglou, & Roberts, 2015).

Synthetic Organic Chemicals

The research literatures on the impacts of exposure to synthetic organic chemicals are not as well-developed as those on the pollutants discussed above. These chemicals include polyhalogenated compounds such as polychlorinated biphenyls (PCBs), and polybrominated diphenyl ethers (PBDEs). PCBs were banned in the US in the 1970s but because of their resistance to degradation, they persist in the environment. PBDEs are used as flame retardants in a wide variety of products. Sharing many of the properties of PCBs, they accumulate and persist for long periods in the environment and in human fat tissue. A systematic review and meta-analysis of studies on children's intelligence and prenatal exposure to PBDEs at levels typical of the general population found a consistent inverse relationship (Lam et al., 2017). A ten-fold increase in PBDE exposure was associated with a decrement of nearly 4 IQ points.

Perfluorinated compounds (PFCs) are commonly used in a variety of consumer products (e.g., non-stick cookware, stain resistant fabrics, fast food packaging). To date, the evidence pertaining to the neurodevelopmental risks associated with such exposures are mixed (Liew, Goudarzi, & Oulhote, 2018).

Endocrine Disruptors

Concerns have been raised about exposure during development to chemicals that alters the function(s) of the hormonal system, causing adverse effects in an organism or its progeny (Braun, 2017). Such chemicals are called "endocrine disrupting chemicals" (EDCs) and can mimic the effects of endogenous hormones, antagonize the effects of endogenous hormones, disrupt the synthesis and metabolism of endogenous hormones, disrupt the synthesis of hormone receptors, and alter target cell sensitivity. Hormone levels in early development are critical in organizing brain development, and perturbations can have long-lasting effects on hormonal programming. For example, adequate levels of thyroid hormone are critical for various processes of brain development, including cell migration, differentiation, and signaling. Given that intellectual disability is a result of congenital hypothyroidism, and even subclinical reductions in thyroid function during pregnancy are associated with IQ deficits in children (Levie et al., 2018), it is plausible to hypothesize that prenatal exposures to chemicals that affect thyroid hormone levels produce more modest impacts on children's intelligence. Increased concentrations of chemicals such as phthalates are inversely associated with total serum thyroid hormone levels in pregnant women and neonates and thyroid stimulating hormone in neonates (Romano et al., in press). However, evidence that the alterations that occur at levels of phthalate exposure typical in the general population affect intelligence is presently inconsistent (Factor-Litvak et al., 2014; Nakiwala et al., 2018). Several studies have reported that early exposure to EDCs such as phthalates do, however, influence sexually dimorphic behaviors, that is, those that tend to differ between the sexes. For example, prenatal phthalate exposure might reduce masculine play in boys (Swan et al., 2010).

Estimating the Population Impact of Environmental Chemicals and the Burden of Disease

An argument frequently advanced by those skeptical about the importance of environmental chemicals is that their impact on the neurodevelopment of an individual child is modest, failing to reach the level of clinical significance. This argument fails to consider the issue in the context of population health. Effect estimates from epidemiologic data are in essence population average effects and should be interpreted in the context of a population and not at the individual level. Some individuals will be resistant and some will be more sensitive. Moreover, the impact of a factor at the population level depends not only on the effect size but also on the distribution of the factor or, in the case of a dichotomous factor, its incidence or prevalence. In a set of comparative analyses of pediatric disease and events, such as brain tumors, congenital heart disease, traumatic brain injury, iron deficiency, and lead exposure, Bellinger (2012) estimated the total number of IQ points lost among U.S. children younger than 5 years of age associated with each disease or event. The estimate for the loss associated with lead exposure was nearly 23 million IQ points, exceeded only by preterm birth. Among the reasons for this is the absence of a threshold for its inverse relationship with IQ and the fact that virtually every child has a blood lead concentration above the detection limit. As a result, and in contrast to most other diseases and events, every child contributes to the total IQ loss in the population that is associated with lead exposure. In fact, the greatest contribution to the total loss care is contributed by the very large proportion of children with blood lead concentrations at the low end of the distribution (because that's where most children fall). A similar calculation of the total IQ losses among the cohort of young U.S. children from the late 1970s produced the figure of approximately 125 million points, suggesting that the public health interventions implemented to reduce population lead exposure has produced a benefit of about 100 million IQ points. Given that approximately 25 million children fall into this age range, the average IQ benefit has been about 4 points, close to the estimate of 4–5 points reached by Kaufman et al. (2014) for the gain in adult IQ.

As the research reviewed in this chapter indicates, environmental chemicals cause adversities that extend well beyond a reduction in intelligence, affecting an exposed individual's success in many aspects of future life. Although current efforts to estimate the burden of disease associated with environmental chemicals consider only IQ deficit as the sequelae (GBD 2016 Risk Factors Collaborators, 2017), a full accounting of the burden of disease imposed by environmental chemicals must include these downstream impacts that can seriously impair quality of life (Bellinger, 2018).

Conclusion

The current approach to regulating chemicals is to impose restrictions on their use only after it becomes apparent that people who are exposed to them are demonstrably harmed. In effect, this results in large-scale natural experiments on the population. The fact that children are the most vulnerable subgroup of the population makes this approach particularly unconscionable. Unfortunately, even rudimentary toxicological data are available for only a small fraction of the approximately 80,000 chemicals in use, and most of these data pertain to rather crude health endpoints such as death, cancer, and birth defects rather than brain development and function. A more protective, proactive alternative would be to require a manufacturer to provide evidence of a chemical's safety before permission is granted to introduce it into the marketplace. It is our responsibility to future generations to reduce or, when possible, to eliminate the threats that these chemicals pose to their future well-being.

The Role of Intelligence Tests in the Assessment of Intellectual Disabilities

Mark R. McGowan and Jenna M. Hennessey

An intellectual disability (ID) is a developmental disorder that impacts functioning over the course of an individual's life span and is marked by limitations in both intellectual and adaptive domains. The onset of these limitations must manifest prior to the age of 18. While both genetic and environmental factors contribute to this condition, the most common causes of the disorder are due to chromosomal abnormalities (e.g., fragile X syndrome or Down syndrome) and fetal exposure to drugs or toxins (Walker & Johnson, 2006). ID impacts approximately 1% of the general population (American Psychiatric Association [APA], 2013). Intellectual deficits may impact an individual's reasoning, problem solving, planning, abstract thinking, judgment, or capacity for learning. Additionally, an individual must demonstrate an inability to meet normative expectations for independence and self-sufficiency in either conceptual, social, or practical adaptive skills (Schalock et al., 2010). According to the Diagnostic and Statistical Manual of Mental Disorders, fifth edition (APA, 2013), intellectual deficits are substantiated through the use of "both clinical assessment and individualized, standardized intelligence testing" (p. 33). Although the diagnostic criteria have not changed substantially over the past 50 years, the manner in which intelligence estimates are used in diagnosing ID has changed (Brown, 2007; Schalock, Luckasson, & Shogren, 2007).

Historically, determinations concerning the diagnosis and severity of impairment (e.g., mild, moderate, severe, profound) were based upon the magnitude of deviation of an individual's IQ score from the mean. For example, individuals with IQ scores ranging from 50–55 to 70 were classified as mildly impaired while individuals with IQ scores ranging from 35–40 to 50–55 were moderately impaired. More recently, the diagnostic criteria for ID was changed to emphasize the use of adaptive functioning deficits to determine the level of impairment (Tassé, Luckasson, & Schalock, 2016). This shift in emphasis was based in part on lingering concerns regarding the validity of estimates observed at the lower end of the IQ range (Armstrong, Hangauer, & Nadeau, 2012; Flanagan & Alfonso, 1995). The clinical implications of this change mean that, while intelligence tests continue to play an important role in determining that the criteria necessary for diagnosing ID have been met, clinical determinations concerning the degree of impairment are based on more readily observable behaviors rather than the latent construct of intelligence. In this chapter, we will focus on the role intelligence tests have played in our understanding of ID as a diagnostic construct, the instruments currently used to assess it, and the clinical considerations for their use.

Intellectual Assessment

Intelligence testing has evolved over the course of more than a century. While consensus on a definition of intelligence has been elusive, the history of intelligence testing has, in many respects, developed in parallel with theoretical understandings and contemporary definitions of this construct (see Wasserman, 2012). As we will discuss, a reciprocal relationship exists between the conceptualization of intelligence and how it is measured. This relationship holds great bearing upon how practitioners conceptualize intellectual disabilities (ID). Interestingly, many of the questions that were central to the study and assessment of intelligence at its beginning continue to exist today. Terman's (1916) observation concerning balancing the need for an agreed upon theoretical definition of intelligence and the task of measuring the construct continues to hold relevance.

> To demand, as critics of the Binet method have sometimes done, that one who would measure intelligence should first present a complete definition of it, is quite unreasonable. As Stern points out, electrical currents were measured long before their nature was well understood. Similar illustration could be drawn from the processes involved in chemistry, physiology, and other sciences. In the case of intelligence, it may be truthfully said that no adequate definition can possibly be framed which is not based primarily on the symptoms empirically brought to light by the test method (p. 36).

While agreed upon definitions have been difficult to achieve, intelligence testing has traditionally been the primary method for diagnosing ID. In most clinical settings, IQ scores that are two standard deviations or more below the mean have served as the diagnostic marker for ID. Not surprisingly, the evolution of the diagnostic nomenclature for ID can be traced in the historical tapestry that has developed from the study of intelligence over time. Therefore, a brief history of intelligence testing and the forces that have shaped its development will be introduced prior to reviewing contemporary measures used to assess intellectual capacities in children and adolescents.

A Brief History

The origins of intelligence testing date back to the late 1800s. The history of testing often begins with the work of Francis Galton and James Cattell who pioneered the use of anthropometric measurement to identify human characteristics that could be used to understand individual differences, heritability, and vocational potential (Galton, 1890). These early researchers also laid the groundwork for the use of psychometric principles and statistical analyses in the development and interpretation of assessment instruments (Cattell, 1890). While the work of these early researchers provides an important context for understanding the evolution of contemporary intelligence tests, Alfred Binet is generally credited with developing the first working intelligence test in 1905 and with ushering in the wide-ranging use of testing in western culture (Jenkins & Paterson, 1961; Tuddenham, 1962).

The original Binet-Simon Scale (Binet & Simon, 1905/1916) consisted of 30 items designed to assess a variety of abilities in children ages 3–11 years. He employed standardized test administration procedures that introduced items in a developmentally sensitive sequence from easy to hard and interpretation was based on the number of items a child was able to successfully complete. The impetus for developing the Binet-Simon Scale was in direct response to a need for educators to identify and support the learning needs of children with ID in accordance with mandatory public education laws in France at the time (Wolf, 1969). Later versions of the scale were developed in order to broaden its use by extending the age range from 3 years through adulthood. Binet also pioneered other advancements in the field. For example, he introduced the concept of using mental age to summarize an individual's performance on the test. In doing so, Binet established objective criteria for the diagnosis of intellectual disabilities based on their performance on the Binet-Simon Scale. He suggested that, for children under the age of 9, a 2-year delay in mental age be used as the threshold for an intellectual disability and, for children above the age of 9, a 3-year delay should be used.

The scale measured higher order cognitive functions including language, auditory processing, visual processing, learning and memory, judgment, and problem-solving (Binet, 1911/1916). It is important to note that the Binet-Simon Scale was developed using empirical evidence rather than theory. While Binet was convinced that more complex cognitive processes should be the focus of measurement as opposed to simple motor or sensory processes, he defined the construct of intelligence in fairly broad terms suggesting that it "…marks itself by the best possible adaptation of the individual to his environment" (p. 301).

Interestingly, the Binet-Simon Scale was not used widely in the French educational system at the time (Carson, 2007). However, the importance of the instrument for diagnosing intellectual disabilities was noted by an American, Henry H. Goddard (Zenderland, 1998). Goddard promoted the use of both the instrument and Binet's method for diagnosing ID in the United States. While Goddard was instrumental in having Binet's work translated into English, it was Lewis Terman who would later adapt the Binet-Simon Scale for widespread use in the United States. Based upon historical accounts, Lewis Terman, a professor at Stanford University, was granted the rights to publish an American revision of the Binet-Simon Scale for a nominal fee (see Wolf, 1973). Terman's work would eventually lead to the first edition of the Stanford-Binet Intelligence Scale, which introduced a number of noteworthy advancements in intellectual assessment. First, Terman's revised scale incorporated theoretical frameworks for guiding test construction and interpretation by purporting to measure "*general intelligence*" (Terman, 1916; p. 48). The concept of general intelligence was introduced earlier by Spearman (1904) in a paper reporting on his discovery of a mathematically derived factor, or psychometric *g*, that was hypothesized to exist based upon shared variance noted between test items. Second, Terman's revision also differed from the original test in its use of an Intelligence Quotient (IQ) to summarize test performance. The IQ score was calculated by dividing the mental age by the chronological age and multiplying the sum by 100. While the use of this type of ratio IQ score would later fall into disfavor due to psychometric vulnerabilities (see Becker, 2003), the use of IQ scores for diagnosing intellectual disabilities has stood the test of time.

Terman's standardization sample for the Stanford-Binet was comprised of 905 youth between the ages of 5 and 14 years who were drawn from schools in California and Nevada. The adult sample included 200 adolescents and 180 men in California and Oregon. The final version of the Stanford-Binet had 90 items, with approximately 60% of the items being adapted from the original test. Based upon frequency distributions found in the American standardization sample for the Stanford-Binet, children with IQs of 70 and below were classified as intellectually disabled, while children with IQs between 80 and 70 were classified as "Border-line" (Terman, 1916, p. 79). Over time, the Stanford-Binet would become the most frequently used intelligence test in the United States for decades (Louttit & Browne, 1947).

However, external forces continued to shape innovation in the field of intelligence testing that resulted in significant advancements in contemporary assessment practices. As noted previously, the genesis of the Stanford-Binet can be traced back to demands facing the public educational system. The successor, in terms of popularity of use, to the Stanford-Binet traces its roots back to demands facing the United States military. At the start of World War I, Robert M. Yerkes, then president of the American Psychological Association (APA), convened the Committee on the Psychological Examination of Recruits in 1917 for the purpose of leveraging psychology to assist the government in a time of war. The APA committee's focus was on using intelligence testing to identify recruits who were either unfit for duty or who demonstrated potential for leadership roles in the military. The product of this committee's work resulted in the development of the Army Examination Alpha and Beta. Army Alpha was an intelligence test intended for use with literate English-language speakers, while the Army Beta was designed for use with limited English-language proficient or illiterate examinees

(Yoakum & Yerkes, 1920). These intelligence tests were designed to be administered to large groups of examinees by Army examiners who were specially trained at the School for Military Psychology. Over the course of the war, Yerkes (1919) estimated that 1,726,000 servicemen had participated in psychological examinations, with an additional 83,000 enlisted men being given individual examinations.

Among the many Army examiners who contributed to this enterprise was a graduate student by the name of David Wechsler. While his contribution to the field of intelligence testing would not manifest for a number of years following the war, Wechsler drew upon his experience as an Army examiner to develop the Wechsler-Bellevue Scales in 1939 (Wechsler, 1939), which would later become the Wechsler-Bellevue Intelligence Scales (Wechsler, 1946). The Wechsler-Bellevue was comprised entirely of subtests taken from other intelligence tests available at that time. Wechsler's intent was to produce an intelligence test that would provide clinicians with a better option for assessing adults than the Stanford-Binet, which received criticism for its limited adult normative sample (Wechsler, 1939). While the development of the Wechsler-Bellevue was not driven by a particular theoretical model, Wechsler did embrace theoretical notions prevalent at the time in his definition of intelligence. According to Wechsler (1939),

> Intelligence is the aggregate or global capacity of the individual to act purposefully, to think rationally and to deal effectively with his environment. It is global because it characterizes the individual's behavior as a whole; it is an aggregate because it is composed of elements or abilities which, though not entirely independent, are qualitatively differentiable. By measurement of these abilities, we ultimately evaluate intelligence. But intelligence is not identical with the mere sum of these abilities, however inclusive (p. 3).

The Wechsler scales offered a number of advantages over its competitors at the time. First, Wechsler used a deviation IQ, which is based on how an individual's performance deviates from the average IQ for the sample. Unlike the ratio IQ used by the Stanford-Binet, a deviation IQ provides an index of intelligence based on the examinee's age and the statistical distance from the mean. A second advancement offered by the Wechsler scales was the inclusion of both Verbal and Performance (nonverbal) tasks, which was an approach adapted from lessons learned from the development of the Army Alpha and Beta tests (Wasserman, 2012). Subtest raw scores were converted to standard scores with a mean of 10 and a standard deviation of 3, while IQ scores had a mean of 100 and standard deviation of 15. The conversion of raw scores to standard scores also provided clinicians with opportunities to analyze intra-individual performance in the interpretation of the results. This approach to profile analysis based on the interpretation of individual strengths and weaknesses continues to shape practice today. Finally, by drawing together well-known tests from other instruments, Wechsler was able to provide practitioners with a single battery of co-normed tests that were administered and scored in a similar manner to produce a psychometrically sound and valid intelligence battery of tests. While critics of the Wechsler scales have commented on its lack of theoretical orientation (Anastasi, 1942), the empirical support and popularity of the test among practitioners made it the instrument of choice for working with adult populations (Rabin & Guertin, 1951). Over time, Wechsler went on to publish many different intelligence measures until his death in 1981 that include the Wechsler Intelligence Scale for Children (WISC; Wechsler, 1949), the Wechsler Adult Intelligence Scale (WAIS; Wechsler, 1955), and the Wechsler Preschool and Primary Scale of Intelligence (WPPSI; Wechsler, 1967). Over the years, these measures have been through multiple revisions and continue to be very popular among practitioners (Oakland, Douglas, & Kane, 2016).

A Contemporary Theory of Intelligence

A comprehensive overview of this topic is beyond the scope of this chapter. However, an effort will be made to focus our discussion on the theory that appears with the greatest regularity in the intelligence tests reviewed in this chapter. Before doing so, it is important to again reflect on how intelligence is currently being defined. While no universally agreed upon definition exist, our understanding of intelligence has continued to evolve in relation to the methods that are used to measure it. Consequently, some researchers have argued that, in the absence of adequate language to define the construct, structural or statistical models should be used to guide our understanding of intelligence (Gottfredson & Saklofske, 2009). This notion has been the foundation for the evolution of the Cattell-Horn-Carroll (CHC) framework which currently represents that most comprehensive and well-accepted model of intelligence to date (Keith & Reynolds, 2010).

The CHC theoretical framework is a structural model of intelligence that developed from the work of Raymond B. Cattell, John L. Horn, and John B. Carroll. The work of Cattell and Horn focused on developing a multifactor model of intelligence based upon Cattell's Gf-Gc theory (Cattell, 1963; Horn & Cattell, 1966). While the original theory hypothesized that general intelligence or (*g*) was the result of fluid and crystallized intelligence factors working in concert in the service of learning, the evolution of the theory has continued to expand the number of factors included in the theory (see Cattell, 1998). Based upon continued factor analytic research, the Horn-Cattell Extended Gf-Gc theory grew from a two-factor model to one that recognized between 9 or 10 broad ability factors (Horn & Noll, 1997). The relevance of this theory rests not only on its empirical replicability, but also on its utility for explaining patterns of variability observed in these results (Schneider & McGrew, 2012).

Carroll's three-stratum model is the other theoretical contributor to contemporary CHC theory. Drawing upon more than 460 factor analytic studies of intellectual abilities available at that time, Carroll's seminal research introduced a hierarchical model that, as the name suggests, is comprised of three strata or levels. The framework takes on a shape of a pyramid. At its pinnacle (stratum III), the model posits that a general intelligence factor (or *g*) is comprised of the broad and narrow ability factors in the other two levels of the model. Stratum II includes eight board abilities that are recruited based upon the task demands faced by the individual. At stratum I, there are a large number of narrow abilities subsumed under each of the broad abilities in stratum II (Carroll, 1993). The three-stratum model demonstrated considerable overlap with the Gf-Gc theory. More specifically, Carroll's broad abilities at stratum II are similar to those found in the Horn-Cattell Extended Gf-Gc theory including fluid intelligence (Gf), crystallized intelligence (Gc), general memory and learning (Gy), broad visual perception (Gv), broad auditory perception (Ga), broad retrieval ability (Gr), broad cognitive speediness (Gs), and reaction time/decision speed (Gt). However, the three-stratum model expanded the framework of the Gf-Gc model by introducing a taxonomy for understanding the narrow factors that contribute to differences at the broad ability level. The importance of understanding these narrow ability factors was summarized by Kevin McGrew who suggested that focusing on these factors would "go far in helping us all better understand what we are measuring, facilitate better communication between and among professionals and scholars, and increase our ability to compare individual tests across and within intelligence batteries" (1997, p. 171). This line of reasoning eventually gave rise to CHC theory.

The first integration of the Horn-Cattell and Carroll models was articulated in a chapter by McGrew (1997). CHC theory has continued to command the attention of researchers and test publishers since 2000 (McGrew, 2005). Currently, the CHC theoretical framework has arguably had the most influential impact on contemporary intelligence testing of any theory to date (Newton & McGrew, 2010). According to Keith and Reynolds (2010), "although most new and revised tests of intelligence are based, at least in part, on CHC theory, earlier versions generally were not. Our review suggests that whether or not they were based on CHC theory, the factors derived from both new and previous versions of most tests are well explained by the theory" (p. 635). In addition to providing the theoretical foundation for the majority of commonly used intelligence tests, CHC theory has also been used to develop practice guidelines for assessment and interpretation of intelligence tests, e.g., cross-battery approaches (see Flanagan, Ortiz, & Alfonso, 2013).

In practice, the relevance of CHC theory to the assessment and diagnosis of intellectual disabilities is less clear. While the CHC model provides for rare common ground between test developers and theorists, practitioners are only beginning to see specific guidance on how CHC may aid in making differential diagnoses. Preliminary research has largely been limited to the identification of specific learning disabilities (Flanagan, Fiorello, & Ortiz, 2010; Niileksela & Reynolds, 2014; Proctor, 2012). As continued efforts are made to identify how CHC ability factors relate to learning outcomes for children (McGrew & Wendling, 2010), the benefits for utilizing CHC theory to guide intervention planning for individuals with ID may prove to be beneficial. Regardless, practitioners must be knowledgeable about the constructs that are being measured in order to make informed decisions concerning the selection of appropriate assessment batteries and to ensure that the interpretations based upon those findings are valid. The remainder of this chapter will review instruments frequently used to measure intelligence in child and adolescent populations. Diagnostic and clinical implications associated with selecting and interpreting these instruments for use with the ID population will also be explored.

Stanford-Binet Intelligence Scales, Fifth Edition (SB5)

The Stanford-Binet Intelligence Scales, Fifth Edition (SB5; Roid, 2003a) is the most current version of the Stanford-Binet Scales. There were significant modifications made to the previous version, Stanford-Binet Intelligence Scales, fourth edition (SB4; Thorndike, Hagen, & Sattler, 1986), when developing the SB5. These changes included an additional factor to the test framework, improved content under the nonverbal index, extended age range, new test items to enhance the measurement of very low functioning individuals, and reintroduced manipulatives from earlier editions of this instrument with the intention of increasing examinees' engagement (Roid, 2003b).

Test Description. The SB5 can be administered to children as young as 2-years of age, which allows for early detection of developmental delay. This instrument also grants examiners the ability to assess intelligence throughout adulthood with norms spanning to age 85+ (Roid, 2003b). Administration times vary based upon the battery of tests administered. These administration times range from 15–20 min for the Abbreviated Battery to 45–75 min for the Full-Scale IQ Battery (Roid, 2003c). The SB-5 was normed on 4800 individuals between the ages of 2 and 85+. Furthermore, approximately 77% of the sample population ranged in age between 2 and 20. "The sample was nationally representative to percentages of the stratification variables identified in the U.S. Census data in 2001" (Roid, 2003c, p.48). The norming sample includes individuals with ID and other developmental disabilities (Roid, 2003c).

Theoretical Orientation and Test Structure. The SB5 exclusively uses the CHC theory to support its test framework. The SB5 includes five broad cognitive abilities highlighted in the CHC model (Roid, 2003b). According to Roid (2003c), "the five factors included in this instrument have the highest factor loading on general intellectual ability (*g*)" (p.9). The average factor loadings on all of the broad cognitive abilities across all age groups for both verbal and nonverbal domains are as follows. The factor loading on *g* for the verbal domain of the five broad abilities are Fluid Reasoning (0.77), Knowledge (0.75), Quantitative Reasoning (0.83), Visual-Spatial Processing (0.82), and Working Memory (0.76). The factor loading on *g* for the nonverbal domains of the five broad abilities are Fluid Reasoning (0.70), Knowledge (0.80), Quantitative Reasoning (0.82), Visual-Spatial Processing (0.74), and Working Memory (0.74). See the *Stanford- Binet Technical Manual* for additional information regarding the factor loadings for this instrument (Roid, 2003c).

Psychometric Properties. The SB-5 is well known for its respectable reliability and validity (Sattler, 2007). According to the *Technical Manual* (Roid, 2003c), the internal reliability is exceptional for the Full-Scale IQ with alpha coefficients ranging from 0.97 to 0.98 across age groupings. The five broad cognitive abilities factors discussed above also yield reputable internal consistency ($r = 0.84–0.96$) across all age groupings. The author of this assessment tool also indicated excellent stability in terms of the Full-Scale IQ and across all five-factor indexes. In regards to validity, high correlation ($r = 0.90$) was noted between the Full IQ Scale of the SB5 to its predecessor's, SB4, Composite Scale. In addition, the SB5s Full IQ Scale also highly correlated ($r = 0.78–0.84$) with other well-known standardized intelligence assessments (Roid, 2003c).

Wechsler Intelligence Scale for Children, Fifth Edition (WISC-V)

The Wechsler Intelligence Scale for Children, Fifth Edition (WISC-V; Wechsler, 2014) is the most current children's version of the original Wechsler Intelligence Scale for Children (WISC; Wechsler, 1949). The WISC-V aimed to improve the content through adding three subtests to the core battery as well as enhance the factor structure through increasing the number of factors by one to better measure isolated domains of intellectual ability, such as visual-spatial ability. Ancillary and complementary diagnostic index scales were also added to provide additional information regarding a child or adolescents' overall cognitive functioning in the areas of reasoning ability, nonverbal reasoning, auditory working memory, and memory retrieval (Wechsler, Raiford, & Holdnack, 2014).

Test Description. The age range for the WISC-V includes children between the ages 6 through the age of 16. The *WISC-V Technical and Interpretive Manual* claims that the administration of the core subtests can be completed in approximately 60 min (Wechsler et al., 2014); however, this assessment is perceived by practitioners to often take upwards of 120 min to administer. Normative data were collected on 2200 children spanning the entire age range of the assessment. The sample is representative of "demographic variables, such as (i.e., age, sex, race/ethnicity, parent education level, geographic region) using October 2012 U.S. census data" (Wechsler et al., 2014, p. 31). Furthermore, the WISC-V norms include participants from various disability classifications including ID and developmental disabilities (Wechsler et al., 2014).

Theoretical Orientation and Test Structure. Dating back to the inception of the WISC, there has not been a single theoretical framework guiding the development of this assessment. The WISC-V encompasses an eclectic theoretical orientation rooted in neurocognitive research, working memory models, and CHC theory of intelligence (Wechsler et al., 2014). The factor structure for the WISC-V includes five primary indexes. The average factor loadings on g for these primary indexes across all age groups are as follows: Verbal Comprehension Index (0.84), Fluid Reasoning Index (0.99), Visual-Spatial Index (0.90), Working Memory Index (0.83), and Processing Speed Index (0.51). Refer to *WISC-V Technical Interpretive Manual* for additional information concerning the factor loadings associated with this assessment tool (Wechsler et al., 2014).

Psychometric Properties. The WISC-V is well known for having sufficient psychometric properties (Sattler, 2007). Internal reliability is very high for Full-Scale IQ at all ages ($r = 96–0.97$). The reliability alpha coefficients across all five primary index scores on all age groupings range between 0.84 and 0.95. The authors of this assessment tool also report excellent stability for the Full-Scale IQ and across all primary indexes. With regard to validity, the WISC-V's Full-Scale IQ highly correlates ($r = 0.86$) with the previous version of this instrument, WISC- IV. Furthermore, this assessment tool is highly correlated ($r = 0.83$ or above) with other Wechsler Scales (Wechsler et al., 2014).

Woodcock-Johnson IV Tests of Cognitive Abilities (WJ IV COG)

Woodcock-Johnson IV Tests of Cognitive Abilities (WJ IV COG; Schrank, McGrew, & Mather, 2014) is the most recent version of this instrument. Noteworthy modifications were made to this assessment tool during test development from the prior version (WJ III COG; Woodcock, McGrew, & Mather, 2001). In addition to renorming, the primary revisions include the addition of new tests as well as new clusters, such as the Gf-Gc Composite, Perceptual Speed, and Number Facility, to improve diagnostic interpretations (McGrew, LaForte, & Schrank, 2014).

Test Description. The WJ IV COG can be administered to children and adults ranging in age between years 2 through 90+. This assessment tool is divided into two batteries. The Standard Battery takes approximately 60 min to administer. The testing duration of the Extended Battery is about 40 min (Mather & Wendling, 2014). The WJ IV COG was normed on 7416 individuals between ages 2 and 90+ years. Over 5000 of these individuals were under the age of 20. The normative sample was collected over 25 months and was representative of U.S. Census data in 2010. Sampling variables included sex, race, ethnicity, community type, parent education, etc. The sample population includes individuals with ID and developmental disabilities (McGrew et al., 2014).

Theoretical Orientation and Test Structure. The WJ IV COG was designed specifically to measure constructs outlined in CHC theory. This instrument incorporates seven broad cognitive abilities encompassed in the CHC theory (Mather & Wendling, 2014; McGrew et al., 2014). The median factor loadings on *g* for these seven broad cognitive abilities across all age groups are as follows: Comprehension-Knowledge (0.83), Fluid Reasoning (1.0), Visual Processing (0.82), Short-term Working Memory (0.76), Long-term Retrieval (0.85), Cognitive Processing Speed (0.57), and Auditory Processing (0.78). See *WJ IV COG Technical Manual* for specific information regarding the factor loadings of this instrument (McGrew et al., 2014).

Psychometric Properties. *WJ IV COG Technical Manual* reports that internal reliability is very high for the Gf-Gc Composite and General Intellectual Ability with alpha coefficients ranging from 0.94 to 0.98. In addition, the broad abilities also have adequate internal consistency of 0.82 or higher on average. The authors of this assessment tool note excellent stability across all seven broad abilities. Adequate criterion-related validity was also reported based upon other commonly used intelligential assessments (McGrew et al., 2014).

Differential Ability Scales, Second Edition (DAS-II)

The Differential Ability Scales, Second Edition (DAS-II; Elliott, 2007a) is the most recent version of this assessment tool. The DAS-II includes an expanded clinical sample of children with a variety of disabilities as well as a Spanish language translation for the nonverbal subtests (Elliott, 2007a).

Test Description. The DAS-II consists of two assessment batteries. The Early Years Battery includes children between the ages of 2 years 6 months through age 6. This battery can also be administered to children ages 7 through 8 with lower cognitive functioning. The School-age Battery includes children from age 7 through 17. Children ages 5 through 6 who display high cognitive functioning can be administered this battery. In regards to administration time, the core battery of the DAS-II takes approximately 45 to 60 min to administer (Elliott, 2007b). If diagnostic subtests are selected by the examiner to acquire additional information on a child's cognitive functioning, administration time needed is approximately 5 min per diagnostics subtest (Sattler, 2007). The normative sample for the DAS-II included 3480 children and was associated with the October 2002 census data across selected demographic variables including age, sex, race/ethnicity, parent education level, and geographic region. As previously mentioned, the revision of this instrument expanded the clinical sample of children among a variety of disabilities including mild to moderate ID and developmental disabilities (Elliott, 2007b).

Theoretical Orientation and Test Structure. The DAS-II was not shaped by a single theory. Rather, this instrument used multiple theories to guide its development including Spearman's theory of general intelligence (Spearman, 1904), Thurstone's (1938) seven primary mental abilities, Wechsler's (1939) overall intelligence, Vernon's (1950) verbal-educational factor and spatial-mechanical factor, and Cattell's and Horn's (Horn & Cattell, 1966) Gf-Gc theory. Based on the above theoretical foundations, the DAS-II yields an overall intellectual score, General Conceptual Ability, along with cluster scores for both the Early Years battery and the School Years battery. For the Early Years battery, the average factor loadings on *g* for clusters across ages 4 through age 5 are as follows: Verbal (0.86), Nonverbal Reasoning (0.99), Spatial (0.90), Visual-Verbal Memory (0.50), and Verbal Short-term Memory (0.65). For the School Years battery, the average factor loadings on *g* for clusters across ages 6 through age 17 are as follows: Verbal (0.84), Nonverbal Reasoning (0.95), Spatial (0.91), Visual-Verbal Memory (0.53), Verbal Short-term Memory (0.84), and Cognitive Speed (0.67). Refer to the *DAS-II Introductory and Technical Handbook* for additional information on factor loadings on *g* that include younger age ranges (Elliott, 2007b).

Psychometric Properties. The DAS-II has reputable reported internal consistency, stability, and criterion-related validity (Elliott, 2012). In particular, the reliability alpha coefficients for the General Conceptual Ability is 0.93 or higher across age groupings. The cluster scores for all age groupings on both the Early Years and School-Age batteries on average range between 0.89 or higher. The DAS-II also displays adequate stability over time. The DAS-II's General Conceptual Ability is highly correlated with the DAS (r = 0.88). Furthermore, this instrument also adequately correlates with other well-known standardized intelligence assessments (Elliott, 2007b).

Kaufman Assessment Battery for Children, Second Edition (KABC-II)

The Kaufman Assessment Battery for Children, Second Edition (KABC; Kaufman & Kaufman, 2004a) was most recently revised in 2004. Consistent with the original version of this assessment tool, the authors claim that this assessment measures intellectual functioning in a culturally fair manner by using universal concepts on test items (Kaufman & Kaufman, 2004b).

Test Description. As previously mentioned, the KABC-II instrument's age range was widened to include children from ages 3 through the age of 18 (Kaufman & Kaufman, 2004b). Administration times vary based on the theoretical model the examiner decides to use. The core battery associated with the Luria model can be administered in approximately 30–55 min. In contrast, the CHC core battery is longer in duration with an estimated administration time between 40 and 70 min (Singer, Lichtenberger, Kaufman, Kaufman, & Kaufman, 2012). The KABC-II's normative sample of 3025 children was intended to accurately represent the 2001 U.S. census across stratification variables such as gender, race, socioeconomic status, and geographical region. Special education classifications incorporated in the sample population include individuals previously diagnosed with ID and developmental disabilities (Kaufman & Kaufman, 2004b).

Theoretical Orientation and Test Structure. The KABC-II was developed to align with two theoretical frameworks, Luria neuropsychological model (Luria, 1966) and CHC model (Horn & Cattell, 1966). The Luria model has a focus on cognitive processing. The four cognitive processes associated with the Luria model that are highlighted in the KABC-II are sequential processing, simultaneous processing, learning ability, and planning ability (Kaufman & Kaufman, 2004b). This model is favored in circumstances such as when a child exhibits bilingual language ability, when a child's cultural background is outside of the mainstream American culture, and when a child presents with a language impairment (Singer et al., 2012). In regards to the CHC model, five broad abilities are utilized in this assessment battery. Of these five broad abilities, the average factor loadings on *g* for age ranges 7 through 12 and 13 through 18 are as follows. The factor loadings on *g* for the age range 7 through 12 are Knowledge (0.85), Simultaneous (0.87), Planning (1.0), Learning (0.77), Sequential (0.58). The factor loadings on *g* for the age range 13 through 18 are Knowledge (0.83), Simultaneous (0.86), Planning (1.0), Learning (0.83), and Sequential (0.66). Refer to the manual for additional information regarding factor loadings on g (Kaufman & Kaufman, 2004b).

Psychometric Properties. The *KABC-II's Manual* (Kaufman & Kaufman, 2004b) reports that the mean internal reliability alpha coefficients' for both Mental Processing Index (MPI), Luria model's Full-scale IQ, and the Fluid-Crystallized Index (FCI), CHC model's Full-scale IQ, across age groups are 0.90 or higher. The alpha coefficients across all broad ability indexes on average range between 0.88 or higher. Performance on this instrument shows suitable stability (Singer et al., 2012). Adequate criterion-related validity was noted when comparing the MPI and FCI to other well-known intelligence assessments for children. It is worth noting that the FCI tends to correlate higher with other assessment instrument's global scales compared to the MPI (Kaufman & Kaufman, 2004b).

Universal Nonverbal Intelligence Test, Second Edition (UNIT-2)

The Universal Nonverbal Intelligence Test (UNIT-2; Bracken & McCallum, 2016a) was developed in 2016. All subtests included in this battery are administered without the use of verbal communication.

Test Description. The UNIT-2 assesses nonverbal intelligence of children and adolescents ranging from age 5 through age 21. Administration time varies depending on the battery given. These administration times range from 5 to 15 min for the Abbreviated Battery to 45–60 min for the Full-Scale IQ Battery (Bracken & McCallum, 2016b). The normative sample includes 1603 individuals. Similar to other intellectual assessments discussed, the chosen sample was representative of the United States population in terms of geographic region, race, ethnicity, gender, parent education, and household income. This instrument contains normative data on the following special populations such as ID and developmental disabilities (Bracken & McCallum, 2016b).

Theoretical Orientation and Test Structure. The UNIT-2 is not based on a single theory. The instrument was developed by drawing upon models of intelligence such as the Jensen's (1980) two-factor model of intelligence (i.e., memory and reasoning) and Carroll's (1993) intelligence model. The UNIT-2 test structure is hierarchical with overall intellectual functioning at the top (i.e., *g*) followed by primary ability scales and then subtests. The primary abilities scales consist of Memory, Reasoning, and Quantitative Reasoning. It is important to note that factor loadings of *g* reported in the *UNIT-2 Examiner's Manual* (Bracken & McCallum, 2016b) used subtests instead of the primary abilities scales. For ages 8 through 10, the average factor loadings on *g* for each subtest is as follows: Symbolic Memory (0.41), Spatial Memory (0.65), Analogic Reasoning (0.77), Cube Design (0.73), Nonsymbolic Quantity (0.60), and Numerical Series (0.72). For ages 11 through 13, the average factor loadings on *g* for each subtest is as follows: Symbolic Memory (0.55), Spatial Memory (0.64), Analogic Reasoning (0.69), Cube Design (0.67), Nonsymbolic Quantity (0.69), and Numerical Series (0.79). For ages 14 through 18, the average factor loadings on *g* for each subtest is as follows: Symbolic Memory (0.46), Spatial Memory (0.68), Analogic Reasoning (0.76), Cube Design (0.76), Nonsymbolic Quantity (0.66), and Numerical Series (0.76). See the technical manual for additional information regarding factor loadings on *g* related to other age ranges.

Psychometric Properties. The UNIT-2 is a psychometrically sound instrument. According to the manual, internal reliability is high across the Full-Scale IQ (r = 0.97–0.99) and all primary abilities scales (r = 0.91–0.99) for all age groupings. Test-retest stability is reportedly adequate for the Full-Scale IQ and all primary ability scales. Related to validity, the UNIT-2 adequately correlates with prior version of this instrument, UNIT (r = 0.96). This measure also highly correlates with well-known intelligence tests (Bracken & McCallum, 2016b).

Leiter International Performance Scale-Third Edition (Leiter-3)

The Leiter International Performance Scale-Third Edition (Leiter-3; Roid, Miller, Pomplun, & Koch, 2013a) is the most recent revision of this instrument. Similar to the UNIT-2, the Leiter-3 is administered nonverbally with pantomimed instructions such as hand gestures, facial expressions, and demonstrations (Roid et al., 2013a).

Test Description. The Leiter-3 assesses nonverbal intellectual functioning of children and adolescents ranging from 3 through 75+. Administration time varies depending on the battery given. The Cognitive Battery can be administered in approximately 45 min and the Attention/Memory Battery can be administered in about 40 min (Roid, Miller, Pomplun, & Koch, 2013b). The Leiter-3 has a normative sample of 1603 and is representative of the U.S. census in 2008 in terms of sex, race, ethnicity, parental educational level, and geographic region. The sample population includes several disability categories including ID and developmental disabilities (Roid et al., 2013b).

Theoretical Orientation and Test Structure. The Leiter-3 is based on the CHC theory that encompasses a hierarchical structure (Roid et al., 2013b). The Leiter-3 includes four cognitive abilities in its test structure. Specifically, these cognitive abilities consist of Fluid Reasoning, Short-term Memory, Visual Processing, and Processing Speed. Both the Cognitive and Attention/Memory batteries contain five subtests that factor into the CHC broad cognitive abilities. The *Leiter-3 Manual* (Roid et al., 2013b) only provides g factor loadings for subtests. For ages 3 through 8, the average factor loadings on g for each subtest are as follows: Figure Grounds (0.66), Form Completion (0.69), Classification/Analogies (0.56), Sequential Order (0.56), and Visual Patterns (0.45). For ages 9 through 15, the average factor loadings on g for each subtest is as follows: Figure Grounds (0.70), Form Completion (0.77), Classification/Analogies (0.49), Sequential Order (0.65), and Visual Patterns (0.57). See the *Leiter-3 Examiner's Manual* (Roid et al., 2013b) for additional information regarding factor loadings on g for older age ranges.

Psychometric Properties. Internal reliability coefficients for the Nonverbal IQ Scale (r = 0.94–0.98) are more than adequate across all age groupings. The authors of this assessment tool also indicated acceptable stability across all subtests on both the Cognitive and Attention/Memory Batteries, except for the Stroop subtest (r = 0.42). Adequate criterion-related validity was noted with commonly used intelligence instruments that include both verbal and nonverbal domains (Roid et al., 2013b).

Diagnostic and Clinical Considerations

A number of factors are important to consider when selecting and interpreting intelligence tests used to evaluate children with ID. While adequate knowledge of an instrument's strengths and weakness (see Table 21.1) is important for selecting an appropriate measure, interpretation of the results requires clinical acumen that carefully considers factors that may limit the validity of the findings. Psychometric considerations that may impact the interpretation include factors related to characteristics of the norming sample. IQ estimates based on norm-referenced tests have been demonstrated to increase in relation to the age of the norming sample. In other words, as the norms get older, the mean IQ increases by several points. This psychometric phenomenon is referred to as the Flynn effect (Flynn, 1984, 1998). This factor is particularly important when selecting a test that has either been recently renormed or one that has not been revised for a number of years. Prior research exploring the

Table 21.1 Clinical implications associated with assessment instruments used to identify intellectual disabilities in children and adolescents

Assessment instrument	Strengths	Limitations
Stanford-Binet Intelligence Scales, Fifth Edition (SB5)	Early identification of developmental risk due to administration age starting at age 2 (Sattler, 2007) Low floors on most subtests allowing examiners to differentiate between subsets of low-functioning ability (Flanagan & Harrison, 2012) Appropriate normative sample of 119 individuals with ID (Roid, 2003c) Verbal and nonverbal formats for each factor measuring intelligence (g) allows for examiners to discern if language, visual, or motor impairment(s) are impacting intellectual functioning (Flanagan & Harrison, 2012)	Many subtests have a steep gradient between test items making it difficult to assess marginal progress, especially for children with low intellectual ability (Flanagan & Harrison, 2012) The SB5 has not been renormed for 15 years, which may result in a potential overestimation of one's intellectual ability related to the Flynn effect (Flynn, 1984)
Wechsler Intelligence Scale for Children, Fifth Edition (WISC-V)	Improved floors from previous edition, WISC-IV, permits examiners to identify various levels of low-functioning ability Appropriate normative sample of children and adolescents with both mild ($n = 74$) and moderate ($n = 37$) ID (Wechsler et al., 2014) Test-rest stability across subtests were reported for Mild and Moderate ID population (Canivez & Watkins, 2001; Wechsler et al., 2014) Nonverbal Index is useful to rule out a ID diagnosis in special populations such as English language learners, language impaired and autism spectrum disorder with language impairment (Mather & Wendling, 2014)	Motor demands are complex on Coding Subtest, which may underestimate a child's ability to process information Limited criterion validity studies on instruments outside of the Wechsler Scales (Sattler, 2007)
Woodcock-Johnson IV Tests of Cognitive Abilities (WJ IV COG)	Test items were added to improve floors and ceilings of this instrument (Reynolds & Niileksela, 2015) Appropriate normative sample of individuals with ID Opportunities for teaching and providing feedback on most subtests, may be useful to ensure understanding of task demands for individuals with ID (McGrew et al., 2014)	A few of the subtests (e.g., Passage Comprehension, Writing Samples, and Word Attack) have steep item gradients for younger children (McGrew et al., 2014) The technical manual does not indicate clearly whether an examiner should use the GIA or Gf-Gc composite when acquiring an estimate of general intellectual functioning. Further research is warranted to inform users of which method would be more appropriate for evaluations of intellectual disabilities (Reynolds & Niileksela, 2015)
Differential Ability Scales, Second Edition (DAS-II)	Appropriate sample population of 74 children and adolescents with mild or moderate intellectual functioning (Elliott, 2007a, 2007b) Extended norms on many of the subtests to better assess children who display low ability (Sattler, 2007) Higher internal consistency was noted for ID population ($r = 0.87–0.99$) (Elliott, 2007a, 2007b) Flexibility in using the Early Year Battery for children ages 7 through 9 with lower cognitive functioning (Flanagan & Harrison, 2012) Nonverbal composite is helpful to assess intellectual functioning in children with hearing and language impairments Test materials and manipulatives assist in retaining attention of examinees (Sattler, 2007)	The DAS-II has not been renormed for over 11 years, which may result in a potential overestimation of one's intellectual ability related to the Flynn effect (Flynn, 1984) Intellectual functioning (GCA) for ages 2 years 6 months through 3 years 5 months should be interpreted with caution since only four subtests comprise the Full-Scale IQ. The DAS-II should instead be used as a screener (Sattler, 2007)

(continued)

Table 21.1 (continued)

Assessment instrument	Strengths	Limitations
Kaufman Assessment Battery for Children, Second Edition (KABC-II)	This instrument was adequately normed on 42 children with a diagnosis of mild intellectual disability Low floors (e.g., as low as a standard score of 40 on scales) to sufficiently measure low levels of intellectual functioning There is flexibility in the response modalities (i.e., signing, writing) provided by examinees to more appropriately portray intellectual ability when individuals present with language impairments The additional nonverbal scale is intended for use to English language learners to rule out intellectual disability (Kaufman & Kaufman, 2004a, 2004b)	Complex directions can lead to difficulties with understanding task demands, especially for children with low intellectual functioning (Flanagan & Harrison, 2012)
Universal Nonverbal Intelligence Test-Second Edition (UNIT-2)	Adequate norming sample of individuals with intellectual disability High internal consistency ($r = 0.96–0.98$) across all composites and age groups of individuals with ID Subtests test items gradually increase in difficulty (Bracken & McCallum, 2016a, 2016b) This instrument is useful to rule out a ID diagnosis in special populations with communication and/or language deficits (Bracken & McCallum, 2016a, 2016b)	This instrument only measures nonverbal reasoning and memory skills Responses are limited to gestures, which can have an influence on children with severe motor impairment (Bracken & McCallum, 2016a, 2016b)
Leiter International Performance Scale-Third Edition (Leiter-3)	Adequate sample population of children and adolescents with low levels of intellectual functioning Manipulatives were redesigned in the Leiter 3 to accommodate individuals with cognitive and physical disabilities The manual discusses, in detail, adaptations for examinees with significant motor and/or communication deficits This instrument assist in measuring intellectual functioning in children with hearing and language impairments(Roid et al., 2013a, 2013b)	Due to the nonverbal nature of this instrument, verbal and communication abilities are not measured on this instrument. Further assessments measuring the above constructs are needed for a comprehensive evaluation of an individual's cognitive ability

impact of the Flynn effect on estimates of children with IQ scores in the deficient range have suggested that using a recently renormed instrument increased the percentage of children who would meet diagnostic criteria for ID by "nearly threefold" (Kanaya, Scullin, & Ceci, 2003, p. 785). These fluctuations in IQ estimates underscore the importance of using confidence intervals when interpreting test scores and considering multiple sources of data when rendering a diagnosis.

Regression to the mean is another psychometric phenomenon related to the norming sample that is important to consider in the diagnosis of ID. Regression to the mean occurs when standard scores occurring at the extreme ends of the normal curve are reassessed and demonstrate a tendency to become less extreme by moving closer to the mean. For example, an IQ score of 50 is significantly below the mean (more than 3 standard deviations) and relatively rare in that it occurs in less than 0.1% in a standard normal distribution. Extreme IQ scores, while relatively rare, are prone to move toward the mean upon reassessment. While IQ scores tend to be relatively stable over time, this phenomenon has been observed in prior research studies with ID children. Spitz (1983) found that the mean IQ scores of a group of children with ID to be 55 at age 13 and 58 at age 15. Clinically, this phenomenon becomes more important when scores are nearer to the threshold for diagnosing ID, e.g., standard scores of 70. Again, practitioners are well advised to consider this psychometric phenomenon when making clinical judgments in their work with this population.

Test construction also presents factors that must be considered in both the selection and interpretation of the results. More specifically, practitioners need to consider factors related to floor effects and test demands. Floor effects occur when an instrument does not have enough test items at the beginning of the subtest in order to yield a valid score. While issues related to floor effects are more likely to occur when evaluating younger children or individuals with lower-functioning ID (Flanagan & Alfonso, 1995), these effects limit the utility and validity of the findings. Similarly, factors related to test demands also play a role in valid interpretation of intelligence test results. For example, practitioners must take into consideration the impact the use of manipulatives (i.e., blocks) during a subtest may have on a child's performance who has motor delays or sensory deficits. In these situations, the findings are likely to underestimate intellectual ability and increase the likelihood of misdiagnosis.

It is also critically important to consider language and cultural differences as a factor that may bias test results. This goes beyond simply ensuring that the instrument has a representative norming sample. It includes considering factors that may influence the meaning assigned to information gathered from the assessment. As such, language and cultural factors are not specific to the assessment of intelligence, rather they pertain to all data collection methods being used as part of the assessment. Competency in this area requires knowledge of how language and cultural factors influence particular aspects of the assessment process in order to reduce the potential for bias. While a comprehensive overview of this topic is beyond the scope of this chapter, we will highlight those aspects most germane to the assessment of intelligence.

Research in this area that has examined the influence of language and cultural factors on psychometric properties of tests has suggested that the reliability of the instruments used are less susceptible to bias than the validity of their findings (Reynolds & Carson, 2005). More specifically, the validity of these findings is influenced most by the developmental language proficiency and the acculturative knowledge acquisition of the examinee (Ortiz, Ochoa, & Dynda, 2012). According to Ortiz (2014), "it is only the degree to which an individual possesses both age- or grade-related proficiency in the language in which the test is being administered, as well as the child's equivalent levels of opportunity for acquiring the culture-specific knowledge contained or expected by the test (as compared with individuals on whom the test was normed), that directly and profoundly affect test performance" (p. 63). While these factors are more apparent among individuals who have recently emigrated from other countries, it is relevant to note that these differences have also been observed in populations that are native to the United States, such as Native Americans (Coutinho & Oswald, 2000; Nakano & Watkins, 2013). Given the potential for obtaining lower IQ estimates due to language or cultural differences, practitioners working with diverse populations need to be cognizant of these factors when selecting and interpreting intelligence tests being used to make a diagnosis of ID.

The last factor that will be discussed relates to score variability. As noted previously, intellectual ability is typically represented by a single score or IQ estimate. In certain instances, unusual variability among the scores that make up the IQ is observed. While some score variability is relatively common in general practice, an unusual difference noted between index or subtest scores makes summarizing intellectual ability as a single score potentially misleading (Donnell, Belanger, & Vanderploeg, 2011; Hale & Fiorello, 2001). The term unusual difference refers to differences that are both statistically significant and occur rarely in the population. As a rule of thumb, differences that are both statistically significant and occur in 10% or less of the standardization sample are considered unusual (Sattler, 2007). When the IQ score is not unitary or "best measure" of intellectual ability due to unusual differences among scores, there is no clear-cut answer as to which composite score should be used in its place. The decision depends on a number of factors, some of which have already been reviewed.

The first consideration should be the instruments factor structure. Using information concerning the test's factor structure as a guide, the practitioner can identify which composite scores account for the most variance in the measurement of general intelligence. For example, in the majority of intelligence tests reviewed, measures of fluid reasoning and crystallized intelligence accounted for the preponderance of variance in the full-scale score. Therefore, examinees who present with low average scores on a particular composite such as in fluid reasoning (e.g., a standard score of 82) may not have an ID even if their full-scale IQ score was 70 due to below average scores on the other composites. Detailed information on the factor structures for the tests reviewed in this chapter has been provided for your reference. Second, prudent evidence-based practice suggests that a theoretical rationale also be used to guide decision-making (Hale & Fiorello, 2001). While the instruments reviewed vary in terms of their theoretical orientation, CHC theory is likely to provide the best option for test interpretation of scores across all of the measures reviewed (see Flanagan et al., 2013). From a theoretical standpoint, a particular pattern of score variably may be explored in order to arrive at a final diagnosis. As an example, practitioners may not consider near average processing speed to be as central to the final diagnosis as near average fluid reasoning.

Conclusions

The advancement of intelligence testing over time has played an instrumental role in shaping how ID is defined and assessed. The use of theoretical models to guide test development has become a more universally accepted practice. Nonetheless, continued research efforts are needed in order to better understand how these models will inform clinical practice and intervention planning. Throughout history, improvements in our knowledge of this construct have continued to enhance the instruments we use to measure intelligence as well as how we interpret their findings.

Selecting, using, and interpreting intellectual assessments is a multifaceted endeavor. As illustrated throughout this chapter, ID evaluations require practitioners to reflect on a number of clinical considerations. These considerations not only assist practitioners in selecting an assessment tool that is likely to yield a valid measure of intellectual functioning, but also ensure that the practitioner is using evidence-based decision-making when interpreting the findings. In closing, it is important to keep in mind that the assessment process should seldom rely solely on measurements of intellectual and adaptive functioning alone. Rather, best practice suggests that multiple methods of assessment including background information, developmental history, behavioral observations, and academic achievement should also be considered. By drawing upon multiple sources of information, the likelihood that the results will contribute to accurate diagnostic conclusions and meaningful intervention planning are increased.

Early Assessment and Tests for Adaptive Behavior

Esther Hong and Johnny L. Matson

Introduction

Individuals with intellectual disability (ID) experience deficits in intellectual and adaptive functioning across conceptual, social, and practical domains. Standardized measures of developmental and adaptive behavior have been designed to assess an individual's level of functioning across various skill domains. These measures screen for specific skill deficits and aid in the diagnostic process of ID or other developmental disabilities. The results from developmental and adaptive tests may assist parents, practitioners, and educators in making decisions regarding eligibility of services, types of services required, and level of support a child requires to function across various settings. Additionally, developmental and adaptive behavior scales can be used to monitor treatment progress and measure intervention outcomes. This chapter discusses the implications for early childhood assessment and reviews several commonly used developmental and adaptive behavior scales.

Intellectual Disability

Intellectual disability (ID) is a disorder characterized by deficits in both intellectual functioning and adaptive behavior (American Psychiatric Association [APA], 2013; American Association on Intellectual and Developmental Disabilities Association [AAIDD], 2010). Intellectual functioning is typically assessed using standardized intelligence tests, with an Intelligence Quotient (IQ) below 70 indicating impairment in intellectual functioning. However, in recent years, the construct of "intelligence" has shifted from the measurement of an individual's IQ to as a measure of an individual's adaptive functioning. As a result, the focus of a diagnosis of ID is on an individual's level of impairment in adaptive functioning rather than intellectual functioning.

Adaptive behavior is defined as "the collection of conceptual, social, and practical skills that have been learned by people in order to function in their everyday lives" (Schalock et al., 2010). Individuals with impairment in adaptive functioning demonstrate deficits across all three skill domains. Conceptual skills include skills related to academics, language, numbers, time, money, executive functioning, memory, and abstract thinking. Skills that fall under the social domain include social communication, interpersonal skills, emotion regulation, social cues, and social problem solving. The practical domain includes

activities of daily living (e.g., eating, dressing, toileting, hygiene), occupational skills, recreational skills, healthcare, safety, and vocational skills. Standardized tests of adaptive behavior are used to assess deficits in adaptive functioning.

In accordance with the Diagnostic and Statistical Manual of Mental Disorders (DSM-5; APA, 2013), the severity level of ID is determined based on the individual's overall adaptive functioning, not IQ. The severity level (i.e., mild, moderate, severe, or profound) corresponds to the level of supports that an individual requires to adequately function in daily activities, across environments. By definition, individuals with ID fail to meet the "developmental and socio-cultural standards for personal independence and social responsibility." As a result, examiners should consider cultural differences as well as the individual's community, school, and work environments during the diagnostic process.

The prevalence of ID is approximately 1% (Maulik, Mascarenhas, Mathers, Dua, & Saxena, 2011), with higher rates of ID found in low and middle-income populations. Of the individuals diagnosed with ID, the majority experience mild ID (85%), followed by moderate ID (10%), severe ID (4%), and profound ID (2%; King, Toth, Hodapp, & Dykens, 2009). The high prevalence of ID is associated with high costs, as healthcare providers, schools, and public entities provide resources and support services to individuals with ID across the lifespan. However, these costs can be mitigated by early assessment and early intervention of ID and developmental disabilities.

Early Childhood Assessment

To meet the diagnostic criteria for ID, the DSM-5 specifies that the onset of deficits in intellectual and adaptive functioning occur during the developmental period. Individuals with ID exhibit intellectual and adaptive impairments at an early age, and these impairments persist throughout their lifespan. Given the early onset of ID, the early detection and early intervention of adaptive skills is critical in improving intervention outcomes and quality of life.

Several studies have demonstrated that early intervention is effective in improving outcomes of toddlers and young children with ID and other developmental disabilities (Lovaas, 1987; Sharav & Shlomo, 1986; Smith, Groen, & Wynn, 2000). While there is heterogeneity in treatment outcomes (due to child-specific and treatment-specific factors), there is a general consensus that early intervention is effective in remediating developmental delays and reducing the developmental gap between children with ID and their typically developing peers (Guralnick, 2005). When children learn adaptive skills during the developmental period, their outcomes improve (Maulik et al., 2011).

Given the evidence-based research on early intervention and mandated early intervention services for preschool aged children (Individuals with Disabilities Education Improvement Act of 2004 [IDEIA]), there has been an increased research focus on the development and evaluation of early assessment tools to measure developmental and adaptive functioning. There is a need for standardized, valid behavior scales that accurately assess and diagnose young children with ID and other developmental disabilities. Further, the assessment measures should be sensitive enough to correctly categorized children into the different severity levels of ID.

These screening tools and behavior scales are crucial to the diagnostic process because they are objective measures of how infants, toddlers, and young children are meeting their developmental milestones. The scales capture the child's distinct abilities (i.e., strengths and weaknesses) across various skill domains, which help guide decisions regarding eligibility for special education services, classroom accommodations, support services, and intervention planning. Normative data gathered from developmental and adaptive scales also provide insight into how the child is developing in relation to their typically peers.

Developmental Scales

The assessment of developmental functioning provides valuable information on the child's current level of functioning across various developmental domains, such as language, communication, social, motor, learning ability, feeding, dressing, and toileting. The developmental scales that are discussed in this chapter have been developed in accordance with the existing literature on child development. Rather than focusing a specific child development theory, these developmental measures were designed based on the broad theoretical foundation of child development (Albers & Grieve, 2007). While these measures are used during the initial diagnostic process, they should also be administered periodically, in order to monitor treatment progress and determine if adjustments to the intervention program need to be made.

Bayley Scales of Infant and Toddler Development, Third Edition (Bayley-III)

The *Bayley Sales of Infant and Toddler Development* (*Bayley-III*; Bayley, 2006) is a comprehensive measure designed to assess the developmental functioning of infants and toddlers between the ages of 1 and 42 months. Test administration ranges from approximately 50–90 min, with testing time increasing for older children. The Bayley-III comprises five scales: Cognitive, Language (Receptive and Expressive), Motor (Fine and Gross), Social-Emotional, and Adaptive Behavior (Conceptual, Social, and Practical).

For the Cognitive, Language, and Motor domains, the examiner directly administers the items to the child. Based on the child's inability or ability to complete the tasks, the items are scored as "0" (no credit) or "1" (credit), respectively. The Cognitive scale assess for aspects of cognitive processing such as sensorimotor development, memory, object permanence, concept formation, and object relatedness. The Language scale is composed of the Receptive and Expressive Communication subtests. The Receptive Communication subscale assesses the child's ability to understand and respond to verbal stimuli and identify pictures and objects. The Expressive Communication subscale assesses for skills such as babbling, gesturing, turn taking, and naming objects and pictures. The Motor scale consists of Fine and Gross motor subscales. The Fine Motor subscale assesses for perceptual-motor integration, motor planning, motor speed, visual tracking, grasping, and functional hand skills, while the Gross Motor subscale assesses for body positioning, dynamic movement (e.g., walking, crawling, jumping, running), balance, motor planning, and perceptual-motor integration.

The evaluations for the Social-Emotional and Adaptive Behavior scales are completed by the child's primary caregiver, using parent questionnaires. The Social-Emotional scale consists of 35 items, which measure the child's social-emotional development and functioning based on his or her current age. Items are rated on a 6-point Likert scale: "0"—can't tell, "1"—none of the time, "2"—some of the time, "3"—half of the time, "4"—most of the time, or "5"—all of the time. The Adaptive Behavior scale is the broadest of the five scales and assess for the child's level of functioning across several skill areas: communication, community use, health and safety, leisure, self-care, self-direction, functional pre-academics, home living, social skills, and motor skills. Items are rated on a 4-point Likert scale: "0"—is not able, "1"—never when needed, "2"—sometimes when needed, or "3"—always when needed.

The Bayley-III has been found to have high internal consistency reliability coefficients across scales and subscales, ranging from 0.86 to 0.93. The validity of the Bayley-III was evaluated through several special group studies, which included children with Down syndrome, pervasive developmental disorders, cerebral palsy, language impairment, risk for developmental delays, prenatal alcohol exposure, and premature or low birth weight.

Bayley Scales of Infant and Toddler Development, Third Edition (Bayley-III Screening Test)

The *Bayley Scales of Infant and Toddler Development, Third Edition (Bayley-III Screening Test*; Bayley, 2006) is a screening tool that was designed to quickly assess the developmental functioning of infants and toddlers between the age of 1 and 42 months. The Bayley-III Screening Test can be administered in approximately 15–25 min, depending on the age of the child. The Bayley-III Screening test consists of three scales: Cognitive, Language (Receptive and Expressive Communication), and Motor (Fine and Gross Motor).

The test items were selected from the Bayley-III, to include the main components of the Bayley-III. As with the Bayley-III, the examiner directly administers the items to the child, and based on the child's response, items are scored as "0"—no credit or "1"—credit. The scores are calculated to assesses the level of risk the child has for developing a developmental delay. The risk categories include: At Risk, Emerging, or Competent. Scores falling within the "At Risk" range indicate that the child is at a high risk for a developmental delay, scores in the "Emerging" range indicate that the child has some risk for a developmental delay, and scores in the "Competent" range indicate that the child is at low risk for a developmental delay.

Mullen Scales of Early Learning: AGS Edition (MSEL:AGS)

The *Mullen Scales of Early Learning: AGS Edition* (Mullen, 1995) assesses for cognitive functioning in infants and young children from birth to 68 months. Test administration ranges from 15 min for children around 1 year old, 25–35 min for children around 3 years old, and 40–60 min for children around 5 years old. The MSEL:AGS comprises four cognitive scales (i.e., Fine Motor, Visual Reception, Expressive Language, and Receptive Language) and one Gross Motor scale.

The Fine Motor scale assesses the child's ability to manipulate small objects and demonstrate fine motor control and coordination. The Visual Reception scale assesses for visual processing, visual discrimination, and visual memory skills. The Expressive Language scale assesses the child's verbal response to items, verbal utterances, and concept formation (Dumont, Cruse, Alfonso, & Levine, 2000). The Receptive Language scale assesses the child's ability to respond to verbal input. Prerequisite skills are required for the child to complete to the Receptive Language scale items, as some items require the child to point or respond using one to three-word verbalizations. The Gross Motor subscale assesses a range of gross motor skills (e.g., walking, walking up the stairs) in children between the ages of 0 and 33 months. Most items on the MSEL:AGS are scored based on the examiner's observation of how the child performs a task. The point scale varies per item, from 0–1, 0–2, 0–3, 0–4, and 0–5. The scores on the four cognitive scales are summed together to provide the Early Learning Composite (ELC), which is a measure of general intelligence.

The purpose of the MSEL:AGS is to identify the strengths and weaknesses of the child and assess for early intellectual development, with percentile ranks and age equivalents provided for each of the scales. The MSEL:AGS was designed for educational purposes and can help assess a child's level of school readiness and determine the child's eligibility for intervention and/or special education services. Further, the MSEL:AGS may assist service providers and clinicians with individualized program planning (Dumont et al., 2000).

The internal reliability of the MSEL:AGS is adequate, with internal consistency reliability coefficients ranging from 0.83 to 0.95. However, the validity of the measure is questionable, as children from certain ethnic groups (i.e., African Americans, Hispanics) and socioeconomic statuses (i.e., rural communities, parental occupation) were underrepresented in the standardization sample. Further, the standardization data were collected across two different time periods. As such, the results from the MSEL:AGS should be interpreted with caution (Dumont et al., 2000). The test manual recommends that the MSEL be used in conjunction with other measures of social-emotional functioning (i.e., Vineland Social-Emotional Early Childhood Scales) in order to complete a comprehensive early childhood evaluation.

Battelle Developmental Inventory, Second Edition (BDI-2)

The *Battelle Developmental Inventory, Second Edition (BDI-2;* Newborg, 2005*)* is a comprehensive, early childhood assessment for children from birth to 7 years, 11 months of age. The BDI-2 comprises 450 items and takes 60–90 min to administer, depending on the age of the child. The BDI-2 assesses a child's strengths and weaknesses across five global developmental domains, including Personal-Social, Adaptive, Motor, Communication, and Cognitive functioning. Each domain comprises several subdomains. The Personal-Social domain includes adult interaction, peer interaction, and self-concept and social role subdomains. The Adaptive domain includes the self-care and personal responsibility subdomains. The Motor domain includes gross motor, fine motor, and perceptual motor subdomains. The Communication domain includes receptive and expressive communication subdomains. The Cognitive domain consists of attention and memory, reasoning and academic skills, and perception and concepts subdomains. Not all subdomains are administered to each child, as the subdomains are administered according to the child's current age.

Multiple methods of assessment may be used, including structured play-based activities with manipulatives, direct behavioral observations of the child, and parent/caregiver interviews. The test items are scored as either: "0"—no ability, "1"—emerging ability, or "2"—ability present. The subdomain scores are summed to provide a total domain score, and the five domain scores are calculated to provide the BDI-2 total score. The results of the BDI-2 can help determine school readiness and supplemental services.

The BDI-2 has excellent internal consistency, with reliability coefficients for BDI-2 total score ranging from 0.98 to 0.99 (Bliss, 2007). The reliability coefficients for the domain scores were also excellent; however, the Adaptive domain reliability coefficient was the lowest, at 0.80.

The BDI-2 has been found to be valid in distinguishing children with various diagnoses, such as autism spectrum disorders (ASD), developmental delays, motor delays, and speech and language delays (Bliss, 2007; Sipes, Matson, & Turygin, 2011).

Battelle Developmental Inventory Screening Test

The *Battelle Developmental Inventory Screening Test* (Newborg, 2005) is an abbreviated version of the BDI-2 and takes 10–30 min to administer. The BDI Screening Test is used to screen for deficits in developmental functioning and determine if further comprehensive assessments are needed. The BDI Screening Test comprises the same developmental domains and subdomains assessed by the BDI-2. The BDI Screening Test includes 96 items that had the highest correlation with the BDI-2 total score, with factor loading values of 0.70 and above (Bliss, 2007). As with the BDI-2, multiple methods of assessment are used, such as direct administration of the items to the child, behavioral observations of the child, or parent/caregiver interviews. Items of the BDI Screening Test are rated on the same 3-point Likert scale as the BDI-2 items. The results of the BDI Screening Test can be used to determine children who are at risk for developmental disabilities and provide an overview of the child's current level of developmental functioning.

Ages and Stages Questionnaires: A Parent-Completed Child Monitoring System, Third Edition (ASQ-3)

The *Ages and Stages Questionnaires: A Parent-Completed Child Monitoring System, Third Edition (ASQ-3;* Squires et al., 2009*)* is a screening tool that is completed by the primary caregiver. The ASQ-3 was designed to screen for developmental delays in young children ages 1–66 months, across five skill domains: Communication, Gross Motor, Fine Motor, Problem Solving, and Personal-Social. The ASQ-3 comprises 21 questionnaires, and the questionnaires are administered at designated age intervals. Each questionnaire consists of 30 items, 6 items per each of the five developmental domains. The primary caregiver rates whether their child is: able to complete the task, sometimes able to complete the task, or not yet able to complete the task.

Based on the caregiver's responses, the examiner calculates the total score for each domain. The examiner then compares the child's scores to the cutoff scores. Scores that are above the cutoff score indicate typical development; scores at or close to the cutoff score indicate that the child is functioning at 1 or 2 standard deviations below the mean and may be at risk for developmental disabilities; scores that are below the cutoff score indicate that the child is performing at 2 or more standard deviations below the mean. Children that are below the cutoff score may need further comprehensive assessment.

Reliability of the ASQ-3 was found to be adequate, with internal consistency ranging from 0.51 to 0.87 and test-retest reliability ranging from 75 to 0.82. Test validity has also been established, with high sensitivity (82.5–89.2%) and specificity (77.9–92.1%). The ASQ-3 is an evidence-based screening tool that can be used to gather comprehensive information regarding developmental functioning as well as monitor intervention progress.

Developmental Assessment of Young Children, Second Edition (DAYC-2)

The *Developmental Assessment of Young Children-Second Edition (DAYC-2;* Voress & Maddox, 2013) is a developmental measure designed to assess for developmental delays in infants and toddlers from birth to 5 years, 11 months. The DAYC-2 was originally developed in accordance with the guidelines of as specified in the federal legislation for children with disabilities (i.e., IDEIA). General developmental functioning of the following five domains are measured: Cognition, Communication, Social-Emotional Development, Physical Development, and Adaptive Behavior. If a specific skill area needs to be assessed, the domains may also be assessed independently. Administration time takes 10–20 min for each domain.

The Cognition domain assesses skills related to memory, planning, decision-making, and discrimination. The Communication domain includes Receptive Language and Expressive Language subdomains. The Social-Emotional Development domain assesses for skills related to social development, emotion regulation, and social interaction. The Physical Development domain includes Gross Motor and Fine Motor subdomains. The Adaptive Behavior domain assesses for daily living skills, self-help skills, and level of independence.

The DAYC-2 can be administered using multiple methods of assessment, including behavioral observation, structured caregiver interview, and/or direct assessment of skills. Observations of the child's behavior may be conducted in the home and/or school environment. The examiner rates each item as either "0" (i.e., the child does not exhibit the behavior; the child exhibits the behavior inconsistently) or "1" (i.e., the child exhibits the behavior most of the time; the child exhibited the behavior when he/she was younger but has outgrown the behavior). Item ratings are calculated to produce the raw scores, which are converted to standard scores, age equivalent scores, and percentile ranks. The composite score from all five domains produce the General Development Index (GDI), which represents the child's overall general development.

The DAYC-2 was found to have good reliability, with alpha coefficient values of 0.90 or greater for all five domains (Swartzmiller, 2014). The correlation coefficient for GDI was excellent, ranging from 0.98 to 0.99. The test sensitivity, specificity, and classification accuracy were found to be above 0.70 for all five domains in children with ASD, the Physical Development domain in children with physical disabilities, and the Communication domain in children with language delays. These findings suggest that for special populations, additional behavioral measures may need to be used in conjunction with the DAYC-2 in order to conduct a comprehensive assessment of developmental disabilities.

Developmental Assessment for the Severely Handicapped, Third Edition (DASH-3)

The *Developmental Assessment for the Severely Handicapped, Third Edition (DASH-3*; Dykes & Mruzek, 2012) is a criterion-referenced test that assesses a range of skills in individuals (i.e., 6 months to adulthood). The DASH-3 was designed for use with individuals with intellectual, developmental (e.g., ASD), physical, and sensory disabilities, across various impairment levels (e.g., mild, moderate, severe). The DASH-3 can be used to determine if an examinee is demonstrating the skills relevant to his or her developmental stage.

The DASH-3 comprises five scales: Sensory-Motor, Language, Social-Emotional, Activities of Daily Living, and Academics. The Sensory-Motor scale measures gross motor, sensory, reflexes, and hand skills. The Language scale assesses the individual's ability to understand and use nonsymbolic communication, expressive language, and receptive language. The Social-Emotional scale assesses social skills and measures the awareness and understanding the individual has have the self and others. The Activities of Daily Living Scales measures skills rated to independence and self-sufficiency, such as feeding, dressing, toileting, home routines, and travel and safety. The Academics scale measures the individual's ability to learn and use information related to pre-academic and academic skills (e.g., number skills, reading skills, concept formation).

The measure can be administered using multiple methods of assessment. The DASH-3 may be completed by an examiner based on a 2 to 3-h direct observation of the examinee. A time-efficient option is to administer the test by interviewing a primary caregiver, teacher, or other adult who is able to report on the examinee's abilities. Individuals may also complete the DASH-3 independently, using self-report. Items are rated on a 7-point Likert scale, with a rating of "1" indicating that the individual cannot complete the task and a score of "7" indicating that the individual can complete the task without assistance. The scale scores are summed together to estimate the examinee's overall developmental age. Examiners may also use the Intervention Planning Worksheet, to identify the developmental skill areas that require treatment, guide intervention planning, and track treatment progress over time.

A major strength of the DASH-3 is that the test was specifically designed to assess development in children with significant intellectual and developmental delays. More specifically, this measure was designed to measure discrete, fine-grained skills among individuals with lower developmental age and severely impaired functioning. This test design allows examiners to detect small behavior changes that other developmental assessment scales are not sensitive enough to capture.

Tests for Adaptive Behavior

Developmental measures are often used in conjunction with adaptive behavior measures in order to capture a comprehensive picture of the child's overall level of functioning. There are two broad types of adaptive behavior scales in the existing research: normative measures and criterion-based measures. Normative measures of adaptive functioning identify the broad skill areas in which the individual demonstrates behavioral deficits. Criterion-based measures provide a more fine-grained assessment of adaptive functioning, as they identify the specific behavioral deficits within a particular skill domain.

Even though a measure of adaptive behavior is a crucial component of the ID diagnosis, there is a dearth of research evaluating whether standardized adaptive behavior scales accurately identify individuals with ID vs. individuals without ID (Balboni et al., 2014). Out of the hundreds of adaptive behavior scales available (Schalock, 1999), only four have been standardized using a representative sample of the general population. These four behavior scales (i.e., Vineland Adaptive Behavior Scales, Third Edition, Adaptive Behavior Assessment System, Third Edition, Scales of Independent Behavior-Revised, and Adaptive Behavior Scale- School Version) are reviewed below. Despite this limitation, all of the adaptive behavior scales reviewed in this chapter were found to be psychometrically sound and were developed in accordance with the definition of ID as defined by the AAIDD, DSM-5, and federal mandates for special education and disability classification (i.e., IDEIA).

Vineland Adaptive Behavior Scales, Third Edition (Vineland-3)

The *Vineland Adaptive Behavior Scales, Third Edition (Vineland-3;* Sparrow, Cicchetti, & Saulnier, 2016) is the most commonly used measure to aid in the diagnosis of intellectual and developmental disabilities. The Vineland-3 measures adaptive functioning across the lifespan, from birth to 90 years of age. The measure comprises three, broad adaptive behavior domains: Communication, Daily Living Skills, and Socialization. The measure also includes optional Motor Skills and Maladaptive Behavior domains. The Communication domain consists of Receptive, Expressive, and Written subdomains. The Daily Living Skills domain includes Personal, Domestic, and Community subdomains. The Socialization domain includes Interpersonal Relationships, Play and Leisure, and Coping Skills subdomains. The Motor domain consists of Fine and Gross Motor subdomains. The Maladaptive Behavior domain includes Internalizing and Externalizing Behavior subdomains.

The test administration time ranges from 10 min to 60 min, depending on the type of form used. There are two forms: Comprehensive Form and Domain-Level Form. The Comprehensive Form is the full-length version that provides a more in-depth evaluation of adaptive functioning. This form produces the Adaptive Behavior Composite (ABC) score, domain scores, subdomain scores, and item scores. The Domain-Level Form is the abbreviated version of the Vineland-3 that can be used to reduce administration time. This version produces the ABC score, domain scores, and item scores. Additionally, there are multiple rater forms for both the Comprehensive and Domain-Level Forms: Interview Form, Parent/Caregiver Form, and Teacher Form.

The Interview Form is completed by the examiner using a semi-structured interview method of assessment, and the examiner rates the measure items based on the caregiver's responses. In the Parent/Caregiver Form, the primary caregiver rates each item independently. The Teacher Form is used for school-aged children between the ages of 3 and 21 years. As with the Parent/Caregiver Form, the child's teacher rates the measure items. Items are rated on a 3-point Likert scale, depending on the individual's ability to complete a task. A rating of "0" indicates that the individual is never able to perform the task, a rating of "1" indicates that the individual is sometimes able to perform the task, and a rating of "2" indicates that the individual is usually able to perform the task. Some items are rated as "yes" or "no."

Scores from the Vineland-3 meet the AAIDD and DSM-5 requirements for the diagnosis of ID. The previous version of the Vineland-3, the Vineland-II (Sparrow et al., 2005), has been found to accurately classify 71–100% children (i.e., 6–18 years old) and 97–100% of adults (19–86 years old) into the different severity levels of ID (i.e., mid, moderate, severe, and profound). Results from the Vineland-3 may help determine eligibility for special services and aid in intervention program planning. Further, the Vineland-3 can be used to assess adaptive behavior in individuals with ASD, attention deficit hyperactivity disorder, post-traumatic brain injury, hearing impairment, and dementia or Alzheimer's disease.

Adaptive Behavior Assessment System, Third Edition (ABAS-3)

The *Adaptive Behavior Assessment System, Third Edition* (*ABAS-3;* Harrison & Oakland, 2003) is a behavior rating scale used to assess for adaptive behavior in individuals from birth to 89 years of age and can aid in the diagnosis of various developmental disabilities, learning disorders, and behaviors disorders. The ABAS-3 assesses three adaptive domains: Conceptual, Social, and Practical. The domains include 11 subdomains: communication, community use, functional academics, health and safety, home or school living, leisure, motor, self-care, self-direction, social, and work. There are several rating forms; (1) Infant and Preschool: Parent/Primary Caregiver Form (rated by the primary caregiver, for children 0–5 years); (2) Infant and Preschool: Teacher/Daycare Provider Form (rated by the teacher, for 2–5 years); (3) School: Parent Form (rated by the primary caregiver, for children 5–21 years); (4) School: Teacher Form (rated by the teacher, for children 5–21 years); (5) Adult Form (rated by self or primary caretaker, for individuals 16–89 years).

The ABAS-3 takes approximately 15–20 min to complete. Raters provide a frequency rating and an ability rating based on a 4-point Likert scale. Raw scores are converted to scaled scores. Each subdomain scaled score is then summed to produce the composite score and percentile ranks for each of the three adaptive domains. Finally, the domain composite scores are added together to produce the General Adaptive Composite (GAC) score. There is also an option to compare ratings across different respondents (e.g., between parent and teacher).

The standardization sample for the ABAS-3 included typically developing individuals as well as individuals with mild disabilities, across all ages. The reliability coefficients for the three adaptive domains were above 0.85 and the reliability coefficients for GAC were excellent, ranging from 0.96 to 0.99. In the sample of individuals with disabilities, the reliability coefficient for GAC was 0.99 and the reliability coefficients for the adaptive domains ranged from 0.96 to 0.99.

Scales of Independent Behavior-Revised (SIB-R)

The *Scales of Independent Behavior-Revised (SIB-R;* Bruininks, Woodcock, Weatherman, & Hill, 1996) was designed to measure adaptive functioning and functional independence for individuals 3 months to 80+ years. The SIB-R evaluates four adaptive skill areas: Motor Skills, Social Interaction and Communication, Personal Living Skills, and Community Living Skills. The adaptive domains are further divided into the following 14 subdomains: Gross Motor, Fine Motor, Social Interaction, Language Comprehension, Language Expression, Eating and Meal Preparation, Toileting, Dressing, Personal Self-Care, Domestic Skills, Time and Punctuality, Money and Value, Work Skills, and Home/Community Orientation. An optional Problem Behavior scale may also be administered. The Problem Behavior scale includes 3 maladaptive domains (i.e., Internalized, Externalized, Asocial), which include the following 8 subdomains: Hurtful to Self, Hurtful to Others, Unusual or Repetitive Habits, Withdrawal or Inattentive Behavior, Socially Offensive Behavior, Uncooperative Behavior, Destructive to Property, and Disruptive Behavior.

The SIB-R is administered to the primary caregiver using a semi-structured interview format or as a respondent checklist. There are three different forms available. The Full Scale Form is a comprehensive evaluation that assess all 14 adaptive behavior subdomains. It consists of 259 items and takes approximately 60 min to complete. The Short Form is used as a screening tool and comprises 40 items from the Full Scale SIB-R. The Early Development Form was designed to be used with young children or individuals with a developmental age under 8 years. The Short Form and Early Development Form take approximately 15–20 min to complete.

The Adaptive Behavior items are rated on a 4-point Likert scale, based on the degree to which the individual completes a task without help or supervision. A rating of “0” indicates that the individual never or rarely is able to do the task, even if asked; “1” indicates that the individual does not perform the task well and may need to be asked to do the task 25% of the time; "2" indicates that the individual does the task fairly well and does the task 75% of the time when asked; "3" indicates that the individual does the task very well always or almost always, without being asked. The Problem Behavior scale items are rated on frequency and severity of the behavior. Frequency of the behavior is rated as: "1"—occurs less than once a month; "2"—occurs 1–3 times per month; "3"—occurs 1–6 times per week; "4"—occurs 1–10 times per day; "5"—occurs 1 or more times per hour. Severity of the behavior is rated as: "0"—not serious, not a problem; "1"—slightly serious, mild problem; "2"—moderately serious, moderate problem; "3"—very serious, severe problem; "4"—extremely serious, critical problem. The ratings are calculated to produce a Broad Independence Score, Relative Mastery Indexes (RMI), Support Score, age equivalents, and percentile ranks. The Support Score estimates the level of support score an individual will require (i.e., pervasive to infrequent support, no support) based on individual's current adaptive functioning and frequency and severity of problem behaviors. Higher scores indicate that an individual is functioning with more independence.

The SIB-R has demonstrated adequate test sensitivity and specificity, as 76% of the standardization sample were correctly classified into their respective ID severity groups (i.e., mild, moderate, non-ID). Specifically, 51% of individuals with mild ID were accurately identified, 74% of individuals with moderate ID were accurately identified, and 82% of individuals without ID were accurately identified.

AAMD Adaptive Behavior Scales (AAMD ABS)

The *AAMD Adaptive Behavior Scales (AAMD ABS)* was first published in 1969, following the inclusion of adaptive behavior in the definition of the former "mental retardation" diagnosis (Hopp & Baron, 2011). Since then, the AAMD ABS has undergone several revisions. The AAMD ABS has two versions, the Adaptive Behavior Scales-Residential and Community, second edition (ABS-RC:2; Nihira, Leland, & Lambert, 1993) and the Adaptive Behavior Scale- School, second edition (Lambert, Nihira, and Leland, 1993).

The ABS-RC:2 is used to assess adaptive behavior in residential and community settings, in individuals from birth to 79 years of age. Part One of the ABS-RC:2 comprises 10 domains: Independent Functioning, Physical Development, Economic Activity, Language Development, Numbers and Time, Domestic Activity, Prevocational/Vocational Activity, Self-Direction, Responsibility, and Socialization. Part Two assesses for Social Adjustment (i.e., Social Behavior, Conformity, and Trustworthiness) and Personal Adjustment (i.e., Stereotyped and Hyperactive Behavior, Sexual Behavior, and Self-Abusive Behavior). Each domain includes subdomains that assess for specific skill areas. For the domains included in Part One of the ABS-RC:2, raw scores can be converted to standard scores, percentile ranks, and age equivalents.

The ABS-S:2 is used to assess adaptive behavior in school settings, in children between the ages of 3 and 21 years. Part One comprises nine domains (i.e., Independent Functioning, Physical Development, Economic Activity, Language Development, Numbers and Time, Prevocational/Vocational Activity, Self-Direction, Responsibility, and Socialization) and 18 subdomains. Part Two comprises seven domains: Social Behavior, Conformity, Trustworthiness, Stereotyped and Hyperactive Behavior, Self-Abusive Behavior, Social Engagement, and Disturbing Interpersonal Behavior.

The ABS-RC:2 and ABS-S:2 can be completed by the examiner or by the primary caregiver. Some items are rated on a 3-point Likert scale, with "0" indicating the least amount difficulty with the item and "3" indicating the most amount difficulty with the item. Other items are rated as frequency of behavior, with "N" indicating that the individual never engages in the behavior, "O" indicating that the individual occasionally engages in the behavior, or "F" indicating that the individual frequently engages in the behavior. Some items are rated as "yes" or "no."

The standardization sample for the ABS-RC:2 included individuals with unspecified developmental disabilities in the United States. Individuals included in the standardization sample also had disabilities such as blindness, deafness, learning disability, and speech/language impairments. The reliability coefficient of the ABS-RC:2 was found to range from 0.80 to 0.99. The ABS-S:2 was standardized on individuals with and without ID in the United States. The reliability coefficient of the ABS-C:2 was found to be around or above 0.90. Criterion and content validity were found to be adequate for both versions.

Diagnostic Adaptive Behavior Scale (DABS)

The *Diagnostic Adaptive Behavior Scale (DABS;* Tasse et al., 2012) is a comprehensive standardized assessment of adaptive behavior designed for individuals between the ages of 4 and 21 years. The DABS measures adaptive behavior in the Conceptual, Social, and Practical domains. The Conceptual domain includes skills such as literacy, self-direction, and number concepts, time concepts. The Social domain includes interpersonal skills, social responsibility, self-esteem, following rules, gullibility, and following social rules. The practical skill includes skills related to daily living (i.e., self-care), safety, healthcare, use of money, and occupation skills.

The DABS is administered using an interview format, in which the examiner asks the primary caregiver to rate the individual's ability to perform the task item. Each domain consists of 25 items, and each item is rated on a 4-point Likert scale. A score of "0" indicates that the individual is rarely or never able to do the task and a score of "3" indicates that the individual always or almost always independently does the task. The three domain scores are calculated to produce an Overall Adaptive Behavior Standard Score (OABSS). Scaled scores that are 2 standard deviations below the mean indicate that individuals demonstrate "significant limitations" of adaptive functioning and indicate that a diagnosis of ID or other related developmental disability may be warranted.

The standardization sample for the DABS included individuals with formal diagnoses of ID or developmental delay, individuals without deficits in adaptive behavior, and individuals with disorders not related to ID (e.g., learning disability, ADHD). The DABS was found to accurately identify 81%–98% of individuals with ID and 89%–91% of individuals without ID. Further, the DABS demonstrated good to excellent accuracy in differentiating among the different severity levels of ID (i.e., mild, moderate, severe and profound). A limitation of the DABS is that it does not provide a detailed assessment of specific skill areas. As such, the test authors recommend that the DABS should not be used for treatment planning or to monitor specific intervention areas (Balboni et al., 2014).

Adaptive Behavior Evaluation Scale, Third Edition (ABES-3)

The *Adaptive Behavior Evaluation Scale-Revised (ABES-R;* McCarney & House, 1995) is an adaptive behavior rating scale that was designed to screen for adaptive functioning in educational and residential settings. The ABES-R is used to screen for deficits in specific skill areas, identify areas that require support, and aid in the diagnosis of ID, learning disabilities, behavior disabilities, and other developmental delays. In accordance with the AAIDD definition of adaptive behavior, the ABES-R assesses adaptive skills across the Conceptual, Social, and Practical domains. These three domains include 10 subdomains: Communication, Self-Care, Home Living, Social, Community Use, Self-Direction, Health and Safety, Functional Academics, Leisure, and Work.

There are two versions of the ABES-R: the home version (HV), which is completed by the parent or primary caregiver and school version (SV), which is completed by the teacher. Raters rate each item based on direct observation of the individual's behaviors. The ABES-R is further divided by age group. The ABES-3:4–12 HV and ABES-3:4–12 SV are used to assess children between 4 and 12 years old. The ABES-3:13–18 HV and ABES-3:13–18 SV are used to assess adolescents between 13 and 18 years old. All versions of the ABES-R comprise 104 items and take 15–20 min to complete. Raters rate each item based on a 6-point Likert scale: "0" indicates that the skill is not developmentally appropriate for the individual's age, "1" indicates that the individual does not demonstrate the skill, "2" indicates that the individual is developing the skill, "3" indicates that the individual demonstrates the skill inconsistently, "4" indicates that the individual demonstrates the skill most of the time, and "5" indicates that the individual consistently demonstrates the skill at all times. If the rater has not had an opportunity to observe a particular skill, they may consult with another caretaker or educator who is able to rate the item. The ratings are calculated to produce an Adaptive Skills Quotient (ASQ), which represents a general measure of the individual's adaptive functioning.

Adaptive Behavior Inventory (ABI)

The *Adaptive Behavior Inventory (ABI;* Brown & Leigh, 1986*)* was designed to assess daily living skills in school-aged children between 6 and 18 years old. This measure can be used as a diagnostic tool to identify children with intellectual, developmental, or other emotional disabilities. The ABI is composed of 5 subscales: Self-Care Skills, Communication Skills, Social Skills, Academic Skills, and Occupational Skills. The Occupational Skills domain may be omitted for very young children or children with severe skill impairments.

The ABI was designed to be completed by the child's classroom teacher or other professional staff who has relevant knowledge of the child adaptive abilities. The ABI takes about 30 min to complete and comprises 150 items, with approximately 30 items per subscale. A Short Form is also available for screening or research purposes. The ABI-Short Form comprises 50 items and takes 5–10 min to complete. Test items are rated on a 4-point Likert scale: "0" indicates that the child does not perform the skill, "1" indicates that the skill is emerging, "2" indicates that child performs the skill most of the time, and "3" indicates that the child has mastered the skill. Subscale items are calculated to produce an Adaptive Behavior Quotient and percentile ranks.

The ABI was standardized using a sample of students with and without intellectual disabilities. However, the test has not been revised since its publication in 1986, and the ABI may need to be re-normed. Nevertheless, test reliability of the ABI has been demonstrated, with subtest-by-age reliability coefficients ranging from 0.86 to 97. The reliability coefficient of the Adaptive Behavior Quotient was found to exceed 0.90 for all age groups.

Checklist of Adaptive Living Skills (CALS)

The Checklist of Adaptive Living Skills (CALS; Bruininks & Morreau, 2004) is a criterion-referenced behavior scale that was designed to assess adaptive living skills in individuals with or without ID, from infancy to adulthood. The CALS is compose of 800 specific behavior items, which are categorized into four broad adaptive domains: Personal Living Skills, Home Living Skills, Community Living Skills, and Employment Skills. These domains are further divided into 24 subdomains.

Total administration time of the CALS is 60 min; however, if there are concerns regarding specific areas of adaptive functioning, the CALS can be administered at the domain level. Caregivers rate each item based on the individual's ability to complete the task independently. Additionally, items are rated according to the type of prompting the individual requires to complete the task (i.e., gestural, verbal, physical). Based on the informant's response, a prompting score of "independent performance,"

"performance with prompt," or "nonperformance" are produced.

The CALS was designed to be used in conjunction with the Adaptive Living Skills Curriculum (ALSC; Bruininks, Morreau, Gilman, & Anderson, 2004), to integrate assessment and treatment of adaptive skills. Each item on the CALS is categorized by domain, subdomain, and item number, which corresponds with a specific instructional item on the ALSC. This integrated approach to assessment helps guide the intervention planning process by identifying the specific treatment targets that are associated with the individual's skill deficits. Further, the CALS and ALCS can be used to identify treatment goals and determine mastery of targeted behaviors.

Children's Adaptive Behavior Scale, Revised (CABS-R)

The *Children's Adaptive Behavior Scale, Revised* (*CABS-R*; Kicklighter & Richmond, 1983) is an adaptive behavior measure that was specifically designed to assess adaptive functioning of children (5–11 years old) in the school setting. The CABS-R evaluates five areas of adaptive functioning: Language Development, Independent Functioning, Family Role Performance, Economic-Vocational Activity, and Socialization. Each domain is composed of 16 to 30 items.

The CABS-R differs from the other measures of adaptive behavior described in this chapter because it is administered directly to the child, in the educational setting. The total test administration time is approximately 45 min, as the child is required to respond to all test items. This unique method of assessment inevitably limits the range of children that can be evaluated using the CABS-R. The CABS-R is likely not appropriate for administration with children with limited nonverbal and/or verbal skills, certain medical conditions, cognitive impairments, and developmental delays. In response to these limitations, the test authors recommend that examiners corroborate the child's responses with another individual who is familiar with the child's level of adaptive functioning. Additionally, the test authors suggest that other measures of adaptive behavior be used to supplement the CABS-R and get a comprehensive picture of the child's overall adaptive functioning. However, these recommendations challenge the uniqueness of the CABS-R and have implications for inter-rater reliability of responding between the child and other adult.

Survey of Functional Adaptive Behaviors

The *Survey of Functional Adaptive Behaviors (SFAB*; Dial, Mezger, Massey, Carter, & McCarron, 1986) is a rating scale that was designed to assess adaptive skills in individuals 16 years old and older. The SFAB is composed of 135 test items, which are categorized into four adaptive skill areas: Residential Living Skills, Daily Living Skills, Academic Skills, Vocational Skills. The Residential Living Skills domain evaluates self-care and home management skills. The Daily Living Skills assesses skills related to money management, travel, and community resources. The Academic Skills domain assesses skills related to language, literacy, writing, and number concepts. The Vocational Skills domain evaluates the individual's physical abilities and skill related to vocational tasks.

The SFAB can be completed using multiple methods of administration, including case history review, interview, and/or direct behavioral observation. Test items are rated as: "0"—task not performed, "1"—task performed inadequately or requires assistance, prompting, or cueing; "2"—task performed independently. The scores are calculated to produce a Total Adaptive Behavior score. However, the results should be interpreted with caution, as there is a lack of research evaluating the interpretability of the test findings. As such, it would be beneficial to use the SFAB as a screening tool rather than as a diagnostic tool.

Conclusions

With increased recognition that early intervention is crucial in remediating developmental delays in young children, there has been an increase in research evaluating the efficacy of developmental behavior scales to accurately assess developmental delays in young children. Broadly, these developmental skill areas include language, communication, motor, social, and adaptive skills. Adaptive behavior scales are often used in conjunction with developmental scales to provide a more fine-grained assessment of a child's adaptive skills within conceptual, social, and practical domains. This chapter discussed several developmental and adaptive behaviors scales that have been designed to screen for developmental delays and aid in the early diagnosis of ID or other developmental disabilities. Further, many assessment measures that were reviewed in this chapter have been found to reliably measure developmental delays across the lifespan, from infancy to adulthood. Additionally, these measures offer multiple methods of assessment, so test administration can be modified according to the availability of time and resources. Administration of developmental and adaptive behavior scales is a critical first step in the early diagnosis of ID and developmental disabilities. These tools should also be administered periodically to guide intervention planning, determine the types and level of support services required, and monitor treatment progress, in order to optimize treatment efficacy and improve learning outcomes.

Tests for Dual Diagnosis

23

Carmen Vargas-Vargas, Anna Costa-Vargas, and Dunia Montalvo-Pérez

Introduction

Before 1970, researchers believed that people with intellectual disabilities (ID) were unable to experience emotional and psychopathologic disorders due to insufficient strength of the ego (Deb, Thomas, & Bright, 2001). However, this point of view has been disappearing for the last decades, since researchers have demonstrated that not only can they experience associated psychopathologic disorders, but also have a bigger risk of having them in comparison with the general population (Borthwick-Duffy, 1994). Due to this high prevalence of detected psychopathologic disorders, it has become a much-studied area. A great number of researchers have provided proof that people with ID are more likely to have associated psychopathologic disorders, when compared with the general population (Cherry, Penn, Matson, & Bamburg, 2000; Matson & Bamburg, 1998).

The development of psychometric tests to evaluate the mental health of these people has been a well-established area of investigation. Its growing expansion has allowed great advances in the last four decades, with the emergence of a large number of evaluation instruments for both adults and children, some of them widely studied both in North America and in Europe (Matson, Belva, Hattier, & Matson, 2012).

The identification of mental disorders in these people is frequently complicated, seeing as they often have difficulty communicating the symptoms (Konstantareas & Hewitt, 2001). Some of these complications include expression and comprehension problems, as well as a smaller level of introspection that may influence their description or recognition.

The lack of adequate instruments makes it necessary to use complementary materials (alternative communication systems) and to be flexible (regarding the place of evaluation, its duration, the language used, etc.).

In addition to the previously stated, there is a frequent occurrence of what is commonly known as "diagnostic eclipse" (Reiss, Levitan, & Szyszko, 1982). This is a phenomenon in which the mental health disorder is not diagnosed or is not accurately so, since the tendency is to attribute all behavioral or cognitive change to the condition of the person with ID and not to a possible associated psychopathology.

Fortunately, today, the recognition of the rights of people with ID to adequate medical attention according to the normalization principles, which

ensure that people with disabilities have a right to live in a community and use their resources, and force an improvement of the skills to detect and diagnose mental disorders.

It is necessary to have information from carers, people with direct contact or relatives as the closest key informants. These are important pieces to the diagnosis. A precise diagnosis allows an adequate treatment (Deb et al., 2001).

The interest for instruments designed to assess psychopathology in people with ID is not only growing but has also had repercussions in the way treatment is administered. Despite the creation of several scales to evaluate the presence of co-occurring psychopathologic disorders in these individuals, some of these instruments were barely studied (Matson et al., 2012).

It was the investigations in the 1980s, specifically, that allowed the community to recognize the need to develop mental health scales specific to this population. The first evaluation instrument developed, the Psychopathology Instrument for Mentally Retarded Adults (PIMRA) which evaluates people with severe and profound ID (Kazdin, Matson, & Senatore, 1983), appeared as a psychopathologic tool specific for adults with ID. This scale is still generally used and has been translated to several languages. This was followed by other scales, including the Reiss Screen, as well as by the diagnosis evaluation measures for people with severe disabilities.

The clinical work and the investigation regarding ID and dual diagnosis were mainly based on investigation derived from general population. Several scales of clinical assessment were developed from the general population and were adapted for use in people with ID.

Recognizing the diagnosing problems that the health professionals face when trying to achieve a diagnostic evaluation in this area, the National Association for the Dually Diagnosed (NADD), in association with the American Psychiatric Association (APA), created the *Diagnostic Manual—Intellectual Disability (DM-ID): A Textbook of Diagnosis of Mental Disorders in Persons with Intellectual Disability* (Fletcher, Barnhill, Mccarthy, & Strydom, 2016).

The DM-ID was designed as a complement to the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR). This manual serves as a guide for the evaluation and diagnosis of specific disorders in people with ID and offers information on how to recognize the problematic behaviors, as well as on how to differentiate them from psychopathology. Regarding this, it has been observed that mental health symptoms are, originally, not related to environmental factors and that, conversely, challenging behaviors tend to be independent from the psychopathology and are in large measure determined by environmental factors (Matson & Shoemaker, 2011).

People with ID have cognitive and communicational difficulties, and therefore may not be capable of giving direct information regarding their psychopathologic problems. This makes evaluating them difficult and forces the professionals to deeply investigate the diagnosis bases and to be up-to-date on the advances and developments of the instruments in use. Therefore an adequate evaluation and intervention is required, given that mental health problems cause social exclusion. Current laws protect people with ID and require that they are adequately studied, including their mental health, so that the interventions are appropriate. In this context, the psychopathologic tools are useful and necessary to the clinical evaluation, but if they are used without proper validity and psychometric reliability then they have failed in the identification of the psychopathologic disorders and, consequently, have failed to provide an effective treatment.

Although there are several tools available for a general psychopathologic evaluation, their validity for patients with ID is questionable, since many of those tools were standardized for people without ID and make no reference to the way the examiner must evaluate this population (Kishore, Nizamie, & Nizamie, 2010). Currently, there are multiple psychometric scales that evaluate psychopathology in these people; however, the number of adapted and validated tools is scarcer (Matson et al., 2012).

Description of the Instruments

Tools for the psychopathologic evaluation of people with ID have existed for decades, and a large number of standardized tests have been developed so far. Most of these can be completed in 15–30 min, and are designed to allow the detection of multiple psychopathologic disorders (Matson & Shoemaker, 2011). The tools detailed in this chapter are the most commonly used and with a larger scientific follow-up according to the available literature.

We also included others that need further investigation, as well as some that are still expanding. A mention is made regarding some that have marked history, allowing for the evolution and development of other psychometric instruments that still exist.

We have grouped the different instruments into two main types: (1) ***General psychopathologic tools*** (Table 23.1) and (2) ***Specific psychopathologic tools*** (Table 23.2). Within the specific ones there are three different groups: (A) *Anxiety disorders and depression*, (B) *Dementia* and (C) *Autism spectrum disorders*.

The first deal with how to detect possible psychopathologic diagnosis associated with ID, cover a large range of mental disorders and are based essentially on criteria from the current diagnosis manuals (DSM-III-R, DSM-IV-TR), where the factor analysis is the main method of establishing diagnostics categories. Thanks to these criteria there are a good number of well-established evidence. The second group assesses specific mental disorders. The ones described here are the most widely studied, deriving from more current evidence-based investigation that assesses the diagnostic of a concrete psychopathologic disorder in people with ID. In many cases, these presuppose a follow-up beyond the more general evaluation instruments.

General Psychopathologic Tools

We detail the first scales of clinical evaluation used as general psychopathology measures for the dual diagnosis of people with ID. These were the first tools to be developed and then used as a foundation for the latter unfolding of specific scales.

Table 23.1 General psychopathological scales

Abbreviation	Instrument name	Year	Authors
ABCL	Adult behavior checklist	2003	Achenbach et al.
ADD	Assessment of dual diagnosis	1988	Matson et al.
BSI	The brief symptom inventory	1983	Derogais
CBCL	Child behavior checklist	1983	Achenbach et al.
DASH-II	Diagnostic assessment for the severely handicapped	1991	Matson et al.
DBC	Developmental behavior Checklist	1995	Einfeld et al.
N-CBRF	Nisonger child behavior rating form	1996	Aman et al.
PAID	Psychopathology checklists for adults with intellectual disability	2007	Hove et al.
PAS-ADD	Psychiatric assessment Schedules for adults with developmental disabilities	1993	Moss et al.
PIMRA	Psychopathology instrument for mentally retarded adults	1984	Matson
RSMB	Reiss screen for maladaptive behavior	1987	Reiss

Adult Behavior Checklist (ABCL)

Author(s) and year: Achenbach et al., 2003.

Provenance/adaptations: USA. The ABCL follows the Aberrant Behavior Checklist (ABC) (Aman, Singh, Stewart, & Field, 1985), which in turn follows the Adaptive Behavior Scale (ABS) (Nihira, Foster, Hellhaas, & Leland, 1975). The ABS was the first adaptive behavior scale, important for the development of other scales that assess nonadaptive behavior.

Usage: The ABC was not specifically designed for people with ID. It was later used in people with moderate to profound ID and, after that, in a sample of people with an limit- or low-intelligence quotient without apparent loss of the psychomet-

Table 23.2 Specific psychopathological scales

Abbreviation	Instrument name	Year	Authors
Anxiety disorders and depression			
ADAMS	Anxiety, depression, and mood scale	2003	Esbensen et al.
BDI-II	Beck depression inventory	1978	Beck
GAS-ID	Glasgow anxiety scale for people with an intellectual disability	2003	Midham et al.
GDS-LD	Glasgow depression scale for people with a learning disability	2003	Cuthill et al.
SAS	Zung self-rating anxiety scale	1971	Zung
SAED	Scheme for appraisal of emotional development	1990	Dosen
MIPQ	The mood interest & pleasure questionnaire	2003	Ross et al.
Dementia			
ABDQ	The adaptive behavior dementia questionnaire	2004	Prasher et al.
CAMDEX-DS	The Cambridge examination for mental disorders of older people with Down's syndrome and others with intellectual disabilities	2004	Ball et al.
DMR	Dementia questionnaire for persons with mental retardation	1992	Evenhuis
DRS	Dementia rating scale	1976	Mattis et al.
DSQIID	Dementia screening Questionnaire for individuals with intellectual disabilities	2007	Deb et al.
G-DSDS	Gedye dementia scale for Down syndrome	1998	Gedye
NTG-EDSD	National task group—Early detection screen for dementia	2013	Esralew et al.
Autism spectrum disorders			
ADI-R	The autism diagnostic interview—Revised	1994	Lord et al.
ACL	Autism checklist	2014	Sappok et al.
ADOS	Autism diagnostic observation schedule	2000	Lord et al.
ASD-DA	Autism spectrum disorders—Diagnosis for intellectually disabled adults	2008	Matson et al.
CARS	Childhood autism rating scale	1980	Schopler et al.
DiBAS-R	Diagnostic behavioral assessment for autism spectrum disorder—Revised	2014	Sappok et al.
PDD-MRS	Pervasive developmental disorder in mentally retarded persons	2005	Kraijer et al.
SCQ	Social communication questionnaire	2003	Rutter Bailey et al.

ric integrity of the scale (Rojahn & Helsel, 1991). There is also a new version (ABC-Community), destined for people inserted in the community. This was considered adequate for the age group of 18–59 years old.

Evaluators: Proxy informant.

Duration of test: Indeterminate.

Objective: To assess the psychopathology in adult population with ID and its severity.

Dimension/score: The ABCL (Achenbach & Rescorla, 2003) contains 118 behavioral issues and is scored in a three-level classification scale: *1—Not certain*; *2—Somewhat or sometimes true*; and *3—Very certain or true*. With the analytical factor methods, it is possible to distinguish eight syndromes according to the subscales: *1—Anxious-depressive*; *2—Withdrawnness*; *3—Somatic complains*; *4—Thought problems*; *5—Attention problems*; *6—Aggressive behavior*; *7—Disruptive behavior*; and *8—Intrusive behavior*. Besides these, two wide-reaching syndrome systems, labeled "Internalization" and "Externalization," were identified following the analysis of second order factors.

Antecedents/description: This is not the first instrument developed for general population used in people with ID, since the vast majority come from use in general population. The scale, complemented with proxy informants rather than being self-informed, is made potentially adequate for the evaluation of psychopathology in adults with ID.

Validity: Its factorial structure has been confirmed by several authors, demonstrating its ability to be sensitive to behavioral changes in most studies that measured the effects of the treatment (Aman et al., 1985). Tenneij's study (Tenneij & Koot, 2007) examined the reliability and validity of the scale with 124 adults with mild ID. Inter-rater reliability was good and DSM-IV-TR criteria for particular disorders correlated well with corresponding disorders on the ABCL.

Assessment of Dual Diagnosis (ADD)

Author(s) and year: Matson et al., 1998.

Provenance: USA.

Usage: Adults with mild and moderate ID.

Evaluators: Proxy informant.

Duration of test: 20 min.

Objective: To detect psychopathologic disorders in people with ID.

Dimension/score: It is composed of 79 items and is a screening instrument. The items are related to the DSM-IV criteria. It contains 13 subscales: *1—Mania*; *2—Depression*; *3—Anxiety*; *4—Post-traumatic stress disorder*; *5—Substance abuse*; *6—Somatoform disorder*; *7—Dementia*; *8—Behavioral disorder*; *9—Generalized developmental disorder*; *10—Schizophrenia*; *11—Personality disorder*; *12—Eating disorder*; and *13—Sexual disorders*. It evaluates the frequency, duration and severity of the symptoms, with an emphasis on those detected in the month previous to the evaluation.

Antecedents/description: The ADD has developed according to reported symptoms by the clinical investigation of people with mild or moderate ID. The items that make up the scale derive from the DSM-IV, as well as from published studies with this population (Aman et al., 1985). Through this scale it was possible to find a larger rate of psychopathology in people with mild or moderate ID, in comparison to people with severe and profound ID (Matson & Bamburg, 1998).

Validity: Convergent validity was obtained for the ADD with other well-established evaluation instruments of psychopathology in the population with ID, including the Psychiatric Assessment Schedules for Adults with Developmental Disabilities—short version (Mini-PAS-ASS), the Diagnostic Assessment for the Severely Handicapped (DASH-II) and the Reiss Screen (Myrbakk & von Tetzchner, 2008). These authors evaluated 17 adults with all levels of ID and realized these scales assessed different aspects of the psychopathology and that, along with behavior disorders, it occurs with high percentages. There are few recent studies that prove its validity and reliability.

The Brief Symptom Inventory (BSI)

Author(s) and year: Derogatis, 1983.

Provenance: USA.

Usage: Hospitalized psychiatric patients or outpatients over the age of 13.

Evaluators: Proxy informant.

Objective: To provide a brief description of the symptoms and their intensity in patients with psychologic and psychiatric treatment. It can also provide information in different moments of the treatment.

Dimension/score: The scale is a general screening tool that has been widely used in general psychiatry, and has 53 items that encompass nine symptomatic dimensions: *1—Somatization*; *2—Obsessive-compulsive*; *3—Interpersonal sensitivity*; *4—Depression*; *5—Anxiety*; *6—Hostility*; *7—Phobic anxiety*; *8—Paranoid ideation*; and *9—Psychoticism*. It has a self-informed version.

Antecedents/description: Several studies showed that the BSI had an adequate internal consistency for general population, with alphas from 0.71 to 0.85, and four of the nine scales had an alpha score of 0.80. The BSI also had an adequate validity in its construction, with a nine-factor structure (Derogatis, 1983).

Validity: The study led by Kellet (Kellett, Beail, & Newman, 2003), the first to use this instrument for people with mild ID, evaluated the brief use of this instrument where each element is classified in a 5-points Likert scale. The results suggest that the BSI has a practical use and adequate validity and internal consistency (Cronbach's alpha between 0.63 and 0.7). The use of the normal varimax method of rotation obtained a derivation in eight interpretable factors and a high level of overlapping with the existent factorial structure. Another study, by Wieland (Wieland, Wardenaar, Fontein, & Zitman, 2012), applied to outpatients with ID, obtained an adequate internal consistency, supporting its usage. Nonetheless, it is one of the instruments with the lowest number of validity and reliability studies (Matson et al., 2012).

Child Behavior Checklist (CBCL)

Author(s) and year: Achenbach et al., 1983.

Provenance: Vermont, USA.

Usage: Children and, later, children with ID.

Evaluators: Proxy informant.

Duration of test: Indeterminate.

Objective: This instrument is heavily used to evaluate psychopathologies in children in general. Given its acceptance, its use in children with ID is not surprising.

Dimension/score: Achenbach and Edelbrook's (1983) CBCL has eight scales: *1—Aggressive behavior*; *2—Anxiety*; *3—Depression*; *4—Attention problems*; *5—Disruptive behavior*; *6—Somatic complaints*; *7—Social problems*; and *8—Alterations of thought*.

After 2001, it also includes a set of scales based on the DSM-IV according to items of the diagnosing criteria for said disorders. It also uses a normative sample to create standard scores. These are set where 50 is the age and gender average of the child, with a standard deviation of 10 points. Any score below percentile 93 is considered normal, scores between percentiles 93–97 are clinically borderline, and any score above percentile 97 is in the clinical range.

Antecedents/description: It is a widely used scale to identify problematic behavior in child and juvenile populations, and has a school-age version divided in groups of 6–10-year-olds and 11–18-year-olds. It has been translated to over 90 languages and includes normative data, including information from multiple societies. Due to the addition of a basic set of items since the 1980s, the scale provides a good measure for mental health and behavioral problems.

Validity: The psychometric properties have been proven in several studies, but the results do not confirm the factors established in previous studies in children without ID. Some authors (Embregts, 2000) point out poor psychometrics. Karen P. de Ruiter study's (de Ruiter, Dekker, Verhulst, & Koot, 2007) major conclusion, using a wide sample (N = 2047 of people without ID and N = 978 with ID), was that there was a higher risk of psychopathology in children with ID (Matson et al., 2012). Koskentausta, Iivanainen, and Almqvist (2004) studied 90 Finnish children aged 6 to 13. They found differences in problem behaviors based on the level of ID. Children with moderate ID had higher internalizing and externalizing scores than children with profound ID. The results regarding the validity of the instrument are limited. Nevertheless, it is one of the most used scales to evaluate psychopathology in children and young people.

Diagnostic Assessment for the Severely Handicapped (DASH-II)

Author(s) and year: Matson et al., 1991.

Provenance: USA.

Usage: Adults with severe and profound ID.

Evaluators: Proxy informant.

Duration of test: 20 min.

Objective: To assess psychopathology in people with severe and profound ID.

Dimension/score: It includes 84 items and assesses 13 mental health disorders. The subscales are: *1—Organic syndromes*; *2—Mood*; *3—Anxiety*; *4—Mania*; *5—Pervasive development disorder (PDD)*; *6—Autism*; *7—Schizophrenia*; *8—Stereotypies*; *9—Self-harming behavior*; *10—Elimination disorders*; *11—Eating disorders*; *12—Sleeping disorders*; and *13—Sexual disorders*. It measures the duration and severity of the symptoms in a 3-point scale. The frequency is classified as: 0—No occurrences; 1—It happened between one and 10 times in the previous 2 weeks; or 2—It happened more than 10 times in the previous 2 weeks. The duration is classified as: 0—Less than 1 month; 1—One to 12 months; or 2—More than 12 months. The severity of the symptoms is: 1—Did not cause any interruption or damage; 2—It caused no damages but it interrupts the activity of others at least once; or 3—Lesions or damages caused at least once. The 13 symptoms scales have cutoff scores that indicate when a diagnosis is considered necessary. For the first eight scales, the adjustment for a cutoff score for the request of a psychopathologic diagnosis is one standard deviation over the average of the standardized sample (Matson, Gardner, Coe, & Sovner, 1991).

Antecedents/description: The scale derives from the DSM-IV-TR and it evaluates the presence of psychiatric disorders in people with severe and profound ID. It has been used as a strong measure to validate other psychopathologic scales. It has also been used to study patters on behavior disorders (Matson et al., 1996).

Validity: The psychometric characteristics have been evaluated in many studies, finding reliability and test-retest values of 0.84, and frequency and duration values of 0.84 and 0.91, respectively (Sevin, Matson, Williams, & Kirkpatrick Sanchez, 1995). It is the most widely studied evaluation scale of psychopathology in people with severe and profound ID. The convergent validity of the ABC was proven by analyzing its high correlation in some of the subscales. Its validation should be studied according to the new DSM-5 criteria.

Developmental Behavior Checklist (DBC)

Author(s) and year: Einfeld et al., 1995.

Provenance: Ohio, USA.

Usage: Children in general and, later, children and adults with ID.

Evaluators: Proxy informant.

Duration of test: Indeterminate.

Objective: To evaluate the behavioral and emotional problems in young people.

Dimension/score: The DBC (Einfeld & Tonge, 1995) is a questionnaire answered by parents, primary carers or teachers. It shares its structure with the CBCL (Achenbach & Edelbrook, 1983) which means that each behavioral description has a value range between 0 and 2 (0—Not true; 1—Sometimes certain; and 2—Very certain). The items are derived from a medical study with 7000 children with ID. There are five versions: the parent/carer version (DBC-P); the teacher version (DBC-T); the adult version (DBC-A); the short version (DBC-P24); and the follow-up table (DBC-M). It has been translated into other languages: Dutch, Finnish, and French. Furthermore, it provides a scoring software that is very useful for registering information.

The DBC-P has 96 items used to evaluate behavioral and emotional problems in young people between 4 and 18 years old with ID and development disorders. The DBC-A is an instrument with 107 items to evaluate the behavioral and emotional problems of adults with ID.

Validity: It has high inter-evaluator reliability between parents and teachers. The reliability and internal consistency test is also high. The validity is high, with the existence of a high correlation with the American Association for Mental Deficiency Adaptive Behavior Scales (AAMD ABS) (Perry & Factor, 1989) and the independent behavior scale Inventory for Client and Agency Planning (ICAP) (Delfín Montero, 1993).

Nisonger Child Behavior Rating Form (N-CBRF)

Author(s) and year: Aman et al., 1996.

Provenance: Ohio, USA.

Usage: Children and adolescents with ID.

Evaluators: Informants (parents and/or teachers).

Duration of test: 15 min.

Objective: To evaluate the behavior of children and adolescents with ID.

Dimension/score: It is an adapted behavior scale, containing 76 items, 10 evaluating social competence and 66 behavioral problems. It is composed of three sections: in the first, the qualifiers can identify unusual circumstances that might have influenced the behavior; in the second, the competency behaviors are classified; and the third consists of a list of behavior problems. The informant rates the child's behavior between 0 and 3 in a Likert scale.

Antecedents/description: The authors (Aman, Tassé, Rojahn, & Hammer, 1996) point out that the N-CBRF has been modified through a change in the instructions and the addition of new items that describe the behavior problems that happen in children with ID. Its subscales are: *1—Irritability, agitation, crying*; *2—Lethargy, social isolation*; *3—Stereotyped behavior*; *4—Hyperactivity/noncompliance*; and 5—

Inappropriate speech. In its factorial analysis, it obtains a six-factor solution. Nisonger's CBRF has a considerable contents overlap with the ABC, but they also differ in other important contents. The ABC was mainly developed in order to monitor the effects of treatment, while the N-CBRF was meant for evaluation purposes.

Validity: Several investigations gathered that the scale is reliable and valid for the assessment of children and adolescent behavior. The authors (Lecavalier, Aman, Hammer, Stoica, & Mathews, 2004) found that the internal consistency was high, the degree of agreement from parents and teacher was satisfactory and the subscales were similar to the ABC. Sarimski (2004) described a German sample and concluded that the N-CBRF was reliable and had a good convergent and divergent validity. Lecavalier's study (Lecavalier, 2006) evaluated 487 people with pervasive development disorders and used conglomerate analysis to define subgroups within this sample, categorized as: no problems, well adapted, hyperactive, anxious, and undifferentiated behavior disorder.

It is an instrument popularly used in measuring emotional problems, where the psychometric evaluation of the scale obtains mixed results. The majority of investigation seems destined to demonstrate and/or justify the effects of some psychotropic drugs and therefore its use in this area is limited (Matson et al., 2012).

Psychopathology Checklists for Adults with Intellectual Disability (PAID)

Author(s) and year: Hove et al., 2008.

Provenance: Norway.

Usage: Adults with ID.

Evaluators: Proxy informant.

Duration of test: Undetermined.

Objective: To evaluate the psychopathology in adults with ID.

Description/dimension: The PAID represents the first attempt at developing control-lists for psychopathologies based on the *Diagnostic criterion for psychiatric disorder for use with adults with learning disabilities/mental retardation* (DC-LD) and, in addition, contains references to the *International Classification of Diseases, 10th Edition* (ICD-10). It contains a total of 280 items and comprises 10 psychiatric diagnosis and 8 types of behavioral problem. 18 lists in total were developed, each indicative of a disorder containing a set number of items: *Dementia* (25 items), *Psychosis* (40 items), *Depression* (37 items), *Mania* (24 items), *Anxiety* (93 items), *Obsessive-compulsive disorder* (5 items) and *Behavioral problems* (61 items).

Validity: It is a fairly recent instrument with a reliability of between 0.63 and 0.88 and an acceptable internal consistency, where the specificity was low. Its factorial analysis supported a four-factor solution (Hove & Havik, 2008). Overall, the psychometric properties of the scale seem consistent, despite some scores being below the recommended level, such as the subgroup of people with severe and profound ID. The scale is promising but it requires additional studies (Matson et al., 2012).

Psychiatric Assessment Schedules for Adults with Developmental Disabilities (PAS-ADD)

Author(s) and year: Moss et al., 1993.

Provenance: London.

Usage: Adults with mild and moderate ID.

Evaluators: Proxy informant and subject (self-informed version).

Duration of test: Indeterminate/depending on the version.

Objective: To evaluate mental health problems in people with ID.

Dimension/score: It collects information regarding different situations that may occur to a person with mental health problems. The person delivering the questionnaire should know the subject for longer than 6 months.

Antecedents/description: It is a semi-structured interview designed to detect mental disorders in people with ID (Moss et al., 1993). It includes the exploration of the current state of the patient followed by an interview with a proxy informant. The assessment allows a diagnosis based solely on the interview to an informant if the patient's language skills are insufficient. The ICD-10 version of the PAS-ADD (PAS-ADD-10) provides a means to extend the scoring principles used in a more general clinical instrument to this specific population. It is based on version 1 of the SCAN and it contains items that cover the following ICD-10 diagnosis: F20.1–9—Schizophrenia; F29—Unspecified non-organic psychosis; F30.0—Hypomania; F32.0–3—Depressive episode; F40.0–2—Phobic anxiety disorders; F41.0–1—Panic and generalized anxiety disorders; and F51.1—Non-organic hypersomnia. The Mini-PAS is a variant of the PAS-ADD with 86 items that cover: *depression*, *anxiety*, *mania*, *obsessive-compulsive disorder*, *psychosis*, *unspecified disorders (with items for dementia and organic symptoms)* and *autism spectrum disorders*.

Validity: The inter-evaluator reliability of the ICD-10 detected an average kappa of 0.65 for individual item scores and a kappa of 0.7 for the agreement in the definition indexes of the SCAN (Schedules for Clinical Assessment in Neuropsychiatry) system, developed by the World Health Organization (Moss, Prosser, & Goldberg, 1996). There is a large amount of high-quality research for the PAS-ADD, and in the United Kingdom it is a well-established scale for measuring the psychopathology in people with ID. As such, it is equivalent to what the DASH-II and the PIMRA have become in North-America (Matson et al., 2012).

Psychopathology Instrument for Mentally Retarded Adults (PIMRA)

Author(s) and year: Matson et al., 1984.

Provenance/adaptations: USA.

Usage: Adolescents and adults with mild and moderate ID. Not appropriate for children.

Evaluators: Proxy informant and self-informed version.

Duration of test: Informant version takes between 6 and 12 min.

Objective: To diagnose psychopathology in people with ID.

Dimension/score: This symptom inventory contains five items that cover a broad psychopathologic spectrum based on the DSM-III-R criteria modified to fit subjects with mental retardation. It provides a score for eight types of disorders or subscales: *1—Schizophrenia*; *2—Affective disorders*; *3—Psychosexual disorders*; *4—Adaptive disorders*; *5—Anxiety disorders*; *6—Somatoform disorders*; *7—Personality disorders*; and *8—Social adaptation disorders* (Matson, Kazdin, & Senatore, 1984).

Its second edition (PIMRA-II) covers more psychopathologic disorder types, containing the original PIMRA's 56 items plus 32 new ones (5 items for autism spectrum disorder [ASD], 7 for attention deficit/hyperactivity disorder [ADHD], 4 for mania, 5 for anxiety, 4 for depression, 3 for behavior, 1 for personality disorder, 1 for sexual disorder, 1 for pica and 1 for hoarding). DSM-5 and ICD-10 guidelines and items from other scales, like the DASH-II and the ADD, were included. Its psychometric properties are comparable with the original PIMRA, with an extensive variety of items, and therefore it is an improved evaluation instrument to detect psychopathologies in people with mild and moderate ID.

Antecedents/description: The scale was developed as a selection instrument to help in the differential diagnosis of people with ID. It was the first standardized instrument designed to evaluate psychopathologies in this group. It has two versions, one for the informant and one for the patient, both with the same number of items.

Validity: It is a frequently studied instrument and it is used as a referent to establish the validity of other psychopathology evaluation instruments in people with ID. The recently obtained validity of this instrument shows good reliability, where the majority of the items obtained coefficients over 0.70, in addition to positive correlations (intraclass correlation coefficient [ICC] = 0.70) with the total ADD score.

Future investigation should examine the validity of the self-informed version of the PIMRA-II, given that internal states often cannot be behaviorally evident. Recent investigation suggest that many individuals with ID are capable of answering the self-informed questions (Douma, Dekker, Verhulst, & Koot, 2006).

Reiss Screen for Maladaptive Behavior (RSMB)

Author(s) and year: Reiss, 1987.

Provenance: Ohio, USA.

Usage: Adolescents and adults with ID.

Evaluators: Proxy informant.

Duration of test: 10 min.

Objective: To evaluate psychiatric symptoms or categories of maladaptive behavior in adolescents and adults with ID.

Dimension/score: The scale has different versions, covers all the psychopathologic range and has 38 symptoms (Reiss, 1987) organized in eight subscales: *1—Aggression scale*; *2—Autism scale*; *3—Psychosis scale*; *4—Paranoia scale*; *5—Depression (behavioral) scale*; *6—Depression (physical) scale*; *7—Dependent personality*; and *8—Avoidant personality disorder*. Each item is classified in a three-point scale regarding the functioning basis of the person during the previous 2 months. It measures the severity index of the problems of the person. The total score is the sum of the 26 points that have available normative data, and a cutoff score of 9 has been proposed to differentiate psychiatric diagnosis.

Antecedents/description: Each item is defined in nontechnical language and includes concrete examples. They measure the severity of the challenging behavior, the psychiatric diagnosis and the less frequent but significant symptoms, such as suicidal behavior.

With the 1.0 version of Reiss and Valenti-Hein (1994), it was established as a 72 item evaluation instrument, classified with a severity index: *1—Not a problem*; *2—Is a problem*; and *3—Is an important problem*. There is also a version for children (4–18 years old), the Reiss Scales for Children's Dual Diagnosis, which contains 60 items that offer, similarly to the adult version, information regarding a vast range of psychiatric disorders, including hyperactivity, autism, low self-image and isolation tendency. It also provides scores for behavioral problems and significant symptoms (episodes of crying, hallucinations, pica, self-harm, sexual problems, and suicidal tendencies).

Validity: It has an estimate Cronbach's alpha of 0.91 for the total score and between 0.63 and 0.86 for the scales. The RSMB constitutes a valuable screening method. It is one of the oldest scales established to measure psychopathologies in people with ID. The studies made with important samples show that the prevalence rates obtained not only coincide with the diagnoses of the ICD-10 but also detect profiles of specific behavior. In the USA and the United Kingdom it has been suggested that, compared to others, the scale is psychometrically solid and contains normative data for these people. This instrument is one of the most studied and is translated to several languages (Matson et al., 2012).

Specific Psychopathologic Tools

Anxiety Disorders and Depression

Anxiety disorders in people with ID have been given important attention with the existence of studies that show its frequent association in this group (Holden & Gitlesen, 2004). Depressive disorders have also been examined, showing that they exist in a lot of people with ID (Cicchetti, 1994). It is known that the prevalence of depression in adults with ID varies between 2.2% and 8.9% (Deb et al., 2001). Next, we will observe the tools most used in these disorders.

Anxiety, Depression, and Mood Scale (ADAMS)

Author(s) and year: Esbensen, Rojahn, Aman, & Ruedrich, 2003.

Provenance: Ohio, USA.

Usage: People with ID over the age of 10.

Evaluators: Proxy informant.

Duration of test: Indeterminate.

Objective: To evaluate symptoms of anxiety, depression, and mania in people with ID.

Dimension/score: The instrument contains a total of 28 items that score in a 3-point scale combining the frequency and the severity of the behavior. The items measure: *anxiety*, *fear*, *compulsion*, *appetite*, *communication*, *concentration*, *depression*, *energy levels*, *mood*, *physical state*, *sleep disorders,* and *social interaction*. Each element is classified between 0 and 3, scoring the frequency and the severity of the behavior or symptom.

Antecedents/description: Initially, Esbensen created a list of 131 items using criteria from the DSM-IV, from previous assessment instruments (Prout-Strohmer Assessment System, DASH-II, PIMRA and Self-Report Depression Questionnaire [SRDQ]) and from clinical evaluation of people in the Nisonger Center.

Validity: Esbensen's study (Esbensen et al., 2003) demonstrated that the ADAMS was a valid instrument for the screening of bipolar disorder, depression, and obsessive-compulsive disorder. Additional studies with a larger sample are required, as well as investigation that assesses the convergent and differentiating validity of the 28 items.

Beck Depression Inventory (BDI-II)

Author(s) and year: Beck, 1996.

Provenance: USA.

Usage: Adults without ID, over 13 years old.

Evaluators: Proxy informant.

Duration of test: Indeterminate.

Objective: To measure the severity of depression.

Dimension: The BDI-II (Beck, Steer, & Brown, 1996) contains 21 multiple answer questions. It is composed by items pertaining to depressive symptoms, like despair and irritability, to feelings of guilt or punishment, as well as physical symptoms related to depression (for example, fatigue, weight loss, and loss of sexual appetite). There are multiple versions and the instrument is used more often in investigation; it has been translated in multiple languages.

Validity: Authors such as Kazdin (Kazdin et al., 1983) have studied previous versions of the BDI in people with ID through a version with modified language in a sample of 110 people with limit to severe ID between the ages of 18 and 71 years old. The scales used (BDI, Minnesota Multiphasic Personality Inventory [MMPI], Thematic Apperception Test [TAT] and PIMRA) correlated significantly with each other and related constantly with the diagnostic of depression.

There are not many studies using the scale specifically for people with ID (Hermans & Evenhuis, 2010); one of the most recent studies is Powell's (Powell, 2003), where positive results for use in people with ID were obtained. The findings suggest that the test has good clinical utility and that depression can be more severe in these people.

Glasgow Anxiety Scale for People with an Intellectual Disability (GAS-ID)

Author(s) and year: Mindham et al., 2003.

Provenance: United Kingdom.

Usage: Adults with mild and moderate ID.

Evaluators: Proxy informant.

Duration of test: Indeterminate.

Objective: Scale for the detection of anxiety disorders in people with ID.

Dimension/score: The GAS-ID is a self-informed questionnaire containing 27 items regarding physiologic symptoms of anxiety and specific worries and fears. The total score varies between 0 and 54 (Mindham & Espie, 2003).

Validity: The authors studied its reliability and validity in 35 adults with ID and found an internal consistency of 0.96, a test-retest reliability of 0.95 and a sensitivity and specificity of 100%.

Hermans' study (Hermans, Wieland, Jelluma, Van der Pas, & Evenhuis, 2013) obtained the reliability and validity of the Dutch translation of the GAS-ID in 195 adults with mild or moderate ID, showing a good reliability, with an internal consistency of 0.86 and a test-retest reliability of 0.89. The validity is moderate, with a cutoff score of 17. Comparing with Mindham and Espie's (2003) results, it is demonstrated that the reliability coefficients are smaller, although still good. In conclusion, the GAS-ID seems like a reliable screening tool both for investigation and for clinical practice.

Glasgow Depression Scale for People with a Learning Disability (GDS-LD)

Author(s) and year: Cuthill et al., 2003.

Provenance: Royal College of Psychiatrists, Prescot Street, United Kingdom.

Usage: Adults with mild and moderate ID.

Objective: To detect depressive symptoms.

Dimension/score: 17 items were selected and four more not superimposed items were extracted from the ICD-10 (World Health Organization, 1992) and from the DSM-IV (American

Psychiatric Association, 1994). Several published depression scales were also reviewed: BDI-II (Beck et al., 1996), Hamilton Depression Rating Scale (Hamilton, 1960) and Zung Self-rating Depression Scale (Zung, 1965). From these, seven additional elements were aggregated to the group, forming 28 items in total.

Antecedents/description: The scale was developed according to a content revision of the existing diagnostics criteria and of the symptom scales for identifying a descriptive group of items. The starting point was the DC-LD depression subscale, developed by the Royal College of Psychiatrists (2001) for people with learning disabilities, which contains elements not included in the diagnostics programs developed for general population (Cuthill, Espie, & Cooper, 2003).

Validity/reliability: The results showed that the GDS-LD differentiated between depression and non-depressive groups correlated with the BDI-II ($r = 0.88$). It obtained a good retest reliability ($r = 0.97$), good internal consistency (Cronbach = 0.90), and a cutoff score of 13 determined a sensitivity of 96% and a specificity of 90%. The scale seems useful for screening, follow-up and contributes to the assessment of the results.

Zung Self-Rating Anxiety Scale (SAS)

Author(s) and year: Zung, 1971.

Provenance: United Kingdom.

Usage: People with normal IQ.

Objective: To evaluate anxiety and the effects of treatment.

Description: The SAS (Zung, 1971) evaluates anxiety and the effects of treatment in a clinical population with normal CI. It consists of 20 questions, to which the interviewee answers using a four-point Likert scale. Each question references some general aspect of nervousness or anxiety.

The adaptation of this scale for using with adults with mild and moderate ID was done by Lindsay (Lindsay & Michie, 1988). The 20 items were reformulated and the answer format was simplified to the presence or absence of symptoms.

Validity: In Ramirez study (Ramirez & Lukenbill, 2008), the authors analyzed the psychometric properties of a SAS adaptation. The internal consistency and the reliability coefficient were 0.80 and the correlation with other anxiety-measuring tools was low to moderate. It was concluded that, even though the present study provides preliminary data of the acceptable psychometric properties of the SAS-ID, more investigation is required to substantiate the findings, especially with samples representing other geographic areas and socioeconomic groups.

There is evidence of good test-retest reliability, with the discriminating validity being particularly necessary. Nonetheless, it is considered potentially useful for investigation and clinical purposes, as well as to assess the effectiveness of the treatment.

Scheme for Appraisal of Emotional Development (SAED)

Author(s) and year: Došen, 1990.

Provenance: Belgium.

Usage: Children, adolescents and adults with ID.

Evaluators: Proxy informant.

Antecedents: Došen's SAED (Došen, 1990) constitutes a change in the development perspective. It is innovative and very useful for the assessment, diagnostic and psychopathologic treatment of people with ID.

Researchers from different countries (Holland, Belgium, Germany and Italy) agree, in their studies, with the practical relevance of the SAED (Sappok et al., 2013), although the tool had not been widely validated until 2012. Then, Došen and a group of Belgian professionals took the initiative of making the SAED more widely available for use in clinical practice and, as a result, the Scale for Emotional Development—Revised (SED-R) was developed. In 2016, Stijin Vandevelde presented a systematic description of the SED-R development as well as the results of a study of the tool's reliability (Vandevelde et al., 2016).

Objective: To evaluate the emotional development of children, adolescents, and adults with ID. It is based on the typical emotional development that happens until the age of 12 and must be considered from the point of view of a continuum, incorporating adaptive and maladaptive behavior and psychiatric disorders.

Dimension/score: It is based on the observation of behavior through a semi-structured interview. Došen's SAED consisted of 10 domains or subscales, each with three items. These domains are described as follows: *1—How the person takes care of their own body*; *2—The interaction with the carer*; *3—The interaction with the peers*; *4–The manipulation of material objects*; *5—Affective component*; *6—Verbal communication*; *7—Anxiety*; *8—Object permanence*; *9—The experience of the self*; and *10—Aggression control*. The emotional development was assessed according to what had been established by Došen: *1—Adaptation (0–6 months)*; *2—Socialization (6–18 months)*; *3—Individuation (18 months-3 years old)*; *4—Identification (3–7 years old)*; and *5—Reality Awareness (7–12 years old)*. Three more domains were included in the SED-R, for a total of 13 subscales. The additions were: Daily activity—play development, Moral development, and Emotional regulation.

Validity: The SED-R reliability results indicate high internal consistency and substantial inter-evaluator reliability, although not for all domains. 10 of the 13 domains obtained moderate to substantial reliability between the evaluators. The advantage of using this tool resides in its focus on the importance of basic needs and motivations. It can be considered an adequate tool for integrating information regarding emotional development in the assessment and support planning processes. More investigation is required regarding its psychometric properties.

The Mood, Interest & Pleasure Questionnaire (MIPQ)

Author(s) and year: Ross et al., 2003.

Provenance: Birmingham, United Kingdom.

Usage: Adults with severe and profound ID.

Evaluators: Proxy informant.

Duration of test: 25 min.

Objective: To evaluate the person's mood and interest-pleasure.

Dimension/score: It is a 25-items Likert questionnaire with two subscales (mood, and interest and pleasure). The scale assesses the mood and the interest-pleasure for an activity in people with severe ID. It must be complemented by a qualified professional who knows the person well, preferably a psychologist. Each item must be answered with what has been observed regarding the subject in the two previous weeks (Ross & Oliver, 2003).

Antecedents/description: The rating of the MIPQ items is designed to match mood and interest-pleasure levels and it is based on the DSM-IV's description of the main depression symptoms (low mood and anhedonia), as well as behaviors regarding interest-pleasure, selected by the close correspondence to the main symptoms of major depression in the DSM-IV.

Validity: The first study's results regarding the psychometric properties, made by Ross (Ross & Oliver, 2003), are encouraging given that they obtained a good rate of validity and reliability. As a measure of emotional correlation, it offers an alternative perspective to the phenomenology of depression and to the assessment of the interventions. Petry's study (Petry, Kuppens, Vos, & Maes, 2010) suggests that the proposed factorial structure did not show an adequate adjustment to the data. A 3-factor factorial analysis (positive mood, negative mood, and interest) obtained a better adjustment. Its validation requires additional investigation, including other measurements of the individual's well-being.

Dementia

The life expectancy in people with ID is increasing, due to the improvement in medicine and in living conditions (Eyman & Call, 1991), and these people should have an equal life expectancy to the general population (Patja, Iivanainen, Vesala, Oksanen, & Ruoppila, 2000). In people with Down syndrome (DS), advanced-stage dementia usually sets in at around 50 years old (Janicki & Dalton, 2000).

The Adaptive Behavior Dementia Questionnaire (ABDQ)

Author(s) and year: Prasher et al., 2004.

Provenance: Birmingham, United Kingdom.

Duration of test: 10 min.

Objective: To identify the presence of dementia in adults with DS.

Description: The decrease in the functioning of adaptive behavior beyond the reference levels is a characteristic for the diagnosis of dementia. The ABDQ (Prasher, Farooq, & Holder, 2004) is a tool that detects changes in the adaptive behavior and is designed specifically to detect dementia in Alzheimer's disease in adults with Down syndrome. The questionnaire has 15 items and is derived from the ABS (Nihira et al., 1975).

Validity: The ABDQ is reliable and valid, and shows an excellent global precision (92%) when identifying dementia in adults with Down syndrome. The informants provide a relevant assessment of a variety of daily life activities that include getting dressed, hygiene, eating, manual dexterity, and geographic orientation.

The Cambridge Examination for Mental Disorders of Older People with Down Syndrome and Others with Intellectual Disabilities (CAMDEX-DS)

Author(s) and year: Ball et al., 2004.

Provenance: United Kingdom.

Usage: People with Down syndrome.

Evaluators: Subject and proxy informant.

Duration of test: 40 min.

Objective: To detect dementia in people with Down syndrome.

Dimension/score: It contains three parts: an interview to the subject, another to the proxy informant, and the third is a neuropsychological battery (Cambridge Cognitive Examination for Older Adults with Down syndrome—CAMCOG-DS).

Description: The CAMDEX-DS (Ball et al., 2004) is a diagnostic tool for the detection of dementia in people with DS and other causes of ID. It was originally developed in 1986 (Roth, Tym, & Mountjoy, 1986) as a standardized tool for diagnosing cognitive deterioration in general population. It is a diagnostic tool divided into two sections, a structured interview with an informant (family member or carer) who provides information regarding the current state of the patient and the patient's medical history and a direct assessment of the patient. The brief structured clinical interview collects information regarding the current mental health status as well as additional information regarding the dementia symptoms the patient presents. It also includes a brief neuropsychological battery (CAMCOG-DS) that allows the assessment of the cognitive functions affected by the dementia. The structured summaries of the CAMDEX, ICD-10, and DSM-IV diagnostics criteria for dementia are presented in list form. The information gathered through the informant interview is used to determine if the criteria for dementia are met and is complemented by the CAMCOG-DS results.

Validity: The sensitivity and the specificity of the CAMDEX-DS for the diagnosis of dementia in English-speaking people with ID are 0.88 and 0.94, respectively.

Dementia Questionnaire for Persons with Mental Retardation (DMR)

Author(s) and year: Evenhuis, 1992.

Provenance: Netherlands.

Objective: To evaluate cognitive deterioration.

Description/dimension: This is the best-known tool for the assessment of dementia in adults with ID (Evenhuis, 1992). It is a screening tool to assess the suspicion of cognitive deterioration that causes the recommendation of an exhaustive study. It is formed by a total of 50 items, grouped into eight scales: *1—Short-term memory*; *2—Long-term memory*; *3—Temporal-spatial orientation*; *4—Speech*; *5—Mobility*; *6—Humor*; *7—Activities and interests*; and *8—Behavioral changes*.

The sum of these scales obtains two indexes, which are calculated separately: a cognitive index (cognitive scores [SCS], sum of the scales for short- and long-term memories and temporal-spatial orientation) and a social index (social scores [SOS], sum of the scales for speech, mobility, activities and interests, and behavioral changes).

There are numerous investigations using the DMR as screening tool for the detection of dementia (Boada-Rovira, Hernandez-Ruiz, Badenas-Homiar, Buendia-Torras, & Tarraga-Mestre, 2005; Prasher, Adams, & Holder, 2003).

Validity: Evenhuis reported a DMR sensitivity of 100% for the identification of dementia and suggested cutoff scores indicative of cognitive deterioration. Prasher's study (Prasher, 1997), where he evaluates 100 people with SD, suggests modifications to the cutoff score in this population according to the level of ID. It is concluded that the DMR, when using the modified criteria, may help screen dementia in the population with Down syndrome.

Dementia Rating Scale (DRS)

Author(s) and year: Mattis, Bellak, & Karasu, 1976.

Provenance: New York, USA.

Usage: General population.

Objective: To evaluate cognition in dementia.

Description and subscales: Mattis' DRS (Mattis et al., 1976) is a neuropsychological battery designed to assess dementia, validated by Marson et al., in 1997 (Marson, Dymek, Duke, & Harrell, 1997), from the Department of Neurology and Alzheimer's Disease Center, University of Alabama, in Birmingham.

It has five rating criteria: *1—Wechsler Attention/Concentration Index*; *2—The Controlled Oral Word Association (CFL)* (Benton, Varney, & Hamsher, 1987); *3—The Wechsler Adult Intelligence Scale's (WAIS) block design subtest* (Wechsler, 1955); *4—The WAIS similarities subtest*; and *5—The DRS MEM subtest*, consisting on short-term recovery tasks.

Validity: The validity of the construct and the sensitivity of each DRS subscale were demonstrated by Marson et al. (1997) in a study of people with Alzheimer's disease. An internal consistency of 0.90 was established for the total scale in a geriatric population hospitalized with neurologic disorders (Gardner, Oliver-Munoz, Fisher, & Empting, 1981).

The studies that test the DRS in people with ID and, especially, DS only included a total of 147 participants (Das, Divis, Alexander, Parrila, & Naglieri, 1995; McDaniel & McLaughlin, 2000). Therefore, to support the findings further, more investigation using this tool is required, particularly including a larger sample (Elliott-King et al., 2016).

Dementia Screening Questionnaire for Individuals with Intellectual Disabilities (DSQIID)

Author(s) and year: Deb et al., 2007.

Provenance: Birmingham, United Kingdom.

Usage: Adults with DS and adults with ID.

Evaluators: Proxy informant.

Duration of test: 15 min.

Objective: To evaluate dementia in people with ID.

Description/score: The DSQIID is a questionnaire evaluated by an observer filled by the carers of people with DS who have known the person for some time (Deb, Hare, Prior, & Bhaumik, 2007). It is divided in three parts. The first asks questions regarding the "best" capacity that the person has or has had. The second contains 43 questions regarding the behavior or symptoms that are generally associated with dementia in adults with DS. Each item is scored in a four-point scale, scoring the changes in the behavior and not just the current behavior. The third part of the DSQIID contains 10 questions, all of which are comparative; for example, "speaks less" and "generally looks more tired." A "yes" answer is scored a 1 and a "no" is scored a 0. The second and third parts' scores are aggregated to get a total score.

The 53 items of the DSQIID cover areas such as memory loss, confusion, loss of skills, social isolation, behavioral changes, psychological symptoms, physical symptoms, sleep changes, and speech abnormalities.

Psychometric characteristics: A cutoff score of 20 allowed for optimal sensitivity and specificity, with 92% and 97% respectively. The DSQIID is quick (10–15 min) and easy to score. The single and fixed cutoff may limit its usefulness in more advanced stages of dementia and in people with different degrees of ID (Clune & O'Caoimh, 2013).

Gedye Dementia Scale for Down Syndrome (G-DSDS)

Author(s) and year: Gedye, 1995.

Provenance: Canada.

Usage: Adults with DS and adults with ID.

Evaluators: The questionnaire is answered by a family member or carer.

Duration of test: 30 min.

Objective: To detect dementia in people with ID.

Description: This scale is a tool based on informants created by Gedye (Gedye, 1995). It was developed in British Columbia (Canada) and standardized in 70 adults with, for the larger part, a severe or profound degree of DS. It was standardized in Ontario, with the psychiatrist from the Rideau Regional Centre Dr. Bruce McCreary, the psychologist Ms. Margie Thake, staff, and adults with severe or profound DS.

Validity: The inter-evaluator reliability kappa coefficient was 0.91 and the convergent validity coefficient was 0.81. In people with DS, the G-DSDS has good specificity but a mediocre sensitivity. An independent study by Deb and Braganza (1999), performed in adults with mild and moderate DS, found a specificity of 0.8 and a sensitivity of 0.85. The G-DSDS obtained a correlation of 0.87 with the DMR (Evenhuis, 1992).

To this date, the tool is used in a large part of the USA, Canada, Europe, Japan, and Brazil.

The National Task Group Section on Early Detection and Screening for Dementia (NTG-EDSD)

Author(s) and year: Esralew et al., 2013.

Provenance: United States. Members of the National Task Group Section on Early Detection and Screening for Dementia.

Antecedents/description: The NTG-EDSD (Esralew et al., 2013) is a classification tool based on the information provided by a third person, aimed at adults with intellectual or developmental disorders suspected of cognitive, behavioral and skill changes. It is a screening tool not meant for clinical assessment. The NTG-DST is an instrument adapted from several sources, including the DSQIID (developed by Deb et al., 2007) and the Dementia Screening Tool (2010; adapted from the DSQIID by the Philadelphia Coordinated Health Care Group). The NTG-DST also uses comorbidity items adapted from the Longitudinal Health and Intellectual Disabilities Survey (LHIDS), developed by Hsieh, Rimmer, and Heller (2012) at the University of Illinois, Chicago.

Autism Spectrum Disorders

ID and autism spectrum disorders (ASD) are frequently associated. In fact, it has been positioned that the most frequently associated disorders with ID are autism spectrum disorders (Wilkins & Matson, 2009). Approximately 40% of people with ID fit the diagnostics criteria for ASD (Matson & Shoemaker, 2009). Its combination with autism leads to phenotypes and more serious decline in comparison with people with only ID. Other studies have reached the conclusion that 70% of people with autism have a diagnosis of ID (Magnússon & Sæmundsen, 2001), which represents a significant proportion in severe and profound ID. Most instruments are derived from children's population, later studied and adapted to adults with ID.

The Autism Diagnostic Interview: Revised (ADI-R)

Author(s) and year: Lord et al., 1994.

Provenance: Illinois, USA.

Usage: Children aged between 4 and 5 years old.

Objective: To diagnose ASD.

Description/dimension: The ADI-R is a diagnosing interview to the parents, widely used to diagnose ASD (Lord, Rutter, & Le Couteur, 1994). It is a standardized, semi-structured interview conducted by doctors to the parents and carers of people possibly affected by ASD. It includes 93 ordinal items corresponding to different functioning domains: communication, reciprocal social interactions, and restrictive, repetitive and stereotyped behavioral patterns, as well as other behavioral aspects. Specialized training is required for the administration of the scale.

Validity: In Sappok's study (Sappok et al., 2013), conducted in a sample of adults with ID, the results for the ADI-R indicate good sensitivity (87.5%) and specificity (80%), and its psychometric properties are more balanced than the Autism Diagnostic Observation Schedule (ADOS). On the other hand it has been suggested that the ADI-R is too inclusive for people who are nonverbal or with a severe cognitive decline (Lord et al., 1994). De Bildt's (De Bildt et al., 2004) work has informed that age and level of functioning do not seem to have significant effects in the validity of the tool. ADI-R's diagnostics validity in adults with ID that show characteristics of ASD has not yet been sufficiently assessed.

Autism Checklist (ACL)

Author(s) and year: Sappok et al., 2014.

Provenance: Berlin, Germany.

Duration of test: Approximately 10 min.

Objective and usage: To detect autism during childhood.

Description: It is a screening tool that derives from the ICD-10 investigation criteria for early childhood (before the age of 3 years old), specifically for autism (F84.0) and atypical autism (F84.1x). Its use in adults with ID is recent. In the tool's psychometric study (Sappok, Heinrich, & Diefenbacher, 2014), it obtained a sensitivity of 90.7%, with an acceptable specificity of 67.6%. 11 of the 12 criteria with significant discriminating characteristics derive from the ICD-10.

Dimension/score: The ACL is a scale designed for specialized doctors or psychologists. Each ICD-10 domain (CL1—Social interaction; CL2—Social communication; CL3—Stereotypies and restricted behaviors) is assessed using four ordinal item scales, which ask if a certain symptom is present, partially present or not present. The result of the assessment is obtained if a person scores at least two points in the domain 1 (CL1), at least one point in domain 2 (CL2) and domain 3 (CL3) and at least six points in the three domains.

Validity: Initial evaluation of the diagnostics validity in a sample of adults with ID in Germany showed that the tool was promising, with a sensitivity and specificity of 91% and 68%, respectively (Sappok, Heinrich, & Diefenbacher, 2014). It can be used in people with ID as a brief screening tool.

Autism Diagnostic Observation Schedule (ADOS)

Author(s) and year: Lord et al., 2000.

Provenance: Chicago, USA.

Usage: Children.

Duration of test: 30–60 min.

Objective: To detect autism.

Description/dimension: The ADOS (Lord et al., 2000) is an observation tool designed to assess social and reciprocal interaction, communication, play and imagination. Frequently used to differentiate autism diagnostics from other pervasive developmental disorders not otherwise specified (PDD-NOS), its contribution for a precise diagnosis has been proven in several studies (De Bildt et al., 2004; Lord, Rutter, DiLavore, Risi, & Gotham, 2012). It is a structured observation tool which contains 4 units for the evaluation of social and communication skills in people suspected of having autism. It can be used to plan teaching. The ADOS was originally designed to be used with the ADI and has been considered the gold standard for the assessment of ASD (Filipek et al., 2000). The ADOS and the ADI-R turned out to be valuable tools for the diagnosis of ASD in adults with ID (Sappok, Diefenbacher, et al., 2013). Specialized training is required for the administration of the ADOS.

Autism Spectrum Disorders-Diagnosis for Intellectually Disabled Adults (ASD-DA)

Author(s) and year: Matson, Wilkins, Boisjoli, & Smith, 2008.

Provenance: USA.

Usage: Young people older than 16 years old.

Evaluators: Key-informant.

Duration of test: 10 min.

Objective: To rapidly provide relevant information that allows the differentiation between people with and without ASD in people with ID.

Dimension/score: The items are scored as 0 (not different, without decline) or 1 (different, some decline) through the comparison of the objective person and people of the same age that live in the community. The highest total scores are an indication of a bigger decline.

A cutoff score of ≥19 indicates comorbid ASD, while ≥19 indicates that the adult has ID but no ASD. Scores of 11 over factor I (social decline) and 8 over factor III (restricted behavior) were established as cutoff scores to distinguish between autism and PDD-NOS.

Antecedents/description: It is a structured interview used mostly to differentiate between adults with ID and ASD (autism, pervasive developmental disorder not otherwise specified, and Asperger syndrome) and adults with only ID.

The items are derived from the DSM-IV-TR and ICD-10 criteria for autism, PDD-NOS, and Asperger syndrome. It includes items from other autism diagnosis scales (Childhood Autism-Rating Scale [CARS]) and the autism/PDD-NOS subscale from the DASH-II, as well as from an exhaustive investigation of the literature revisions regarding ASD, diagnostic guidelines and clinical specialists' observations on this population.

Validity: The initial studies established its validity and a factor structure, as well as the cut-off scores to differentiate between ASD and ID, and autism and PDD-NOS (Matson, Boisjoli, González, Smith, & Wilkins, 2007). In the broader field-test conducted on adolescents and adults with ID aged 16 to 88 years old (*N* = 307), using the DSM-IV and ICD-10 criteria, it demonstrated good sensitivity and specificity in comparison with other disorders (Volkmar et al., 1994). The convergent validity of the ASD-DA showed correlation with other symptom evaluation instruments of ASD: a checklist composed of criteria from the DSM-IV-TR and ICD-10 used for diagnosing autism and PDD-NOS (Matson et al., 2008). In a study by Planelles-Fernández et al. (2017), replicating their former one, good test-retest reliability values were obtained through the ASD-DA. The items showed a significant load in the specified factor, with a perfect adjustment to the data.

Childhood Autism Rating Scale (CARS)

Author(s) and year: Schopler, Reichler, DeVellis, & Daly, 1980.

Provenance: USA.

Usage: Children with autism.

Evaluators: Proxy informant.

Description: It is an evaluation tool developed to identify children with autism, compared with other developmental disorders, in order to determine the severity of the symptoms (Schopler et al., 1980). It was designed for children older than 2 years old and it contains 15 four-point scales, where the child's behavior is scored in chronological age. The scores are grouped to categorize autism in mild, moderate and severe.

Validity/reliability: Matson's study (Matson, Nebel-Schwalm, & Matson, 2007) obtained an internal consistency of 0.94 and an acceptable inter-evaluator reliability of 0.71. In 2004, Rellini (Rellini, Tortolani, Trillo, Carbone, & Montecchi, 2004) compared the CARS with the DSM-IV criteria, obtaining a sensitivity of 100% for children with autism.

Diagnostic Behavioral Assessment for Autism Spectrum Disorder: Revised (DiBAS-R)

Author(s) and year: Sappok et al., 2014.

Provenance: Germany.

Objective: To assess autistic behaviors.

Description/dimension: The DiBAS-R is a screening scale with 20 items based on the ICD-10 and the DSM-5. It consists of two DSM-5 domains corresponding to the evaluation of typical autistic behavior over social communication, interaction, and stereotyped and restrictive behaviors, and to the sensorial interests (Sappok et al., 2014).

The tool is a semi-structured interview aimed at the parents. The questions were written in simple language to allow the evaluation by people with no knowledge of ASD.

Validity: Sappok's study (Sappok, Heinrich, & Diefenbacher, 2014), given to a sample of 219 adults with ID, obtained significant average correlations with other scales (ACL, Social Communication Questionnaire [SCQ] and Pervasive Developmental Disorder in Mentally Retarded Persons [PDD-MRS]). This finding supports the diagnostics validity of the DiBAS-R, since all its scales aim to detect behaviors characteristic to ASD. Other recent study (Heinrich, Böhm, & Sappok, 2018) revealed, in its validity analysis, a sensitivity of 0.82 and a specificity of 0.67 in the global sample. The sensitivity (0.79) and the specificity (0.84) are more balanced in people with mild to moderate ID (83.3% agreement), while the specificity was lower in people with severe to profound ID (sensitivity: 0.83; specificity: 0.34). The level of ID, as well as its interaction with ASD, explained a significant proportion of the variation in the DiBAS-R scores. It is considered an adequate screening tool, especially in people with mild to moderate ID.

Pervasive Developmental Disorder in Mentally Retarded Persons (PDD-MRS)

Author(s) and year: Kraijer et al., 2005.

Provenance: Netherlands. The original PDD-MRS version is from 1990; since then, it has been widely used in the Netherlands.

Usage: People with mild to profound ID, between 2 and 55 years old.

Evaluators: Proxy informant.

Duration of test: Between 10 and 20 min.

Objective: The main objective of the scale is to evaluate the entire range of ASD.

Description/dimension: The PDD-MRS, or pervasive developmental disorder scale for people with ID (Kraijer & De Bildt, 2005) and, in its original Dutch version, AVZ-R, covers ASD as well as all PDD (World Health Association: ICD-10, 1992; American Psychiatric Association: DSM-III-R/-IV/-IV-TR, 1987, 1994, 2000). It contains 12 dichotomous items and assigns a higher score when the referenced behavior shows in some degree. The scores vary between 0 and 19, corresponding to the DSM-III-R criteria for autism disorder and PDD. It is a complementary test for other scales, such as the ADOS and the ADI-R. Compared to the PDD-MRS, the ADOS and the ADI-R are preferable in investigation projects.

Validity: The rules of the scale are based on investigation protocols in 1230 Dutch people with ID. Both the sensitivity and the specificity of the scale were found to be 92.4%, which is a high value. Therefore, it must be considered a useful tool in identifying PDD in people with ID.

Social Communication Questionnaire (SCQ)

Author(s) and year: Rutter Bailey & Lord, 2003.

Provenance: Los Angeles, USA.

Usage: The SCQ helps to evaluate the communication skills and the social functioning in children (4–18 year olds).

Evaluators: Proxy informant.

Duration of test: 10 min.

Objective: The early detection of ASD.

Dimension/score: It consists of a categorical scale containing 40 items, answered by the parents. Six of the items are suppressed in case the person answering is nonverbal.

A score of 1 is assigned to the presence of abnormal behavior and a score of 0 if the behavior is not present. A cutoff score of >15 indicates a possible pervasive developmental disorder and a score of 22 or more indicates autism. In one study (De Giacomo, De Giambattista, Balducci, & Craig, 2015) the patients with ID received a higher score. Recently, the use of the simple version for the screening of ASD in adults has been supported by Sappok, Gaul, et al. (Sappok et al., 2015).

Description: The SCQ derives from the ADI-R (Lord et al., 1994). The tool, developed by Michael Rutter and Catherine Lord (Rutter Bailey & Lord, 2003), is a social communication questionnaire based on the DSM-IV and on the contents of the ADI-R.

Current Situation and Future Directions

The development of psychopathologic tools for people with ID has leaped in the last three decades. A large number of tests for adults and children have appeared, some of them extensively studied both in North America and in Europe. Investigation has focused, for the most part, in a single comorbidity diagnosis associated with ID; there is less investigation regarding the presence of two or more axis I disorders co-occurring with ID (Kozlowski, Matson, Sipes, Hattier, & Bamburg, 2011). It is also a necessity to have specific scales for children and adults with mild and moderate ID and other evaluation instruments for severe and profound ID. One of the limitations of the studies made through measuring scales is the origin of the information, since the parameters that define who can and cannot provide it still have not been determined. Adults with milder ID are capable of completing the self-informed ones, whereas the very young, the ones with severe ID, or the person developing dementia or other late-onset cognitive disorders are not capable of completing the task.

Tools such as the CBCL, the DBC, and the N-CBRF are valid psychometric tests, but are only applicable to children with ID. The evaluation of psychopathological disorders in people with severe ID through the DASH-II allows a solid psychometric analysis, but it is limited to adults with severe and profound ID (Matson, Smiroldo, Hamilton, & Baglio, 1997). Among the subpopulation of people with severe and profound ID there is a lack of tools directed towards children (Hermans & Evenhuis, 2010).

The BSI is psychometrically valid but has been applied to people with ID scarcely. The PAID is promising, however it still needs further investigation to establish its psychometric properties. Lastly, the ADD, the RSMB and the PASS-ADD are strong instruments to evaluate the psychopathology in adults with mild and moderate ID, but lack the necessary range to cover the totality of the psychopathologic disorders. It is still necessary to evaluate the capacity of the subscales in the screening of depression, where sensitivity and specificity have not yet been determined (Hermans & Evenhuis, 2010). Scales such as the ABC, the DASH-II, and the MIPQ are considered to have a good level of support regarding the methodological quality for use in people with severe and profound ID. Regarding the foundation of the tools currently available, the DASH-II and the ABC are reliable instruments in the evaluation of mental disorders and the MIPQ has a good reliability measure regarding mood. The tools rarely include a reference to the theoretical process of its development (Flynn et al., 2017).

Despite this, some tools, like PIMRA's second edition (PIMRA-II), have been revised with the inclusion of more items, therefore covering a wide range of psychopathologic disorders. These reasons make the tool significant for the assessment of the psychopathology in people with mild and moderate ID. The scales will soon need to be compared to the DSM-5 (Belva & Matson, 2015).

Tools such as the DBC-P and the PAID have psychometric studies and checks with encouraging results, but still require more investigation to establish its psychometric properties. Validity and reliability tests of these tools must occur before employing them in clinical practice.

The existing tools' psychometric properties should be more studied, instead of developing new ones. It is important to improve methodological and statistical quality as well as to inform regarding useful themes for clinical practice such as application details, evaluation time, etc. (Hermans, van der Pas, & Evenhuis, 2011).

There are few tools for evaluating depression and only three are promising: the ADD, the RSMB and the CDI. However, these tools' ability to measure depression was never completely studied (Hermans & Evenhuis, 2010). In the same way, there are limited tools used for studies regarding anxiety with sufficient psychometric properties; they need to be reliable and valid (Hermans et al., 2011).

The development of tools that evaluate dementia in these people has been growing, especially considering that longevity has increased considerably. The list of tools has been increasing significantly since the most recognized scale appeared, the DMR. It is recommended the use of sets that combine the different methods used (structured interviews with informants and cognitive function tests), since they can offer more information regarding the loss of cognition (Elliott-King et al., 2016). The shorter tools are preferable when the ID is more severe. The linearity of the tests may emphasize any decline by allowing a follow-up of the cognitive functions in years previous to the onset of dementia.

The interest in the study of ASD in people with ID has been relevant in the last decades and clinical criteria that allow a precise diagnosis are necessary. This may be a complex task given that the ID are associated with changes in the three main functioning domains in which autism diagnosis is based, where communication problems, repetitive behaviors and difficulty in social interactions are a common trait (De Bildt et al., 2003). Nonetheless, some authors consider that it is possible to detect ASD co-occurring with ID and that it is possible to make the distinction between the two (Matson, Boisjoli, et al., 2007). It has also been determined that the presence of ASD can be a vulnerability factor (La Malfa et al., 2007), while others have come to the conclusion that approximately 70% of people with autism have a diagnosis of ID. A good number of the scales that have been used to evaluate were, for the most part, originally used in children and only a few tools have been developed for adults. The data regarding their validity are scarce, especially for people with lower functioning (Sappok, Heinrich, & Underwood, 2015).

An additional limitation to the existing investigation is not only the lack of data but also that the published data are often informed by the same people that developed the tools. There is, consequently, a lack of independent evidence from the tools themselves. Furthermore, in many occasions, the populations studied are for the most part in residential and hospital environments, and therefore the generalization of the results cannot be extrapolated.

The current research is focused on the tests that may help the diagnostics of the specific types of psychopathology. We are witnessing the development of these tools, this movement towards specialized scales as a continuation of the general evaluation instruments. It is possible that this continues and that it may be very valuable in order to not only improve the accuracy of the diagnoses but also to allow a better comprehension of the nature of the disorders themselves, where the specificity of the symptoms may turn out useful for the treatment (Matson & Shoemaker, 2011).

There is diversity in the lines of study of comorbidity in ID. North America has followed a distancing from the study of the different forms of psychopathology, turning its focus mainly to autism. Europe seems to have kept a more balanced focus on diverse forms of psychopathology. A positive fact is the emergence of ID investigation in Asia (China and Taiwan).

The current challenge is to be up-to-date in the broadest specialized training in the knowledge of how these disorders manifest themselves, and how they are evaluated and treated in an effective way (Matson & Shoemaker, 2011). The development of specific evaluation instruments will entail the establishment of more specialized interventions.

24 Assessing Challenging Behaviors

Renee O. Hawkins, Tai A. Collins,
and J. Meredith Murphy

Children and adolescents diagnosed with intellectual disabilities (ID) display challenging behavior at about three times higher the rate than typically developing peers (Baker & Blacher, 2015). Unfortunately, without appropriate intervention, these problem behaviors can persist though adulthood (Carr et al., 2002; Lloyd & Kennedy, 2014). Common challenging behaviors include noncompliance, aggression (e.g., hitting, scratching, biting, verbal aggression), property destruction, and self-injurious behavior (Emerson et al., 2001; Wadsworth, Hansen, & Wills, 2015). In addition, deficits in social skills, adaptive functioning, and communication can further exacerbate challenging behaviors in those with ID (Matson et al., 2011).

Individuals with ID are among the most disadvantaged and socially excluded in society (Kozma, Mansell, & Beadle-Brown, 2009). Individuals with ID who also emit challenging behaviors are more likely than others to live in out-of-home care, be excluded from community services, placed in secure living facilities, be subjected to abuse and restrictive practices, and experience poor outcomes from community services (Beadle-Brown, Murphy, & DiTerlizzi, 2009; Beadle-Brown, Murphy, & Wing, 2006; Emerson, Malam, Davies, & Spencer, 2005; Felce, Lowe, Beecham, & Hallam, 2000; Kozma et al., 2009; Myrbakk & von Tetzchner, 2008). In the school setting, students with ID may have a more difficult time assimilating to inclusive classrooms due to their cognitive limitations and challenging behaviors that occur throughout the learning process (Smith, Polloway, Patton, & Dowdy, 2001). Students with ID may also exhibit a range of challenging behaviors that cause disruptions in the classroom and interrupt the learning environment for themselves and peers (Bilias-Lolis, Chafouleas, Kehle, & Bray, 2012). There is a clear need for early and effective interventions to positively change behavior (Delgado, Gonzalez-Gordon, Aragon, & Navarro, 2017). To inform the development, implementation, and evaluation of intervention supports, reliable and valid assessment methods must be used to understand the challenging behaviors displayed by individuals with ID.

Relevant professionals must engage in evidence-based practice by appropriately assessing the behaviors of concern at an individual level. Information about the challenging behaviors of concerns, including when do they occur, how often, at what intensity, under what conditions, and why, should be collected through the assessment process in order to establish an

understanding of behavior. The assessment of maintaining variables for challenging behavior, with a goal of developing prosocial intervention procedures, is a prominent topic in the literature on ID (Matson & Wilkins, 2009). There is a strong evidence-base supporting the use of functional behavioral assessment (FBA) methods to understand the contextual variables supporting challenging behavior (Hanley, Iwata, & McCord, 2003). Results from FBAs identifying the environmental variables linked to problem behavior are used to develop effective intervention plans that are customized to meet individual needs (Matson & Wilkins, 2009). In addition, once interventions are implemented, ongoing data-based progress monitoring is essential to systematic problem-solving. Data are used to evaluate the effectiveness of intervention plans and make changes as needed (Pluymert, 2014).

This chapter presents an overview of a variety of methods that can be used to assess challenging behavior. The first section reviews general methods for assessing behavior, including interviews, systematic direct observation, rating scales, and direct behavior ratings. This section of the chapter also provides a description of can't do/won't do assessment methods. The second section of the chapter is focused on FBA methods. Descriptions of general methods and procedures are provided as well as information on published assessment tools.

General Assessment Methods

Given the prevalence of problem behaviors in individuals with ID, it is important that assessments methods accurately and consistently capture various dimensions of behaviors for the purposes of data-based decision-making (e.g., target behavior selection, screening, progress monitoring). A later section of this chapter will focus on function-based assessment, which includes a variety of methods assessing the variables maintaining problem behaviors; however, the current section will discuss general assessment procedures and their application to assessing challenging behaviors in individuals with ID. Behavioral assessment measures can be used to identify target behaviors, determine the contingencies acting on behaviors, monitor intervention effectiveness, as well as a host of other uses (Cooper, Heron, & Heward, 2007). According to Mayer, Sulzer-Azaroff, and Wallace (2014), strong measurement systems are (1) sensitive, in that they detect small changes in behavior; (2) objective, as they must measure observable behaviors with little inference or bias; (3) reliable, consistently measuring behaviors; and (4) valid, in that they measure what they are intended to measure. As such, a number of indirect and direct assessment methods may be used to measure target behaviors in individuals with ID, including interviews, direct observation, rating scales, direct behavior ratings, permanent products, and can't do/won't do assessment.

Interviews

Interviews are assessment methods in which stakeholders provide information with regard to target behaviors (e.g., severity, chronicity, topography, maintaining variables), as well as characteristics of the target individual and environment. Interviews are often the initial step in consultation to address problem behaviors with individuals with ID, and the data obtained via interviews are often verified via direct observation (Cooper et al., 2007). Interviews can be useful to obtain information from caregivers, parents, and others who interact with the target individual (Kelley, LaRue, Roane, & Gadaire, 2011), as well as the target individual themselves (Cooper et al., 2007).

Interviews are typically categorized as structured or semi-structured. Structured interviews include a series of questions asked in a specific order (e.g., the interview form of the Vineland Adaptive Behavior Scales—Third Edition; Vineland-3; Sparrow, Cicchetti, & Saulnier, 2016). Structured interviews may be useful to ensure that all parties interviewed are asked the same questions in the same order; however, they are often considered inflexible (Kelley et al., 2011). Semi-structured interviews (e.g., problem identification interview, typical day interview) allow for responsiveness to the interviewee's answers, as they include a framework of themes and potential questions that do not have to be asked in a specific order. When utilizing a semi-structured interview, follow-up questions may be asked to clarify any of the interviewee's responses (Kelley et al., 2011). Although helpful in the early stages of case conceptualization, interviews should not be relied on exclusively due to the indirect nature of the assessment and the reliance on stakeholders' recollections and perceptions (Cooper et al., 2007).

Direct Observation

Direct observation is often the preferred method of behavioral assessment for behavior analysts because data are taken at the time and place of the target behavior (Cooper et al., 2007). Rather than relying on reports from stakeholders, direct observation requires an observer to be present during the session to gather a direct account of the behavior and aspects of the environment. Two types of direct observation methods are typically used, including non-systematic/informal direct observation and systematic direct observation (SDO). Non-systematic or informal direct observation includes methods such as ABC recording (described later in the chapter) and narrative recording, wherein observers record behaviors, social interactions, setting characteristics, antecedents, and consequences of behaviors without predetermined definitions or coding schemes (Cooper et al., 2007). Non-systematic direct observation methods can be used to identify patterns in behavior and maintaining variables, as well as to develop operational definitions of target behaviors; however, qualitative data obtained with these methods may be difficult or impossible to quantify or compare (Thompson & Borrero, 2011). With SDO, observers utilize specific operational definitions and structured coding schemes to collect data, which leads to quantifiable and comparable data (Thompson & Borrero, 2011).

When collecting SDO data, commonly used methods include event recording, duration recording, and time sampling. With event recording, the number of occurrences of the target behavior is tallied. This is a relatively easy method of data collection in schools and other educational settings, as teachers can collect tally data while engaging in instruction (Cooper et al., 2007). Event recording methods are best for data with discrete beginning and ending points (Mayer et al., 2014). They are not appropriate for long-duration behaviors (e.g., on-task behavior) or behaviors that occur too frequently to be recorded accurately and reliably (e.g., rapid self-injurious behavior; Cooper et al., 2007). Event recording methods include count (i.e., number of occurrences of problem behavior during a session); rate/frequency (i.e., count per unit time); celebration (i.e., change in rate over time); trials to criterion (i.e., the number of opportunities necessary to meet a predetermined performance level); and percentage (i.e., ratio of responses to opportunities; Cooper et al., 2007; Mayer et al., 2014).

Duration recording requires observers to measure the amount of time behaviors occur or the time between behaviors and other events. When measuring duration, observers often utilize a stopwatch or other instrument to measure when behaviors start and stop, thereby calculating a total amount of time per behavior and within sessions (Cooper et al., 2007). Response latency is a measure of the amount of time between a behavior and some other stimulus or event, such as between a request or demand and the corresponding behavior. Inter-response time is the amount of time between two consecutive behaviors (e.g., smoking cigarettes). When using duration recording to measure duration, latency, and inter-response time, precision is required when measuring starting and ending points of behaviors relative to other behaviors and events (Cooper et al., 2007).

In time sampling methods, SDO sessions are divided into intervals and estimates of the overall duration or rate of behaviors are obtained (Cooper et al., 2007). The four types of time sampling methods include whole interval, partial interval, momentary time sampling, and planned activity check. With whole interval time sampling, an interval is coded if the target behavior occurs throughout the entire interval. Whole interval recording is best for long-duration behaviors, as well as behaviors that occur so frequently that they may be indistinguishable from each other (Cooper et al., 2007). Whole interval methods may underestimate the actual duration of a behavior because the behavior may occur during portions of intervals but not the entire interval (Thompson & Borrero, 2011). This underestimation becomes more problematic when longer intervals are used (Cooper et al., 2007). With partial interval time sampling, intervals are coded if the behavior occurs at any time during the interval, or for prespecified portions of the interval. Partial interval recording may overestimate the duration of behaviors because entire intervals are counted even if behaviors occur during a brief portion of the interval (Thompson & Borrero, 2011); however, partial interval time sampling may also underestimate the rate of frequently occurring behaviors because intervals are coded once no matter how many times they occur during the interval (Cooper et al., 2007). With momentary time sampling, the observer codes whether behaviors occur at the end of each interval. This may be a more feasible method of time sampling data collection, as observation is not required throughout intervals; however, this method is not appropriate for behaviors that occur infrequently or for short durations (Cooper et al., 2007). Momentary time sampling may over- or underestimate problem behavior, but results are more similar to the actual duration of problem behaviors when intervals are short (e.g., Powell, Martindale, Kulp, Martindale, & Bauman, 1977). Finally, planned activity check (PLACHECK; Cooper et al., 2007) is a measure of group behavior whereby the number of individuals in a group engaged in a target behavior at the end of each interval is recorded.

Baer, Wolf, and Risley (1968) described SDO, or “the direct observation and recording of a subject’s target behaviors by an observer under the stimulus control of a written behavior code” (p. 316) as the gold standard of behavioral assessment in applied behavior analysis, which has been repeatedly echoed throughout the SDO literature (e.g., Stichter & Riley-Tillman, 2014). Advantages of SDO include that it can be used to assess various dimensions of problem behaviors (Gresham, 2015), interobserver agreement can be calculated to assess for reliability of data collection, it requires little interference relative to other behavioral assessment methods (e.g., interviews, rating scales), and it has high treatment validity (i.e., results can be used to directly inform intervention efforts).

Although SDO is the preferred method of data collection in many fields, a number of disadvantages should also be considered. Reactivity, or the extent to which individuals behave differently when they are being observed, can affect the validity of SDO (Mayer et al., 2014); however, the effects of reactivity are often temporary and can be overcome by utilizing unobtrusive observers (Cooper et al., 2007; Gresham, 2015). SDO is often time-consuming and utilizes considerable resources, as it requires a trained observer to be present at the time and place of the behavior, but technology such as video recording may reduce the labor required for SDO (Gresham, 2015). Because SDO is a sampling of behavior at a particular time and place, it may not represent a general outcome measure of an individual’s behavior that is generalizable across time and settings (Gresham, 2015). Additionally, multiple observations may be necessary to ensure reliable and useful data (Chafouleas, 2011; Gresham, 2015). For example, Hintze and Matthews (2004) did not establish adequate, dependable SDO measurement when observing twice a day, indicating that four observations per day for a minimum of 4 weeks would be required. In contrast, Briesch, Chafouleas, and Riley-Tillman (2010) indicated that 3–5 observations were required to ensure a dependable estimation of academic engagement. As such, it is unlikely that one isolated SDO session is adequate when assessing target behaviors. Finally, observer biases such as the halo effect (i.e., data affected by the observer’s judgments of the person or situation) and expectancy effect (i.e., data influenced by the observer’s knowledge of the situation) may impact the validity and reliability of systematic direct observation (Cooper et al., 2007).

Behavior Rating Scales

Recent developments of psychometric sound instruments, such as behavior rating scales and checklists, can be used to identify variables in the environment that maintain challenging behaviors (Matson, Tureck, & Rieske, 2012). Behavior rating scales and checklists require stakeholders (e.g., target individual, parents, teachers, caregivers) to respond to descriptions of behaviors, often in a Likert format with a fixed choice of ratings (Kelley et al., 2011). Rating scales are particularly useful at the beginning of consultation to identify potential behaviors to be targeted by treatment and intervention efforts (Cooper et al., 2007), as they allow practitioners to better understand the type, frequency, and severity of challenging behaviors to inform treatment planning (Rojahn, Matson, Lott, Esbensen, & Smalls, 2001). When completing rating scales, raters are asked to respond based on their recollections of the target individual's behavior over some length of time (Campbell & Hammond, 2014). A number of broad-band rating scales can be useful to assess a variety of behaviors, including externalizing and internalizing problem behaviors, as well as school and family problems (e.g., Achenbach System of Empirically Based Assessment [ASEBA]; Achenbach & Rescorla, 2001), Behavior Assessment System for Children—Third Edition [BASC-3]; Reynolds & Kamphaus, 2015; Conners—Third Edition [Conners 3]; Conners, 2008). Additionally, narrow-band rating scales assess a more limited number of symptoms, but can be particularly helpful to pinpoint more prescribed dimensions of problem behaviors to target (e.g., Beck Depression Inventory [BDI-II]; Beck, Steer, & Brown, 1996; Revised Children's Manifest Anxiety Scale, second Edition [RCMAS-2]; Reynolds & Richmond, 2008; Social Skills Improvement System Rating Scales [SSIS]; Gresham & Elliott, 2008).

Rating scales have been developed specifically to assess problem behaviors in individuals with ID, including the Behavior Problems Inventory (BPI-01; Rojahn et al., 2001) and the Developmental Behavior Checklist (DBC; Einfeld & Tonge, 2002). The Behavior Problems Inventory is a 52-item rating scale assessing disruptive and aggressive behavior, stereotypic behavior, and self-injurious behavior in individuals with ID (Rojahn et al., 2001). The rating scale was developed for various functions, such as clinical assessment for individuals at risk for behavior problems, as a treatment outcome measure, and for administrative decision-making (Rojahn et al., 2001). Several studies have been completed to provide evidence for convergent, divergent, and concurrent validity of the measure (e.g., Gonzalez et al., 2008; Hill, Powlitch, & Furniss, 2008; Rojahn, Aman, Matson, & Mayville, 2003). Researchers have developed and established some psychometric properties of the Behavior Problems Inventory-Short Form (BPI-S), a more feasible 30-item measure (Mascitelli et al., 2015; Rojahn et al., 2012). The Developmental Behavior Checklist (DBC) is a suite of measures including a 93-item teacher form (DBC-T) and 96-item parent/caregiver form (DBC-P). These assessments, originally developed in Australia for the purposes of assessing problem behaviors in individuals with ID, include subscales for social behaviors, disruptive behaviors, anxiety, and communicative behaviors (Dekker, Nunn, Einfeld, Tonge, & Koot, 2002). As such, a variety of measures are available for practitioners treating individuals with ID, including assessments normed on general populations as well as measures specifically developed for individuals with ID.

Behavior rating scales are associated with a number of advantages that make them useful when assessing problem behaviors. Because many rating scales assess a broad range of behaviors or symptoms, they can yield a comprehensive assessment of the target individual's functioning (Gresham, 2015). They are also typically efficient, in that they often require fewer than 20 min to produce a large amount of data (Campbell & Hammond, 2014). Rating scales often have alternate forms that can be completed by multiple raters, allowing for cross-informant agreement to be analyzed. In addition, rating scales produce quantifiable data that can be compared to normative samples for overall populations, as well as populations of interest (Campbell & Hammond, 2014; Kelley et al., 2011). Quantitative information from rating scales can be more easily compared across settings, raters, and assessment locations than qualitative information gathered from interviews, and reliability and validity data can be calculated and interpreted with less bias (Kelley et al., 2011).

Although they are commonly used in many settings, some disadvantages are also associated with behavior rating scales. The most consequential disadvantage of behavior rating scales is the indirect nature of the assessment, as stakeholders' perceptions of individuals' typical rates of behavior, rather than actual direct rates of behavior, are obtained (Gresham, 2015). Additionally, although cross-informant agreement is considered a strength, it can also be a weakness of behavior rating scales when there is low agreement among raters (Gresham, 2015). Variance between raters can be problematic for interpretation and may be due to rater biases (e.g., biases to more severely or leniently rate behaviors, the central tendency effect, or halo effects and reputational biases) or setting variance (i.e., that expectations and demands vary between settings and may result in differences in stakeholders' perceptions of rates of problem behaviors; Campbell & Hammond, 2014). Omnibus rating scales may also lack sensitivity for small changes in problem behavior, which, along with administration times and number of items, may limit the ability of rating scales to be used for the purpose of progress monitoring. Each of these disadvantages should be considered when utilizing behavior rating scales to assess rates of behaviors in individuals with ID.

Direct Behavior Ratings

Direct Behavior Ratings (DBR) are evaluative judgments typically completed immediately after an observation period (Chafouleas, 2011). Common examples include teachers, school or clinic staff, parents, and the target individual providing a rating of behaviors after a session or classroom period (e.g., rating on a percentage scale or Likert scale the amount of time a target student was on task during a class). DBRs were designed as a hybrid technique to capitalize on the advantages of SDO and behavior rating scales (Chafouleas, 2011; Christ, Riley-Tillman, & Chafouleas, 2009). Specifically, like SDO, DBRs are typically completed at the time and place of the behavior, require little inference, and can be administered repeatedly for progress monitoring purposes, while, also capitalizing on the efficiency of behavior rating scales (Chafouleas, Riley-Tillman, & Christ, 2009). A strong literature base supports the technical adequacy of DBR, as moderate correlations were found between teacher-completed DBR and observers' SDO data (Chafouleas, McDougal, Riley-Tillman, Panahon, & Hilt, 2005; Riley-Tillman, Chafouleas, Sassu, Chanese, & Glazer, 2008).

Many advantages make DBRs appropriate for use in a variety of settings. First, because DBRs are brief, they are often considered a feasible and acceptable measure of behavior (Chafouleas, Riley-Tillman, & Sassu, 2006). As such, DBR-Single Item Scales (DBR-SIS; Chafouleas, 2011) have been developed with a single item to improve the efficiency of measurement. Also, DBRs may not need to be completed immediately after the observation session, as Dart et al. (2017) found in an analog study that latency of completing a DBR did not affect the accuracy of obtained data. Finally, DBRs are flexible, in that they can be personalized to the target individual, and the rater and frequency of rating occasions can be varied (Gresham, 2015). The personalization of DBRs may also be a disadvantage, in that the technical adequacy of the resulting instrument may be unverified.

Permanent Products

Permanent products are byproducts or outcomes produced by behaviors that last long enough to be measured and recorded (e.g., homework assignments, number of correct math problems; Cooper et al., 2007). Permanent products may also be contrived, such as with audio or video recordings of sessions. An advantage of permanent products is that observers are not required to be present during the session of interest, as some behaviors occur during times and in places that are not able to be observed (Cooper et al., 2007). Also, permanent products allow for the utilization of more complex coding schemes and measurement of multiple behaviors since they are analyzed after the observation session, and interobserver agreement may be calculated (Cooper et al., 2007). With regard to disadvantages, some behaviors may not produce long-lasting byproducts that can be collected as permanent products (e.g., on-task behavior), and, if the observation session is not recorded, important aspects of the environment may not be assessed and it may not be clear whether the target individual or some other person produced the permanent product (Cooper et al., 2007). As such, permanent products are best utilized when real-time data are not needed for decision-making, for behaviors that reliably produce measurable outcomes, and when measurement by permanent product would be unobtrusive to the natural environment (Cooper et al., 2007).

Can’t Do/Won’t Do Assessment

Can’t do/won’t do assessment refers to a variety of procedures used to determine whether problem behaviors are acquisition or performance deficits. Acquisition deficits are behaviors that are not in the individual’s repertoire (i.e., the individual cannot currently do them), while performance deficits are in the individual’s repertoire, but they are not performed adequately or in the appropriate situations (i.e., the individual will not do them; Gresham & Elliott, 2008). With regard to academic problems, can’t do/won’t do assessment is typically conducted by offering the individual a preferred reward for exceeding a previously obtained score and determining whether the next score is altered by the presentation of a reinforcer (e.g., VanDerHeyden, 2014). In the realm of social skills, the SSIS-RS (Gresham & Elliott, 2008) is a behavior rating scale that indicates whether problem behaviors are performance or acquisition deficits. Regardless of the methods, can’t do/won’t do assessments are useful in treatment planning, as direct instruction with performance feedback is appropriate for acquisition deficits, while performance deficits require behavioral interventions including differential reinforcement, prompting, and feedback (Gresham & Elliott, 2008).

Functional Behavioral Assessment

Functional behavioral assessment (FBA) refers broadly to methods for identifying environmental factors contributing to challenging behavior (Cooper et al., 2007; Steege & Watson, 2009). FBA relies on the assessment techniques already described in this chapter, including interviews, systematic direct observation, and rating scales, to describe and analyze problem behavior in the context in which it occurs. The goal of FBA is to determine the antecedents and consequences that trigger and maintain challenging behavior. Antecedents are events, activities, and stimuli that occur before problem behavior presents whereas consequences are events, activities, and stimuli that occur after the challenging behavior. Antecedents may include discriminative stimuli, which are stimuli that signal that reinforcement is available for a particular response. For example, a box of cereal on the kitchen table may serve as a discriminative stimulus for asking to eat breakfast. As another antecedent event, motivating operations change how valuable a reinforcer is to an individual. For example, the day after Halloween, a child might not be as motivated by a candy as a reinforcer as they were previously, when candy was not as readily available. Consequences include positive reinforcement (social attention, activities, tangibles), negative reinforcement (escape or avoidance of social attention, settings, task demands, or activities), and automatic reinforcement (a change in sensory stimulation). Antecedents and consequences each affect the likelihood that a problem behavior will occur. By identifying functional relationships between environmental variables (i.e., antecedents and consequences) and problem behavior, FBA aims to determine why a problem behavior is occurring (i.e., the function of the behavior). This information about function can then be used to develop intervention plans that manipulate the environment to effectively decrease challenging behavior and promote positive behavior (Cooper et al., 2007; Steege & Watson, 2009).

There is a strong evidence base supporting the use of FBA. Over the last four decades, researchers have repeatedly demonstrated that FBA is a valid approach for assessing problem behaviors and there are several books dedicated to the topic (e.g., Cipani, 2018; Crone, Hawken, & Horner, 2015; Steege & Watson, 2009). Research has been conducted using FBA to examine a variety of challenging behaviors including aggression, noncompliance, property destruction, stereotypy, off-task, self-injury, tantrums, elopement, inappropriate vocalizations (Anderson, Rodriguez, & Campbell, 2015; Hanley et al., 2003); across clinical, school, and home settings (Hanley et al., 2003); for typically developing children and adults (Hanley et al., 2003); and for children and adults with disabilities, including ID (Wadsworth et al., 2015), autism spectrum disorder (Larkin, Hawkins, & Collins, 2016), emotional and behavior disorders (Gage, Lewis, & Stichter, 2012), and attention-deficit/hyperactivity disorder (Miller & Lee, 2013). This extensive literature base has highlighted continuously the importance of identifying the function of problem behavior for effective intervention development (Didden, Korzilius, Van Oorsouw, & Sturmey, 2006; Harvey, Boer, Meyer, & Evans, 2009). In fact, researchers have noted that interventions based on the results of FBA result in better outcomes than interventions that are developed without information regarding function (Ingram, Lewis-Palmer, & Sugai, 2005; Newcomer & Lewis, 2004; Payne, Scott, & Conroy, 2007).

Three approaches to FBA are described in the literature, including (1) indirect FBA, (2) direct descriptive FBA, and (3) functional analysis (Cooper et al., 2007; Steege & Watson, 2009). All three fall under the umbrella term FBA, yet they differ in the intensity of the assessment procedures involved. Based on the strengths and limitations of the assessment methods used within each type of FBA, indirect and direct descriptive FBA lead to clear descriptions of challenging behavior and hypothesized functions of the behavior while functional analysis is used to confirm functional hypotheses by systematically manipulating the environment. To conserve often-limited resources in providing assessment and intervention services to individuals with ID, problem-solving teams should try to match the intensity of the FBA approach selected with the intensity of the challenging behavior.

Indirect FBA

Indirect FBA relies on indirect data sources including interviews, rating scales, and record reviews to generate functional hypotheses (Iwata & Worsdell, 2005). Given the often-questionable reliability and validity of indirect assessments, relying solely on indirect FBA methods is not recommended but rather can be seen as a first step in developing a clear understanding of the challenging behavior, its context, and possible functions. Further, when a problem behavior is relatively minor (e.g., occurs infrequently, does not cause harm to the individual or others), problem-solving teams may decide that it is appropriate to move forward with intervention planning based only on information collected through indirect FBA. In this context, problem-solving teams may determine that resources (i.e., time, personnel) may be better utilized addressing concerns related to more severe challenging behavior rather than expending valuable resources collecting additional information. A team may decide that data collected through an indirect FBA may provide enough to develop an intervention plan with a high likelihood of success.

FBA interviews. To guide FBA interviews and help address concerns with the technical adequacy of clinical interviews in general, several structured FBA interview forms have been developed. Generally, FBA interview forms provide prompts to gather information about the individual displaying the challenging behavior (e.g., demographic information, strengths, likes/dislikes, social skills, communication strategies), descriptions of the problem behaviors, contextual variables that affect the behavior (e.g., routines, sleep patterns, medications, eating habits, triggering events, consequences), and previous intervention strategies that have been implemented. Prompts are also included to generate hypotheses regarding the function of the problem behavior. The major goals of the FBA interview are to operationally define the challenging behavior in observable and measureable terms; to identify the antecedents and consequences that are associated with the problem behavior; to generate a hypothesized function for the behavior; and to identify and clearly define appropriate, desired, alternative behaviors (Gresham, Waston, & Skinner, 2001). Several interview forms have been designed to support the accomplishment of these goals and most are readily available to practitioners. Table 24.1 lists the indirect FBA tools reviewed in this chapter and how to access them.

The Functional Assessment Checklist: Teachers and Staff (FACTS) is a brief semi-structured interview form designed with school-based problem-solving teams in mind (March et al., 2000). A review of research on the FACTS supported its reliability (0.77 test-re-test reliability; 0.50–0.88 inter-rater reliability; 1.00 interobserver agreement) and validity, with 80% of students receiving interventions developed based on information collected with the FACTS showing at least a 50% decrease in the presentation of challenging behavior (McIntosh et al., 2008). Similar to the FACTS, the slightly longer Functional Assessment Interview (FAI) is a semi-structured interview designed for use in school and clinical settings to assess the behaviors of individuals with and without developmental disabilities (O'Neil et al., 1997). Research on the FAI has found high inter-rater reliability (86–88%) for the tool as well as evidence of convergent validity with other FBA methods (e.g., rating scales, direct observations) and treatment utility (Dufrene, Kazmerski, & Labrot, 2016). The Functional Assessment Informant Record-Teacher (FAIR-T) is another semi-structured interview form to collect information on the context of problem behavior (Edwards, 2002). Results from the FAIR-T also have shown convergence with other FBA methods and led to the development of effective intervention plans (Dufrene et al., 2016).

FBA rating scales. Rating scales specifically designed to consider the function of problem behaviors also have been developed to strengthen

Table 24.1 Indirect functional behavioral assessment tools

Tool	Format	Availability
Functional assessment checklist for teachers and staff (FACTS)	Semi-structured interview	Positive Behavioral Interventions and Supports: OSEP Technical Assistance Center https://www.pbis.org/resource/246/functional-assessment-checklist-for-teachers-and-staff-facts
Functional assessment interview (FAI)	Semi-structured interview	The Center on the Social and Emotional Foundations for Early Learning (Vanderbilt University) http://csefel.vanderbilt.edu/modules/module3a/handout5.pdf
Functional assessment informant record for teachers (FAIR-T)	Semi-structured interview	Included in full in: Steege, M.W. & Watson, T.S. (2009). *Conducting school-based functional behavioral assessment (2nd Ed.).* New York: The Guilford Press
Questions about behavior function (QABF)	Rating scale	Available for order from Disability Consultants, LLC http://www.disabilityconsultants.org/Order.php
Functional analysis screening tool (FAST)	Questionnaire	Included in full as Appendix to: *Journal of Applied Behavior Analysis,* Volume 46, Spring 2013
Motivation assessment scale (MAS)	Rating scale	Available for order from Monaco & Associates https://www.monacoassociates.com/products
Contextual assessment inventory for problem behavior (CAI)	Rating scale/ inventory	Included in full as appendix to: McAtee, M., Carr, E. G., & Schulte, C. (2004). A contextual assessment inventory for problem behavior: Initial development. *Journal of Positive Behavior Interventions, 6(3),* 148–165

the FBA process and results (Matson et al., 2012). The information obtained from these rating scales can serve as a foundation for follow-up interviews and observations and can also provide antecedent or consequent event information to be included in a functional analysis (Iwata, DeLeon, & Roscoe, 2013).

The Questions About Behavioral Function (QABF) is the most studied and psychometrically sound FBA rating scale used to achieve an understanding of challenging behavior presented by individuals with ID in a simpler way than experimental functional analysis (Matson et al., 2012; Matson & Vollmer, 1995). The QABF contains 25 items with five items in each of five factors: attention, escape, non-social, physical, and tangible (Matson et al., 2012). Items are scored on the following dimensions: occur, does not occur, and does not apply (Matson et al., 2012). The challenging behaviors are also rated on severity (e.g., rarely, some, and often). The scale can be completed in 20 min (Matson et al., 2012), saving professionals valuable time. Researchers have repeatedly established the reliability and validity of the QABF and documented convergence with functional analysis results (Matson et al., 2012).

The Functional Analysis Screening Tool (FAST) is a 16-item questionnaire about antecedent and consequent events that may be correlated with the occurrence of problem behavior (Iwata et al., 2013; Iwata & DeLeon, 1996). The FAST was developed to prompt dialogue about conditions under which problem behavior might occur and to organize the reports around positive and negative reinforcement (Iwata et al., 2013). The contingencies are then divided based on whether the source of reinforcement is social (delivered by others) or automatic (produced directly by the response), which yields four functional categories: (1) social-positive reinforcement (access to attention or tangible items), (2) social-negative reinforcement (escape from task demands or other types of social interaction), (3) automatic-positive reinforcement (self-stimulatory behavior), and (4) automatic-negative reinforcement (alleviation of pain or discomfort; Iwata et al., 2013). Assessment of the FAST's reliability and validity are considered adequate, in that they compare well with other rating scales, but it lacks appropriateness for the purpose of treatment development (Iwata et al., 2013).

The Motivation Assessment Scale (MAS) produces scores for an indicated challenging behavior related to four potential functions: sensory, escape, attention, and tangible (Durand & Crimmins, 1992). The MAS is frequently used to assess learned function of challenging behavior in people with ID (Koritsas & Iacono, 2013). The MAS consists of 16 questions related to the challenging behavior that are rated on a 6-point Likert scale (0 = never, 1 = almost never, 2 = seldom, 3 = half the time, 4 = usually, 5 = almost always, 6 = always), (Fee, Schieber, Noble, & Valdovinos, 2016). The function is then determined by the subscale with the highest average score. The MAS has been tested with functional analysis results in the past and was found to have statistically significant correlations with functional analysis results (Herzinger & Campbell, 2007); however, other studies have found mixed results regarding MAS convergence with other FBA approaches, including functional analysis (Arnforfer, Miltenberger, Woster, Rortvedt, & Gaffaney, 1994; Crawford, Brockel, Schauss, & Miltenberger, 1992; Paclawskyj, Matson, Rush, Smalls, & Vollmer, 2000).

The Contextual Assessment Inventory for Problem Behavior (CAI) is a rating scale/inventory to identify environmental variables contributing to challenging behavior in individuals with developmental disabilities (McAtee, Carr, & Schulte, 2004). The CAI includes 80 rating scale items and 13 open-ended questions. For rating scale items, raters are asked to indicate the likelihood that the individual will display the problem behavior based on the information provided based on 5-point scale (1 = never, 3 = half the time, 5 = always). Research studies have indicated moderate to strong internal consistently and temporal stability (Dufrene et al., 2016). In addition, researchers found evidence supporting the convergent and predictive validity of the instrument (Carr, Ladd, & Shulte, 2008) and for the effectiveness of interventions based on the results (Moskowitz, Carr, & Durand, 2011).

Direct Descriptive FBA

Direct descriptive FBA typically incorporates the indirect measures used in indirect FBA but adds and heavily relies on the collection of direct observation data, including the use of the SDO methods described previously. Direct observation is used to clearly define and record the occurrence of not only the challenging behavior but also the co-occurring environmental events, providing context for the problem behavior.

In the simplest form, direct observations may include narrative recordings of the antecedents, challenging behavior, and consequences as they occur during the observation session (i.e., A-B-C recording; O'Neil et al., 1997). A-B-C recoding can be modified to include additional relevant information such as the setting, time of day, or delayed consequences. Scatterplot assessments track when the challenging behavior occurs throughout the day for several days, while also noting the co-occurring tasks and activities. Data are visually analyzed to determine correlates of problem behavior and generate hypotheses regarding function (Touchette, MacDonald, & Langer, 1985). Through descriptive assessments, data are systematically collected to quantify not only the occurrence of the problem behavior, but also the occurrence of antecedent and consequences. Based on these data, conditional probabilities can be calculated (e.g., the student avoids task demands following 90% of occurrences of challenging behavior; conditional probability of 0.90) and used to develop functional hypotheses (Dufrene, Doggett, Henington, & Watson, 2007).

While indirect and direct descriptive FBA methods are supported in the research for developing effective, function-based interventions, they are not without limitations. These FBA approaches result in hypotheses regarding the variables supporting challenging behavior but do not actually confirm such functional relationships. Functional analysis procedures, however, are designed to do just that. By systematically manipulating the environment, functional analysis procedures can verify functional relationships and increase the likelihood that subsequent intervention plans based on the results will be effective. Researchers have noted that the results of indirect FBA methods, in particular, do not consistent align with the results of functional analysis, highlighting the importance of experimentally validating functional hypotheses for intervention planning (Dufrene et al., 2016; Fee et al., 2016)

Functional Analysis

Iwata, Dorsey, Slifer, Bauman, and Richman (1982/1994) were the first to describe functional analysis procedures. They examined the effects of four conditions (three test conditions and one control condition) on the self-injurious behavior (SIB) of nine children with developmental disabilities. Each test condition provided a different potential reinforcer contingent on display of the SIB. Conditions were designed to determine the degree to which each of the following potential reinforcers was functionally related to SIB: attention, escape/avoid task demands, and automatic sensory reinforcement. In the social disapproval condition, which tested for attention as the maintaining consequence, the participant was instructed to play with some toys while the experimenter engaged in another task. The experimenter then provided attention in the form of verbal redirections, and statements of disapproval and concern, accompanied by a brief, neutral physical contact contingent upon the display of challenging behavior. In the academic demand condition, which tested for escape/avoidance as the maintaining reinforcer, participants were instructed to engage in academic tasks that had a low probability of occurrence (i.e., the student typically would not complete them). Upon the display of SIB, the experimenter took away the task and turned away from the participant. In the alone condition, which tested for automatic sensory reinforcement, the participant was placed in a room without access to any external stimulation (i.e., toys, other people). In the unstructured play condition, which served as the control condition, no task demands were placed on participants and they had access to toys and social attention contingent upon appropriate behavior. Conditions were administered repeatedly, with session durations of up to 30 min and the total number of sessions ranging from 24–53 across participants. Although there was variability in the occurrence of SIB across and within individuals, for 6 of the participants SIB consistently occurred at higher rates in one test condition as compared to the other conditions. Since this original study, researchers have repeatedly used these and similar procedures to empirically determine functional relationships between the environment and challenging behavior (Hanley et al., 2003).

While functional analysis is still considered the "gold standard" in FBA methods, concerns have been raised regarding the feasibility and validity of procedures. First, the traditional or extended functional analysis procedures described by Iwata et al. (1982/1994) require an extensive time commitment. On average, a traditional functional analysis requires six and a half hours to complete (Iwata et al., 1994; Tincani, Castrogiavanni, & Axelrod, 1999). Each condition is administered repeatedly, often requiring several days to carry out the procedures. In addition, clinicians need significant training and expertise to ensure the procedures are designed and implemented consistent with the research supporting functional analysis (Iwata et al., 2000). Finally, traditional functional analysis has been criticized for the contrived nature of the experimental conditions, with researchers and clinicians that the conditions often do not resemble real-life scenarios (Carr, Yarbrough, & Langdon, 1997). These issues have led researchers to explore modified functional analysis procedures, including brief functional analysis, trial-based functional analysis, and Interview-Informed Synthesized Contingency Analysis.

Brief functional analysis involves the same procedures and conditions typically included in extended functional analysis but the number of sessions is fewer and each session is briefer (Northup et al., 1991). More specifically, while extended functional analysis procedures may involve 30 or more sessions, with session durations of up to 30 min, brief functional analysis procedures typically involve 8–10 sessions of 10–15 min each (Cihak, Alberto, & Fredrick, 2007; Northup et al., 1991; Steege & Watson, 2009). Research indicates that the average amount of time to conduct a brief functional analysis is 90 min (Asmus et al., 2004). Cihak et al. (2007) used brief functional analysis procedures to identify the environmental variables maintaining the challenging behaviors displayed by four high-school students with ID. Initially, three conditions (escape from task demands, attention, and control) were each implemented once, with each session lasting 10 min. To confirm the results, the condition which resulted in the highest levels of problem behavior was then implemented again, followed by the condition resulting in the second highest levels of problem behavior, and finally reimplementation of the condition with the highest levels of problem behavior in the final functional analysis session. Based on the results, the researchers identified a function for the challenging behavior displayed by each participant and developed an effective function-based intervention.

Trial-based functional analysis is another alternative to traditional functional that has emerged in the literature as an effective way to empirically determine contingencies maintaining challenging behavior (Larkin et al., 2016; Sigafoos & Saggers, 1995). With this method, trial-based assessments of different contingency conditions (attention, escape, tangible, and automatic sensory) are embedded throughout the individual's typical daily routine and activities. Trials last only up to 60s each, with 10–20 trials implemented per condition (Chezan, Drasgow, & Martin, 2014; Sigafoos & Saggers, 1995). Each trial consists of a control part, consisting of free access to reinforcers (attention, tangibles, break from demands), and a test part in which the reinforcement is delivered contingent upon the display of the challenging behavior (Kodak, Fisher, Paden, & Dickes, 2013). Data collection simply involves recording whether or not the challenging behavior occurs during each trial. To interpret the results and determine function, data are compared (1) across test and control parts within conditions and (2) across conditions. Chezan et al. (2014) carried out trial-based functional analysis procedures to determine the function of challenging behavior displayed by three adults with ID.

Trials were embedded in relevant activities. For example, trials for attention occurred during one-on-one time and trials for tangibles occurred during snack time. The results of the trial-based functional analysis clearly pointed to a function for each participant, which informed the implementation of successful function-based intervention plans.

Most recently, Interview-Informed Synthesized Contingency Analysis (IISCA) has been introduced as a modified approach to functional analysis that requires significantly less time (Jessel, Hanley, & Ghaemmaghami, 2016). IISCA first relies on interviews to determine hypothesized functions of behavior. Based on the interview, the subsequent functional analysis includes only one test condition and one control condition. Similar to brief functional analysis, conditions are tested during a limited number of brief sessions. In the initial study of IISCA procedures, researcher reported that it required only 23 min to conduct the analysis and the function of behavior was confirmed for the three children with autism (Hanley, Jin, Vanselow, & Hanratty, 2014). In a follow-up study, researchers conducted 30 analyses using the IISCA procedures (Jessel et al., 2016). The average time to complete the analysis was 25 min, range, 15–75 min. Although more research is needed, IISCA show promise as an efficient option for conducting a functional analysis.

FBA in Law

Due to the strong research supporting its use, FBA is mandated for serving students with disabilities who display challenging behavior by the Individuals with Disabilities Improvement Act (2004). IDEA requires that an FBA be conducted when there is a change in a child's educational placement as a disciplinary measure in response to behavioral misconduct that is (a) a manifestation of the child's disability or (b) a result of the school's failure to implement the Individualized Education Program. IDEA also includes language suggesting that schools consider conducting a FBA when a child's behavior interferes with their learning and/or the learning of others. Further, approximately 30 states include reference to FBA methods in their special education laws (Collins & Zirkel, 2017). Given the strong research evidence for FBA methods for effectively serving individuals with challenging behavior and the inclusion of recommendations around the use of FBA in federal and state laws, it is critical that professionals serving individuals with disabilities gain knowledge and skills in FBA to implement best practice.

Conclusion

Unfortunately, there is a large body of research documenting the negative social, emotional, learning, and occupational outcomes for individuals with ID displaying challenging behavior (Coe et al., 1999; Lloyd & Kennedy, 2014). Evidence-based assessment methods can be used to help inform intervention planning and monitor intervention effects to continuously improve and modify plans to improve these outcomes. A variety of methods have been studies for the assessment of challenging behaviors. Indirect methods such as interviews and rating scales provide a starting point for describing problem behavior and understanding why it occurs. Direct methods, including systematic direct observation, can further this understanding by quantifying behavior in the context in which it naturally occurs. Functional behavioral assessment provides a comprehensive assessment framework for assessing challenging behavior, with varying levels of intensity of assessment procedures that can be tailored to match the intensity of the problem behavior and the resources of the professionals serving the individual demonstrating the behavior.

Indirect and direct descriptive FBA approaches offer methods to generate hypotheses about the environmental contingencies maintaining problem behaviors. Many assessment methods used in indirect and direct descriptive FBA require little time and are straightforward in their procedures and purpose. These approaches are an excellent "first line of defense" for understanding challenging behavior but they are limited in that they do not empirically validate hypothesized functions of behavior. To do so, a functional analysis should be conducted. Functional analysis procedures, however, require resources that are not always available in every setting serving individuals with ID. Conducting a functional analysis requires trained professionals to ensure that the analysis is carried out with integrity and a significant time commitment, which can vary based on the approach used. However, the time spent conducting a functional analysis may be time saved implementing ineffective intervention plans as research supports the increased effectiveness of function-based interventions (Ingram et al., 2005; Newcomer & Lewis, 2004; Payne et al., 2007).

School-, clinical-, and community-based problem-solving teams need to weigh the costs and benefits of different FBA approaches, given the context of their system and the severity of the challenging behavior. At a minimum, all challenging behavior should be considered in terms of function through indirect FBA methods. With increasing intensity of the challenging behavior, additional assessments should be conducted to increase the likelihood that intervention plans will efficiently improve behavior. When faced with challenging behavior that significantly interferes with an individual's daily functioning and/or when the results of indirect and direct descriptive FBA are unclear, functional analysis represents the most widely research and well supported approach for the assessment of challenging behavior.

Vocational Skills and Their Assessment

25

Miriam Heyman, Holly E. Jacobs, and Gary N. Siperstein

Introduction

Almost 30 years ago, the Americans with Disabilities Act (ADA) was enacted. This landmark legislation was hailed as "a pillar of civil rights," as it mandated equal access across virtually every sector of society (Obama, 2013). The ADA prohibited employment discrimination on the basis of disability and required employers to provide "reasonable accommodations" to employees with disabilities to enable access to work. However, almost 30 years after the passage of this monumental civil rights mandate, the vast majority of adults with intellectual and developmental disabilities (IDD) remain unemployed. The rate of competitive employment for people with intellectual disabilities hovers below 20% (Siperstein, Parker, & Drascher, 2013).

The absence of employment for people with IDD who are capable of work is problematic for several reasons. Unemployment blocks access to financial independence and thus poses an unnecessary burden on taxpayers (Schur, 2002). Businesses are missing out on a potential boost to their bottom line because companies that hire people with disabilities, including IDD, benefit from an improved public perception of those companies and therefore enjoy a wider and more loyal customer base (Burge, Ouellette-Kuntz, & Lysaght, 2007; Siperstein, Romano, Mohler, & Parker, 2006). And not to be overlooked is the fact that the lives of people with IDD can be greatly enhanced through work. We know that employment generates positive results for people with IDD, including improved self-esteem and opportunities to develop meaningful social relationships (Kober & Eggleton, 2005; Schur, 2002).

The low employment rate for adults with IDD is somewhat puzzling, because it exists despite the tremendous potential of the ADA. The low employment rate also persists despite tremendous financial investment provided by the federal government to promote competitive employment for all adults with disabilities through federal initiatives including *Employment First*, as implemented by the United States Department of Labor. *Employment First* identifies competitive employment as "the first option for employment services for youth and adults with significant disabilities" (United States Department of Labor, 2014), including IDD, and it provides platforms through which leaders from across the country can work together to enact change. This initiative is intended to advance *competitive* employment: employment opportunities that enable adults

with IDD to work alongside co-workers without disabilities and earn at least minimum wage. This is in contrast to sheltered employment, where most workers have disabilities and often do not earn minimum wage. Competitive employment is the focus of current federal policy, and it is also the focus of this chapter.

Given the ADA and federal financial investment, why do so many adults with IDD lack competitive employment? The problem is complex; if there were a simple solution to boost the employment rate, that solution would have been implemented decades ago. One important barrier is that many parents, service providers, educators, employers, and people with IDD themselves hold low expectations for employment. Spreading the mindset that people with IDD can and should be competitively employed will be a key component to the change that we wish to see. The *Employment First* initiative, with the premise that competitive work should be the goal for all adults with IDD, is an important step toward promoting this mindset.

A second key component to this problem of pervasive unemployment is the need to identify the skills that facilitate success in the workplace for people with IDD and the most effective techniques to assess and teach these skills. Skills are critical because if someone with IDD is hired for a job for which they are not qualified, the story will not end well. The employee won’t experience workplace success and the pride and satisfaction that accompany it. Meanwhile, the employer will be hesitant to hire individuals with IDD in the future.

Fortunately, there is a vast amount of knowledge about the skills that facilitate access to jobs and success on the job for individuals with IDD. Researchers have spent decades identifying and untangling the skills that predict positive employment outcomes. A second and related topic of research has focused on assessment, in order to identify methods to assess individuals’ skill levels. This measurement ultimately enables individuals to be hired for the jobs for which they are qualified and supports programs to deliver instruction that is appropriate for each individual learner. Finally, a third strand of research has focused on programs, with the goal of identifying how to most effectively teach the skills that have been identified as the most critical. Considerations include instructional strategies, contexts for instruction (i.e., school-based or on the job), and who should receive this instruction and when.

Throughout the chapter, as we review what we know about skills, assessment, and programs, we take a holistic approach and strive to apply a contextual lens to the accumulated knowledge about skills, assessment, and programs. This contextual lens includes the acknowledgement, for example, that behaviors and skill levels vary within and across environments. Two people within one environment bring different assets, and their behaviors and skills vary accordingly. Equally important is the contention that one person might manifest different skills and behaviors across two different contexts since environmental supports and demands are unique to each place. A holistic approach, which identifies and targets individual skill levels in addition to environmental opportunities and constraints, will lead to new opportunities for employment for individuals with IDD.

Skills

A positive work experience depends on a good “fit” between the employer and the employee. This fit involves a number of factors, including schedules, degree of flexibility, employee interests, location and commute, and more. Also, and perhaps most critically, a person must be qualified for the job, meaning they must possess the skills necessary to succeed on the job. The sections that follow summarize the research on the skills that are related to employment success, including finding and keeping a job, for individuals with IDD. These skills include adaptive skills and self-determination and advocacy skills, which are relevant for virtually any occupation. They also include the finite skills that are only relevant for very specific occupations, such as bagging groceries or working a cash register. Each skill is presented from a contextual lens, such that the role of the environment in eliciting or obstructing a skill is considered.

Adaptive Skills

The construct of adaptive functioning is defined as conceptual, social, and practical skills utilized in everyday life or "the behavioral skills that people typically exhibit when dealing with the environmental demands they confront" (Luckasson et al., 2002; Widaman & McGrew, 1996, p. 97). A critical element of the definition of adaptive functioning is the emphasis on skills *typically* exhibited *within environments*. Demands and resources both differ across environments, and therefore adaptive functioning is highly context-dependent. An individual might receive reminders of socially appropriate behaviors from a job coach at work but lack these reminders at home. Therefore, this person's adaptive functioning, specifically social skills, will differ across work and home. Specific adaptive skills include communication, social skills, and daily living skills, such as dressing, eating, bathing, and navigating transportation systems. By definition, individuals with IDD have limitations in adaptive functioning; these limitations are a necessary condition for diagnosis of intellectual disability (American Association on Intellectual and Developmental Disabilities, 2018a; American Psychiatric Association, 2013).

For individuals with IDD, decades of research make it abundantly clear that adaptive skills, particularly social skills, facilitate workplace success (e.g., Malgady, Barcher, Towner, & Davis, 1979; McDermott, Martin, & Butkus, 1999; Tomaszewski, Fidler, Talapatra, & Riley, 2018; White & Dodder, 2000). These skills have also been indirectly identified by federal policy makers as critical to employment success. In 2014, the Workforce Innovation and Opportunity Act (WIOA) was signed into law, which requires vocational rehabilitation (VR) agencies to provide pre-employment transition services to students with disabilities. These services, moreover, must include workplace readiness training that addresses adaptive skills, including communication, cooperation, good manners, and good hygiene.

Social skills fall under the umbrella of adaptive skills and emerge as salient to success throughout the employment process. Several studies have identified behavior problems and/or lack of social skills as a barrier to obtaining competitive employment (e.g., Lemaire & Mallik, 2008; Mank, Cioffi, & Yovanoff, 1998; Moran, McDermott, & Butkus, 2001; Murphy, 2009; Noel, Oulvey, Drake, & Bond, 2017), and other studies have found that social skills are important for workplace success, and therefore the influence of social skills extends beyond simply getting a job. For example, higher social skills are related to higher supervisor ratings (Butterworth & Strauch, 1994; McConaughy, Stowitschek, Salzberg, & Peatross, 1989) and have been linked with higher levels of on-the-job productivity (Park, Kim, & Kim, 2016) and longer periods of job tenure (Foss & Peterson, 1981).

Social skills are arguably the most critical for workplace success, but other skills under the construct of adaptive functioning, such as hygiene and self-care skills, are relevant to the conversation. Self-care includes abilities to feed, bathe, and dress and is thus closely linked to hygiene, a critical consideration for employers who rely on employees to represent them and their businesses. It is easy to imagine a scenario in which a person who lacks ability in self-care and/or hygiene interviews for a position that involves interaction with clients and does not receive an offer because the interviewer is hesitant to have this person represent the organization. It is therefore not surprising that proficiency in self-care among adults with IDD is associated with the likelihood of getting a job (Carter, Austin, & Trainor, 2011; Carter, Austin, & Trainor, 2012; Poppen, Lindstrom, Unruh, Khurana, & Bullis, 2017). In one study of adolescents with severe disabilities, those who communicated well with others and were independent in their self-care (i.e., were able to feed and dress themselves) were more likely than their peers without these skills to have paid employment (Carter et al., 2011). Another study examined 4443 Oregon high school students with disabilities and found that challenges with self-care reduced the likelihood that students obtained employment (Poppen et al., 2017). Moreover, hygiene is not only important for getting a job—it is also important for keeping a job. For people with IDD, hygiene has been cited as an essential factor in job tenure (Spence, 2004). Skills related to hygiene and self-care might be necessary for positive social interactions in the workplace because clients and co-workers might be more willing to socialize with individuals who have prerequisite skills in these areas. These social interactions, in turn, are critical for learning on the job and thus enhance work success and tenure.

Transportation skills are a third critical element of adaptive functioning and one that receives relatively little attention in the research literature but remains an essential consideration. The first responsibility of an employee is to show up on time—first to the interview and then to the first day on the job. Candidates and employees need modes of transportation that will get them from Point A to Point B, *reliably and on time*. They also need to understand how to access this transportation, which can be difficult given the complexity of many public transportation systems. A few studies have examined the role of transportation in promoting positive employment outcomes (Carter et al., 2011; Moore, Feist-Price, & Alston, 2002; Simonsen & Neubert, 2013). Transportation skills are associated with obtaining competitive employment (Simonsen & Neubert, 2013), as are transportation services (provided under a larger umbrella of vocational rehabilitation services) and the availability of accessible transportation options in the community (Carter et al., 2011; Moore et al., 2002).

Not only do transportation skills facilitate getting a job, expertise in transportation might enable people to get a job *of their choosing*. The more adept a person is at navigating a transportation system, the more potential employers he or she can access, so that people are not restricted to the one or two businesses within walking distance or on a single bus line. While transportation barriers to employment are pervasive (Noel et al., 2017), at least one study has demonstrated the efficacy of an intervention designed to enhance the navigation skills of young adults with IDD (Price, Marsh, & Fisher, 2017), indicating the potential for meaningful progress in this area.

A vast body of research identifies social skills, hygiene, and transportation skills as essential ingredients for successful employment outcomes for adults with IDD. While skills are usually conceived of as “things” that reside within a person, it is important to acknowledge that they also depend on context. Many of the studies cited above that focused on transportation as a component of employment success utilized transportation as an ecological variable—researchers measured and reported the receipt of transportation services within a VR service system (Moore et al., 2002), or the availability of accessible transportation within and across communities (Carter et al., 2011). Since transportation (or lack thereof) is a huge barrier to employment for adults with ID (Noel et al., 2017), policy makers and practitioners should address this issue on both individual and systemic levels. This would likely involve teaching people to utilize public transportation and also expanding the availability of accessible public transportation.

The contextual approach is relevant for social skills and hygiene as well. For example, frustration and/or boredom can elicit behavior problems, and behavioral outbursts are often incompatible with rules for social interaction in the workplace. Therefore, the most impactful way to enhance someone’s social functioning might be to remove or modify the elements of the environment that are frustrating or boring. Similarly, environmental modifications can enhance self-care abilities. For example, employers can add visual aids above bathroom and kitchen sinks, and these aids can serve as reminders to wash hands or brush teeth. These contextual approaches, alongside interventions targeting individual skill levels, have great potential.

Self-Determination and Self-Advocacy Skills

A policy statement from the American Association on Intellectual and Developmental Disabilities asserts that “People with intellectual and/or developmental disabilities have the same right to self-determination as all people. They must have opportunities and experiences that enable them to exert control in their lives and to advocate on their own behalf” (AAIDD, 2018b). Self-determination, moreover, is largely dependent on self-advocacy skills, which depend on awareness of one’s abilities and challenges, knowledge of the types of supports and accommodations that facilitate success, and the abilities to communicate effectively in order to receive these supports and accommodations.

The possession of these skills contributes to positive employment outcomes. Higher levels of self-determination are associated with longer job retention, more job satisfaction, and better job performance (Akkerman, Kef, & Meininger, 2018; Fornes, Rocco, & Rosenberg, 2008). This relationship between self-determination and employment success is intuitive. When people like the work that they do, when they find it meaningful, and when they go to work on their own accord, they are motivated to do well at work. In these ideal circumstances, work is more than a paycheck—it is a source of identity, self-esteem, and social connectedness. When people gain these nonfinancial benefits from work, they devote more energy and passion to the job, and their performance benefits. The field has recognized self-determination and self-advocacy as critical for employment success, and interventions designed to improve employment outcomes target these areas (Green, Cleary, & Cannella-Malone, 2017).

Finite Skills

All of the research on skills reviewed thus far rests on a basic premise that for any given position a person must meet minimum requirements. These requirements might include minimal fine or gross motor skills, or color differentiation abilities for sorting tasks, for example. This chapter began with the acknowledgement that if someone with IDD is hired for a job for which they are not qualified, the experience will not be positive. The employee will not achieve workplace success and the fulfillment that accompanies it. Meanwhile, the employer will not benefit from the experience and will be reluctant to hire adults with IDD in the future.

The skills highlighted thus far, including adaptive and self-advocacy skills, are important for employment generally. The vast majority of positions require the ability to interact with co-workers and clients, and thus social skills are usually if not always relevant. In addition to these universally relevant skills, certain jobs require specific skills that many not be relevant for other businesses or positions. Early research on employment of adults with IDD focused on the identification of specific skills required for specific jobs (Cohen & Williams, 1961; McCartney, 1958; Posner, 1966). For example, one study identified the following activities (and skills required for those activities) as essential for work within food and domestic service positions: making beds, cleaning windows, polishing, mopping, waxing, dusting, sweeping, setting tables, cleaning food utensils, serving food, washing, ironing, and folding clothes (Cohen & Williams, 1961). This study also outlined perquisite skills for employment within the industry and business sectors (Cohen & Williams, 1961). Other early work emphasized manipulative dexterity as a critical skill for the types of jobs that were available to adults with IDD, including packaging and assembling (Tobias & Gorelick, 1960). For adults with IDD, extent of manipulative dexterity was considered indicative of work ability (Neeman, 1986; Tobias & Gorelick, 1960).

From this foundational research, the field has evolved to develop a focus on the more broadly defined skills, like social skills. This new focus on the broader skills should not be interpreted as finite skills lacking importance. More currently, researchers have turned their attention to complex skills, like social skills, which are perhaps more difficult to define and measure but still important.

The identification of critical skills comprises an essential contribution to the field of employment for IDD. A second key contribution is the research on assessing these skills, given the fact that assessment must precede teaching in order to ensure that the skills being taught are relevant for each individual learner. The following section provides an overview of the field of assessment and describes considerations related to assessment spanning the entire employment process—from before a person enters a vocational training program, continuing throughout participation in a program, and as needed after the person has begun employment.

Assessment

Assessment is a key consideration even at the early stage of the employment process, before an individual has entered a vocational training program (Marston, 2015). In order to maximize the likelihood that any given program will be effective for any given individual, it is critical to ensure a good match between program and participant. The skill levels and interests of a potential program participant need to be identified in order to avoid a situation in which a person enters a program that does not address his or her goals and/or provide appropriate level of instruction. Other considerations at the outset include the type of job the person wants and what skills are necessary for that occupation, what types of jobs are available in the area (and again what skills are necessary for these jobs), and what types of supports will be available after the person starts working and how these supports (or lack thereof) will impact what skills are necessary (Marston, 2015). Thus, assessment must occur at the level of a person (i.e., the abilities and interests of a job candidate) and also at the level of the environment (i.e., availability of job opportunities and supports). The sections that follow describe research at both of these levels.

Person-Level Assessment

At the person level, since many key skills fall under the umbrella of adaptive functioning, the research on assessment of adaptive functioning is of central importance. As described in the review of skills, adaptive functioning, defined as "the ability to respond to environmental demands" (Arias, Verdugo, Navas, & Gómez, 2013, p. 156) or "the behavioral skills that people typically exhibit when dealing with the environmental demands they confront" (Widaman & McGrew, 1996, p. 97), is a construct that subsumes many of these considerations, particularly daily living skills and social skills and, relatedly, reaction to supervisors. Adaptive functioning is a multidimensional domain, with constructs including daily living and social skills, among others. There are four scales of adaptive behavior that meet the following criteria: reflect a multidimensional construct which includes multiple distinct domains; have demonstrated adequate reliability and validity; and "have been standardized on people with and without ID" (Arias et al., 2013, p. 157). These four measures include (1) the Vineland Adaptive Behavior Scales Third Edition (Sparrow, Cicchetti, & Saulnier, 2005); (2) the Adaptive Behavior Assessment System Third Edition (Harrison & Oakland, 2015); (3) the Scales of Independent Behavior-Revised (Bruininks, Woodcock, Weatherman, & Hill, 1996); and (4) the Adaptive Behavior Scale-School Version Second Edition (Lambert, Nihira, & Leland, 1993). Clearly, the School Version scale was not designed for implementation in a vocational training program or in the workplace.

Several studies that have identified relevant employment skills utilize one or more subscales of the measures listed above or use items selected from these measures, as their predictors of employment (Siperstein, Heyman, & Stokes, 2014; Tomaszewski et al., 2018; White & Dodder, 2000). For example, performances on the socialization, communication, and daily living subscales of the Vineland Adaptive Behavior Scales were each explored in relation to employment outcomes in one study of adults with Down syndrome (Tomaszewski et al., 2018). Within each subscale of this assessment, there are additional subcategories, providing the opportunity for assessment of more specific facets of adaptive functioning. The communication subscale yields specific scores for receptive, expressive, and written communication skills. The daily living subscale provides scores for personal (i.e., hygiene and self-care), domestic, and community (i.e., transportation) skills. The socialization subscale includes coping skills, interpersonal skills (i.e., social skills), and engagement in play and leisure. Thus, general measures of adaptive functioning also provide assessment data that is specific to several skills that have been identified as relevant for employment success, including hygiene, transportation, and social skills.

In addition to the measures of social skills within larger measures of adaptive functioning, there are also measures that focus on this skill set explicitly. For example, the Social Skills Improvement System (formerly the Social Skills Rating System) provides scores on each of seven social skills (communication, cooperation, assertion, responsibility, empathy, engagement, and self-control) and each of five problem behaviors (externalizing, bullying, hyperactivity/inattention, internalizing, and autism spectrum; Gresham & Elliott, 2008). Items from this measure have been used to generate social skill scores, which are then explored in relation to employment outcomes (Carter et al., 2011). Importantly, the use of any scale of adaptive behavior or social skills should reflect the premise that because adaptive functioning represents behavior in the context of environmental demands, levels of adaptive functioning will differ across context, including time and place. The supports and demands in a workplace differ from the supports and demands at home, and a person's level of functioning will vary accordingly.

Functional behavioral assessment (FBA) is a technique that is designed to "find effective ways of addressing significant challenging behaviors" (Marston, 2015, p. 117), and it is relevant to workplace assessment because challenging behaviors are a critical barrier to employment obtainment and retention for adults with IDD. The underlying premise behind FBA is that behavior is goal-directed. With FBA, the problematic behavior is defined and observed to yield information about the frequency of the behavior and also the antecedents and consequences of that behavior. Information about the antecedents and consequences informs intervention. It might be possible to remove triggers for problematic behaviors once these triggers (antecedents) have been identified. Or, a FBA might demonstrate that a consequence (i.e., being removed from the job site) is actually serving to reinforce the behavior, if the consequence is in fact desired by the person exhibiting the challenging behavior. After the assessment has yielded one or more hypotheses about the function of a behavior, functional behavioral *analysis* involves the systematic manipulation of antecedents and consequences in order to reduce or eliminate the identified challenging behavior.

As the section on skills describes, in addition to adaptive and social skills, self-determination and self-advocacy have been identified as fundamentally important to positive employment outcomes. The ARC's Self-Determination Scale (Wehmeyer, 1996) is a commonly used measure that was specifically designed for individuals with IDD. The scale measures self-determination generally and also subcomponents including autonomy, self-regulation, psychological empowerment, and self-realization. Scores from this assessment are related to positive employment outcomes, including job satisfaction and job retention (Fornes et al., 2008).

Finally, the measures reviewed thus far are assessments of complex and multifaceted skills, adaptive behavior including social skills, and self-determination. While these skills and their assessment are practically universally relevant for employment of adults with IDD, it is also essential to assess the finite and specific skills that are required for specific tasks. Foundational work in this area culminated in assessments of dexterity and fine motor skills, including the Purdue Pegboard Assembly Task and O'Connor Finger Dexterity Test as measures of finger dexterity, the Hand-Tool Dexterity Test, and the Steadiness Test, which measures accuracy of movement (Bennett, 1972; Corlett, Salvendy, & Seymour, 1971; Human Resources Center, 1967; Neeman, 1986; O'Connor, 1965; Tobias & Gorelick, 1960). These measures indicate ability to perform the finite tasks in industrial and clerical areas, such as packaging, assembling, typing, etc.

As the preceding paragraphs demonstrate, the field of assessment has produced instruments that measure and document the skills and behaviors that are crucial for employment success. With the data that we generate from any of these assessment techniques and when measuring progress on any skill, we should not only ask “did this person learn this skill?” but also “does this skill translate into something meaningful?” For example, one vocational training program resulted in a 50% reduction in need for support on the job (Gomes-Machado, Santos, Schoen, & Chiari, 2016). Even when the skills being taught and assessed are finite and specific, the outcome can have meaningful impact in the real world.

Job-Level Assessment

At the job level, assessment must yield an understanding of the skills that are necessary for a person to complete assigned job duties. Decades ago, researchers understood the importance of identifying the “microunits” of a job or the specific tasks and their associated physical and cognitive requirements (Drewes, 1961). This recognition has led to the use of techniques including task analysis, in order to break down skills and ultimately provide relevant and simple instruction.

Job-level assessment also provides an understanding of the work environment including what might be challenging and what might be supportive to the individual. In a sense, then, FBA can be considered an assessment at the job level since its purpose is to identify environmental determinants of behavior. A holistic approach to job-level assessment is an inherent aspect of customized employment and an approach which is increasingly recognized as a promising alternative to more traditional strategies for obtaining employment, such as submitting an application that aligns with a specific job description put forth by an employer (Nord, Luecking, Mank, Kiernan, & Wray, 2013). Customized employment, in contrast to these traditional strategies, involves creating a job that aligns with the unique and individualized skills, interests, talents, challenges, and limitations of an adult with ID. The creation of this job requires an assessment (either formal or informal) of the workplace in order to ensure appropriate alignment. The approach is promising, as research has begun to link customized employment practices with positive employment outcomes that extend beyond obtaining employment and encompass things like higher wages and more hours (Nord et al., 2013).

The following section reviews research that has examined how to most effectively teach the skills that facilitate employment success for adults with IDD, beginning by describing how a holistic approach can be applied to program implementation. Successful program implementation, in turn, will impart necessary skills for employment.

Programs

This section presents research on programs for individuals with IDD that aim to facilitate success in competitive employment, including the ability to obtain a job, keep a job, and experience career development and advancement. The section begins with an overview of very specific instructional strategies, including specific app-based technology, and how these instructional strategies are utilized in employment programs. Following the review of specific instructional strategies, the section continues with general considerations related to program implementation. These considerations include program context and the extent to which instruction should be delivered in a classroom or in the workplace. Attention is also paid to the emergence of opportunities for postsecondary education for adults with IDD and postsecondary education as a new context for employment programs. Other considerations include how programs can address holistic circumstances that are unique to each program participant (i.e., the availability of social support).

Instructional Strategies

There is a vast amount of research on instructional techniques and approaches to teaching employment skills, including Applied Behavioral Analysis (ABA), audio-based cues, video instruction, and more (Gilson & Carter, 2016; Gilson, Carter, & Biggs, 2017; Nord et al., 2013; Park et al., 2016). ABA was developed in the 1960s for young children with autism and rests on the premise that behavior is contingent on the environment. Therefore, rewarding desired behaviors increases the likelihood that an individual will continue to display these behaviors. For several decades, ABA has also been widely utilized to enhance employment skills of adolescents and adults with IDD (Wakabayashi, 2009). One early study on this approach demonstrated the effectiveness of ABA within a job training program in improving social skills, particularly reducing noncompliance and inappropriate social interaction (Bates & Pancsofar, 1983).

Promisingly, one meta-analysis of studies examining job-related social skills training found that a wide variety of instructional approaches, including direct instruction and instruction via technology, each yielded positive effects (Park et al., 2016). This meta-analysis also found that direct instruction, where an in-person teacher delivers a curriculum, had a larger positive effect than other strategies, including video- or Internet-based approaches. An example of a direct instruction program is the WAGES program, a job-related social skill curriculum for adolescents delivered via 33 lessons with activities including resume building and mock interviews (Murray & Doren, 2013). The WAGES program has yielded improvements in adolescents' vocational expectations, social skills, and skills relevant to the workplace, such as time management and problem-solving skills (Murray & Doren, 2013).

WAGES is an example of direct instruction delivered within a classroom setting, and despite the evidence for its effectiveness, techniques other than direct instruction may be particularly useful settings outside of the classroom. For example, technology can play a critical role on the job, especially when proximity to a live coach limits an employee's interactions with co-workers, who could potentially serve as sources of natural support (Gilson & Carter, 2016). Technology such as in-ear devices can allow employees to receive cues from coaches and can also facilitate physical space from these coaches, providing opportunities for natural interaction with co-workers (Gilson & Carter, 2016). Technology can be instrumental in providing cues to help employees with IDD achieve specific job-related tasks, such as an assembly task in a factory (Mihailidis et al., 2016). It can also provide cues for more general workplace competencies, including social skills (Gilson & Carter, 2016).

Program Context

In addition to instructional strategies, the context of the program itself is an important consideration and refers to the questions of whether programs should deliver skill instruction in the workplace or in the classroom and the type of classroom setting most conducive to relevant skill instruction. Given the salience of adaptive skills for employment success, a review of the research relating to this skill category seems especially important. Hundreds of studies have examined instructional methods for teaching adaptive skills to people with IDD; the ones included in this discussion have an explicit employment focus.

For programs that are delivered in the classroom, practitioners and policy makers need to juggle teaching adaptive skills and an emphasis on inclusion (Bouck, 2010). One study utilizing data from the National Longitudinal Transition Study-2 (NLTS2), including 99,923 students with IDD, identified an overall lack of "life skills" instruction in secondary school, especially for students with mild IDD (Bouck, 2010). The author concluded that:

> given the current educational policy situation (i.e., a predisposition towards inclusive general education placements for students with disabilities and participation in the accountability system for all students), educators who believe in the value of a life skills curriculum will need to be creative in its implementation. (p. 1093)

While the importance of maximizing the inclusion of students with IDD in general education cannot be overstated, it should not be at the expense of teaching the life skills that are important for future employment. This comes with the caveat, however, that one study that analyzed data from the NLTS2 compared employment outcomes between high school students with moderate and severe IDD that received academic instruction and high school students that received instruction emphasizing functioning skills (i.e., adaptive skills; Bouck, 2010). There were no differences in employment outcomes between the two groups, possibly indicating that present methods of school-based instruction of adaptive skills including social skills are limited in its effectiveness, a conclusion that has been supported by other studies as well (Leffert & Siperstein, 2003). However, since we know that adaptive skills including social skills are perhaps the most important for employment success, these findings should not be interpreted as a call to cease instruction in these areas. Rather, the findings suggest the importance of finding new and impactful methods for school-based instruction of adaptive and social skills, particularly given the push for inclusive education as noted above.

In addition to this need to identify effective methods of school-based social skill instruction, social skill instruction should not be *restricted* to the classroom. In one longitudinal study, adults with IDD who entered employment demonstrated gains in social skills (Stephens, Collins, & Dodder, 2005). The sample for this study consisted of 2760 individuals who were receiving services from the Developmental Disabilities Division of the Oklahoma Department of Human Services, and their employers and positions varied. This suggests that the overall experience of employment, independent of explicit instruction, promotes social skills. The relationship between social skills and employment is therefore bidirectional—in addition to the agreed-upon fact that social skills facilitate employment success, time spent working provides the opportunity for social skill development.

There is a convincing body of research indicating that *early* work experience benefits job seekers with IDD, and this consistent finding is an argument for expanding instruction beyond the classroom (Benz, Lindstrom, & Yavanoff, 2000; Carter et al., 2012; Simonsen & Neubert, 2013). In one study of youth who were participating in a transition program in Oregon, those who had paid jobs while they were in the program were more likely to have competitive employment after the program had ended (Benz et al., 2000). In another study of transitioning youth, prior work experience was a significant predictor of community employment (Simonsen & Neubert, 2013). A third study demonstrates that having a paid job while in high school is strongly predictive of competitive employment 2 years after graduation (Carter et al., 2012). These findings make intuitive sense: it benefits all job seekers to have an employment history on their resume and to provide the names and contact information of former supervisors who were pleased with their performance. Also, work experience provides the opportunity to gain social skills, as described earlier. Moreover, not only is it important to have work experience, it is important to have *early* work experience. In one nationally representative study of adults with IDD, 72% of the adults who were competitively employed held their first jobs before they turned 21 years old (Siperstein et al., 2014). From this body of work, we can conclude that successful employment programs incorporate work experience. Also, this work experience should occur early—the path to employment should begin before youth transition out of the public school system.

Questions related to program context are complex, and there is not a one-size-fits-all approach. Despite opportunities to learn on the job as described in the previous paragraphs, a meta-analysis of studies that evaluated job-related social skills training programs for secondary students found that school-based programs were more effective than job-based programs in achieving social skills outcomes, specifically empathy, cooperation, and assertiveness (Park et al., 2016). It is important to note that this meta-analysis only included secondary students. In light of the documented importance of social skills, it is imperative to identify the program context that works best for each individual, based on their age, disability status, preferences, and other factors.

An additional consideration related to program context is the idea that it does not have to be a question of either/or—programs can have school-based and employment-based elements. In review of employment skill programs for secondary students with ID, Gilson et al. (2017) identified 10 studies (out of 56 included in their review) that were school-based initially but had an employment or community generalization component. Schools must have some level of involvement in explicitly preparing students with IDD for employment, since federal law mandates career development for students before they leave the public education system (Biggs & Carter, 2016). The question that remains, then, is how to use in-school programming time most effectively.

Also, the question of program context contains more nuance since the Higher Education Opportunity Act of 2008 facilitated access to postsecondary education for students with disabilities one decade ago, and as a result, as many as 40% of colleges and universities around the country are including students with IDD on campus (Grigal, Hart, & Weir, 2012). Research indicates that students with disabilities who attend postsecondary education enjoy diverse and meaningful benefits across domains, including health and social relationships (Butler, Sheppard-Jones, Whaley, Harrison, & Osness, 2016). Improving employment outcomes for people with disabilities is an explicit goal of inclusion in postsecondary education, and there is preliminary data showing that postsecondary education leads to positive employment outcomes (Butler et al., 2016; Moore & Schelling, 2015). These studies do not differentiate between students with mild and more severe IDD, and more longitudinal studies are needed in order to conclude that postsecondary education leads to long-term employment success.

Also, a focus on promising practices *within* postsecondary education programs is just beginning. Grigal et al. (2012) identified 149 institutions of higher education that serve students with IDD, and they report great variability across these programs. Programs vary in the extent to which they offer and/or emphasize a wide range of services, including career and vocational counseling, self-advocacy instruction, internships, natural supports, person-centered planning, collaboration with vocational rehabilitation agencies, and more (Petcu, Chezan, & Van Horn, 2015; Plotner & Marshall, 2016). Despite this variability, evidence suggests that the experience of postsecondary education is a valuable one for students with IDD. One study explicitly compared outcomes across an inclusive versus segregated model of postsecondary programming for students with IDD and found that students who attended both types of programs were more likely to be employed after school completion than students with IDD who never attended postsecondary education (Moore & Schelling, 2015). From some postsecondary programs, success rates are extraordinarily high; for example, 80% of graduates from one particular program achieved long-term competitive employment following graduation (Kelley & Buchanan, 2017). This program attributes its success to multiple factors, several of which are highlighted in this chapter, including the provision of work experience while participants are still in school, holistic approaches that incorporate perspectives of family members and other natural supports, and person-centered planning that takes into account individuals' preferences and skills, thus adhering to principles of self-determination (Kelley & Buchanan, 2017). It is also likely that the experience of postsecondary education results in the accumulation of social capital through relationship building and personal connections to future employers—an ingredient for employment success for people without IDD. In addition, successful postsecondary education programs should address and promote adaptive skills of program participants. According to one study, students in postsecondary education report that adaptive skills are an area of concern and difficulty, indicating that these programs should support students in these areas (Berg, Jirikowic, Haerling, & MacDonald, 2017). Emphasis on adaptive skills should not end in high school.

Finally, success of postsecondary education programs in the realm of employment comes with a caveat that is still preliminary, as research in this area is new—programs may have limited success in opening doors to diverse employment options for students with IDD. One study compared graduates of two postsecondary education programs to young adults with IDD who did not attend postsecondary education. While employment rates for the postsecondary group were higher than the comparison group, the postsecondary group and the comparison group had similar occupations (Moore & Schelling, 2015). It is possible that the graduates of secondary and postsecondary institutions chose similar occupations, but it is also possible that regardless of educational level, certain occupations remain elusive to people with IDD. Employment fields in which no graduate worked included art, design, installation/maintenance/repair, and programming/mathematician, among others. Ultimately, the field should strive for postsecondary education programs that will result in employment *and* in the ability to choose widely among potential occupations.

Holistic Considerations

In addition to program context, successful employment programs are those that are holistic in the sense that they take other environmental opportunities and constraints into account. For example, because access to transportation and related services has emerged as a significant predictor of positive employment outcomes for adults with IDD, programs can only be successful to the extent that they consider and address each individual participant's transportation opportunities and limitations (Moore et al., 2002; Noel et al., 2017). Other holistic considerations include a person's level of social support. Studies show that parental expectations predict employment such that higher expectations relate to more successful employment, presumably because parents with high expectations help their children to access the most relevant programs and also because parents' expectations might motivate children (Carter et al., 2012).

Successful programs look beyond the skill levels and characteristics of individuals served and consider the larger ecology of factors that contribute to workplace success. This is a complicated and difficult mandate, but there are programs that implicitly acknowledge the need to look beyond individual characteristics of potential employees with IDD. For example, the Bridges from School to Work Program serves youth with all disabilities (including but not limited to IDD) and is an "employer-driven program," meaning that program staff considers the needs of each individual employer, in addition to the skills and interests of the youth served by the program (Hemmeter, Donovan, Cobb, & Asbury, 2015). The skills that are targeted through intervention thus reflect the employment landscape—who is hiring in the local area, for what position, etc. More than 18,000 youth across the country have participated in the program, which provides career counseling, help with job placement, and on-the-job support (Hemmeter et al., 2015). The program has demonstrated success; at age 30, approximately 75% of the individuals who were in the Bridges Program as youth were employed (Hemmeter et al., 2015).

As we have seen throughout this section, there are a wide range of program techniques and contexts. Program techniques include ABA, the use of technology, direct instruction, or some combination of each. The program context refers to whether it is school-based or employment-based and the individual participants' ecology—factors such as availability of social support, the needs of local employers, and more.

Conclusions

The vast majority of adults with IDD have the potential to work yet lack access to competitive employment (Siperstein et al., 2013). This is despite decades of research focusing on employment for this population. From this research, we have identified the skills that are primary predictors of successful competitive employment for adults with ID, including social skills, and other skills falling under the umbrella of adaptive functioning, like transportation and self-care. There is also a solid base of research indicating which experiences lead to competitive employment; early work experience is pivotal, and it seems like research is now converging on postsecondary education as a step toward employment. We are beginning to address questions about how to deliver social skills in changing contexts, such as secondary education classrooms that are increasingly inclusive and postsecondary education programs that are welcoming more and more students with IDD. We have identified impactful instructional techniques and techniques for assessment. We also underscore the importance of assessing individual skill level, along with environmental opportunities and constraints. We have effective and reliable techniques for each type of assessment.

The current challenge, then, is to merge all that we know into a holistic approach. Research, practice, and policy must reflect the premise that there is not a one-size-fits-all approach to employment. People's unique life circumstances will dictate which employment experiences will be suitable for them and which will not. For example, individuals who receive Social Security Disability Insurance have to follow specific guidelines in order to maintain receipt of benefits (Nord et al., 2013). Also relevant are individual skills, preferences, dreams, geographic areas, and more. Skill instruction, program design, and assessment each needs to reflect the reality that a one-size-fits-all approach will not work. An approach that considers the unique circumstances of each individual participant is especially challenging in light of the "fragmented education, vocational rehabilitation, and human services systems" that serve adults with IDD, yet it is necessary nevertheless (Nord et al., 2013).

Also, as much of the research cited in this chapter has done, let's not expect getting a job to be the ultimate outcome. People with IDD, like all people, want to be at a job that they *like*. Many people with IDD want to develop and advance within their careers; they strive for higher wages and more responsibility. Research is beginning to address questions relating to job quality and has demonstrated that career development and advancement are possible for adults with IDD (Heyman, Stokes, & Siperstein, 2016). Other studies have identified links between job satisfaction and work productivity (Hall, Morgan, & Salzberg, 2014) and investigated job choice, job complexity, and salary among workers with ID (Kaye, 2009; McDaniels, 2016). Findings are bleak, as most people with disabilities who are employed are still under the federal poverty line (Nord et al., 2013). However, this body of work is a step in the right direction, as it acknowledges that getting a job is not and should not be the end of the story.

As a final consideration, a complete holistic approach will acknowledge the role of the employers as well. Employers need to recognize that hiring people with disabilities is not an act of charity but a boost to their bottom line. Inclusive hiring improves the public's perceptions of businesses, thereby creating a more robust customer base (Siperstein et al., 2006). As we merge all that we know about skills, programs, and assessment into a holistic approach to increasing the employment rate, let's bring our partners from the business sector on board as well. Through this combined effort, we will achieve the change that we have worked toward for decades.

Neuropsychology

26

Graham M. L. Eglit

Abnormalities in brain structure and/or function are common in developmental, psychiatric, and neurological disorders, including intellectual disabilities. These abnormalities are central to defects in cognitive processing in these conditions, which, in concert with other factors, impact an individual's academic achievement, functional independence, and vocational outcome (Yeates, Ris, Taylor, & Pennington, 2009). A central focus in clinical neuropsychology is to identify and describe the fundamental cognitive processing deficits in brain-based disorders and to explain these deficits in terms of brain structure and function (Lezak, Howieson, Bigler, & Tranel, 2012). As such, neuropsychology is essential to the understanding of intellectual disabilities, and neuropsychological assessment is a key component of patient care (Yeates et al., 2009).

This chapter will discuss defining features of neuropsychology, assumptions made by neuropsychology, essential methods in neuropsychological research, approaches to clinical neuropsychological assessment, and core domains of cognitive functioning assessed in neuropsychology. Finally, this chapter will discuss emerging research areas in neuropsychology that have great potential to advance our understanding of brain-behavior relationships in normal and clinical populations.

What Is Neuropsychology?

Neuropsychology can be defined as the study of brain-behavior relationships (Kolb & Whishaw, 2009). Behavior, in this definition, can be understood in a broad sense to include cognition, emotion, and behavioral responses; however, traditionally, cognitive processing has been the main focus of neuropsychology (Ogden, 2005). The central aim of neuropsychology is to develop a science of cognition, emotion, and behavior that explains these three phenomena in terms of the function of the human brain (Kolb & Whishaw, 2009). As the name implies, neuropsychology is an inherently trans-disciplinary field, drawing from a diverse set of research areas, including anatomy, biology, biophysics, ethology, pharmacology, physiology, physiological psychology, neurosurgery, psychometrics, cognitive psychology, and philosophy, among others (Kolb & Whishaw, 2009).

Neuropsychology itself is composed of two distinct but partially overlapping sub-disciplines. Cognitive neuropsychology attempts to understand and characterize normal cognitive function through the study of brain-damaged patients. Cognitive neuropsychology is often less inter-

ested in brain localization of cognitive processes and instead emphasizes the implications of brain damage-induced cognitive changes for theories of normal cognitive information processing (Ward, 2006). In contrast, clinical neuropsychology places greater emphasis on the behavioral expression of central nervous system dysfunction (Lezak et al., 2012). Accordingly, the focus in clinical neuropsychology is on brain pathology and the associated signs and symptoms of this pathology. This chapter principally focuses on clinical neuropsychology. It should be noted, however, that the research questions, methods, and findings of these two sub-disciplines overlap to a significant extent.

Although described as a clinical discipline, clinical neuropsychology has both research and applied clinical branches. Clinical neuropsychological research is aimed at characterizing cognitive phenotypes, identifying cognitive markers of disease states, describing longitudinal trajectories of cognitive deficits, and developing measures to facilitate diagnosis, cognitive profile characterization, and evaluation of response to intervention. As a clinical practice, neuropsychology attempts to infer brain functioning and characterize lesion location, clarify cognitive strengths and weaknesses, predict functional difficulties, contribute to the determination of legal competency, and inform intervention targets and measure intervention outcomes (Heaton & Marcotte, 2000).

Foundational Assumptions of Neuropsychology

An important aspect of any discipline is the assumptions made by practitioners within that discipline. The discipline of neuropsychology rests on three key assumptions, which serve as the preconditions for investigation. The first of these assumptions is the brain hypothesis. The brain hypothesis maintains that the brain is the source of behavior (Kolb & Whishaw, 2009). This assumption commits neuropsychology to materialism, which maintains that behavior can be explained by the complex interaction of physical entities and events. However, neuropsychology typically does not embrace a reductive materialism, in which behavior, such as memory, can be reduced to individual neurons. Instead, it is more commonly assumed that behavior is an emergent property of the complex interactions among numerous neurons and neuronal networks (Pennington, 2009). Moreover, the influence between the brain and behavior is typically assumed to be bidirectional. In this sense, the brain is both the source of behavior and in turn is shaped and molded by one's learning history and experience. There is now a wealth of evidence demonstrating synaptic plasticity-driven changes in neural wiring due to unique experience histories, such as those found among musicians, blind readers of Braille, and the congenitally deaf, among others (Galaburda & Pascual-Leone, 2003).

The second assumption provides more specificity to the brain hypothesis. This second assumption is the cerebral localization hypothesis (also termed domain specificity), which maintains that specific cognitive functions can be localized to regions or circuits within the brain. The cerebral localization hypothesis consists of three key claims: (1) the brain has a modular organization; (2) each module is specialized for a particular cognitive process; and (3) these modules can be reliably localized to specific brain regions (Greiffenstein, 2014). Notably, cerebral localization does not entail that these brain-behavior modules are isolated and independent of one another. Instead, efficient performance of a behavior, such as speech production, requires the orderly integration of multiple modules. In addition, many of these modules are localized to distinct regions of the brain, with information processed both simultaneously and sequentially in these modules. Taken together, a more nuanced view of cerebral localization entails not only that cognitive functions are localized but also that they are distributed in multiple regions of the brain, operate in parallel to one another, and are integrated in a hierarchical fashion, with more complex modules built on simpler ones (Kolb & Whishaw, 2009).

Finally, the third assumption of neuropsychology is the psychological or cognitive assumption. This assumption holds that the use of psychological or cognitive constructs to explain normal or abnormal behavior is more parsimonious than a wholesale inventory of correlated behavioral abnormalities or a reduction of behavior to neurophysiology (Morton & Frith, 1995; Pennington, 2009). While some may interpret this assumption as maintaining that single cognitive deficits underlie specific disorders, such as phonological processing for dyslexia or theory of mind for autism, a more nuanced and scientifically plausible understanding of this assumption is that these disorders are characterized by multiple cognitive deficits acting in combination with one another. A key task of neuropsychology is to identify these fundamental cognitive constructs and explain how their interactions explain characteristic behavioral abnormalities within specific disorders (Pennington, 2006).

Clinical Neuropsychology: The Key Role of Psychometrics

One of the defining features of clinical neuropsychology is the emphasis placed on strong psychometric theory to inform clinical assessment. In fact, this focus on psychometrics distinguishes clinical neuropsychology from the closely related discipline of behavioral neurology. While both clinical neuropsychology and behavioral neurology specialize in the behavioral expression of brain dysfunction, behavioral neurology evaluates and characterizes this behavioral expression in terms of pathological signs, which are either present or absent. In contrast, clinical neuropsychology is firmly grounded in the psychometric tradition of empirical psychology, emphasizing the measurement of continuously distributed behavioral variables with known acceptable reliability and validity (Horton & Puente, 1986; Rourke & Brown, 1986). Thus, psychometrically informed measurement of behavior is an essential feature of clinical neuropsychology.

Several core psychometric considerations in neuropsychology warrant discussion. The first of these considerations is the reliance on continuously distributed variables. Continuously distributed variables are preferred in neuropsychology because their frequency distributions often conform to a normal curve (also known as a normal distribution or bell curve). The normal curve reflects the probability of obtaining a score or range of scores when randomly sampled from the population. This probability is often described in terms of percentile ranks or their associated deviate scores. A percentile rank indicates the percentage of individuals from the population who score at or below a given test score. Deviate scores, which include z, T, scaled, and standard scores, are standardized expressions of raw scores and reflect the number of standard deviation units from which a score differs from the mean of the distribution. Deviate scores thus function to convert raw scores into percentile ranks. Conceptually, deviate scores and percentile ranks are used to characterize the degree of abnormality of an obtained score, with abnormal scores reflecting poor test performance interpreted as indicative of neuropsychological impairment (Slick, Strauss, Sherman, & Spreen, 2006). There is considerable debate over optimal cutoffs for defining abnormality/neuropsychological impairment, but most definitions range from ≥1 standard deviation below the mean (16th percentile or below) to ≥2 standard deviations below the mean (0.4th percentile or below) (Heaton & Marcotte, 2000).

The use of percentile ranks and deviate scores to detect neuropsychological impairment relies on the use of a comparison sample to derive a standard normal distribution. This process is often referred to as norming and the data resulting from this process as normative data. Conceptually, normative data should reflect the distribution of test scores in the general population. Creation of normative data for test score interpretation therefore requires a large (greater than at least 200 cases) sample in order to avoid sampling error and to increase the representativeness of the sample to the general population

(Nunnally & Bernstein, 1994). In addition, the demographic composition of the normative sample should be comparable to the general population. Recognizing that demographic factors, such as age, education, gender, and race/ethnicity, can affect neuropsychological test scores independent of brain dysfunction, demographic corrections are commonly applied to normative data in neuropsychology. In general, there are two main approaches to normative comparisons in clinical neuropsychology: (1) comparing individual test scores to normative data that approximates as closely as possible the general population and (2) comparing individual test scores to normative data that matches as closely as possible the unique subgroup to which the examinee belongs (e.g., non-Hispanic Caucasian males with 14 years of education) (Mitrushina, Boone, & D'Elia, 2005; Strauss, Sherman, & Spreen, 2006). Notably, adaption of either of these approaches may be dictated by the purposes of the evaluation. For instance, in attempting to diagnose intellectual disability or learning disability, comparison to all other persons of the same age in the general population is most appropriate. However, if the purpose of the evaluation is to characterize cognitive strengths and weaknesses to inform diagnostic considerations and/or plan classroom accommodations, comparison to the examinee's unique subgroup may be more apposite (Strauss et al., 2006). Ultimately, availability of appropriate normative data is crucial to rendering informed clinical decisions based on neuropsychological test performance (Heaton & Marcotte, 2000).

In addition to the availability of adequate normative data, the reliability of neuropsychological tests and the validity of the interpretations based on neuropsychological test scores are important psychometric considerations. Reliability reflects the degree to which a test consistently measures a given construct. There are several types of reliability, including internal consistency reliability (which indicates the extent to which items on a test measure the same construct), test-retest reliability (which reflects the temporal stability of a measure), alternate forms reliability (which denotes the similarity of scores across two measures of the same construct), and inter-rater reliability (which indicates the similarity of scores across two raters of the same test). The greater the reliability of a test, the more confidence an examiner can have in the precision of a score based on performance on that test. In contrast, validity refers to the extent to which a test actually measures what it intends to measure. Similar to reliability, there are multiple types of validity evidence that include, at a minimum, content-related validity (i.e., the degree to which the content of the test is relevant, representative, and of high technical quality), construct-related validity (i.e., the extent to which a test measures what it intends or purports to measure), criterion-related validity (i.e., the extent to which a test is related to an external outcome), and response process validity (i.e., the degree to which the response processes implemented by examinees are consistent with measurement on the intended construct) (although for further types of validity information, see American Educational Research Association, 1999; Messick, 1995). Adequate validity is essential to the interpretation of a test score as indicative of a specific construct. A considerable amount of research is dedicated to evaluating the reliability and validity of neuropsychological measures and deriving appropriate normative data in order to facilitate test selection, administration, and interpretation.

Essential Research Methods in Neuropsychology

There are several essential methods used in neuropsychology to identify brain-behavior relationships. Historically, the lesion study has been the most important method to neuropsychology. Lesion studies evaluate the impact of brain damage on patient behavior. These types of studies were central to the development of the cerebral localization hypothesis and remain key in the determination of brain-behavior relationships. The central premise of the lesion study is that the function of a given brain region can be inferred on the basis of impaired and spared abilities resulting from lesions to that area. Lesion studies can be described in terms of single dissociation studies or double dissociation studies. In single dissociation studies, a patient with brain damage exhibits impairment on one task (task A), but a relatively normal performance on a separate task (task B). This type of finding suggests that task A and task B utilize different cognitive processes that rely on separate neural regions. However, a key shortcoming of single dissociation studies is the possibility that tasks A and B require the same cognitive processes/neural regions but that task B requires more of this cognitive process than task A. Conclusions about brain-behavior relationships can be strengthened through demonstration of a double dissociation. In a double dissociation, one patient with brain damage exhibits impairment on task A, but relatively normal performance on task B, while another patient with a lesion in a different brain region is impaired on task B, but normal on task A. Double dissociations provide strong evidence for the distinctness of closely related cognitive processes and their neural correlates (Ward, 2006).

Neuroimaging represents another essential research method in neuropsychology. Neuroimaging can be classified as structural or functional neuroimaging. Structural neuroimaging refers to brain imaging methods that produce static images of the spatial configuration of different types of brain tissue. Obtaining static images of the brain is based on the fact that different types of brain tissue (e.g., the skull, gray matter, white matter, cerebrospinal fluid, etc.) have different physical properties. Correlation of a structural abnormality with specific impairment on neuropsychological testing yields valuable information on the potential causal role of that region to that neuropsychological ability. Structural imaging modalities include computerized tomography and magnetic resonance imaging, which differ in their method of measuring physical properties of different tissue types (Ward, 2006).

In contrast to structural imaging, functional imaging creates dynamic images of changes in physiological characteristics of the brain that may be correlated with task-related cognitive processes. Most functional imaging modalities are based on the fact that additional regional blood flow is needed to supply oxygen and glucose to meet the metabolic demands of carrying out specific cognitive tasks. Comparison of this task-related physiological response to a baseline level of physiological activity during a control condition can thus shed light on brain region recruitment for that cognitive task, which suggests specialization of that region for the specific cognitive function under investigation. Selection of a baseline condition is a complex process, however, and requires isolating the specific cognitive process under investigation from other cognitive processes that may be involved in the task. There are several experimental designs that have been used for this comparison, which include cognitive subtraction, factorial designs, and parametric designs (see Friston, 1997, for a review of these designs and their relative advantages and disadvantages and Kosslyn, 1999, for a discussion of the difficulties of functional neuroimaging interpretation). Positron emission tomography and functional magnetic resonance imaging are the two most common functional imaging modalities (Huettel, Song, & McCarthy, 2014).

Additional methods of neuropsychological investigation include electroencephalography (EEG), single cell recordings, transcranial magnetic stimulation, computational modeling, and animal models; however, discussion of these other methods is beyond the scope of this chapter.

Approaches to Neuropsychological Assessment

A typical assessment in neuropsychology involves the administration of a multitude of cognitive and behavioral tasks. Through integration of the qualitative and quantitative data obtained by these measures, a neuropsychologist can clarify key deficits in cognitive processing, identify syndrome-level patterns of these deficits, and surmise most likely etiologies for these syndromes (Heaton & Marcotte, 2000). Historically, several distinct assessment approaches have been followed to achieve these ends. This section provides a brief description of four of the most common assessment approaches.

Qualitative Approach (Luria)

The qualitative approach to neuropsychological assessment is most often associated with the Russian neuropsychologist A.R. Luria (Glozman, 2007). Luria assumed that mental and behavioral functions were complex constellations of more fundamental component parts and that it was the neuropsychologist's role to ascertain whether and which of these fundamental components was impaired in a patient (Lezak et al., 2012). To write, for instance, involves, at a minimum, skilled movement, spatial organization, word selection, and grapheme sequencing. Impairment in any one of these fundamental cognitive processes can result in a disturbance in writing ability. Moreover, impairment in one of these fundamental abilities is likely to impact performance on other tasks. For instance, impaired word selection may also emerge as word finding problems in spontaneous speech and difficulty identifying the names of pictures and objects. Detection and characterization of neuropsychological impairment for Luria and his followers in the qualitative approach primarily involved assessing qualitative aspects of patient behavior, placing particular emphasis on the nature of deviations or errors, while the use of psychometric instruments was considerably less common. Assessment for Luria was highly individualized, following a hypothesis-driven approach in which the particular behaviors assessed were selected by the neuropsychologist based upon the neuropsychologist's working hypothesis regarding the underlying fundamental deficits from which the patient suffered (Ardila, 1992).

The qualitative approach is not without its critics. For one, several authors have questioned whether this method can be properly classified as clinical neuropsychology, preferring instead to place Luria in the tradition of behavioral neurology. As discussed above, in contrast to clinical neuropsychology, which relies on the measurement of continuously distributed variables within a psychometric tradition, behavioral neurology emphasizes dichotomous classification based on pathological signs (Horton & Puente, 1986; Rourke & Brown, 1986). For another, given the non-standardized nature of the assessment and the lack of emphasis on quantitative measurement, the qualitative approach of Luria has been criticized for being subjective, occasionally obscure and resulting in conclusions of questionable validity (Reitan, 1976). Nonetheless, Luria's emphasis on breaking down complex mental and behavioral functions into component parts and his attention to the nature of errors were highly influential to future neuropsychological developments (Ardila, 1992).

The Fixed Battery Approach (Halstead-Reitan)

In contrast to the qualitative approach, the fixed battery approach involves administration of the same comprehensive set of tests to all examinees, regardless of presenting complaints, purposes of the evaluation, or diagnostic considerations. This approach is most commonly associated with Ward Halstead and Ralph Reitan and their battery of tests, the Halstead-Reitan neuropsychological battery (HRNB), although a number of other fixed batteries exist. Historically, the HRNB emerged from the recognition that no single neuropsychological test could accurately detect and characterize the effects of brain damage. Instead, Halstead and subsequently Reitan noted that there was considerable heterogeneity in presentation, functional ability, and test performance among individuals with brain damage (Hom & Nici, 2015). Halstead initially developed a small battery of ten tests designed to measure the complex operations of higher-level mental functions of the central nervous system. Reitan further evaluated these ten tests, as well as dozens of others, to empirically determine their ability to reliably detect the presence of brain damage, lateralization of brain damage, recovery potential, and type of lesion or disease. Tests that contributed to the accurate detection and localization of brain lesions were retained and compiled to create the Halstead-Reitan neuropsychological battery (Goldstein, 2015; Hom & Nici, 2015; Reitan & Wolfson, 2009).

The fixed battery approach has both advantages and disadvantages. In terms of advantages, fixed batteries tend to yield more information on the performance of specific tests across a wide range of clinical populations. As a result, there is often a greater wealth of empirical research to ground interpretation of test scores using fixed batteries, including better norms, greater knowledge of the psychometric properties of tests, and greater knowledge of how to integrate test data across the battery (Heaton, Grant, Anthony, & Lehman, 1981; Reitan, 1964). On the other hand, however, fixed batteries can be unnecessarily lengthy and expensive and cause examinee stress and/or exhaustion due to over testing. In addition, fixed batteries are more likely to become outdated over time as the field develops and may inadequately assess certain cognitive domains, thus requiring administration of supplemental tests (Heaton & Marcotte, 2000). Nonetheless, the fixed battery approach is common in research contexts where a premium is placed on the use of a uniform set of tests and procedures so as to facilitate comparison across study participants.

The Flexible Battery Approach (Iowa-Benton)

The flexible battery approach involves the administration of a tailor-made set of tests to assess patients in a highly individualized manner, with test selection guided by the neuropsychologist's working hypothesis about the condition(s) the examinee is known or suspected to have. This approach is most typically associated with the work of Arthur Benton at the University of Iowa. The development of this approach was based on observation of clinical examinations conducted by psychiatrists and neurologists, which were noted to be highly flexible and efficient. These examinations began with a broad mental status exam, from which the clinician pursued diagnostic possibilities through diverse questions. Exams could last from anywhere between 15 min to over an hour, depending on the degree of diagnostic uncertainty involved in the exam. Benton was impressed by the flexibility and hypothesis-driven nature of these examinations and believed that neuropsychological assessment should follow this model. In this view, neuropsychological assessment should consist of standardized objective tests, similar to Halstead-Reitan, but these tests should be implemented in a highly flexible, hypothesis-testing-driven manner, more akin to Luria (Tranel, 2009).

Benton's approach to assessment consisted of a small, core battery of between two and six standard tests administered to every patient. Then, based on the referral question and the patient's performance on the core battery, additional tests were administered to explore diagnostic possibilities. This approach might be better conceptualized as a fixed-flexible approach, given that a standard set of batteries was always administered and a large set of additional measures were implemented to pursue the remaining diagnostic hypotheses. More recently, the Iowa-Benton school has undergone subtle revision in its approach. In particular, the core battery has expanded in length, and additional information has been incorporated to guide the flexible, hypothesis-testing-driven component of the assessment, including the patient's complaints, impressions gained from an initial clinical interview, the patient's medical history, neurological findings, and neuroimaging data (Tranel, 2009).

The flexible and fixed-flexible battery approach has much to recommend it. These approaches avoid unnecessary testing and allow the neuropsychologist to probe more precisely into the nature of a patient's deficits. However, there is often less psychometric and clinical information available on how tests should be interpreted in conjunction with one another. In addition, flexible and fixed-flexible battery approaches tend to be more reliant on patient- and informant-report of cognitive symptoms to guide test selection, which may lead to imprudent test selection if patient and/or informants lack accurate knowledge of cognitive deficits (Heaton & Marcotte, 2000).

Boston Process Approach (Kaplan)

The final approach to neuropsychological assessment reviewed in this chapter is the Boston Process Approach, which is most commonly associated with the work of Edith Kaplan. At its core, the Boston Process Approach has three main aims: (1) to understand the qualitative nature of behavior assessed by clinical psychometric instruments, (2) to reconcile descriptive richness with reliable and valid assessment, and (3) to incorporate recent insights from cognitive neuroscience and experimental psychology into clinical neuropsychological assessment (Delis, Kramer, Fridland, & Kaplan, 1990). This approach stemmed from the realization that there was considerable variability in the manner in which patients exhibited the loss of one and the same specific cognitive function and that this variability often correlated with lesion size and location. For instance, performance on Wechsler Adult Intelligence Scale-IV Block Design test reliably differs among individuals with left vs. right hemisphere lesions. Patients with right hemisphere lesions are more likely to exhibit configural processing errors, in which they fail to retain the 2 × 2 or 3 × 3 configural structure of produced block constructions. In contrast, patients with left hemisphere lesions are more likely to produce internal block rotation errors while retaining the configural structure of the design. This pattern of performance is consistent with accounts of hemispheric specialization, in which the right hemisphere is dominant for global processing and the left hemisphere for local processing (Delis, Kiefner, & Fridlund, 1988; Delis, Robertson, & Efron, 1986; Robertson & Delis, 1986). Thus, in the Boston Process Approach, the emphasis is placed on the manner in which a patient solves, or fails to solve, items on a neuropsychological test, rather than just their final quantitative score on that test. Over the past two decades, there have been a growing number of tests and methods developed to provide standardized ways of scoring these process outcomes, such as those implemented in the California Verbal Learning Test-II (Delis, Kramer, Kaplan, & Ober, 2000). The Boston Process Approach is most typically associated with a flexible assessment approach, although it can be used with a fixed battery as well.

Core Domains of Neurocognition in Neuropsychology

Neuropsychological assessment involves the administration of a battery of cognitive tasks across several domains of cognition. Assessment with numerous tasks across domains is necessary because neuropsychological tasks are multi-determined, such that poor performance on any given task can be the result of several cognitive and/or non-cognitive factors. To tease apart these potential contributing factors and identify underlying spared and impaired abilities and processes requires the evaluation of the pattern of performance across tasks. In addition to the evaluation of cognition, neuropsychological assessment should include, at a minimum, a global measure of intellectual functioning; an estimate of adaptive, social, behavioral, and emotional functioning; and evaluation of academic achievement in reading and math. As other chapters in this handbook are more specifically devoted to assessment of intelligence (Chaps. 2 and 22), adaptive behavior (Chap. 23), and emotional functioning (Chaps. 8, 24, 47, 48, and 49), this section will cover issues specific to the assessment of core cognitive domains in neuropsychology. Core cognitive domains include attention, memory, executive functions, language, and visuospatial ability.

Attention

Attention refers to a set of processes that enable efficient allocation of cognitive resources to the task at hand (Cohen, Malloy, Jenkins, & Paul, 2014). Unlike other cognitive domains, attention is not a fundamental substrate of cognition, but instead governs the flow and processing of information within other cognitive domains, such as memory, language, and visuospatial abilities (Cohen et al., 2014). This ability is achieved through at least four distinct attentional processes

(Cohen et al., 2014; Mirsky, Anthony, Duncan, Ahearn, & Kellam, 1991).

The first of these processes is sensory selective attention. As the name implies, sensory selective attention involves the selection of sensory input for additional cognitive processing. This selection process occurs outside of conscious awareness and at a very early stage of information processing. In order to successfully selectively attend to sensory stimuli, three subprocesses must be integrated: the ability to filter out irrelevant information, the ability to enhance the processing of relevant/filtered information, and the ability to remain engaged on a stimulus or to disengage from a stimulus and selectively orient/attend to a new stimulus.

The second attentional process is referred to as intention. Intention is important for the selection and control of behavioral responses. Unlike sensory selective attention, intention is a controlled, effortful process that requires conscious awareness. Given its controlled, effortful nature, intention partially overlaps with aspects of executive functioning (see the executive function section below for further detail).

Third, attention is constrained by an individual's attentional capacity. Attentional capacity refers to the amount of information to which an individual can allocate additional cognitive resources at any one time. Attentional capacity is impacted by state factors, such as fatigue, and trait factors, including neural transmission and processing speed, working memory capacity, and spatial and temporal processing constraints.

The fourth core attentional process is sustained attention. Sustained attention refers to the ability to maintain levels of attention across time. Individuals with sustained attention difficulties will often exhibit variability in performance over extended periods of time, often due to loss of interest and/or susceptibility to distraction.

The neuroanatomy of attention is complex and cannot be localized to a single brain system. Instead, multiple brain systems interact as a coherent network to control attention. These regions include the inferior parietal cortex, frontal cortex, limbic system, thalamus, basal ganglia, and the midbrain (Cohen et al., 2014).

Neuropsychological assessment of attention is challenging for a number of reasons. For one, as mentioned above, it is not a fundamental cognitive substrate, but rather functions to enhance other cognitive processes. As such, pure measures of attention do not exist. For another, attention by definition varies over time and may be situation specific. Thus, attention is usually assessed on tasks that load on more than one cognitive domain and may be best evaluated by examining performance across tasks that differ with respect to attentional parameters (e.g., attentional capacity load, time on task, etc.). For sensory selective attention, key tests include letter and symbol cancellation tasks, which involve searching an array of stimuli to identify targets from distractors (Lezak et al., 2012). Intention, on the other hand, is often assessed qualitatively through tasks such as double alternating movements, alternating graphic sequences (e.g., Rampart figures), and motor impersistence (Royall, Mahurin, & Gray, 1992). Attentional capacity is most often measured with the digits forward subtest of, for instance, the Wechsler Adult Intelligence Scale-IV (Wechsler, 2008). More complex tasks of attentional capacity that also require focus typically involve varying both the amount of information attended to and the complexity of effortful processing necessary to perform some operation on that information. A popular measure of attentional capacity and focus is the paced auditory serial addition test (PASAT; Gronwall, 1977). Finally, tests of sustained attention evaluate the temporal characteristics of performance on tasks that involve detecting targets among distractors. The most common of these measures are continuous performance tests (CPT), such as the Connors CPT-II (Connors, 2000).

Memory

Memory is a remarkably complex cognitive domain composed of several distinct memory systems. These memory systems differ in both their time course and the type of information for which they are specialized. Regarding time course, there are three distinct stages of memory.

The first of these stages is the sensory storage (or sensory registration). This stage refers to the point in time in which sensory information (e.g., visual, auditory, gustatory, etc.) is initially registered. This stage is very short in duration, lasting milliseconds to seconds. If no additional processing is conducted, this sensory information quickly dissipates. The second stage of memory processing is referred to as short-term or working memory. Short-term memory has a duration of up to approximately 30 s. In addition, short-term memory has a limited storage capacity in which individuals can typically only maintain 7 ± 2 distinct items (e.g., to-be-remembered words). Unless further processing is applied to items in short-term memory, such as rehearsal or organization, these items will be forgotten. Information that has been sufficiently processed in short-term memory will be transferred into the third and final stage of memory, long-term memory. Long-term memory is relatively permanent and with unlimited capacity (Scott & Schoenberg, 2011d).

There are several different types of long-term memory, which differ in the nature of the information for which they are specialized. Squire and Zola (1996) proposed the most influential taxonomy of long-term memory. In their model, memory can be divided into declarative and non-declarative types. Declarative (explicit) memory refers to long-term memories that can be retrieved and reflected on consciously, including memory for names, people, places, events, and facts. Within declarative memory, there are two further subtypes. The first subtype of declarative memory is semantic memory. Semantic memory is memory for facts and general world knowledge, such as the name of 17th President of the United States and the day of the year on which Christmas falls. This is in contrast to episodic memory, which refers to memory for personally experienced and remembered events, such as what you ate for breakfast today. As opposed to semantic memory, episodic memory requires the active recall of the learning event. Episodic memory is the more important type of memory in neuropsychological assessment (Scott & Schoenberg, 2011d). Episodic memory can be further characterized by whether it involves verbal or visual material, whether it is learned intentionally or incidentally, and whether the episodic memory is for a recent or remote event. In addition, episodic memory can be subdivided into three subprocesses, encoding, consolidation, and retrieval. Encoding refers to the process of learning material, consolidation refers to the process of transferring new material from short- to long-term memory, and retrieval is the process of activating information from long-term memory back to short-term memory for conscious recollection (Scott & Schoenberg, 2011d).

In contrast, non-declarative (implicit) memory refers to information that can influence thought and behavior without conscious awareness. Non-declarative memory includes memory for skills, priming, classical conditioning, and nonassociative learning. Non-declarative memory is seldom evaluated in neuropsychological assessment (Squire & Zola, 1996).

Given the complexity of long-term memory, it is perhaps unsurprising that the functional neuroanatomy of this cognitive domain is similarly complex. Episodic memory is subtended by two functional neurocircuits, a medial circuit (often referred to as the Papez circuit) involving the hippocampus, fornix, mammillary bodies, anterior medial nucleus of the thalamus, and the cingulate, and a lateral circuit (often referred to as the amygdaloid circuit) involving the amygdala, thalamic nuclei, orbitofrontal cortex, piriform cortex, insula, hypothalamus, limbic striatum, and nucleus basalis of Meynert (Mishkin, 1982). Amnestic syndromes are most commonly associated with damage to three distinct regions. First, damage to the medial temporal lobe (hippocampus, parahippocampal gyrus, and entorhinal cortex) often leads to an anterograde amnesia characterized by preserved insight into memory difficulties, increased rate of forgetting, limited retrograde amnesia, and lack of confabulation. Second, patients with damage to the diencephalic regions, especially the medial thalamus region and the mammillary bodies, exhibit anterograde amnesia, but with normal rates of forgetting. Due to disruption of frontal areas, patients with damage to this are may also present with limited insight and a tendency to confabulate. Third, damage to the basal forebrain region results in profound attention difficulties that adversely impacts encoding and retrieval processes, but may leave consolidation intact. Patients with damage to this area have poor insight into their memory difficulties and demonstrate a tendency to confabulate (O'Connor & Race, 2013).

Multiple aspects of episodic memory should be evaluated in order to comprehensively characterize this domain. In particular, memory testing should include measures of verbal (e.g., list learning, story passage recall) and nonverbal (e.g., figure recall) memory. In addition, memory for these stimulus types should be conducted immediately after learning trials (i.e., immediate recall), over the course of multiple repetitions of the stimuli (i.e., learning over trials), following an approximately 20–30 min delay (i.e., delayed recall), and using a yes/no recognition testing format (i.e., recognition) (Scott & Schoenberg, 2011d).

Based on the performance on these learning and memory tasks, one can characterize the episodic memory subprocesses impaired in a patient. For instance, a patient exhibiting poor immediate recall and limited improvement over multiple repetitions of to-be-learned material but who retains most information over a delay likely has a primary deficit in encoding. A patient with poor immediate recall, but some learning over multiple repetitions of information, as well as severely impaired delayed recall that only slightly improves with recognition likely has a primary deficit in consolidation. Finally, a patient with normal immediate recall and learning, impaired delayed recall, and normal recognition likely has a primary deficit in retrieval. Of course, patients can also have deficits in multiple episodic memory processes, leading to even greater specificity in memory profile characterization and neuroanatomical lesion localization (Scott & Schoenberg, 2011d).

Multiple memory tests are available for administration. Representative tests of episodic memory include the Wechsler Memory Scale-IV (Wechsler, Holdnack, & Drozdick, 2009), California Verbal Learning Test-II (Delis et al., 2000), California Verbal Learning Test-Children's Version (Delis, Kramer, Kaplan, & Ober, 1994), and Children's Memory Scale (M. Cohen, 1997).

Executive Functions

Executive functions are a heterogeneous collection of cognitive processes. Fundamentally, executive functions are involved in integrating other cognitive domains to make decisions and initiate complex actions. There are several component processes involved in executive functions. These processes include planning, problem-solving, concept formation (i.e., identify abstract concepts), set shifting, verbal fluency, inhibitory control, and working memory. Certain aspects of memory, especially encoding strategy use and memory retrieval, also involve executive operations. These processes rely principally on the integrity of the frontal lobes. Notably, executive functions undergo rapid change during development. As such, greater inter-individual variability in executive function performance is expected among children and adolescents (Floden, 2014; Scott & Schoenberg, 2011b).

One popular model of frontal lobe functioning divides the prefrontal cortex into three functional regions. The first of these regions involves the dorsolateral prefrontal cortex. Dysfunction in this region is characterized by difficulty carrying out complex goal-directed behavior due to difficulties with organization, planning, sequencing, and selecting and implementing strategies, comprising a so-called dysexecutive syndrome. Individuals with damage to the dorsolateral prefrontal cortex may also appear mentally inflexible and perseverate on incorrect strategies and exhibit poor working memory, especially with regard to mental manipulation of information. In addition, this region supports complex aspects of attention, including selective attention and attention shifting. As such, individuals with damage to the dorsolateral prefrontal cortex may appear highly distractible. The dorsolateral prefrontal cortex is also important for implementing encoding strategies (e.g., semantically categorizing to-be-remembered material) and retrieving items from episodic long-term memory (Floden, 2014; Scott & Schoenberg, 2011b). There is some suggestion of hemispheric specialization for these operations, with the left dorsolateral prefrontal cortex specialized for encoding strategy use and the right dorsolateral prefrontal cortex for retrieval (Habib, Nyberg, & Tulving, 2003).

The second important region of the prefrontal cortex is the orbital/ventromedial region. Damage to this region often results in a "disinhibition syndrome," characterized by lack of impulse control and social filter, inability to delay gratification, and emotional dysregulation. Individuals with damage to this region often exhibit poor judgment, with their behavior governed by the pursuit of immediate reinforcers. In addition, these individuals are often hyperverbal and hyperactive, have difficulties with sustained attention, and have little insight into their behavior (Floden, 2014; Scott & Schoenberg, 2011b).

The third important functional region of the prefrontal cortex is the medial frontal region. Damage to this area results in an "apathetic syndrome." Patients often exhibit lethargy, lack of spontaneous initiation of behavior, and appear disengaged from their environment. They may also appear to be emotionally indifferent, dull, and unmotivated and to lack curiosity (Floden, 2014; Scott & Schoenberg, 2011b).

A variety of measures are available for executive function assessment. Planning can be measured with Tower tests (Delis, Kaplan, & Kramer, 2001) or through more qualitative methods such as inspection of complex figure copying strategy (Meyers & Meyers, 1995). Verbal fluency is often measured with phonemic (Benton, Hamsher, & Sivan, 1983) or semantic (Lezak et al., 2012) word generation tasks. The Wisconsin Card Sorting Test is one of the most popular measures of executive functions, measuring abstract concept formation, set maintenance and set switching, and novel problem-solving (Heaton, 1981). Complex attention can be measured in a variety of ways. The Trail Making Test is a popular measure of task set switching of attention (Reitan, 1958), and the Stroop Test (Golden, 1976) is a class measure of selective attention and the ability to suppress a prepotent response. There are considerably fewer measures available for assessment of the disinhibition syndrome. The Iowa Gambling Task is a commonly administered measure of orbital and ventromedial prefrontal cortex function and involves the ability to learn and adapt behavior to response-reward contingencies (Bechara, Damasio, Damasio, & Anderson, 1994). Assessment of the apathetic syndrome is often achieved through self- or informant-report instruments, rather than performance-based measures. Finally, the Frontal Systems Behavior Inventory evaluates common symptoms resulting from frontal lobe damage and provides separate scales for dysexecutive, disinhibited, and apathetic symptoms. This measure provides both self- and informant-report forms, enabling evaluation of discrepancies across raters, which may shed additional light on patient insight into executive deficits (Grace & Malloy, 2001).

Language

Language is arguably the most distinctly human of all cognitive abilities. While other animals are able to communicate, the scope and complexity of human language is unparalleled. At its core, language refers to the use of arbitrary symbols to convey meaning and involves the ability to comprehend, formulate, and produce spoken, written, and gestural symbolic representations. These abilities are distinct from speech, which involves the ability to control the articulatory movements necessary to produce oral expression. Most language functions are mediated by the dominant (often left) hemisphere, although the ability to comprehend and produce prosody in language involves the non-dominant (often right) hemisphere. Due to the relative importance of non-prosodic aspects of language function, this section will focus only on dominant hemisphere language abilities (Sabsevitz & Hammeke, 2014; Schoenberg & Scott, 2011; Scott & Schoenberg, 2011c).

The ability to use language depends on several constituent processes, including orthographic processing (grouping individual letters into words), phonological processing (deciphering, mentally maintaining, and retrieving the articulatory movements and sound structure of speech), and semantic processing (storing and accessing word meanings). These three fundamental language processes rely on distinct neuroanatomical regions. Orthographic processing is subserved by the left inferior temporal-occipital region. Individuals with damage to this area often exhibit adequate language production, comprehension, writing, and identification of single letters, but their reading of words is slow and effortful (Sabsevitz & Hammeke, 2014). In contrast, phonological processing involves a broader network of brain regions in the dominant hemisphere, including the supramarginal gyrus, superior temporal gyrus and sulcus, and the inferior frontal gyrus. Damage to this area can lead to difficulties selecting and sequencing phonemes during speech production and/or difficulties maintaining or manipulating phonological information in working memory (Sabsevitz & Hammeke, 2014). Semantic processing is widely distributed throughout the temporal and parietal lobe, especially the lateral temporal lobe and angular gyrus. Impairments in semantic processing can result in difficulties with spoken word comprehension, semantic categorization, and object naming (Binder, Desai, Graves, & Conant, 2009).

Language functions are typically divided into two major groups, receptive and expressive language, which both rely on varying degrees of the three abovementioned language processes. Receptive language consists of the ability to comprehend language, both written and spoken, and is localized to the posterior dominant hemisphere. Language comprehension requires processing the phonological elements of speech sounds, retaining phonological information long enough to enable processing of semantic content, and deciphering the semantic content of words and sentences. The dominant hemisphere temporal-parietal area including Wernicke's area is central to comprehension of spoken and written language (Scott & Schoenberg, 2011c). This region is located adjacent to the primary auditory cortex and is key to isolating specific phonemic characteristics of sound into known phonemic systems (Kolb & Whishaw, 2009).

In contrast, expressive language deficits involve difficulties in producing speech. To produce speech, an individual must use multiple language subprocesses, including those involved in semantics (to conceptualize the intended communication), syntax (to order the intended communication), phonology (to map semantic knowledge onto speech sounds), and motor planning (to activate the appropriate motor programs for the intended communication). These processes depend on the posterior inferior frontal lobe as well as the dorsal prefrontal cortex (Sabsevitz & Hammeke, 2014).

Assessment of expressive language should involve at a minimum an analysis of spontaneous speech for output fluency, accuracy of word retrieval, integrity of grammar/syntax, length of utterances, omission of words, meaningfulness of content, and articulatory precision of word production. In addition, tests of picture naming, verbal fluency, phrase repetition, story description, and a writing sample should be administered as part of an assessment of expressive language. Measures of auditory comprehension are key to the assessment of receptive language. Measures of auditory comprehension include simple and complex command following, word-picture matching, yes/no questions, word reading, and sentence comprehension (Sabsevitz & Hammeke, 2014; Schoenberg & Scott, 2011; Scott & Schoenberg, 2011c). Several language-specific batteries have been developed to assess each of these areas of language functioning, including the Boston Diagnostic Aphasia Examination (Goodglass, Kaplan, & Barresi, 2000) and the Western Aphasia Battery Revised (Kertesz, 2006).

Visuoperceptual, Visuospatial, and Visuoconstructional Abilities

Visuoperceptual and visuospatial abilities are central to competent everyday functioning. Most of these abilities occur automatically and outside of awareness, thus obscuring their importance. However, when the brain regions that underlie these functions are damaged, a number of deficits may occur. These deficits may include an inability to process basic aspects of stimuli (e.g., color, form, and orientation), recognize familiar objects, find one's way in the environment, copy or draw designs, or attend to objects in the left hemispatial field. The nature of these deficits and their corresponding functional neuroanatomy are the topic of this section.

Visuoperceptual and visuospatial functional anatomy involves two separate streams of visual information processing that occur in parallel, despite the unitary nature of conscious experience of the visual world. Initial analysis of visual information occurs in the primary visual cortex in the occipital lobe. Primary visual cortex is responsible for extracting very basic visual information from stimuli, including orientation, spatial frequency, and direction of visual stimulus movement. This information is then sent to brain regions involved in higher levels of visual processing, which integrate these initial visual perceptual features into integrated wholes. These higher-level visual functions are predominantly processed in the right hemisphere and involve two separate pathways, a ventral stream involved in visuoperceptual analysis for object recognition and a dorsal stream involved in visuospatial analysis to guide movement in relation to visual information (Scott & Schoenberg, 2011a).

The ventral stream runs from the occipital to temporal lobe. These regions are involved in the perception of form, color, and shape. Damage to this stream can result in difficulties discriminating between colors (termed achromatopsia), defects in form discrimination, problems with matching identical stimuli, and difficulties mentally synthesizing fragmented pictures into complete wholes. Bilateral damage to the fusiform gyrus can result in a more specific inability to recognize faces (termed prosopagnosia). More extensive damage to the occipitotemporal region can result in visual agnosias, which are characterized by an inability to recognize visually presented objects. Two types of visual agnosias have been identified. Apperceptive visual agnosia involves an inability to group together visual stimulus elements into a whole object, despite accurate perception of attributes of the object. Associative visual agnosia consists of accurate perception of a whole, integrated object, but a failure to link semantic knowledge to that perception (Bauer, 2014; Scott & Schoenberg, 2011a).

The dorsal stream runs from the occipital cortex through the superior temporal gyrus and into the parietal lobe. This region is involved in visuospatial processing and visuomotor interaction. Damage to the dorsal, visuospatial stream also results in a range of deficits, including difficulties attending to the left hemispatial field (termed attentional neglect), an inability to localize objects in space, difficulties finding one's way in the environment with respect to the self (termed egocentric disorientation), and problems with judging the relative orientation of lines. Deficits in visuoconstructional abilities, such as putting blocks together to construct designs or drawing complex figures, can result from damage to either ventral or dorsal streams, although the nature of deficits may differ depending on the region of damage (Bauer, 2014; Scott & Schoenberg, 2011a).

A variety of measures are available to assess visuoperceptual and visuospatial abilities. As a first step, sensory functioning, including visual acuity, oculomotor ability, and visual field deficits, should be evaluated (Scott & Schoenberg, 2011a). Commonly administered measures of visuoconstruction include the WAIS-IV Block Design task (Wechsler, 2008) and the Rey-Osterrieth Complex Figure Test (Meyers & Meyers, 1995). Visuospatial ability can be measured with the Judgment of Line Orientation test (Benton, Varney, & Hamsher, 1978) and hemispatial neglect by line bisection and cancellation tasks (Lezak et al., 2012). Finally, measures of visuoperceptual ability include the Benton Visual Form Discrimination test (Benton, Sivan, & Hamsher, 1983) and the Hooper Visual Organization Test (Hooper, 1983).

Future Directions in Neuropsychology

Clinical neuropsychology is a rapidly advancing field. Technological developments as well as increasing recognition of the limitations of neuropsychological assessment to nonmainstream cultural groups have led to some of the most exciting and important new research areas in neuropsychology. This section discusses three of these emerging research areas: cultural neuropsychology, connectomics, and the integration of genomics with neuropsychology.

Cultural Neuropsychology

The United States is currently undergoing a dramatic demographic shift that is changing the composition of the country (Bureau, 2011). This, among other factors, has led to growing interest on the impact of culture on neuropsychological test performance. Traditionally, neuropsychology has struggled to account for cultural contributions to test performance, leading to reduced diagnostic specificity with examinees from nonmainstream cultural groups (Cagigas & Manly, 2014). This has largely been due to a mismatch between normative standardization samples and culturally diverse examinees, with most standardization samples consisting of well-educated, English-speaking, US-born, culturally mainstream Whites. Cultural neuropsychology is an attempt to improve the discipline of neuropsychology by exploring the effects of and pathways by which cultural experiences impact brain-behavior relationships. In this way, cultural neuropsychology may be defined as the study of brain-behavior relationships that emerge out of the manner in which human being engage in culture-specific practices that shape the organization, development, and revision of their cognition and behavior (Cagigas & Manly, 2014).

There are several important strains of cultural neuropsychological research. First, a considerable amount of research has explored the causes of test sore differences across cultural groups. In the aggregate, individuals from nonmainstream cultural backgrounds typically score lower on neuropsychological tests than their culturally mainstream counterparts. This may be due to one or more of the following factors: (1) improper translation of tests, including culturally inappropriate wordings and use of inappropriate norms (van der Vijver & Hambleton, 1996); (2) discrepancies in the quality of education across cultural groups, despite similar number of years of education (Manly & Jacobs, 2002); (3) low levels of acculturation to the culture in which the tests were developed and normed (Artiola, Fortuny, Heaton, & Hermosillo, 1998); and (4) reduced comfort and confidence during the test session due to racial socialization (Cagigas & Manly, 2014). In addition, bilingualism has also been shown to affect neuropsychological test performance, leading to poorer scores on measures of vocabulary (Bialystok, Luk, Peets, & Yang, 2009), picture naming (Gollan, Fennema-Notestine, Montoya, & Jernigan, 2007), and semantic fluency (Gollan & Ferreira, 2009; Gollan, Montoya, & Werner, 2002). However, some research suggests that bilingualism confers advantages on executive functioning tasks, presumably due to greater familiarity with managing and switching between two competing representations of language among bilinguals (Bialystok, Craik, & Luk, 2008).

Second, cultural neuropsychological research has explored approaches to developing more culturally sensitive approaches to neuropsychological assessment. Chief among these efforts has been the development of separate norms for racial/ethnic or language groups. This approach has been shown to improve diagnostic accuracy (Miller, Heaton, Kirson, & Grant, 1997). However, some have noted that there is still considerable variability within racial/ethnic and language groups that remains unaccounted for. Ultimately, it has been argued that race and ethnicity may more accurately be considered proxies for, and thus confounded by, other more meaningful variables, such as language proficiency, educational quality, or socioeconomic status (Cagigas & Manly, 2014). In addition, in developing culturally sensitive neuropsychological measures, it is important not to simply assume that the validity of the measure demonstrated in the culturally mainstream group generalizes to a new cultural group. Thus, a growing body of research has sought to evaluate the construct validity of neuropsychological measures across cultural groups (Cagigas & Manly, 2014).

Third, some research has demonstrated differences in cognitive processes across individuals from different cultures. Studies have found that culture can impact a number of cognitive processes, ranging from facial (Goh et al., 2010) and visual object processing (Gutchess, Welsh, Boduroglu, & Park, 2006) to semantic categorization use to facilitate free recall (Gutchess et al., 2006). In fact, culturally specific cognitive information processing has long been recognized in neuropsychology. Luria studied remote rural communities in Uzbekistan and noted that individuals from these communities did not categorize objects based on abstract rules, like their educated adult counterparts, but rather did so based on the relationship of the stimulus objects to their everyday lives (Nell, 1999, 2000). Nonetheless, evaluation of the culture-specific nature of cognition has largely been overlooked in subsequent years. An exciting new area of research has begun to explore the manner in which cultural practices shape cognition, emotion, and behavior as well as brain structure and function (Cagigas & Manly, 2014)

Connectomics

Historically, most neuroimaging research in clinical populations has focused on regional abnormalities in brain structure and/or functioning. However, recent advances in neuroimaging and network modeling have led to growing interest in the dynamics of large-scale brain networks within normal populations and abnormalities within and between these networks in clinical populations (Menon, 2011). A central goal of this research is to provide a comprehensive characterization of the structural pathways connecting remote brain regions and the functional interactions between these remote regions. The study of these large-scale networks is referred to as connectomics and the descriptions derived therefrom as the human connectome (Sporns, 2013). Emerging findings from connectomics suggest that the human brain consists of several distinct functional networks and that these networks are organized in a modular fashion, with networks interlinked through sub-networks or core hub regions, which enable global information flow and integration (Sporns, 2013).

Adopting a network-level analysis of brain-behavior relationships has led to novel findings among several clinical populations. For instance, traditional neuroimaging studies evaluating regional abnormalities in brain structure and function among individuals with autism have often reported abnormalities in the frontal lobes, amygdala, and cerebellum (Amaral, Schumann, & Nordahl, 2008). However, many of these findings have been inconsistent across studies. Moreover, descriptions of regional abnormalities may be insufficient to characterize the distributed nature of a disorder like autism, especially given the heterogeneity of the cognitive and behavioral phenotype of this disorder. As such, evaluation of the structure, integrity, and integration of distributed functional networks may be more revealing of brain-behavior relationships in autism.

Recent research on network functional connectivity in autism has revealed important findings. For one, autism is most consistently characterized by underconnectivity between the prefrontal cortex and posterior brain regions and regional overconnectivity within the extrastriate cortex, frontal lobe, temporal lobe, amygdala, parahippocampal gyrus, and temporo-thalamic regions (Maximo, Cadena, & Kana, 2014; Murphy, Foss-Feig, Kenworthy, Gaillard, & Vaidya, 2012; Noonan, Haist, & Muller, 2009; Shih et al., 2010; Shih et al., 2011; Uddin et al., 2013; Welchew et al., 2005). These findings have been taken to suggest inefficient brain network integration, with overabundant connectivity occurring in nonessential regions, leading to poor distributed network coordination in the midst of high levels of regional noise. It remains to be determined whether regional overconnectivity in autism is a cause or an effect of observed underconnectivity across distributed brain regions (Maximo et al., 2014). For another, emerging research has shown that irregularities in specific networks are associated with distinct behavioral abnormalities. For instance, overconnectivity within specific nodes in the default mode network has been associated with lower verbal and nonverbal communication ability, more severe repetitive behaviors, and restricted, repetitive behaviors (Agam, Joseph, Barton, & Manoach, 2010; Monk et al., 2009; Weng et al., 2010). In this sense, brain network abnormalities may serve as promising intermediate phenotypes linking genes to behavior (Sporns, 2013).

Genetics and Neuropsychology

Another promising avenue is the integration of genomics with neuropsychology. Genomic research is focused on identifying genetic contributions to normal and pathological phenotypes and has been made possible by rapid advances in human genome sequencing and techniques for identifying single nucleotide polymorphisms and quantifying gene expression. Cognition has emerged as an important phenotype in these investigations, due to the contribution of cognition to functional outcomes (e.g. vocation, academic achievement) and the presence of cognitive impairment in pathological conditions as diverse as autism, schizophrenia, Parkinson's disease, and Alzheimer's disease. Neuropsychology specializes in teasing apart the multiple cognitive processes contributing to performance on cognitive tasks and linking these specific processes to brain structure and function. As such, neuropsychology is well positioned to assist in genomic research on cognitive phenotypes (Kremen, Panizzon, & Cannon, 2016).

For instance, Panizzon et al. (2011) explored performance on the California Verbal Learning Test-II (Delis et al., 2000), a word list learning episodic memory task, among twin pairs. These authors found that while the same set of genes contributed to short- and long-delay free recall, a different set of genes was associated with performance during learning trials. Short- and long-delay free recall as well as learning trials involve free recall; however, only learning trials additionally involve acquisition of to-be-remembered content. As such, these authors reasoned that there are separate genetic influences on recall and acquisition processes. This implies that episodic memory tests are not interchangeable at the genetic level. Studies that fail to take into consideration this specificity of the multiple cognitive processes contributing to a particular cognitive domain may thus obscure the genetic contribution to these processes.

Exploration of gene-environment interactions is an especially exciting area of genetic and neuropsychology research. Gene-environment interactions deal with the manner in which the response to an environmental factor varies as a function of one's genotype (Kremen et al., 2016). These interactions are important insofar as they indicate the mutability of one's genetic endowment and indicate the potential for psychosocial or behavioral intervention. For instance, Ferencz et al. (2014) created a genetic risk score based on several genes previously associated with episodic memory among individuals differing in levels of physical activity. These authors reported that the effect of the risk score on episodic memory differed across individuals with high vs. low physical activity. In particular, the genetic risk score was associated with episodic memory impairment only among individuals in the low physical activity group. In other words, physical activity was protective against genetic effects on episodic memory. Incorporation of these and other gene-environment interactions has the potential to improve interventions for cognition and can assist in the development of individualized treatment recommendations, a main goal of the emerging field of precision medicine (Collins & Varmus, 2015).

Conclusion

Neuropsychology is an expansive and rapidly developing field. Neuropsychological investigations have deepened our understanding of brain-behavior relationships in the normal brain and the manner in which these relationships are disrupted in a variety of developmental, psychiatric, and neurological disorders. Technological developments in brain imaging and genetics and the expansion of neuropsychology to previously understudied populations promise to yield further transformative insights into brain structure and function.

Part VII

General Issues in Treatment

Evidence-Based Treatment

27

Nicole M. DeRosa, William E. Sullivan,
and Henry S. Roane

Introduction

Individuals with intellectual disabilities have not always had access to appropriate care. In fact, throughout history there is evidence of how individuals with disabilities were shunned and considered a detriment to society. Institutions, which segregated individuals with disabilities from the mainstream public, were commonplace in the late 1800s and early 1900s. The "care" individuals received in these institutions was often inhumane, lacked a focus on the needs of each individual, and was geared toward lessening the burden of individuals with disabilities on the general public. The advent of the civil rights movement sparked a shift in the acceptance and care of individuals with disabilities. The mistreatment of individuals within institutions was revealed and led to improved conditions, as well as eventually the deinstitutionalization of people with disabilities. Movement toward incorporating individuals with disabilities into society and addressing individual needs to improve their quality of life emerged.

An integral part of meeting the needs of individuals with intellectual disabilities involves identifying and implementing effective treatments. Selecting the most appropriate treatment for individuals with intellectual disabilities can be challenging, in part due to the heterogeneity of the population. That is, the unique needs of individuals diagnosed with intellectual disability do not necessarily adhere to a "one-size fits all" approach. Thus, caregivers, practitioners, physicians, and educators are tasked with finding efficient and effective treatments to meet the specific needs of individuals with intellectual disability.

Caregivers (e.g., parents, educators) must be aware of the most effective treatment options in order to provide appropriate care for individuals with intellectual disability. Historically, limited information or guidance has been available regarding the best treatments and how to effectively implement these treatments. However, the evidence-based practice (EBP) movement brought to light the importance of applying research findings into everyday clinical practice. Thus, the feasibility of non-researchers to access the relevant research in order to identify and implement the most appropriate treatments for individuals with intellectual disabilities has not only been made possible but is also now commonplace. As a result of the EBP movement, information regarding evidence-based practices and treatments (more commonly referred to as empirically supported treatments) for a variety of populations, diagnoses, and symptoms is readily disseminated through registries, guides, and journals. The accessibility of this information

---

Series, https://doi.org/10.1007/978-3-030-20843-1_27

allows for individuals with intellectual disabilities to obtain the care they need and deserve.

This chapter will first review the history or evolution of the EBP movement to guide the reader in understanding EBP as it is known today. Next, the definition of EBP will be presented along with a breakdown of the three main components: (1) research evidence, (2) clinical expertise, and (3) patient characteristics, preferences, and values. A brief discussion regarding the differences between EBP and empirically supported treatments (ESTs) is then provided, followed by a detailed section on the evaluation of ESTs for individuals with intellectual disabilities. Finally, the chapter concludes with consideration of barriers to identifying and implementing ESTs, as well as discussion of the future directions of EBP.

Evolution of Evidence-Based Practice

Evidence-based practice (EBP) is a decision-making model rooted within the field of medicine (Sackett, Rosenberg, Muir Gray, Haynes, & Richardson, 1996; Thoma & Eaves, 2015). Although the philosophical foundation of evidence-based medicine can be traced back to Europe in the eighteenth and nineteenth centuries, a more widespread movement toward evidence-based medicine across Europe and North America did not occur until the mid-twentieth century. It wasn't until the early 1990s that the more modern concept of EBP emerged (APA, 2006; Sackett et al., 1996; Zimerman, 2013). The philosophical underpinnings of EBP are closely linked to epidemiology, which focuses on the needs of populations. In the late 1930s, John R. Paul founded clinical epidemiology, which stemmed from the desire to address not only the needs of entire populations but also of individual patients (Zimerman, 2013). That is, the practices of employing measurable theories and approaches to study diseases and other health-related incidents in populations were incorporated into the everyday decision-making model of clinical practice to positively affect individual patient outcomes. The use of scientific models to inform clinical practice is the impetus behind the EBP movement.

The focus on specific patient needs within clinical practice, as well as refinement of the medical decision-making process, proliferated during the 1960s, as described in a review of EBP conducted by Sur and Dahm (2011). Alvan Feinstein, a follower of Paul's who studied mathematics prior to becoming a physician, played an integral role in incorporating basic science into the practice of medicine (Zimerman, 2013). During his involvement in a rheumatic fever epidemiological study, Feinstein identified an overreliance on clinical expertise alone when determining the presence of relevant symptoms of the disease. This led Feinstein to develop scientific-based criteria for evaluating the symptoms of study participants, which resulted in a more accurate classification of the symptoms of rheumatic fever. In turn, a dramatic decrease in the prevalence of the disease was observed following improved patient outcomes. Furthermore, given Feinstein's criticism of the ability of public health studies to appropriately train physicians in clinical care, he paved the way for improving the value of medical research by linking science and clinical experience. That is, the subjective nature of public health research limited the ability to apply the research findings to improve clinical care. Thus, Feinstein began to modify traditional medical teaching by merging statistical methods, inherent to epidemiology, with clinical reasoning to positively affect patient outcomes.

Around the same time that Feinstein's work was unfolding, events that influenced the movement toward EBP were also occurring in Canada, namely, a shift toward universal healthcare (Zimerman, 2013). One outcome of the change in the Canadian healthcare system during the mid-1960s was the emergence of new medical schools aimed at incorporating basic science into the medical curriculum. Of particular importance was the founding of McMaster University, where the first department of clinical epidemiology and biostatistics emerged, a program heavily influenced by the work of Feinstein who served as a visiting professor during the program's initial years. A key feature of the McMaster program was the development of a "problem-based learning" (Zimerman, 2013; p. 72) technique in which clinical scenarios were presented in a group format in order to incorporate both the basic sciences and clinical medicine into the teaching experience. Although Feinstein's involvement with the newly developed department was crucial in fostering the novel "problem-based learning" teaching method, much of the development of the curriculum and training techniques that influenced the future of EBP is credited to the department head at the time, David Sackett (Sur & Dahm, 2011).

Trained in Public Health, Sackett saw a need for clinical practice to be driven by science in order to better affect the health outcomes of individuals; however, he recognized that most epidemiological training programs addressed public health issues in a manner that was not readily accessible to physicians (Thoma & Eaves, 2015). At the time, clinical practice predominantly involved patient observation and physician opinion. That is, medical programs were not training physicians to be consumers of epidemiological research such that they could apply those findings to their patients. Thus, during his time as head of the Department of Clinical Epidemiology and Biostatistics, Sackett focused on structuring the curriculum such that issues related to public health and practices rooted in science (e.g., biostatistics) were readily incorporated into physician training.

In addition to a novel epidemiological curriculum that encompassed the problem-based learning approach, Sackett and colleagues published a series of articles to assist physicians with effectively accessing information from the literature that could then be applied at the bedside (Thoma & Eaves, 2015). These articles were published in the *Canadian Medical Association Journal (CMAJ)* in the early 1980s and eventually titled "Readers' Guides" (Zimerman, 2013). Following the initial publication of the Readers' Guides, Sackett and colleagues continued to disseminate information on the problem-based learning technique through workshops and additional publications. This laid the groundwork for the future of EBP (i.e., linking science and clinical medicine).

Although Sackett was pivotal in the movement toward EBP, it was Gordon Guyatt, a young faculty member at McMaster, who is officially credited with coining the term "evidence-based medicine" (Thoma & Eaves, 2015; Zimerman, 2013). Furthermore, Guyatt was instrumental in continuing the work of Sackett throughout the 1990s and further disseminating the methods of the newly termed concept of evidence-based medicine. During his time at McMaster, Guyatt further cultivated evidence-based teaching methods, as well as developed a medical residency program based on these methods (Zimerman, 2013). Additionally, Guyatt and colleagues partnered with US academic institutions in the early 1990s to form a workgroup aimed at assessing the state of evidence-based medicine at that time. Conclusions of the workgroup suggested that although Sackett's Readers' Guides affected the bedside practice of medical professionals, limitations of the work existed. More specifically, the workgroup noted that the Readers' Guides included a heavy focus on the quality of evidence but lacked focus on the application of evidence to individual patient needs. That is, guidance was needed on how to appropriately apply the evidence to specific clinical cases, particularly when the relevant evidence may be limited (Sur & Dahm, 2011).

The decision to republish Sackett's Readers' Guides into the *Journal of the American Medical Association* (*JAMA*) in the early 1990s allowed for the opportunity to address the limitations noted by the workgroup. An updated, two-part series of the Guides was developed that included a section on evaluation of clinical measurements, edited by Sackett, and a new section, "Users' Guides to the Medical Literature," headed by Guyatt. This update on the Readers' Guides more heavily focused on the application of evidence into the daily practice of clinical medicine (Zimerman, 2013). The first publication of the new series appeared in the pages of *JAMA* in 1992 and publication continued for 8 years, concluding with a total of 32 articles. During the initial years following the first publication, the evidence-based medicine literature was predominantly maintained by McMaster researchers. However, beginning in 1995 the number of outside researchers who published using the phrase "evidence-based medicine" surpassed that of McMaster researchers, indicating that these methods had successfully infiltrated the field of medicine (Zimerman, 2013). Furthermore, a PsychInfo search conducted by DiGennaro-Reed and Reed (2008) displayed a notable increase in publications using the term "evidence-based practice" beginning in the early 2000s demonstrating the breadth of the evidence-based movement beyond the field of medicine.

Although, the evidence-based movement is largely credited to the field of medicine, education and psychology are also known to have strong roots in an evidence-based approach to assessment and treatment. Of particular significance is Lightner Witmer's establishment of the first psychological clinic at the University of Pennsylvania in 1896, which is known as one of the first institutions to conduct experimentation on the implementation of various teaching strategies (APA, 2006; DiGennaro-Reed & Reed, 2008; Fagan & Wise, 2000). Additionally, in 1908 Witmer founded the journal *The Psychological Clinic*, which focused on clinical services and disabled children (Fagan & Wise, 2000). Likewise, in the late nineteenth and early twentieth century, schools began to adopt an evidence-based approach to improving students' success in the classroom through the work of G. Stanley Hall, the founder of the American Psychological Association (APA). Hall's work influenced the development of the first clinic facility to function in a public school, the Department of Scientific Pedagogy and Child Study (Fagan & Wise, 2000). Furthermore, in the 1960s, during the time in which the evidence-based medicine movement was taking off, it became increasingly common for researchers in psychology and education to conduct treatment comparisons to identify the most effective strategies to improve client and student outcomes (Biglan & Ogden, 2008). Thereafter, research in education and psychology proliferated on effective treatments for a variety of problems (e.g., mental health issues, classroom behavior, drug use) across populations (e.g., children, adolescents). Thus, history suggests that the fields of education and psychology were frontrunners in the EBP movement (APA, 2006).

Although education has a long-standing history in the EBP movement, recent developments have been significantly impactful in improving EBP within the field of education, notably the Council for Exceptional Children (CEC) *Standards for Evidence-Based Practices in Special Education* (2014). The CEC standards provide quality indicators and criteria to assist educators with evaluating the quality of research studies to aid in developing and refining teaching practices. Additionally, the What Works Clearinghouse (WWC), funded by the Institute for Educational Sciences within the US Department of Education, is a research database that systematically evaluates school-based academic and behavioral interventions in order to guide the practice of educators. The availability of resources offered by the CEC and WWC is critical, particularly given federal mandates regarding instructional strategies. That is, the *Individuals with Disabilities Education Improvement Act* (IDEA, 2004) and the *No Child Left Behind Act* (2001) both specify that instructional strategies must be selected and designed using "scientifically based research." Therefore, with the help of initiatives like the CEC and WWC, educators can be equipped with treatments that have been scientifically shown to produce favorable outcomes within the school setting.

One significant contribution that the field of psychology had on the EBP movement was APA's development of best practice guidelines. In 1992, APA created a joint task force among the Board of Scientific Affairs, the Board of Professional Affairs, and the Committee for the Advancement of Professional Practice, which resulted in the publication of the *Template for Developing Guidelines*: *Treatments for Mental Disorders and Psychosocial Aspects of Physical Disorders* (APA, 1995, 2006). The goal of the "Template" was to have structured criteria for establishing best practice guidelines that included reference to both relevant research and clinical expertise. The "Template" was later replaced with the *Criteria for Evaluating Treatment Guidelines* in 2002 (APA, 2006). The Task Force on Promotion and

Dissemination of Psychological Procedures emerged from Division 12 (Clinical Psychology) of APA in 1993, which developed criteria for identifying empirically supported treatments. This came in response to many psychological treatments being viewed as inferior to medical treatments (e.g., pharmacology), despite proven effectiveness of certain therapies (i.e., psychotherapy) dating back to the 1970s.

Although the development of treatment criteria brought about increased awareness regarding the effectiveness of psychological treatments for specific disorders, many found the criteria to be too restrictive given an emphasis on randomized controlled trials (RCTs) and treatment manuals (APA, 2006). Thus, psychologists within specific disciplines (e.g., counseling) began to develop additional guidelines that also accounted for patient variables to better inform treatment development and application within clinical practice. Additionally, the 2005 APA Presidential Task Force on Evidence-Based Practice was established in an effort to identify global practice standards to benefit all disciplines of psychology, as well as to help guide policymakers who had a newfound interest in EBP.

In the early 2000s, healthcare systems and healthcare policy began to readily adopt the notion of EBP. To date, various federal, state, and local organizations and agencies incorporate guidelines and/or mandates that specify the need for EBP. For example, several states have enacted an autism insurance mandate that provides coverage for several medical and behavioral treatments (e.g., applied behavior analysis), such that individuals with autism are able to access appropriate, EBP-derived care. Additionally, APA Task Forces continue to work toward the development and refinement of criteria for EBP across psychology disciplines (APA, 2006). Similar developments are observed across several other fields, including behavioral medicine, education, and behavior analysis (Council for Exceptional Children, 2006; Davidson, Trudeau, Ockene, Orleans, & Kaplan, 2003; DiGennaro-Reed & Reed, 2008). A major impetus for incorporating EBP across disciplines, organizations, and agencies is to maximize consumer (e.g., patients, students) outcomes, as well as to ensure physicians, psychologists, teachers, and the like are able to not only access the relevant research but also assess and evaluate it and most importantly put it into practice.

Definition of Evidence-Based Practice

The main purpose of EBP is to narrow the research-to-practice gap to ensure that treatment is not only effective for a given individual but also cost-efficient (Spencer, Detrich, & Slocum, 2012). However, variations in wording and perhaps meaning of what EBP actually entails can be found across disciplines, the impact of which will be discussed later in this chapter. Despite this, there are three general variables that encompass EBP: (1) research evidence, (2) clinical expertise, and (3) patient characteristics. For example, the Institute of Medicine (2001) defines EBP as “the integration of best research evidence with clinical expertise and patient values” (p. 147; adapted from Sackett, Strauss, Richardson, Rosenberg, & Haynes, 2000). Similarly, the 2005 APA Presidential Task Force defines EBP as the “integration of the best available research with clinical expertise in the context of patient characteristics, culture, and preferences” (p. 273). Of significance is the emphasis on research evidence rather than expert opinion alone. However, it is also important to note that EBP does not emphasize research evidence over expert opinion but instead stresses a collaboration between the two. That is, EBP encompasses professional opinion and clinical practice that is guided by research to best meet the needs of individual consumers (Cook, Tankersley, & Harjusola-Webb, 2008). Below we discuss each of the three areas of EBP.

Research Evidence. In order to consider a treatment or other clinical practice to be effective, it must be backed by a strong research base. The APA Presidential Task Force on Evidence-Based Practice indicates that “a sizeable body of evidence drawn from a variety of research designs and methodologies attests to the effectiveness of psychological practices" and furthermore states that "evidence derived from clinically relevant research on psychological practices should be based on systematic reviews, reasonable effect sizes, statistical and clinical significance, and a body of supporting evidence" (APA, 2006, p. 284). However, determining the strength of the relevant research may not always be straightforward.

Most researchers and practitioners would agree that a large amount of scientific evidence is necessary in order to be confident that a particular practice is effective and appropriate for a given individual, but the specific amount or type of evidence needed is not always agreed upon. For example, RCTs are commonly referred to as the "gold standard"; however, this type of research design may not always be the most appropriate given a specific research question or analysis. Accordingly, a number of differing criteria for determining the level of evidence available for a given treatment or practice have been developed and will be discussed in detail later in this chapter. Nonetheless, what is vital to EBP is a critical appraisal of the research.

Clinical Expertise. Clinical expertise encompasses a practitioner's theoretical understanding of the relevant topic, clinical training, knowledge and understanding of the relevant research, self-evaluation, and ongoing education and training (APA, 2006). Sackett et al. (1996) described clinical expertise as the "proficiency and judgment" practitioners obtain through their education and training (p. 71). Through clinical expertise, the relevant research can be effectively applied to individual patients given an understanding of the clinical needs of that patient. Although clinical practice should be guided by the relevant research, at times a particular evidence-based treatment targeting a specific concern may not match the client's unique needs or be feasible to implement in the relevant treatment setting. For example, for a student with an intellectual disability that has verbal outbursts in the classroom maintained by teacher attention, evidence would suggest that withholding attention when the student shouts out and providing attention contingent on an appropriate alternative behavior (e.g., the child raises his/her hand and waits to be called on) can reduce the student's vocal outbursts. However, in a classroom setting, it may be very difficult, if not impossible, to ignore the student's vocal outbursts given the impact this may have on the learning of peers. Therefore, clinical expertise may come into play such that appropriate modifications are made to the treatment to best meet the needs of the student while accounting for variables related to the treatment setting (e.g., classroom).

Furthermore, at times there may simply be an insufficient research base related to the specific needs of a given patient or consumer, and thus practitioners must rely on expert opinion and practice principles guided by science. For instance, suppose there are two separate treatments that have been shown to produce favorable outcomes for a particular concern across multiple empirical studies. However, within the literature there are *no* studies that have directly compared these treatments. In a case such as this, the practitioner must rely on their own clinical expertise to select the most appropriate treatment for their client.

Given clinical expertise encompasses not only the relevant research but also practices based on opinions, experiences, and an understanding of the patient or consumer, it is important that practitioners are aware of the limits of their knowledge, as well as their own biases when making clinical decisions (APA, 2006). One manner in which clinical expertise can be evaluated is through examining the efficacy and efficiency of clinical decision-making (e.g., patient outcomes; Sackett et al., 1996). Although relying solely on clinical expertise can produce outdated practices that negatively impact the consumer, clinical practice in the absence of clinical expertise (i.e., relying only research evidence) may result in the unique needs of individual consumers not being reliably met (Sackett et al., 1996).

Patient Characteristics. Consideration of patient characteristics entails more than the target symptoms or problem at hand. Evidence-based practice also considers patient or consumer preferences, values, sociocultural context, and strengths, as these variables are likely to affect treatment outcomes (APA, 2006). Thus, by taking patient characteristics into account, the practitioner is best equipped to apply the relevant research, in conjunction with expert opinion, to best meet the needs of the patient rather than the disorder, symptom, or concern. For example, suppose a contingency has been arranged for a patient with an intellectual disability to increase their physical activity such that for every mile the patient walks, they can earn a specific reinforcer. The effectiveness of this contingency ultimately relies on how motivated the patient is to obtain the programmed reinforcer. One way to increase the chances that the contingency will result in the desired behavior change (i.e., increase the patient's physical activity) is to assess the patient's preference for items they could earn as a reinforcer (e.g., Fisher et al., 1992). By doing so, the patient's most preferred item can be programmed into treatment. Accordingly, contingent access to a highly preferred reinforcer will likely increase the patient's physical activity to a greater extent than earning access to a low-preferred reinforcer.

Along these lines, Swift, Callahan, and Vollmer (2011) conducted a meta-analysis (described later in this chapter) that compiled data from 35 studies comparing outcomes of patients in which preference was incorporated into treatment or not. Findings suggested that for those patients in which preferences were accounted for, significantly better outcomes ($d = 0.31$) were obtained. This study highlights the benefits of incorporating patient preference into treatment and aligns with EBP. For further discussion of incorporating patient characteristics as a component of EBP, please refer to APA Presidential Task Force on Evidence-Based Practice (2006).

Evidence-Based Practice and Empirically Supported Treatments

Evidence-based practice is a comprehensive, global approach to patient or consumer care. In other words, it is a decision-making model that seeks to answer a specific question as it relates to an individual (APA, 2006; Schlosser & Sigafoos, 2008). Thus, it is important to point out that EBP differs from empirically supported treatments (EST), which are treatments with known effectiveness for a given population and/or problem. Schlosser and Sigafoos (2008) define ESTs as treatments that have “obtained a certain threshold of research evidence” (p. 61). Although significant to EBP, ESTs are one component of the decision-making process. That is, when employing EBP, practitioners will select treatments that (a) have a substantial research base (i.e., ESTs), (b) best meet the individual's needs based on the practitioner's clinical expertise, and (c) account for the individual's characteristics and preferences.

Evaluating Empirically Supported Treatments

As previously noted, EST are but one component of the EBP decision-making process. In order for a treatment to be empirically supported, it is imperative that studies investigating the efficacy of the particular treatment are carefully evaluated. Stated differently, the efficacy of any treatment must be documented in carefully controlled empirical research that demonstrates the treatment in question is responsible for the beneficial effects observed, rather than other confounding variables or chance (see Campbell & Stanley, 1963; Kazdin, 1992). Within the literature, a number of criteria have been put forth to classify treatments as evidence-based (Chambless & Hollon, 1998; Kratochwill & Stoiber, 2002; Odom et al., 2005; WWC, 2017). Common to these criteria is assessing the quality of experimental studies employing randomized controlled trials (RCTs), single-case experimental designs (SCEDs), and meta-analyses. Any particular treatment may have an accumulation of evidence supporting its efficacy; however, if that evidence is derived from low-quality sources, the confidence a clinician has in recommending that treatment might be truncated. In the following section, we introduce the aforementioned experimental methodologies (i.e., RCTs, SCEDs, and meta-analyses), the various quality assessments linked to each design, and general criteria outlining the amount of research required for a treatment to be considered an EST.

Randomized Controlled Trials

Randomized controlled trials (RCTs) are experimental group designs that are largely regarded as the "gold standard" of clinical research (Schulz, Altman, & Moher, 2010a, 2010b; Sturmey, 2014). In RCTs, participants are randomly assigned to treatment and control groups. This random assignment is done to ensure that any confounding variables that may influence the outcome of the study are equally dispersed across groups. In the treatment group, participants receive the treatment under investigation (i.e., independent variable), whereas in the control group, participants receive no treatment, an alternative treatment, or a placebo. Then, at specified times during the study, quantifiable data are collected on the participant variable (i.e., dependent variables) and compared across groups. In general, RCTs are highly regarded in clinical research because (1) they carefully control for confounding variables that may threaten internal validity and (2) large groups of participants undergo random assignment, which enhances external validity. In other words, treatment effects derived from a well-designed RCT can be attributed to the treatment under investigation and extended to the larger population. A detailed analysis of RCTs and other group designs go beyond the purpose of this chapter but are available from other sources (Machin & Fayers, 2010; Torgerson & Torgerson, 2008).

Although RCTs have a sound methodological foundation and can produce empirical evidence regarding the effectiveness of a particular treatment, not all RCTs are conducted with the same level of experimental rigor (Grossman & Mackenzie, 2005). Therefore, there are a number of methodological considerations that need to be accounted for when conducting and reporting a RCT, some of which may be difficult to achieve. For instance, Nichol, Bailey, and Cooper (2010) outlined a number of challenges with employing RCTs: (1) unclear hypotheses and multiple objectives, (2) poor selection of endpoints, (3) inappropriate subject selection criteria, (4) non-clinically relevant or feasible treatments, (5) inadequate randomization, stratification, and blinding, (6) insufficient sample size, (7) failure to use intention-to-treat analysis, and (8) failure to anticipate common practical constraints. Although we will not detail each of these potential issues, it is important to acknowledge that even though RCTs are highly regarded in terms of experimental design, the quality of an RCT can vary widely and dramatically impact the level of evidence provided.

Given the number of potential issues with conducting RCTs, it is crucial that studies be adequately described to allow for objective quality assessment. That is, there must be clear descriptions of the methodologies employed and findings obtained in order to assess the quality of the study and determine the level of evidence it provides for a particular treatment. Without such technical information, many flaws in a study may be masked or overlooked by reviewers. To ensure that RCTs receive adequate and objective quality assessment, it was necessary to standardize the manner in which RCTs are reported.

Accordingly, the Consolidated Standards of Reporting Trials (CONSORT standards) were developed and described by Schulz, Altman, Moher, and the CONSORT group in 2010. The primary aim of the CONSORT standards is to ensure that adequate information is reported to allow for a quality evaluation. A total of 25 standards are included in the CONSORT criteria. As an example, Standard 5 states that treatments for each group are described with sufficient detail to allow for replication, including how and when the treatments were administered. We will not be discussing each standard here but want to highlight the importance of these standards as they provide guidelines for how to report RCTs, allowing for quality assessment. Ultimately, this provides an objective basis to determine whether or not a treatment should be considered "evidence based."

Within the educational literature, and as an example of RCT quality assessment, WWC

(2017) developed criteria for evaluating individual studies. First, studies are screened to determine if the study is relevant to the literature base on the treatment in question. Second, the measurement system employed in the study is examined to ensure the researchers selected and used an appropriate (i.e., reliable and valid) measurement system. Third, the design of the study (e.g., RCT) and sample (e.g., participants; sample size) used in the study are assessed. Fourth, baseline data (if obtained) are examined looking for equivalence across treatment and control group for the dependent variables. Then finally, the analyses performed (e.g., statistical analyses) are assessed for appropriateness. Please see *WWC Study Review Guide, Group Design Studies* (2018) for a more detailed description of the evaluation process.

Single-Case Experimental Designs

Single-case experimental designs (SCEDs) have a long history of scientific merit and provide empirical evidence at the level of the individual. Although a thorough discussion of SCEDs is beyond the scope of this chapter, a number of detailed discussions are available elsewhere (DeRosa, Sullivan, Roane, & Kadey, in press; Kratochwill & Levin, 2014; Perone & Hursh, 2013). Like RCTs, SCEDs are experimental in nature. The goal of any SCED is to demonstrate a causal relationship between the independent variable (e.g., treatment) and dependent variable (e.g., behavior targeted for change). This causal, or functional, relation relies on the demonstration of experimental control. When the introduction of the independent variable occasions a change in the dependent variable, and the effect is reliably replicated within and/or across participants, experimental control is demonstrated. By making both within- and between-subject comparisons, threats to internal validity are controlled for, while systematic replication of the effects bolsters external validity (Martella, Nelson, & Marchand-Martella, 1999).

Like all experimental designs, the quality of a SCED also varies and requires quality assessment to determine the level of evidence provided. To assess the level of evidence presented in SCEDs, Horner et al. (2005) established specific criteria. That is, for a treatment to be considered evidence-based derived from SCEDs, five standards need to be met: (1) the treatment is operationally defined, (2) the setting in which the treatment is to be used is defined, (3) the treatment is implemented with fidelity, (4) demonstration of a functional relation between the treatment and a change in behavior, and (5) the experimental effects are replicated across a sufficient number of studies, researchers, and participants. In general, Horner and colleagues suggested that in order for a treatment to be evidence based, a series of experimental studies need to be conducted that demonstrate an effect by the treatment on behavior under specified conditions (i.e., setting and procedures). For a more detailed discussion of these standards please see Horner et al. (2005) or WWC (2017) for SCED standards used in the educational literature.

Meta-analyses

Meta-analyses are an integral part of EBP as they offer an approach to aggregate the results of multiple studies and synthesize their collective findings. Meta-analyses are based on a family of statistical procedures that combine data from multiple studies and calculate average effect sizes. An effect size is a statistical metric that estimates the magnitude of effect the independent variable has on the dependent variable. Stated differently, an effect size estimates how much of an effect the treatment had, rather than simply did it have an effect greater than what would be expected by chance (i.e., p-value).

Meta-analytic strategies have been developed for both RCTs and SCEDs. In the case of RCTs, the most commonly used effect size is Cohen's d, which standardizes differences between group means (i.e., treatment group vs. control group) expressed as a z-score. However, for SCED, Cohen's d is inappropriate as it relies on group differences, which SCEDs inherently do not provide and because SCED data do not meet many of the basic assumptions needed to conduct parametric analyses (e.g., homoscedasticity; Burns, 2012). For these reasons researchers have developed a family of nonparametric effect sizes for use with single-case data, for example, percentage of nonoverlapping data (Scruggs, Mastropieri, & Castro, 1987), percentage of all nonoverlapping data (Parker, Hagan-Burke, & Vannest, 2007), and nonoverlap of all pairs (Parker & Vannest, 2009), to name a few. Similar to RCTs, meta-analytic researchers utilize these nonparametric effect sizes to synthesize the results of numerous studies simultaneously. Thus, meta-analyses are well-suited for questions regarding a particular treatment's evidence base as they can simultaneously synthesize and analyze results from numerous studies employing various types of experimental designs. For a comprehensive review of meta-analytic strategies, please see Faith, Allison, and Gorman (Faith, Allison, & Gorman, 1996) and Schmidt and Hunter (Schmidt & Hunter, 2014).

One method for assessing the quality of individual studies, which may be included in a meta-analysis, is the *Scientific Merit Rating Scale* (SMRS), developed by the National Center on Autism's *National Standards Project* (National Autism Center, 2009). The SMRS checklist uses a 5-point rating scale to evaluate study quality across five domains. First, the research design is considered in terms of the degree to which experimental control is demonstrated and design employed. Second, a rating is given regarding the extent to which reliable and valid measurement of the dependent variable took place. Third, procedural integrity is reviewed to determine if the independent variable was implemented as intended. Fourth, participant characteristics are reviewed to determine if the treatment was evaluated within the appropriate population. And fifth, a rating is given on generalization or the extent to which the study attempted to objectively demonstrate that treatment effects occur across time, setting, stimuli, and responses.

Another method to assess the quality of studies included in meta-analyses was developed by Guyatt et al. (2008) termed the "grading of recommendation assessment, development, and evaluation" (GRADE) system. The GRADE system first assesses the quality of study design, with RCTs starting as "high evidence" and observational studies or SCEDs as "low evidence." From there, five factors may result in a study's quality of evidence being downgraded: (1) study limitations, (2) inconsistency of results, (3) indirectness of evidence, (4) imprecision, and (5) publication bias. In opposition, there are three factors that may improve the quality of evidence provided by a particular study: (1) large magnitude of effect, (2) dose response, and (3) confounding variables likely minimize the effect.

After individual studies have been assessed, the GRADE system applies a broad classification system to the entire body of work on a particular treatment across four levels: "(1) High quality—further research is very unlikely to change confidence in the estimate of effect, (2) Moderate quality—Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate, (3) Low quality—Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate, and (4) Very low quality—Any estimate of effect is uncertain" (Guyatt et al., 2008, p. 926). This leads to an overall rating of the quality of evidence provided across studies related to a particular treatment. The GRADE system then outlines how to decide whether the treatment in question should be recommended based on (a) quality of evidence, (b) cost/benefit analyses, and (c) patient or client values and preferences. For a more complete discussion, please refer to Guyatt et al.

Amount of Evidence Required for EBP

Although high-quality empirical research is needed in order for a treatment to be considered evidence based, one perfectly conducted study does not suffice. For a treatment to be considered evidence based, there not only has to be one quality empirical investigation demonstrating its effectiveness, there must be multiple experimental demonstrations confirming the treatments efficacy.

Horner et al. (2005) proposed that five well-designed single-case studies, conducted by at least three different research groups, across three different geographical locations, with a total of at least 20 participants, are needed to establish a treatment as evidence based. The WWC (2017) also set forth criteria to categorize treatments based on the amount of evidence in the literature. More specifically, the "extent of evidence" for a particular treatment is based on the number and sizes of the studies. A "small" amount of evidence is defined as either one study, one school, or less than 350 participants. Whereas a "medium to large" amount of evidence consists of more than one study, more than one school, and at least 350 participants. The purpose of criteria like these is used to give an indication to the practitioner of how generalizable the research findings are for a given treatment.

Similarly, the National Autism Center (2009) developed a classification system used to describe the strength of evidence available for a particular treatment. This classification system divided the level of evidence provided for a particular treatment into four categories: established, emerging, unestablished, and ineffective/harmful. An established treatment, based on the National Autism Center's criteria, has been documented in either two group experiments with at least 12 participants that display no conflicting results or three group experiments or six, single-case experiments with at least 18 participants with no more than one study that found conflicting results. Additionally, all studies need to have received high ratings (i.e., 3 or greater) on the SMRS to be considered established treatment. Table 27.1 provides an outline of the National Autism Center's criteria, and Table 27.2 provides an example of how these criteria have been applied to behavioral treatments for individuals with autism.

Barriers to Evidence-Based Practice

Despite the breadth of EBP, selecting an appropriate treatment can be met with challenges for several reasons. Differences in terminology used across disciplines, agencies, and organizations are one barrier to an evidence-based approach. Terms that are used interchangeably include

Table 27.1 A summary of the four levels of evidence from the National Autism Center's (2009) *National Standards Project*

Level of evidence	Definition
Established	1. Two group experiments or four single-case experiments with at least 12 participants without conflicting results; three group experiments or six single-case experiments with a minimum of 18 participants with no more than one study presenting conflicting results 2. Had SMRS scores of 3 or greater 3. Reported beneficial treatment effects for specific targets 4. These results may be supplemented by other lower-quality studies
Emerging	1. One group experiment or two single-case experiments with a minimum of six participants without conflicting results 2. Has SMRS scores of 2 3. Reported beneficial treatment effects on one dependent variable for a specific target 4. These studies may be supplemented by those with higher or lower SMRS scores
Unestablished	1. May or may not be based on research 2. Had beneficial effects reported on poorly controlled studies with SMRS scores of 0 or 1 3. Have claims based on testimonials, opinions, or speculation 4. Were ineffective, unknown, or adverse treatment effects based on poorly controlled studies
Ineffective/harmful	1. Had two group experiments or four single-case experiments with at least 12 participants without conflicting results; three group experiments or six single-case experiments with a minimum of 18 participants with no more than one study presenting conflicting results 2. Had SMRS scores of at least 3 3. No beneficial treatment effects for one dependent variable for a specific target or had adverse treatment effects on dependent variable

Adapted from the National Autism Center (2009).

Table 27.2 A summary of treatments for children with ASD under the age of 21 that meet three levels of evidence (Established, Emerging, and Unestablished) from the National Autism Center's (2015) *National Standards Project*

Level of evidence	Treatments
Established	1. Behavioral treatments 2. Cognitive behavior treatment package 3. Comprehensive behavioral treatment for young children 4. Language training (production) 5. Modeling 6. Natural teaching strategies 7. Parent training 8. Peer training package 9. Pivotal response training 10. Schedules 11. Scripting 12. Self-management 13. Social skills package 14. Story-based treatment
Emerging	1. Augmentative and alternative communication devices 2. Developmental relationship-based treatment 3. Exercise 4. Functional communication training 5. Imitation-based treatment 6. Initiation training 7. Language training (production and understanding) 8. Massage therapy 9. Multicomponent package 10. Music therapy 11. Picture exchange communication system 12. Reductive package 13. Sign instruction 14. Social communication intervention 15. Structured teaching 16. Technology-based treatment 17. Theory of mind training
Unestablished	1. Animal-assisted therapy 2. Auditory integration training 3. Concept mapping 4. DIR/floor time 5. Facilitated communication 6. Gluten-free/casein-free diet 7. Movement-based treatment 8. SENSE Theatre treatment 9. Sensory treatment package 10. Shock therapy 11. Social behavioral learning strategy 12. Social cognition treatment 13. Social thinking treatment

Adapted from the National Autism Center (2015).

evidence-based practice, best practice, research-based practice, empirically supported treatments, empirically validated treatment, and scientifically supported treatments (DiGennaro-Reed & Reed, 2008). More specifically, many disciplines (e.g., psychology, medicine, public health) embrace EBP as a decision-making model that incorporates several components to providing appropriate care to consumers, including the identification and selection of ESTs. However, in other disciplines (e.g., education), EBP typically refers to specific interventions or instructional

Table 27.3 A summary of criteria for empirically supported treatments (Chambless & Hollon, 1998)

Level of evidence	Definition
Efficacious	1. Two between-group design experiments (RCTs), showing treatment is superior (based on statistical significance) to another treatment or placebo 2. Three single-case design experiments ($n > 9$), demonstrating experimental control, and compared to another treatment 3. Experimental procedures detailed 4. Participant characteristics specified 5. Effects demonstrated by at least two different research groups
Possibly efficacious	1. Two experiments showing treatment is superior (based on statistical significance) to a wait-list control 2. All experiments conducted by one research group 3. Single-case design experiment(s) ($n < 3$)

Adapted from Tolin, McKay, Forman, Klonsky, & Thombs (Tolin, McKay, Forman, Klonsky, & Thombs, 2015)

Table 27.4 A summary of treatments and level of evidence for the treatment of aggression for individuals with intellectual disabilities

Level of evidence	Treatments
Evidence-based treatment	**Behavioral treatments** • Functional communication training • Differential reinforcement procedures • Function-based reinforcement; mixed-treatment packages
Lacking sufficient evidence	**Behavioral treatments** • Antecedent manipulations and changes in context • Noncontingent reinforcement alone • Antecedent exercise • Response blocking • Contingent positive punishment • Self-monitoring **Other treatments** • Mindfulness • Teaching family model • Vibroacoustic music • Aromatherapy
Inconclusive evidence	Cognitive-behavioral therapy

The level of evidence is based on Chambless and Hollon's (1998) criteria

Adapted from Healy, O., Lydon, S. and Murray, C. (Healy, Lydon, & Murray, 2014). Aggressive Behavior. In Evidence-Based Practice and Intellectual Disabilities (eds P. Sturmey and R. Didden). doi:https://doi.org/10.1002/9781118326077.ch5

strategies that have a strong empirical base. Thus, the differences in terminology regarding EBP can pose challenges to obtaining appropriate care given a multidisciplinary team approach.

Variation in criteria, regarding what constitutes a treatment as empirically supported, is another challenge that interferes with accessing appropriate treatment for individuals with intellectual disabilities. That is, while the research base for a given treatment may be classified as efficacious or established given one set of criteria, evaluation given a different set of criteria may suggest that the treatment is not empirically supported. The National Autism Center's criteria (Table 27.1) and examples of application of the criteria (Table 27.2) were discussed earlier in this chapter. Tables 27.3 and 27.4 are provided for comparative purposes where Table 27.3 outlines Chambless and Hollon's (1998) criteria for categorizing "efficacious" and "possibly efficacious treatments" and Table 27.4 provides an example of the application of these criteria. Additionally, databases outlining ESTs may not be readily available to practitioners and educators, and resources, particularly funding, may be limited, thus restricting the ability to incorporate ESTs into every day practice (DiGennaro-Reed & Reed, 2008).

Finally, the lack of evidence on the implementation of EBP poses a significant barrier to accessing appropriate care. That is, evaluation of treatment integrity and progress monitoring are considered a part of EBP; however, there is limited guidance regarding how often and in what manner these measures should be taken to ensure the decision-making model is effective (Detrich, 2008; DiGennaro-Reed & Reed, 2008). Thus, the future direction of EBP for individuals with intellectual disabilities is evaluating the model itself to understand if efficient and effective outcomes are in fact being achieved.

Summary

The history of EBP has been quite impactful in improving outcomes for patients and students with intellectual disabilities. The EBP movement was integral in shifting the general perception and understanding of individuals with intellectual disabilities, such that these individuals can now more readily access the treatments needed to enhance their quality of life. Furthermore, rigorous treatment evaluation criteria support the relevance of obtaining and implementing research-based findings in the daily care of individuals with intellectual disabilities.

Despite the long-standing history of EBP and improved care for individuals across disciplines, limitations exist in the ability to consistently and effectively access needed treatments within and across populations. Thus, continued work is needed to ensure the effective implementation of EBP, as well as to refine the current model to best meet the needs of individuals with various presenting symptomology. Although the push toward EBP became prevalent in the 1960s, with the ideas being more readily disseminated into literature and practice in the 1990s, EBP has only become *essential* within the field of medicine, education, psychology, and other health-related disciplines (e.g., speech, public health) within the past two decades. Thus, although the work of Sackett and other pioneers of the EBP movement cannot be discounted, it is now integral to move beyond an understanding and basic application and begin to focus on the implementation and effectiveness of EBP for individuals with intellectual disabilities.

Pseudoscientific Therapies for Autism Spectrum Disorder

Bruce A. Thyer

What Is Autism Spectrum Disorder?

The standard approach to diagnosing mental disorders in the United States, and widely used throughout the world, is an authoritative book called the *Diagnostic and Statistical Manual of Mental Disorders* (DSM, American Psychiatric Association 2013). Now in its fifth edition, the DSM has been plagued by controversy from its inception. Some issues deal with the minutia of the various signs and symptoms and duration presented by a given person needed to arrive at a particular diagnosis. Others are much more fundamental, such as serious conceptual problems with the very definition of what constitutes a mental disorder and of the validity of the various categories described. Some diagnoses come and go. The DSM-2 did not include homosexuality and/or autism. Later editions did. Now the DSM-5 does not include them but does claim that obstructive sleep apnea disorder (most commonly caused by being overweight) *is* a mental disorder, as is smoking, called tobacco use disorder. Persons with cognitive impairment due to traumatic brain injury are similarly asserted to suffer from a mental disorder. Some authorities assert that any condition with a clearly evident biological cause (e.g., genetic disease, brain trauma or infection, endocrine abnormality, etc.) should not be construed as a mental disorder at all and that this latter term should be reserved for conditions which have their etiology in the person's mind, not in demonstrable physical pathology of the body.

The phenomena called autism have similarly suffered at the hands of psychiatrists making up their "minds." The DSM-5 uses the term autism spectrum disorder, while previous editions used autistic disorder. The DSM-2 did not contain any diagnosis dealing with autism at all (APA, 1968). Asperger's disorder was found in earlier editions of the DSM, but it has been eliminated by the DSM-5. Now of course the actual disorders in behavior which have been used to label someone variously as autistic, autistic disorder, Asperger's disorder, or autism spectrum disorder do not ebb and flow at the whim of the latest edition of the DSM. The field of human psychopathology is much like the former planet Pluto. For years it was considered a true planet. Now it is not. Pluto the object, whatever we call it, remains unchanged. Similarly the condition called autism spectrum disorder is similarly unmoved, and behavioral scientists and other specialists continue to study persons with this condition, attempt to discover its causes, and develop effective treatments. This can be done regardless of the current favored terminology. Many disciplines do not make use of the DSM-5 system of diagnosis at all. Behavior

analysts, for example, eschew global diagnostic labels in favor of focusing on specific behavioral excesses or deficits, and working directly on behavior change, usually through programs of reinforcement, shaping and extinction (punishment is very rarely used). This is a very successful approach to helping persons with ASD and does not require using the DSM-5.

The DSM-5 criteria for autism spectrum disorder (ASD) cover one and half pages, so just a brief summary will be given here:

> Autism spectrum disorder is characterized by persistent deficits in social communication and social interaction across multiple contexts, including deficits in social reciprocity, nonverbal communicative behaviors used for social interaction, and skills in developing, maintaining, and understanding relationships. In addition to the social communication deficits, the diagnosis of autism spectrum disorder requires the presence of restricted, repetitive patterns of behavior, interests or activities. (APA, 2013, p. 31)

ASD must appear fairly young in the child's life and is often, but not always, accompanied by intellectual disability. In severe ASD the person may be unable to talk or otherwise readily communicate and may display self-injurious behavior or motor stereotypes. The precise causes of ASD remain elusive. The DSM-5 notes that a proportion of ASD cases are associated with a known genetic mutation, but there is currently no genetic test used in practice which is of value in making the diagnosis. At present the diagnosis is arrived at clinically, via observation of the client (preferably over multiple contexts and times, supplemented with valid rating and observational scales), a careful history taking, and interviews with the patient (where possible), parents, and other caregivers. That a diagnosis is arrived at clinically is true for almost all the DSM-5 disorders—there are no legitimate genetic, brain scan, blood, tissue, or other tests which contribute to the diagnoses (except for the IQ tests used to diagnosis intellectual disability). Parents naturally want to know why their child acts the way they do, but the only correct answer at present is "We do not know what causes ASD."

Clinicians can be more confident in asserting what does *not cause* ASD, although many candidate etiological factors have been forward. Of most of these, the evidence is either solely anecdotal, too weak to draw scientifically legitimate conclusions from, or solidly pointing that given candidate causes are *not* responsible—such as sugar, food dyes, heavy metals, gluten or casein intolerance, deficiencies in blood flow to the brain, hormone imbalances (e.g., secretin), vitamin deficiencies, and parental child-caring practices. Our present inability to determine the causes of ASD is frustrating and perhaps hinders the development of treatments more effective than existing therapies. However, the precise etiology of a good many of the conditions found in the DSM is similarly vague, yet intervention research aimed at testing therapies proceeds unabated, and this includes treatments for ASD.

Treatment Versus Cure

When discussing therapies for ASD, it is important to distinguish between cures versus treatments. Many conditions, medical and psychosocial, have cures. Some form of intervention is provided for the clients, and following a course of therapy, the condition is gone. Antibiotics for bacterial infections are one example of a medical cure. Gradual real-life exposure therapy for clinical phobias is a curative example drawn from psychosocial conditions. However, for many conditions, complete cures remain elusive. Most therapies for ASD are efforts to enhance functional behavior, improving social skills, for example, or reading and conversational abilities. Other treatments are aimed at reducing problematic features of ASD, such as self-injurious behavior, movement stereotypies, and self-stimulating activities such as excessively spinning objects. Taken in isolation, these treatments may be beneficial, but you still have a person who displays many other features of ASD. Perhaps their talking is improved, but other behaviors typical of ASD remain. There are promising treatments which when offered very early in the child's life, last hours per day, over several years, have apparently resulted in children who become indistinguishable from normal and function well in school with normal intelligence (see Lovass, 1987), but access to such early intensive behavioral interventions (EIBI) remains quite limited. The US Food and Drug Administration is very clear on this issue: “One thing that it is important to know about autism up front: There is no cure for autism. So, products or treatments claiming to ‘cure’ autism do not work as claimed” (see https://www.fda.gov/ForConsumers/ConsumerUpdates/ucm394757.htm).

What Are Research-Supported Therapies?

For a treatment for ASD to be considered scientific, it should be supported by a substantial amount of empirical research that has been published in quality peer-reviewed journals, with the large preponderance of the evidence indicating that the treatment is, first of all, safe. Next it is important to demonstrate that the treatment is better than doing nothing. The third is that the treatment yields results that are considerably better than those achieved by providing a credible placebo treatment to the client. The fourth is that the new treatment produces results at least equivalent to a therapy which is already considered to be effective. The fifth is that the positive results of the new treatment are maintained over time (ideally months or years). The sixth is that the new treatment does not produce unpleasant side effects (this is related to but not the same as safety). And the seventh is that the new treatment is broadly effective across a wide range of clients, boys and girls, people of different races and ethnicities, etc. To achieve these benchmarks for a novel therapy for persons with ASD requires a significant, long-term period of intensive investigations, ideally conducted by researchers independent of the inventor of the new therapy, and with no significant financial or other potential conflicts of interest which could bias the results of the investigators (e.g., they market a competing form of treatment). To accomplish these tasks, clinical researchers in ASD employ various safeguard in their research. For example, persons being considered for potential inclusion in the treatment study are carefully assessed by expert diagnosticians so we can be sure the clients are really genuine instances of ASD. Assessments of client functioning and behavior are conducted by persons independent of those delivering treatments and, ideally, are unaware of what treatment the client they are assessing will receive or has received. The therapy is delivered via some structured protocol or treatment manual, to ensure faithful adherence to the principles of the intervention. A test evaluating a treatment which was sloppily administered is not a fair evaluation of that therapy. Ideally clients who meet a study’s inclusionary criteria are randomly assigned to the new or experimental treatment and to various control conditions (e.g., no-treatment condition, waiting-list or delayed therapy condition, alternative accepted treatment, placebo treatment). This helps insure that the two or more groups of clients are genuinely similar prior to receiving treatment. If this is done, and the two or more groups are different after treatment, then these differences can be attributed to the various treatment conditions the clients received and not to spurious factors such as the passage of time, placebo influences, therapist biases, etc. Even then, it is desirable that a given new treatment which passes all these hurdles and is seemingly effective be tested *again*, by different researchers in other settings, at least once and preferably more than one more time.

Studies like this are called randomized experiments and, when applied to persons with various medical or psychosocial disorders, are given the further term of randomized clinical trial, or RCT. RCTs are generally considered to be a very credible form of evidence needed to draw legitimate conclusions about the effects of a new treatment. When such treatments are repeatedly tested in RCTs and published in scientific journals, a substantial body of literature can accumulate regarding a given newer treatment, and the results of many such RCTs can be combined and the overall results summarized. A statistical tool to do this is called a meta-analysis (MA), and in a proper MA, the various studies’ strengths and limitations can be taken into account when arriving at a conclusion. For example, a RCT study with a sample size of 200 clients would be afforded more weight in the MA calculations than one involving only 50 persons. By combining mathematically all the results obtained in the various studies, one can get a better estimate of the “true” effects of a given therapy for ASD.

A more elaborate method of combining the results of many studies on a given therapy is called a *systematic review* (SR). Systematic reviews are usually conducted by interdisciplinary treatment teams, and very diligent steps are taken to locate *all* available studies which have evaluated a given therapy. This may include studies that were published in international journals, and perhaps unpublished doctoral dissertations, and even unpublished reports. Studies are independently graded for their overall quality and methodological rigor, and the conclusions from the stronger studies are given more weight than those from weaker ones. Most SRs incorporate meta-analysis into their methodology. The best SRs are produced by two major groups, the Cochrane Collaboration (www.cochrane.org) and the Campbell Collaboration (www.campbellcollaboration.org), and very careful methodological checks and controls are used to reduce bias as much as possible. For example, completed draft reports of SRs are independently reviewed by two or more experts and suggestions made to improve it. One can search the web-based libraries of Cochrane and Campbell for completed SRs dealing with the topic of ASD.

The above processes reflect some of the practices of legitimate *scientific inquiry*, and this approach can generally be labeled *between-subject designs* because comparisons are made between groups of clients. There are other credible paths which can be used however to evaluate treatments. One major alternative is called within-subject designs. In this approach, instead of studying changes on average scores of functioning between groups exposed to different treatments, and analyzing the results using complex statistical analysis, the clinical researcher studies only one client and take multiple measures of their functioning over time prior to a new intervention being applied. Then the same measurement strategy is used to assess client functioning while the new treatment is being applied and perhaps after it is removed. The results are usually depicted via line graphs and interpreted visually, not using statistics. Just as one can look at a graph of how the stock market has performed during the past 2 weeks, one can look at a graph of client functioning. If the pretreatment data (the baseline) are stable and then after treatment is introduced, client functioning dramatically improves, and this is very evident by simply looking at the graph; one has tentative evidence the treatment produced a favorable effect. If the baseline was lengthy and stable, and substantial behavior changes occurred immediately after treatment began, this makes for more robust causal inference than if changes were small or appreciably delayed after treatment began. There are various approaches to strengthening the internal validity (our ability to make valid casual inferences about the effects of the treatment under investigation) of within-subject designs. One way is to deliberately remove and then restore a therapy with short-term effects. If improvement follows the introduction of therapy, and deterioration follows the withdrawal of treatment (and is followed by improvement when treatment is reinstituted), then the potential for causal inference is high (“Yes! Treatment caused those improvements!”). Another approach is to track the functioning of several clients with the same problem and introduce treatment to one but not the others, then to the others sequentially. If the first client who received treatment improved and the others did not, until they too received treatment, causal inferences can also be strongly enhanced. A further variant is called the $N = 1$ randomized trial, which may be possible to undertake when a client is receiving a short-lived treatment. The client’s functioning is baselined, using a valid and reliable measure (or several), and then one of two treatments is randomly allocated to be given that day. In the case of medications, it may be possible to use a blinded approach wherein the caregiver or clinician does not know if they are administering the active drug or a placebo pill. The treatment allocated is determined each day by a coin toss. Functioning is recorded for a number of days, and then the blinding is broken. The data from days the client received the active drug are compared with the days when he/she received placebo or a different medication. If the two treatments exerted differential effects, this will be clearly evident from the graphed data and an informed decision then made about what course of therapy to provide over a longer term. Certain psychosocial interventions can also be evaluated in this manner.

Within-subject designs have been used in many disciplines for a long time. The classic text *An Introduction to the Principles of Experimental Medicine* by Claude Bernard (1865/1927) described their use, and the Russian physiologist Ivan Pavlov used them extensively in his research and was awarded the Nobel Prize for his discoveries. Like between-subject designs, within-subject designs require the use of reliable and valid measures of the client's behavior, except instead of measuring behavior just a few times across many people, as in controlled before and after RCT studies, within-subject studies take many measures before and after treatment from one person. This permits a more fine-grained and detailed analysis of individual change and represents an investigatory methodology that does not require expensive grant funding. Indeed, this is a major strength of within-subject studies in that they can be incorporated into everyday clinical practice aimed at helping persons with ASD. This can and is being done but not widely (Nikles & Springer, 2015; Schork, 2015). Like between-subject designs, within-subject designs are also amenable to having their results aggregated using meta-analysis procedures. See Bellini and Akullian (2007) for an example of this. One of the founders of the evidence-based practice movement has stated that certain forms of within-subject designs are more useful for making decisions in clinical practice about the care of individual patients than are RCTs and SRs (Guyatt, Rennie, Meade & Cook, 2002). Thus there are two major pathways to making legitimate conclusions about the effects of various treatments applied to persons with ASD, between-subject designs and within-subject studies. Each has their merits and limitations.

Legitimate scientific research emphasizes the publication of results of therapeutic trials in professional journals that make use of blind peer review and accords higher weight to such studies than information disseminated via other outlets such as press releases, television talk shows, the Internet, news briefings, reports available on websites or internally produced by a treatment's developers, testimonials, and so forth. Usually an article submitted for possible publication in a professional is sent to two or more reviewers, persons with expertise in the subject matter of the paper. The reviewers do not know the authors' names, gender, or affiliations. They provide a detailed critical appraisal of the research and a recommendation to the journal's editor to accept the work, to reject it, or to suggest that it be revised by the author and resubmitted. This process of blind peer review helps ensure that high-quality work is accepted and low-quality work is not published, at least within that particular journal. This screening is why journal publications are accorded greater credibility than other means of disseminating information.

Another feature of legitimate science is its openness to being disappointed. As Thomas Huxley said "The great tragedy of science - The slaying of a beautiful hypothesis by an ugly fact." Good research on a treatment for ASD does *not* set out to prove that it works. It adopts a more neutral attitude and tries to see what the effects of the treatment *are* and is equally open to learning that the treatment was effective or that it was not. In fact good science bends over backward to prove that a treatment *does not work*! For example, if a group of kids with ASD had their functioning rated by their parents, and the kids then received a treatment which was followed by apparent improvements, rather than taking this for strong proof that the treatment worked, the researchers would design a stronger study, better capable showing that it did *not* really work. This next study might use a no-treatment control group—some kids got the treatment and others did not. If the treated group got better, their results would be compared with those of the group that did not get treatment. If the treated group was no better off than the untreated group, what would that tell the researchers about the value of their therapy? It did not work! This would perhaps be personally disappointing, but it would be better to conduct such a study, and screen out an ineffective therapy, before releasing it to the public for use with kids with ASD. Or another study might use independent observers, not the parents, to rate the kids' functioning, so as to reduce potential biases introduced by parental expectancies. Hence all the successive levels of controls introduced in good-quality RCTs help better demonstrate that something *does not work*. Through progressively more stringent investigations, as a new therapy passes each "test," we can become a little more confident that it really may work, better than the passage of time, better than placebo, etc. Then we hold our breath, so to speak, to see if others can successfully replicate our positive results. If this happens once, then again, and more times, by independent researchers around the world, we grow progressively more and more optimistic that the new treatment is genuinely helpful.

What Are Pseudoscientific Therapies?

Pseudoscience has been defined as "a body of beliefs and practices whose practitioners wish, naively or maliciously, pass for science although it is alien to the approach, the techniques and the fund of knowledge of science" (Bunge, 1998, p. 41). For a variety of reasons, the field of ASD lends itself to being vulnerable to a variety of pseudoscientific claims pertaining to the presumed etiology of the condition, methods of assessing persons with ASD, and most dangerously, methods of treating the condition. Here is how one set of writers explained this vulnerability to pseudoscience:

> "Parents are typically highly motivated to attempt any promising treating, rendering them vulnerable to promising 'cures'. The unremarkable physical appearance of autistic children may contribute to the proliferation of pseudoscientific treatments and theories of etiology. Autistic children typically appear entirely normal; in fact many of these children are strikingly attractive…The normal appearance of autistic children may lead parents, caretakers and teachers to become convinced that there must be a completely 'normal' or 'intact' child lurking inside the normal exterior…the course can vary considerably among individuals…there is a great deal of variability in response to treatments…persons with autism sometime show apparently spontaneous developmental gains or symptom improvement in a particular area for unidentified reasons. If any intervention has recently been implemented, such improvement can be erroneously attributed to the treatment, even when the treatment is actually ineffective. In sum, autism's pervasive impact on development and functioning, heterogeneity with respect to course and treatment response, and current lack of curative treatments, render the disorder fertile ground for quackery." (Herbert, Sharp, & Gaudiano, 2002, p. 24)

What are some of the features of pseudoscientific therapies? Typically these therapies are claimed to be highly effective but lack the robust evidentiary support of scientifically legitimate treatments. Sometimes the level of evidence is solely that of personal anecdote or one individual's (often a parent) experience with something. The claim is made that removing something from the diet (e.g., sugar, gluten, particular food dyes, etc.) of the person with ASD was followed by remarkable improvements. Or that adding something to their diet produced equally miraculous positive changes. Many times some form of therapy (e.g., facilitated communication) was administered which seemingly resulted in amazingly enhanced functioning, and those responsible for the care of the person with ASD make it their personal mission to promote this new miracle cure. Here is an example of the latter type of claim:

"Kalel Santiago…was diagnosed with severe, non-verbal autism. At age 9, he hadn't spoken his first word—until his parents tried a controversial treatment… a hemp oil that includes a form of cannabis. Two days later, he was speaking. Kalel's parents sprayed the compound cannabidiol (CBD) in the boy's mouth twice per day, and they say the results were astounding. "He surprised us in school by saying the vowels A-E-I-O-U. It was the first time ever," dad Abiel told Yahoo Parenting. "You can't imagine the emotion we had, hearing Kalel's voice for the first time. It was amazing. The teacher recorded him and sent it to my wife and me, and we said, 'well, the only different thing we have been doing is using the CBD.'" Soon he was saying full words. "He said, 'amo mi mama,' 'I love my mom,'" Abiel says. "I don't know how to thank [the CBD oil makers]." (https://www.parenting.com/news-break/cannabis-spray-treatment-helps-9-year-old-autism-learn-to-speak)

Anecdotes like this, especially if repeated, can be the focus of popular magazine articles, which spark a flurry of interest resulting in parent purchasing the latest remedy du jour (see for example, Borchardt, 2015), aided and abetted by companies which manufacture and sell the new purported cure for a profit. A variation on the use of testimonials from parents are assertions from various well known respected figures such as celebrities or from 'Doctors'. These people look into the camera and say, in effect, "Take it from me, this treatment really works." This line of persuasion relies on 'authority', sometimes augmented by the accoutrements of the white coat and stethoscope.

Another characteristic of pseudoscientific treatments is the use of jargon, neologisms, or simply nonsensical words of phrases to explain the effects of the new therapy, or the invocation of mysterious forces or energies heretofore unknown to mainstream science. Such language affords the patina of real scientific explanations and may deceive the uninitiated, but legitimately trained researchers will recognize a bogus argument right off the bat. Here are some additional hallmarks of pseudoscience;

- "Exploited expertise—A genuine expert in one field provides testimonials in an area outside the expert's area.
- Bogus expertise: a supposed expert claims to possess scientific or practice credentials that are simply false, or originated from diploma mills or otherwise unaccredited universities (see Thyer, 2019).
- Financial conflicts of interest: The promoters of the new ASD therapy have a financial investment in the success of the treatment.
- Inflated research support: Exaggerated claims are made on the basis of poorly designed or conducted research, or research published in journals with very low scientific standards.
- Misleading research support: Findings from a well done study are misrepresented or outright erroneously reported.
- False research support: A study is published in a scientific journal but the actual study was never conducted. Sometime even highly respected journals get hoaxed by unscrupulous authors, some of whom are even doctors!
- Grandiose claims: The new ASD treatment is said to be curative, or amazingly effective for a wide array of signs and symptoms.
- Claims of a 'Quick Fix': The ASD treatment is said to produce improvements very rapidly.
- Implausible mechanism of action: The new treatment is said to work via processes which seem highly unlikely, given what is known about ASD. For example, the treatment called Facilitated Communication is based on the premise that persons with ASD are of normal intelligence, but are trapped in bodies that do not work properly or permit them to speak. There is no evidence that this is true. Hyperbaric oxygen therapy is premised on the idea that the brains of persons with ASD suffer from enduring levels of oxygen deprivation, or of reduced blood flow to the brain. There is no evidence that this is true.
- Claims that the new ASD therapy is rejected by the mainstream treatment community because it threatens vested interests, those who may not want to see the new highly

effective treatment promoted, and therefore try and suppress it.

- The claim being made is virtually impossible to test, for example, the assertion that ASD is caused by unknown allergies. When test after test fails to reveal a putative allergen, or one dietary restriction after another fails to help the person with ASD, the fault is not with the implausible theory, but is simply that the correct test or food causing ASD has not yet been identified. Parents and caregivers may spend a fortune vainly seeking the Holy Grail of allergens." (this section in quotation marks was adapted from Hupp, Mercer, Thyer, & Pignotti, 2019).

Having provided some hallmarks of potential pseudoscientific treatments for ASD, let us examine a few by name in the following section."

Selected Examples of Pseudoscientific Treatments for ASD

Camel's Milk: Yes, some researchers have suggested camel's milk as a treatment for ASD (e.g., Al-Ayadhi & Elamin, 2013). Before rushing out to the nearest camel dairy, one should read the conclusion of a systematic review on the topic. "Based on the evidence, camel milk should not replace standard therapies for any indication in humans" (Mihic, Rainkie, Wilby, & Pawluk, 2016).

Intravenous Secretin: In 1998, Horvath et al. published a study involving three children with ASD who were administered intravenous secretin, and they claimed, with no quantitative data, that the children had improved eye contact, expansion of expressive language, and heightened alertness. Since that time a number of studies have investigated the effects of secretin, and in 2012 a comprehensive systematic review sponsored by the Cochrane Collaboration was published examining the effects of secretin on ASD. The conclusion?

"There is no evidence that single or multiple dose intravenous secretin is effective and as such currently it should not be recommended or administered as a treatment for ASD" (see https://www.cochranelibrary.com/cdsr/doi/10.1002/14651858.CD003495.pub3/full?highlightAbstract=secretin)

Omega-3 Fatty Acids Supplementation: It has been suggested that children with ASD suffer from insufficient omega-3 fatty acids and that providing dietary supplements of this product could reduce the signs and symptoms of ASD. One early case report on using this treatment was published by Johnson and Hollander (2003) and was followed by a number of other published studies. These studies were collected and analyzed in a systematic review supported by the Cochrane Collaboration in 2011. The overall finding? "To date there is no high quality evidence that omega-3 fatty acids supplementation is effective for improving core and associated symptoms of ASD" (see https://www.cochranelibrary.com/cdsr/doi/10.1002/14651858.CD007992.pub2/full?highlightAbstract=autism).

Chelation: Chelation is a form of treatment which is said to remove stored or circulating stored toxic metals (e.g., lead, mercury), with these metals being the etiological agent causing ASD. With this theory in mind, some practitioners concluded that chelation medical therapies which removed these metals from the body of the child with ASD would help reduce signs and symptoms. This is done via administering a chelating substance which binds to heavy metals to the patient, intravenously, by mouth, or by injection, with the metals subsequently being excreted via urine. The procedure is not without risks, as harmful effects and deaths have been reported. Chelation therapy for ASD was the subject of a 2015 Cochrane-sponsored systematic review. The conclusion?—"The quality of the evidence is poor. Only one trial was included in this review, and we judged it to have high or uncertain risk of bias and methodological problems that limited the interpretation of outcomes presented. Given the deleterious effects of chelation, misinterpretation and misuse of the study of Adams et al. to justify the use of chelation for ASD is unethical and potentially places children unnecessarily in harm's way. Moreover, if these findings are in fact valid, they actually undermine the heavy metal toxicity theory and the rationale for chelation treatment, suggesting that it should not be used in the first place" (cited from https://www.cochranelibrary.com/cdsr/doi/10.1002/14651858.CD010766.pub2/full?highlightAbstract=autism).

If the theory is heavy metals cause autism, heavy metals are removed through chelation therapy, and the child does not improve, this tends to falsify the underlying theory of this treatment. If the theory is incorrect, continuing to deliver treatment based on a demonstrably false theory is unlikely to prove helpful, hence the suggestion by the authors of the above SR that chelation should not even be attempted.

Acupuncture: Acupuncture is based on a theory that the human body is surrounded by an invisible energy field undetectable to science (thus far). These lines of energy intersect at various places on the human body, points called meridians, and that human physical illness and emotional distress are caused by blockages in the free flow of this energy, sometimes called qi or chi. By inserting small needles under the skin at precise meridian positions, it is said that the proper flow of qi can resume and health restored. Variations of conventional acupuncture include pressing or tapping on these meridians (acupressure), passing small amounts of electric current through the needles, twirling the inserted needles, and holding smoldering bundles of herbs near the meridians (called moxibustion). An even more implausible form of acupuncture is called Tong Ren, which involves the Tong Ren practitioner holding a plastic doll with the meridian points depicted on it, and pounding these points with a small magnetic hammer, while thinking of the patient. This is said to produce healing in the distant patient, who may not even be aware that he/she is being remotely treated. Tong Ren is being advertised as a legitimate therapy for persons with ASD (see https://theory.yinyanghouse.com/treatments/tongren_for_autism).

In 2011, the Cochrane Collaboration published a systematic review of the effects of conventional acupuncture for ASD. The conclusion?—"Current evidence does not support the use of acupuncture for treatment of ASD. There is no conclusive evidence that acupuncture is effective for treatment of ASD in children and no RCTs have been carried out with adults" (cited from https://www.cochranelibrary.com/cdsr/doi/10.1002/14651858.CD007849.pub2/full?highlightAbstract=autism).

For clinical researchers, acupuncture lends itself very nicely to placebo-controlled trials, wherein some patients receive "real" acupuncture, with the needles being placed in the theoretically correct positions, and other randomly assigned to have the needles placed in meridians that are deliberately chosen because they are incorrect for the condition being treated, or by randomly placing the needles on spots *not* said to be meridians. For many conditions, when real acupuncture has been compared to sham acupuncture, fake treatment proves as useful as real treatment, suggesting the entire theory and protocols of convention acupuncture are simply an elaborate placebo. This was the conclusion of Moffet (2009), following a systematic review of these studies. If this is the case, we have no reason to anticipate that acupuncture for persons with ASD will produce more any benefits than placebo treatments, since such negative results have been found in the treatment of many other conditions.

Hyperbaric Oxygen Therapy: The rationale for hyperbaric oxygen therapy (HBOT) as a treatment for ASD is the theory that the brains of persons with ASD suffer from reduced blood flow and/or reduced levels of oxygen in the blood going to the brain. HBOT involves placing the patient with ASD, usually with a trusted caregiver, in a hyperbaric chamber, and exposing both to increased air pressure and an oxygen-enriched atmosphere, usually for several hours at a time, for treatments being daily or less frequently for long periods of time, perhaps weeks. Clinic-based treatments can be done in hard chambers, but portable chambers can be acquired for home use. HBOT is very expensive. One review published by Dunleavy and Thyer (2014) concluded:

"Studies reviewed did not offer credible evidence to suggest that HBOT is an effective treatment for autism. Conclusion: It is premature to call HBOT an effective treatment for Autism and ASD. Individuals clinically treated with HBOT outside the context of a RCT should have the effects of the therapy evaluated using rigorous single-subject designs" (p. 1). A more comprehensive systematic review sponsored by the Cochrane Collaboration in 2016 found that: "To date, there is no evidence that hyperbaric oxygen therapy improves core symptoms and associated symptoms of ASD. It is important to note that adverse effects (minor-grade ear barotrauma events) can occur. Given the absence of evidence of effectiveness and the limited biological plausibility and possible adverse effects, the need for future RCTs of hyperbaric oxygen therapy must be carefully considered" (cited from https://www.cochranelibrary.com/cdsr/doi/10.1002/14651858.CD010922.pub2/full#CD010922-abs-0007). Of note here is that the authors not only concluded that the treatment has little evidence to support its clinical use but also that the underlying biological theory is so implausible as to suggest this therapy should not even be studied any more.

Bicom Therapy: The Bicom apparatus (a picture of it can be seen here, (https://lyme-knowledge.wordpress.com/2016/06/30/rife-bio-resonance/) or simply by Googling Bicom is an impressive-looking supposedly medical device which is said to detect pathogens and stressors afflicting someone and causing ill health. It is said to do this by detecting some type of unique "vibration" of the harmful agent residing in the patient's body. Then, once detected, the machine is said to be able to feedback a counter or corrective vibration into the patient's body to eliminate the problem. This is called bioresonance therapy. The Bicom diagnoses not through any legitimate test but through the putative assessment of bodily energies unknown to science, and the therapy too involves vibrations or energies which science cannot otherwise detect. Bicom therapy is being advertised to treat persons with ASD, and caregivers are told:

"Bioresonance therapy has shown promising results when used amongst patients diagnosed with autism – both young and old. The technique utilizes the body's own electromagnetic waves in order to promote improved healing capabilities, better metabolism and improved detoxification. Even though bioresonance therapy is not able to correct the damage that autism has dealt to the patient's brain, this therapy has been shown to enhance the function of the patient's brain; thus allowing them to experience an improvement in their symptoms…."(cited from: https://bioresonance.com/bioresonance-therapy-and-autism/)

Here is another explanation of how the Bicom device works:"Bioresonance therapy is a therapy with patient's own electromagnetic frequency patterns. The patient's own electromagnetic oscillations of his body are received by electrodes working as an antenna and fed into the device. The BICOM device changes the body's own information with the help of special electronic systems into therapy signals, which are returned to the patient by the output cable. Due to this method the electromagnetic pathologic information in the body is eliminated i.e. reduced. The patient and the therapy device enter a feedback cycle." (cited from https://www.quackwatch.org/01QuackeryRelatedTopics/Cancer/bioresonance.html)

One can read online testimonials about the powerful effects of bioresonance therapy delivered via the Bicom (http://www.bioresonance-therapy.com.sg/testimonials-adhdorautism). The treatment is not approved by the Federal Food and Drug Administration for use with humans (only animals), but unscrupulous clinicians use this bogus device and a convincing line of jargon and neologisms to persuade parents and caregivers to bring their child in for diagnostic and therapy services. Some parents purchase the machine themselves and use it at home with their child with ASD. Treatments are very expensive, and another red flag is the vast number of diseases and conditions the Bicom is said to be able to cure. Bicom therapy could be held up as a perfect poster child for pseudoscientific treatments for

ASD. The mechanism of action is theoretically implausible. The level of evidence remains at the testimonial stage, despite more than two decades of use. It is expensive. It uses scientific-sounding jargon to impress. Tellingly, what does the company's own website say, in tiny print at the bottom of the page? "In conventional medicine, however, Bicom bioresonance has not been subject to scientific research and is not yet recognized" (cited from https://www.regumed.com/bioresonance-for-doctors-naturopathic-practitioners/method/costs.html).

This latter confession brings us to the ethics of offering pseudoscientific treatments.

The Ethics of Pseudoscientific Therapies for ASD

Supporters of pseudoscientific therapy often counterarguments such as those presented in this chapter with the view that there is no harm in providing treatments which provide hope and even that the delivery of placebo therapies is legitimate. In juxtaposition to this, the World Medical Association has published its *Declaration of Helsinki—Ethical Principles for Medical Research Involving Human Subjects* (https://www.wma.net/policies-post/wma-declaration-of-helsinki-ethical-principles-for-medical-research-involving-human-subjects/), saying:

"Use of Placebo

> 33. The benefits, risks, burdens and effectiveness of a new intervention must be tested against those of the best proven intervention(s), except in the following circumstances:
> Where no proven intervention exists, the use of placebo, or no intervention, is acceptable; or where for compelling and scientifically sound methodological reasons the use of any intervention less effective than the best proven one, the use of placebo, or no intervention is necessary to determine the efficacy or safety of an intervention and the patients who receive any intervention less effective than the best proven one, placebo, or no intervention will not be subject to additional risks of serious or irreversible harm as a result of not receiving the best proven intervention. Extreme care must be taken to avoid abuse of this option.

Unproven Interventions in Clinical Practice

> 37. In the treatment of an individual patient, where proven interventions do not exist or other known interventions have been ineffective, the physician, after seeking expert advice, with informed consent from the patient or a legally authorized representative, may use an unproven intervention if in the physician's judgement it offers hope of saving life, re-establishing health or alleviating suffering. This intervention should subsequently be made the object of research, designed to evaluate its safety and efficacy. In all cases, new information must be recorded and, where appropriate, made publicly available."

In general the advocates of pseudoscientific ASD therapies have no motivation to conduct properly controlled experimental evaluations of their treatments. They have nothing to gain except unwelcome news; thus few accumulate any substantial body of research evidence. The clinical use of unproved interventions is very strictly limited; thus practitioners who knowingly provide treatments that are essentially placebo-type of therapies are practicing unethically. This appears to be the case for a number of the pseudoscientific interventions described in this chapter. And interventions which simply lack sufficient evidence to draw a conclusion should be tested against best available treatments.

The American Medical Association also weighs in on this topic.

"Code of Medical Ethics Opinion 2.1.4

> A placebo is a substance provided to a patient that the physician believes has no specific pharmacological effect on the condition being treated. The use of placebo, when consistent with good medical care, is distinct from interventions that lack scientific foundation…In the clinical setting, the use of a placebo without the patient's knowledge may undermine trust, compromise the patient-physician relationship, and result in medical harm to the patient.
> Physicians may use placebos for diagnosis or treatment only if they:

(a) Enlist the patient's cooperation. The physician should explain that it can be possible to achieve a better understanding of the medical condition by evaluating

> the effects of different medications, including the placebo.
>
> (b) Obtain the patient's general consent to administer a placebo. The physician does not need to identify precisely when the placebo will be administered. In this way, the physician respects the patient autonomy and fosters a trusting relationship, while the patient may still benefit from the placebo effect.
>
> (c) Avoid giving a placebo merely to mollify a difficult patient. Giving a placebo for such reasons places the convenience of the physician above the welfare of the patient. Physicians can produce a placebo-like effect through the skillful use of reassurance and encouragement, thereby building respect and trust, promoting the patient-physician relationship, and improving health outcomes." (cited from: https://www.ama-assn.org/delivering-care/use-placebo-clinical-practice)."

> The Code of Ethics for Behavior Analysts is particularly strong in advocating for the provision of research-based therapies for clients with ASD. For example:
> "2.09 Treatment/Intervention Efficacy. (a) Clients have a right to effective treatment (i.e., based on the research literature and adapted to the individual client). Behavior analysts always have the obligation to advocate for and educate the client about scientifically supported, most-effective treatment procedures. Effective treatment procedures have been validated as having both long-term and short-term benefits to clients and society" (cited from https://www.bacb.com/wp-content/uploads/170706r_compliance_code_english.pdf).

No other profession serving persons with ASD includes such a strong ethical requirement regarding the practitioner's obligation to provide scientifically supported treatments.

There are good reasons for avoiding placebo-equivalent treatments. A thorough review of clinical trials comparing real therapies to placebo treatments found that the latter had very little meaningful impact on clinical outcomes in medicine. The authors concluded "we found little evidence that placebos in general have powerful clinical effects…The use of placebo outside the aegis of properly designed clinical trials cannot be recommended" (Hrobjartsson & Gotzsche, 2001, p. 1599). Another reason is that a profession which relies primarily on placebo influences to obtain patient-reported improvements (e.g., chiropractic, naturopathy, acupuncture) is held in low self-esteem by health-care professionals operating from more of an evidence-based practice orientation. And certainly one does not need years of graduate and post-graduate training to be a placebo therapist. The hallmark of a legitimate health-care professional is one's capacity to deliver treatments that are *more* beneficial than credible placebos.

Apart from placebo influences, there are a large number of reasons why genuinely ineffective treatment may appear to work. Lilienfeld, Ritschel, Lynn, Cautin, and Latzman (2014) provide a comprehensive discussion of 25 additional reasons. These were grouped into three categories: (1) erroneous perceptions of client change, in its absence (15 possible reasons), (2) misinterpretations of actual client change stemming from extra-therapeutic factors (eight factors), and (3) misinterpretations of actual client change stemming from nonspecific treatment factors (three factors, include placebo). Anyone evaluating treatment outcome studies for ASD should keep these alternative explanations in mind when attempting to account for apparent client improvements. They conclude their compelling article with the following observation: "Science, which is a systematic approach to reducing uncertainty in our inferences… is ultimately our best prescription against being deceived by inadequate evidence" (Lilienfeld et al., 2014, p. 378). Not all purveyors of pseudoscientific treatments for ASD are charlatans, but it matters little to the recipient of such services whether the therapist is honestly misguided or a knowing purveyor of autistic snake oil. The end result is the same. No improvements beyond placebo factors. Loss of money. False hope. Wasted time. Disillusionment. Possible injury.

A chapter-length treatment of topic cannot do justice to the field as only a few examples of pseudoscientific treatments can be briefly described. The reader is referred to several of the book-length analyses devoted to the topic, e.g., Jacobson, Foxx, and Mulick (2005), Foxx and Mulick (2015), and Offit (2010) as well as to some excellent chapters (e.g., Tizikow & Holburn, 2011). This chapter's focus on pseudoscientific therapies for ASD may leave the reader a bit frustrated in that little mention was made of well-established research-supported treatments.
